We present a hybrid natural language generation (NLG) system that consolidates macro and micro planning and surface realization tasks into one statistical learning process. Our novel approach is based on deriving a template bank automatically from a corpus of texts from a target domain. First, we identify domain specific entity tags and Discourse Representation Structures on a per sentence basis. Each sentence is then organized into semantically similar groups (representing a domain specific concept) by  $k$ -means clustering. After this semi-automatic processing (human review of cluster assignments), a number of corpus-level statistics are compiled and used as features by a ranking SVM to develop model weights from a training corpus. At generation time, a set of input data, the collection of semantically organized templates, and the model weights are used to select optimal templates. Our system is evaluated with automatic, non-expert crowdsourced and expert evaluation metrics. We also introduce a novel automatic metric – *syntactic variability* – that represents linguistic variation as a measure of unique template sequences across a collection of automatically generated documents. The metrics for generated *weather* and *biography* texts fall within acceptable ranges. In sum, we argue that our statistical approach to NLG reduces the need for complicated knowledge-based architectures and readily adapts to different domains with reduced development time.

## 1 Introduction

NLG is the process of generating natural-sounding text from non-linguistic inputs. A typical NLG system contains three main components: (1) Document (Macro) Planning - deciding what content should be realized in the output and how it should be structured; (2) Sentence (Micro) planning - generating a detailed sentence specification and selecting appropriate referring expressions; and (3) Surface Realization - generating the final text after applying morphological modifications based on syntactic rules (*see e.g.*, Bateman and Zock (2003), Reiter and Dale (2000) and McKeown (1985)). However, document planning is arguably one of the most crucial components of an NLG system and is responsible for making the texts express the desired communicative goal in a coherent structure. If the document planning stage fails, the communicative goal of the generated text will not be met even if the other two stages are perfect. While most traditional systems simplify development by using a pipelined approach where (1-3) are executed in a sequence, this can result in errors at one stage propagating to successive stages (*see e.g.*, Robin and McKeown (1996)). We propose a hybrid framework that combines (1-3) by converting data to text in one single process.

Most NLG systems fall into two broad categories: knowledge-based and statistical. Knowledge-based systems heavily depend on having domain expertise to come up with hand-crafted rules at each stage of a pipeline. Although knowledge-based systems can produce high quality text, they are (1) very expensive to build, involving a lot of discussion with the end users of the system for the document planning stage alone; (2) have limited linguistic coverage, as it is time consuming to capture linguistic variation; and (3) one has to start from scratch for each new domain because the developed components cannot be reused.

Statistical systems, on the other hand, are fairly inexpensive, more adaptable and rely on having historical data for the given domain. Coverage is likely to be high if more historical data is available. The main disadvantage with statistical systems is that they are more prone to errors and the output text may not be coherent as there are less constraints on the generated text.

Our framework is a hybrid of statistical and template-based systems. Many knowledge-based systems use templates to generate text. A template structure contains “gaps” that are filled to generate the output. The idea is to create a lot of templates from the historical data and select the right template based on some constraints. To the best of our knowledge, this is the first hybrid statistical-template-based system that combines all three stages of NLG. Experiments with different variants of our system (for *biography* and *weather* subject matter domains) demonstrate that our system generates reasonable texts.

Also, in addition to the standard metrics used to evaluate NLG systems (e.g., BLEU, NIST, etc.), we present a unique text evaluation metric called *syntactic variability* to measure the linguistic variation of generated texts. This metric applies to the document collection level and is based on computing the number of unique template sequences among all the generated texts. A higher number indicates the texts are more variable and natural-sounding whereas a lower number shows they are more redundant. We argue that this metric is useful for evaluating template-based systems and for *any* type of text generation for domains where linguistic variability is favored (e.g., the user is expected to go through more than one document in the same session).

The main contributions of this paper are (1) A statistical NLG system that combines document and sentence planning and surface realization into one single process; and (2) A new metric – *syntactic variability* – is proposed to measure the syntactic and morphological variability of the generated texts. We believe this is the first work to propose an automatic metric to measure linguistic variability of generated texts in NLG.

Section 2 provides an overview of related work on NLG. We present our main system in Section 3. The system is evaluated and discussed in Section 4. Finally, we conclude in Section 5 and point out future directions of research.

## 2 Background

Typically, knowledge-based NLG systems are implemented by rules and, as mentioned above, have a pipelined architecture for the document and sentence planning stages and surface realization (Hovy, 1993; Moore and Paris, 1993). However, document planning is arguably the most important task (Sripada et al., 2001). It follows that approaches to document planning are rule-based as well and, concomitantly, are usually domain specific. For example, Bouayad-Agha, et al. (2011) proposed document planning based on an ontology knowledge base to generate football summaries. For rule-based systems, rules exist for selecting content to grammatical choices to post-processing (e.g., pronoun generation). These rules are often tailored to a given system, with input from multiple experts; consequently, there is a high associated development cost (e.g., 12 person months for the SUMTIME-METEO system (Belz, 2007)).

Statistical approaches can reduce extensive development time by relying on corpus data to “learn” rules for one or more components of an NLG system (Langkilde and Knight, 1998). For example, Duboue and McKeown (2003) proposed a statistical approach to extract content selection rules for biography descriptions. Further, statistical approaches should be more adaptable to different domains than their rule-based equivalents (Angeli et al., 2012). For example, Barzilay and Lapata (2005) formulated content selection as a classification task to produce football summaries and Kelly et al. (2009) extended Barzilay and Lapata’s approach for generating match reports for cricket.

The present work builds on Howald et al. (2013) where, in a given corpus, a combination of domain specific named entity tagging and clustering sentences (based on semantic predicates) were used to generate templates. However, while the system consolidated both sentence planning and surface realization with this approach (described in more detail in Section 3), the document plan was given via the input data and sequencing information was present in training documents. For the present research, we introduce a similar method that leverages the distributions of document-level features in the training corpus to incorporate a statistical document planning component. Consequently, we are able to create a streamlined statistical NLG architecture that balances natural

human-like variability with appropriate and accurate information.

### 3 Methodology

In order to generate text for a given domain our system runs input data through a statistical ranking model to select a sequence of templates that best fit the input data (E). In order to build the ranking model, our system takes historical data (corpus) for the domain through four components: (A) preprocessing; (B) “conceptual unit” creation; (C) collecting statistics; and (D) ranking model building (summarized in Figure 1). In this section, we describe each component in detail.

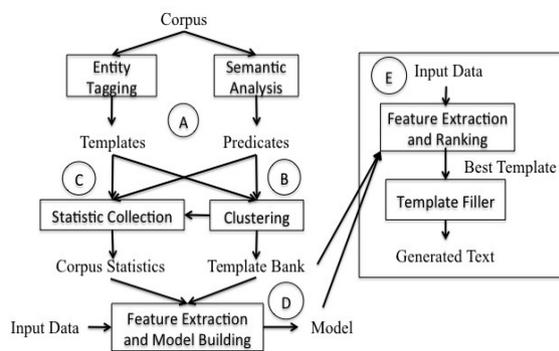

Figure 1: System Architecture.

#### 3.1 Preprocessing

The first component processes the given corpus to extract templates. We assume that each document in the corpus is classified to a specific domain. Preprocessing involves uncovering the underlying semantic structure of the corpus and using this as a foundation for template creation (Lu et al., 2009; Lu and Ng, 2011; Konstas and Lapata, 2012).

We first split each document in the corpus into sentences and create a shallow Discourse Representation Structure (following Discourse Representation Theory (Kamp and Reyle, 1993)) of each sentence. The DRS consists of semantic predicates and named entity tags. We use *Boxer* semantic analyzer (Bos, 2008) to extract semantic predicates such as EVENT or DATE. In parallel, domain specific named entity tags are identified and, in conjunction with the semantic predicates, are used to create templates. We developed the named-entity tagger for the *weather* domain ourselves. To tag entities in the *biography* domain, we used OpenCalais (www.opencalais.com). For example, in the biography in (1), the conceptual

meaning (semantic predicates and domain-specific entities) of sentences (a-b) are represented in (c-d). The corresponding templates are showing in (e-f).

##### (1) Sentence

- a. Mr. Mitsutaka Kambe has been serving as Managing Director of the 77 Bank, Ltd. since June 27, 2008.
- b. He holds a Bachelor’s in finance from USC and a MBA from UCLA.

##### Conceptual Meaning

- c. SERVING | TITLE | PERSON | COMPANY | DATE
- d. HOLDS | DEGREE | SUBJECT | INSTITUTION | EVENT

##### Templates

- e. [person] has been serving as [title] of the [company] since [date].
- f. [person] holds a [degree] in [subject] from [institution] and a [degree] from [institution].

The outputs of the preprocessing stage are the template bank and predicate information for each template in the corpus.<sup>1</sup>

#### 3.2 Creating Conceptual Units

The next step is to create conceptual units for the corpus by clustering templates. This is a semi-automatic process where we use the predicate information for each template to compute similarity between templates. We use *k*-means clustering with *k* (equivalent to the number of semantic concepts in the domain) set to an arbitrarily high value (100) to over-generate (using the WEKA toolkit (Witten and Frank, 2005)). This allows for easier manual verification of the generated clusters and we merge them if necessary. We assign a unique identifier called a CuId (Conceptual Unit Identifier) to each cluster, which represents a “conceptual unit”. We associate each template in the corpus to a corresponding CuId. For example, in (2), using the templates in (1e-f), the identified named entities are assigned to a clustered CuId (2a-b).

##### (2) Conceptual Units

- a. {CuId : 000} – [person] has been serving as [title] of the [company] since [date].
- b. {CuId : 001} – [person] holds a [degree] in [subject] from [institution] and a [degree] from [institution].

At this stage, we will have a set of conceptual units with corresponding template collections (see Howald et al. (2013) for a further explanation of Sections 3.1-3.2).

<sup>1</sup>A similar approach to the clustering of semantic content is found in Duboue and McKeown (2003), where text with stopwords removed were used as semantic input. Boxer provides a similar representation with the addition of domain general tags. However, to contrast our work from Duboue and McKeown, which focused on content selection, we are focused on learning templates from the semantic representations for the complete generation system (covering content selection, aggregation, sentence and document planning).

### 3.3 Collecting Corpus Statistics

After identifying the different conceptual units and the template bank, we collect a number of statistics from the corpus:

- Frequency distribution of templates overall and per position
- Frequency distribution of CuIds overall and per position
- Average number of entity tags by CuId as well as the entity distribution by CuId
- Average number of entity tags by position as well as the entity distribution by position
- Average number of words per CuId.
- Average number of words per CuId and position combination.
- Average number of words per position
- Frequency distribution of the main verbs by position
- Frequency distribution of CuId sequences (bigrams and trigrams only) overall and per position
- Frequency distribution of template sequences (bigrams and trigrams only) overall and per position
- Frequency distribution of entity tag sequences overall and per position
- The average, minimum, maximum number of CuIds across all documents

As discussed in the next section, these statistics are turned into features used for building a ranking model in the next component.

### 3.4 Building a ranking model

The core component of our system is a statistical model that ranks a set of templates for a given position (sentence 1, sentence 2, ..., sentence n) based on the input data. The input data in our tasks was extracted from a training document; this serves as a temporary surrogate to a database. The task is to learn the ranks of all the templates from all CuIds at each position.

To generate the training data, we first filter the templates that have named entity tags not specified in the input data. This will make sure the generated text does not have any unfilled entity tags. We then rank templates according to the Levenshtein edit distance (Levenshtein, 1966) from the template corresponding to the current sentence in the training document (using the top 10 ranked templates in training for ease of processing effort). We experimented with other ranking schemes such as entity-based similarity (similarity between entity sequences in the templates) and a combination of edit-distance based and entity-based similarities. We obtained better results with edit distance. For each template, we generate the following features to build the ranking model. Most of the features are based on the corpus statistics mentioned above.

- **CuId given position:** This is a binary feature where the current CuId is either the same as the most frequent CuId for the position (1) or not (0).
- **Overlap of named entities:** Number of common entities between current CuId and most likely CuId for the position
- **Prior template:** Probability of the sequence of templates selected at the previous position and the current template (iterated for the last three positions).
- **Prior CuId:** Probability of the sequence of the CuId selected at the previous position and the current CuId (iterated for the last three positions).
- **Difference in number of words:** Absolute difference between number of words for current template and average number of words for the CuId
- **Difference in number of words given position:** Absolute difference between number of words for current template and average number of words for CuId at given position
- **Percentage of unused data:** This feature represents the portion of the unused input so far.
- **Difference in number of named entities:** Absolute difference between the number of named entities in the current template and the average number of named entities for the current position
- **Most frequent verb for the position:** Binary valued feature where the main verb of the template belongs to the most frequent verb group given the position is either the same (1) or not (0).
- **Average number of words used:** Ratio of number of words in the generated text so far to the average number of words.
- **Average number of entities:** Ratio of number of named entities in the generated text so far to the average number of named entities.
- **Most likely CuId given position and previous CuId:** Binary feature indicating if the current CuId is most likely given the position and the previous CuId.
- **Similarity between the most likely template in CuId and current template:** Edit distance between the current template and the most likely template for the current CuId.
- **Similarity between the most likely template in CuId given position and current template:** Edit distance between the current template and the most likely template for the current CuId at the current position.

We used a linear kernel for a ranking SVM (Joachims, 2002) (*cost* set to total queries) to learn the weights associated with each feature for the different domains.

### 3.5 Generation

At generation time, our system has a set of input data, a semantically organized template bank (collection of templates organized by CuId) and a model from training on the documents for a given domain. We first filter out those templates that contain a named entity tag not present in the input data. Then, we compute a score for each of the remaining templates from the feature values and the feature weights from the model. The template with the highest overall score is selected and filled with matching entity tags from the input data and

appended to the generated text.

Before generating the next sentence, we track those entities used in the initial sentence generation and decide to either remove those entities from the input data or keep the entity for one or more additional sentence generations. For example, in the *biography* discourses, the name of the person may occur only once in the input data, but it may be useful for creating good texts to have that person's name available for subsequent generations. To illustrate in (3), if we remove *James Smithton* from the input data after the initial generation, an irrelevant sentence (d) is generated as the input data will only have one company after the removal of *James Smithton* and the model will only select a template with one company. If we keep *James Smithton*, then the generations in (a-b) are more cohesive.

(3) *Use more than once*

- a. Mr. James Smithton was appointed CFO at Fordway Internation in April.
- b. Previously, Mr. Smithton was CFO of the Keyes Development Group.

*Use once and remove*

- c. Mr. James Smithton was appointed CFO at Fordway Internation in April.
- d. Keyes Development Group is a venture capital firm.

Deciding on what type of entities and how to remove them is different for each domain. For example, some entities are very unique to a text and should not be made available for subsequent generations as doing so would lead to unwanted redundancies (*e.g.*, mentioning the name of current company in a biography discourse more than once as in (3)) and some entities are general and should be retained. Our system possesses the ability to monitor the data usage from historical data and we can set parameters (based on the distribution of entities) on the usage to ensure coherent generations for a given domain.

Once the input data has been modified (*i.e.*, an entity have been removed, replaced or retained), it serves as the new input data for the next sentence generation. This process repeats until reaching the minimum number of sentences for the domain (determined from the training corpus statistic) and then continues until all of the remaining input data is consumed (and not to exceed the pre-determined maximum number of sentences, also determined from the training corpus statistic).

## 4 Evaluation and Discussion

In this section, we first discuss the corpus data used to train and generate texts. Then, the results of both automatic and human evaluations of our system's generations against the original and baseline texts are considered as a means of determining performance. For all experiments reported in this section, the baseline system selects the most frequent conceptual unit at the given position, chooses the most likely template for the conceptual unit, and fills the template with input data. The above process is repeated until the number of sentences is less than or equal to the average number of sentences for the given domain.

### 4.1 Data

We ran our system on two different domains: corporate officer and director *biographies* and offshore oil rig *weather* reports from the SUMTIME-METEO corpus ((Reiter et al., 2005)). The *biography* domain includes 1150 texts ranging from 3-17 sentences and the *weather* domain includes 1045 weather reports ranging from 1-6 sentences.<sup>2</sup> We used a training-test(generation) split of 70/30.

(4) provides generation comparisons for the system (*DocSys*), baseline (*DocBase*) and original (*DocOrig*) randomly selected text snippets from each domain. The variability of the generated texts ranges from a close similarity to slightly shorter - not an uncommon (Belz and Reiter, 2006), but not necessarily detrimental, observation for NLG systems (van Deemter et al., 2005).

(4) *Weather.DocOrig*

- a. Another weak cold front will move ne to Cornwall by later Friday.  
*Weather.DocSys*
- b. Another weak cold front will move ne to Cornwall during Friday.  
*Weather.DocBase*
- c. Another weak cold front from ne through the Cornwall will remain slow moving.

*Bio.DocOrig*

- d. He previously served as Director of Sales Planning and Manager of Loan Center.  
*Bio.DocSys*
- e. He previously served as Director of Sales in Loan Center of the Company.  
*Bio.DocBase*

<sup>2</sup>The SUMTIME-METEO project is a common benchmark in NLG. However, we provide no comparison between our system and SUMTIME-METEO as our system utilized the generated forecasts from SUMTIME-METEO's system as the historical data. We cannot compare with other statistical generation systems like (Belz, 2007) as they only focussed on the part of the forecasts the predicts wind characteristics whereas our system generates the complete forecasts.

f. He previously served as Director of Sales of the Company.

The *DocSys* and *DocBase* generations are largely grammatical and coherent on the surface with some variance, but there are graded semantic variations (e.g., *Director of Sales Planning* vs. *Director of Sales* (4g-h) and *move ne to Cornwall* vs. *from ne through the Cornwall*). Both automatic and human evaluations are required in NLG to determine the impact of these variances on the understandability of the texts in general (non-experts) and as they are representative of particular subject matter domains (experts). The following sections discuss the evaluation results.

## 4.2 Automatic Metrics

We used BLEU-4 (Papineni et al., 2002), METEOR (v.1.3) (Denkowski and Lavie, 2011) to evaluate the texts at document level. Both BLEU-4 and METEOR originate from machine translation research. BLEU-4 measures the degree of 4-gram overlap between documents. METEOR uses a unigram weighted  $f$ -score less a penalty based on chunking dissimilarity. These metrics only evaluate the text on a document level but fail to identify “syntactic repetitiveness” across documents in a document collection. This is an important characteristic of a document collection to avoid banality. To address this issue, we propose a new automatic metric called *syntactic variability*. In order to compute this metric, each document should be represented as a sequence of templates by associating each sentence in the document with a template in the template bank. *Syntactic variability* is defined as the percentage of unique template sequences across all generated documents. It ranges between 0 and 1. A higher value indicates that more documents in the collection are linguistically different from each other and a value closer to zero shows that most of documents have the similar language despite different input data.<sup>3</sup>

As indicated in Figure 2, the BLEU-4 scores are low for all *DocSys* and *DocBase* generations (as compared to *DocOrig*) for each domain. However, the METEOR scores, while low overall (ranging from .201-.437) are noticeably increased over BLEU-4 (which ranges from .199-.320).

Given the nature of each metric, the results indicate that the generated and baseline texts have

<sup>3</sup>Of course, syntactic and semantic repetitiveness could be captured by *syntactic variability*, but only if this is the nature of the underlying historical data - *financial* texts tend to be fairly repetitive.

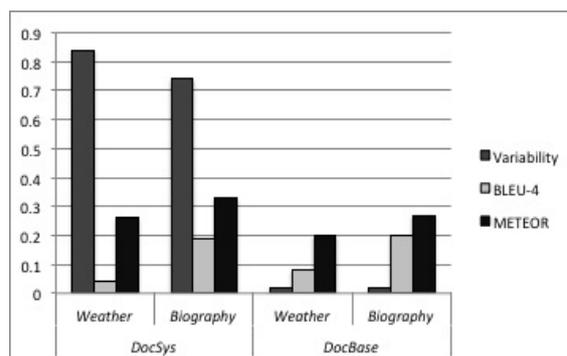

Figure 2: Automatic Evaluations.

very different surface realizations compared to the originals (low BLEU-4), but are still capturing the content of the originals (higher METEOR). Both BLEU-4 and METEOR measure the similarity of the generated text to the original text, but fail to penalize repetitiveness across texts, which is addressed by the *syntactic variability* metric. There is no statistically significant difference between *DocSys* and *DocBase* generations for METEOR and BLEU-4.<sup>4</sup> However, there is a statistically significant difference in the *syntactic variability* metric for both domains (*weather* -  $\chi^2=137.16$ , d.f.=1,  $p<.0001$ ; *biography* -  $\chi^2=96.641$ , d.f.=1,  $p<.0001$ ) - the variability of the *DocSys* generations is greater than the *DocBase* generations, which shows that texts generated by our system are more variable than the baseline texts.

The use of automatic metrics is a common evaluation method in NLG, but they must be reconciled against non-expert and expert level evaluations.

## 4.3 Non-Expert Human Evaluations

Two sets of crowdsourced human evaluation tasks (run on CrowdFlower) were constructed to compare against the automatic metrics: (1) an understandability evaluation of the entire text on a three-point scale: **Fluent** = no grammatical or informative barriers; **Understandable** = some grammatical or informative barriers; **Disfluent** = significant grammatical or informative barriers; and (2) a sentence-level preference between sentence pairs (e.g., “Do you prefer Sentence A (from *DocOrig*) or the corresponding Sentence B (from *DocBase/DocSys*)”).

<sup>4</sup>BLEU-4: *weather* -  $\chi^2=1.418$ , d.f.=1,  $p=.230$ ; *biography* -  $\chi^2=0.311$ , d.f.=1,  $p=.354$ . METEOR: *weather* -  $\chi^2=1.016$ , d.f.=1,  $p=.313$ ; *biography* -  $\chi^2=0.851$ , d.f.=1,  $p=.354$ .

Over 100 native English speakers contributed, each one restricted to providing no more than 50 responses and only after they successfully answered 4 “gold data” questions correctly. We also omitted those evaluators with a disproportionately high response rate. No other data was collected on the contributors (although geographic data (country, region, city) and IP addresses were available). For the sentence-level preference task, the pair orderings were randomized to prevent click bias.

For the text-understandability task, 40 documents were chosen at random from the *DocOrig* test set along with the corresponding 40 *DocSys* and *DocBase* generations (240 documents total/120 for each domain). 8 judgments per document were solicited from the crowd (1920 total judgments, 69.51 average agreement) and are summarized in Figures 3 and 4 (*biography* and *weather* respectively).

If the system is performing well and the ranking model is actually contributing to increased performance, the accepted trend should be that the *DocOrig* texts are more fluent and preferred compared to both the *DocSys* and *DocBase* systems. However, the differences between *DocOrig* and *DocSys* will not be significant, the differences between *DocOrig* and *DocBase* and *DocSys* and *DocBase* **will** be significantly different.

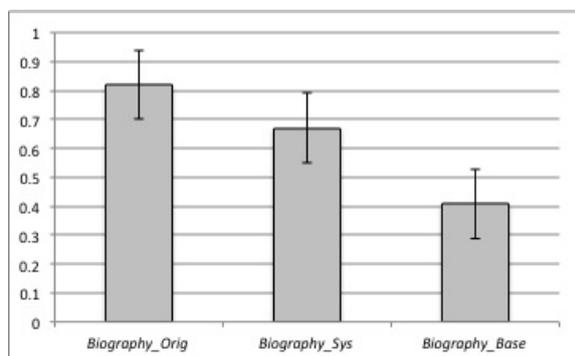

Figure 3: Biography Text Evaluations.

Focusing on fluency ratings, it is expected that the *DocOrig* generations will have the highest fluency (as they are human generated). Further, if the *DocSys* is performing well, it is expected that the fluency rating will be less than the *DocOrig* and higher than *DocBase*. Figure 3, which shows the *biography* text evaluations, demonstrates this acceptable distribution of performances.

For the *weather* discourses, as evident from Figure 4, the acceptable trend holds between the

*DocSys* and *DocBase* generations, and the *DocSys* generation fluency is actually slightly higher than *DocOrig*. This is possibly because the *DocOrig* texts are from a particular subject matter - weather forecasts for offshore oil rigs in the U.K. - which may be difficult for people in general to understand. Nonetheless, the demonstrated trend is favorable to our system.

In terms of significance, there are no statistically significant differences between the systems for *weather* (*DocOrig* vs. *DocSys* -  $\chi^2=0.347$ , d.f.=1,  $p=.555$ ; *DocOrig* vs. *DocBase* -  $\chi^2=0.090$ , d.f.=1,  $p=.764$ ; *DocSys* vs. *DocBase* -  $\chi^2=0.790$ , d.f.=1,  $p=.373$ ). While this is a good result for comparing *DocOrig* and *DocSys* generations, it is not for the other pairs. However, numerically, the trend is in the right direction despite not being able to demonstrate significance. For *biography*, the trend fits nicely both numerically and in terms of statistical significance (*DocOrig* vs. *DocSys* -  $\chi^2=5.094$ , d.f.=1,  $p=.024$ ; *DocOrig* vs. *DocBase* -  $\chi^2=35.171$ , d.f.=1,  $p<.0001$ ; *DocSys* vs. *DocBase* -  $\chi^2=14.000$ , d.f.=1,  $p<.0001$ ).

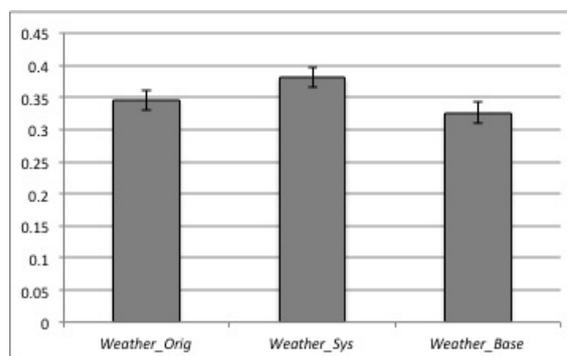

Figure 4: Weather Text Evaluations.

For the sentence preference task, equivalent sentences across the 120 documents were chosen at random (80 sentences from *biography* and 74 sentences from *weather*). 8 judgments per comparison were solicited from the crowd (3758 total judgments, 75.87 average agreement) and are summarized in Figures 5 and 6 (*biography* and *weather*, respectively).

Similar to the text-understandability task, an acceptable performance pattern should include the *DocOrig* texts being preferred to both *DocSys* and *DocBase* generations and the *DocSys* generation preferred to the *DocBase*. The closer the *DocSys* generation is to the *DocOrig*, the better *DocSys* is performing. The *biography* domain illus-

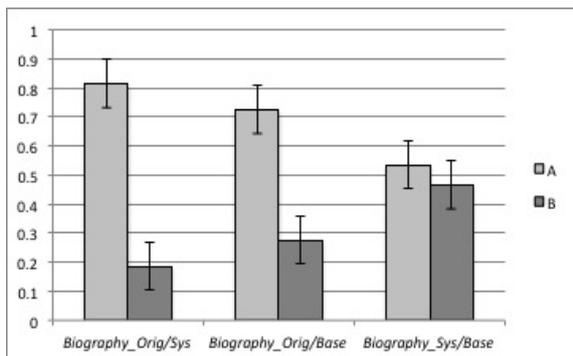

Figure 5: Biography Sentence Evaluations.

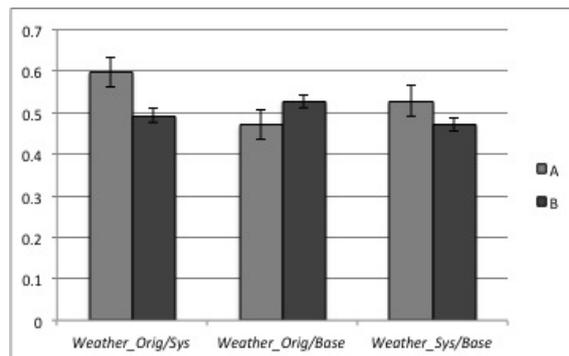

Figure 6: Weather Sentence Evaluations.

trates this scenario (Figure 5) where the results are similar to the text-understandability experiments. In contrast, for *weather* domain, sentences from *DocBase* system were preferred to our system's (Figure 6). We looked at the cases where the preferences were in favor of *DocBase*. It appears that because of high *syntactic variability*, our system can produce quite complex sentences where as the non-experts seem to prefer shorter and simpler sentences because of the complexity of the text.

In terms of significance, there are no statistically significant differences between the systems for *weather* (*DocOrig* vs. *DocSys* -  $\chi^2=6.48$ , d.f.=1,  $p=.011$ ; *DocOrig* vs. *DocBase* -  $\chi^2=.720$ , d.f.=1,  $p=.396$ ; *DocSys* vs. *DocBase* -  $\chi^2=.720$ , d.f.=1,  $p=.396$ ). The trend is different compared to the fluency metric above in that the *DocBase* system is outperforming the *DocOrig* generations to an almost statistically significant difference - the remaining comparisons follow the trend. We believe that this is for similar reasons stated above - i.e., the generation may be a more digestible version of a technical document. More problematic is the results of the *biography* evaluations. Here there is a statistically significant difference between the *DocSys* and *DocOrig* and no statistically significant difference between the *DocSys* and *DocBase* generations (*DocOrig* vs. *DocSys* -  $\chi^2=76.880$ , d.f.=1,  $p<.0001$ ; *DocOrig* vs. *DocBase* -  $\chi^2=38.720$ , d.f.=1,  $p<.0001$ ; *DocSys* vs. *DocBase* -  $\chi^2=.720$ , d.f.=1,  $p=.396$ ). Again, this distribution of preferences is numerically similar to the trend we would like to see, but the statistical significance indicates that there is some ground to make up. Expert evaluations are potentially informative for identifying specific shortcomings and how best to address them.

#### 4.4 Expert Human Evaluations

We performed expert evaluations for the *biography* domain only as we do not have access to weather experts. The four *biography* reviewers are journalists who write short biographies for news archives.

For the *biography* domain, evaluations of the texts were largely similar to the evaluations of the non-expert crowd (76.22 average agreement for the sentence-preference task and 72.95 for the text-understandability task). For example, the **disfluent** ratings were highest for the *DocBase* generations and lowest for the *DocOrig* generations. Also, the **fluent** ratings were highest for the *DocOrig* generations, and while the combined **fluent** and **understandable** are higher for *DocSys* as compared to *DocBase*, the *DocBase* generations had a 10% higher **fluent** score (58.22%) as compared to the *DocSys* **fluent** score (47.97%). Based on notes from the reviewers, the succinctness of the the *DocBase* generations are preferred in some ways as they are in keeping with certain editorial standards. This is further reflected in the sentence preferences being 70% in favor of the *DocBase* generations as compared to the *DocSys* generations (all other sentence comparisons were consistent with the non-expert crowd).

These expert evaluations provide much needed clarity to the NLG process. Overall, our system is generating clearly acceptable texts. Further, there are enough parameters inherent in the system to tune to different domain expectations. This is an encouraging result considering that no experts were involved in the development of the system - a key contrast to many other existing (especially rule-based) NLG systems.

## 5 Conclusions and Future Work

We have presented a hybrid (template-based and statistical), single-staged NLG system that generates natural sounding texts and is domain-adaptable. Our experiments with both experts and non-experts demonstrate that the system-generated texts are comparable to human-authored texts. The development time to adapt our system to new domains is small compared to other NLG systems; around a week to adapt the system to *weather* and *biography* domains. Most of the development time was spent on creating the domain-specific entity taggers for the *weather* domain. The development time would be reduced to hours if the historical data for a domain is readily available with the corresponding input data.

The main limitation of our system is that it requires significant historical data. Our system does consolidate many traditional components (macro and micro-planning, lexical choice and aggregation),<sup>5</sup> but the system cannot be applied to the domains with no historical data. The quality and the linguistic variability of the generated text is directly proportional to the amount of historical data available.

We also presented a new automatic metric to evaluate generated texts at document collection level to identify boilerplate texts. This metric computes “syntactic repetitiveness” by counting the number of unique template sequences across the given document collection.

Future work will focus on extending our framework by adding additional features to the model that could improve the quality of the generated text. For example, most NLG pipelines have a separate component responsible for referring expression generation (Krahmer and van Deemter, 2012). While we address the associated concern of data consumption in Section 3.5, we currently do not have any features that would handle referring expression generation. We believe that this is possible by identifying referring expressions in templates and adding features to the model to give higher scores to the templates having relevant referring expressions. We also would like to investigate using all the top-scored templates instead of the highest-scoring template. This would help achieve better syntactic-variability scores by producing more natural-sounding texts.

<sup>5</sup>Lexical choice and aggregation are “handled” insofar as their existence in the historical data.

## Acknowledgments

This research is made possible by Thomson Reuters Global Resources (TRGR) with particular thanks to Peter Pircher, Jaclyn Sprtel and Ben Hachey for significant support. Thank you also to Khalid Al-Kofahi for encouragement, Leszek Michalak and Andrew Lipstein for expert evaluations and three anonymous reviewers for constructive feedback.

## Abstract

What do we want to learn from a translation competition and how do we learn it with confidence? We argue that a disproportionate focus on ranking competition participants has led to lots of different rankings, but little insight about which rankings we should trust. In response, we provide the first framework that allows an *empirical* comparison of different analyses of competition results. We then use this framework to compare several analytical models on data from the Workshop on Machine Translation (WMT).

## 1 The WMT Translation Competition

Every year, the Workshop on Machine Translation (WMT) conducts a competition between machine translation systems. The WMT organizers invite research groups to submit translation systems in eight different tracks: Czech to/from English, French to/from English, German to/from English, and Spanish to/from English.

For each track, the organizers also assemble a panel of judges, typically machine translation specialists.<sup>1</sup> The role of a judge is to repeatedly rank five different translations of the same source text. Ties are permitted. In Table 1, we show an example<sup>2</sup> where a judge (we’ll call him “jdoe”) has ranked five translations of the French sentence “Il ne va pas.”

Each such elicitation encodes ten pairwise comparisons, as shown in Table 2. For each competition track, WMT typically elicits between 5000 and 20000 comparisons. Once the elicitation process is complete, WMT faces a large database of comparisons and a question that must be answered: whose system is the best?

<sup>1</sup>Although in recent competitions, some of the judging has also been crowdsourced (Callison-Burch et al., 2010).

<sup>2</sup>The example does not use actual system output.

rank	system	translation
1	bbn	“He does not go.”
2 (tie)	uedin	“He goes not.”
2 (tie)	jhu	“He did not go.”
4	cmu	“He go not.”
5	kit	“He not go.”

Table 1: WMT elicits preferences by asking judges to simultaneously rank five translations, with ties permitted. In this (fictional) example, the source sentence is the French “Il ne va pas.”

source text	sys1	sys2	judge	preference
“Il ne va pas.”	bbn	cmu	jdoe	1
“Il ne va pas.”	bbn	jhu	jdoe	1
“Il ne va pas.”	bbn	kit	jdoe	1
“Il ne va pas.”	bbn	uedin	jdoe	1
“Il ne va pas.”	cmu	jhu	jdoe	2
“Il ne va pas.”	cmu	kit	jdoe	1
“Il ne va pas.”	cmu	uedin	jdoe	2
“Il ne va pas.”	jhu	kit	jdoe	1
“Il ne va pas.”	jhu	uedin	jdoe	0
“Il ne va pas.”	kit	uedin	jdoe	2

Table 2: Pairwise comparisons encoded by Table 1. A preference of 0 means neither translation was preferred. Otherwise the preference specifies the preferred system.

## 2 A Ranking Problem

For several years, WMT used the following heuristic for ranking the translation systems:

$$\text{ORIGWMT}(s) = \frac{\text{win}(s) + \text{tie}(s)}{\text{win}(s) + \text{tie}(s) + \text{loss}(s)}$$

For system  $s$ ,  $\text{win}(s)$  is the number of pairwise comparisons in which  $s$  was preferred,  $\text{loss}(s)$  is the number of comparisons in which  $s$  was dispreferred, and  $\text{tie}(s)$  is the number of comparisons in which  $s$  participated but neither system was preferred.

Recently, (Bojar et al., 2011) questioned the adequacy of this heuristic through the following ar-

gument. Consider a competition with systems  $A$  and  $B$ . Suppose that the systems are different but equally good, such that one third of the time  $A$  is judged better than  $B$ , one third of the time  $B$  is judged better than  $A$ , and one third of the time they are judged to be equal. The expected values of  $\text{ORIGWMT}(A)$  and  $\text{ORIGWMT}(B)$  are both  $2/3$ , so the heuristic accurately judges the systems to be equivalently good. Suppose however that we had duplicated  $B$  and had submitted it to the competition a second time as system  $C$ . Since  $B$  and  $C$  produce identical translations, they should always tie with one another. The expected value of  $\text{ORIGWMT}(A)$  would not change, but the expected value of  $\text{ORIGWMT}(B)$  would increase to  $5/6$ , buoyed by its ties with system  $C$ .

This vulnerability prompted (Bojar et al., 2011) to offer the following revision:

$$\text{BOJAR}(s) = \frac{\text{win}(s)}{\text{win}(s) + \text{loss}(s)}$$

The following year, it was BOJAR’s turn to be criticized, this time by (Lopez, 2012):

Superficially, this appears to be an improvement...couldn’t a system still be penalized simply by being compared to [good systems] more frequently than its competitors? On the other hand, couldn’t a system be rewarded simply by being compared against a bad system more frequently than its competitors?

Lopez’s concern, while reasonable, is less obviously damning than (Bojar et al., 2011)’s criticism of ORIGWMT. It depends on whether the collected set of comparisons is small enough or biased enough to make the variance in competition significant. While this hypothesis is plausible, Lopez makes no attempt to verify it. Instead, he offers a ranking heuristic of his own, based on a Minimum Feedback Arc solver.

The proliferation of ranking heuristics continued from there. The WMT 2012 organizers (Callison-Burch et al., 2012) took Lopez’s ranking scheme and provided a variant called Most Probable Ranking. Then, noting some potential pitfalls with that, they created two more, called Monte Carlo Playoffs and Expected Wins. While one could raise philosophical objections about each of these, where would it end? Ultimately, the WMT 2012 findings presented five different rankings for

the English-German competition track, with no guidance about which ranking we should pay attention to. How can we know whether one ranking is better than other? Or is this even the right question to ask?

### 3 A Problem with Rankings

Suppose four systems participate in a translation competition. Three of these systems are extremely close in quality. We’ll call these close1, close2, and close3. Nevertheless, close1 is very slightly better<sup>3</sup> than close2, and close2 is very slightly better than close3. The fourth system, called terrific, is a really terrific system that far exceeds the other three.

Now which is the better ranking?

terrific, close3, close1, close2 (1)

close1, terrific, close2, close3 (2)

Spearman’s rho<sup>4</sup> would favor the second ranking, since it is a less disruptive permutation of the gold ranking. But intuition favors the first. While its mistakes are minor, the second ranking makes the hard-to-forgive mistake of placing close1 ahead of the terrific system.

The problem is not with Spearman’s rho. The problem is the disconnect between the knowledge that we want a ranking to reflect and the knowledge that a ranking actually contains. Without this additional knowledge, we cannot determine whether one ranking is better than another, even if we know the gold ranking. We need to determine what information they lack, and define more rigorously what we hope to learn from a translation competition.

### 4 From Rankings to Relative Ability

Ostensibly the purpose of a translation competition is to determine the relative ability of a set of translation systems. Let  $\mathcal{S}$  be the space of all translation systems. Hereafter, we will refer to  $\mathcal{S}$  as the space of *students*. We choose this term to evoke the metaphor of a translation competition as a standardized test, which shares the same goal: to assess the relative abilities of a set of participants.

But what exactly do we mean by “ability”? Before formally defining this term, first recognize that it means little without context, namely:

<sup>3</sup>What does “better” mean? We’ll return to this question.

<sup>4</sup>Or Pearson’s correlation coefficient.

1. **What kind of source text do we want the systems to translate well?** Say system A is great at translating travel-related documents, but terrible at translating newswire. Meanwhile, system B is pretty good at both. The question “which system is better?” requires us to state how much we care about travel versus newswire documents – otherwise the question is underspecified.
2. **Who are we trying to impress?** While it’s tempting to think that translation quality is a universal notion, the 50-60% interannotator agreement in WMT evaluations (Callison-Burch et al., 2012) suggests otherwise. It’s also easy to imagine reasons why one group of judges might have different priorities than another. Think a Fortune 500 company versus web forum users. Lawyers versus laymen. Non-native versus native speakers. Posteditors versus Google Translate users. Different groups have different uses for translation, and therefore different definitions of what “better” means.

With this in mind, let’s define some additional elements of a translation competition. Let  $\mathcal{X}$  be the space of all possible segments of source text,  $\mathcal{J}$  be the space of all possible judges, and  $\Pi = \{0, 1, 2\}$  be the space of pairwise preferences.<sup>5</sup> We assume all spaces are countable. Unless stated otherwise, variables  $s_1$  and  $s_2$  represent students from  $\mathcal{S}$ , variable  $x$  represents a segment from  $\mathcal{X}$ , variable  $j$  represents a judge from  $\mathcal{J}$ , and variable  $\pi$  represents a preference from  $\Pi$ . Moreover, define the *negation*  $\hat{\pi}$  of preference  $\pi$  such that  $\hat{\pi} = 2$  (if  $\pi = 1$ ),  $\hat{\pi} = 1$  (if  $\pi = 2$ ), and  $\hat{\pi} = 0$  (if  $\pi = 0$ ).

Now assume a joint distribution  $P(s_1, s_2, x, j, \pi)$  specifying the probability that we ask judge  $j$  to evaluate students  $s_1$  and  $s_2$ ’s respective translations of source text  $x$ , and that judge  $j$ ’s preference is  $\pi$ . We will further assume that the choice of student pair, source text, and judge are marginally independent of one another. In other words:

$$\begin{aligned}
& P(s_1, s_2, x, j, \pi) \\
&= P(\pi|s_1, s_2, x, j) \cdot P(x|s_1, s_2, j) \\
&\quad \cdot P(j|s_1, s_2) \cdot P(s_1, s_2) \\
&= P(\pi|s_1, s_2, x, j) \cdot P(x) \cdot P(j) \cdot P(s_1, s_2) \\
&= P_{\mathcal{X}}(x) \cdot P_{\mathcal{J}}(j) \cdot P(s_1, s_2) \cdot P(\pi|s_1, s_2, x, j)
\end{aligned}$$

<sup>5</sup>As a reminder, 0 indicates no preference.

It will be useful to reserve notation  $P_{\mathcal{X}}$  and  $P_{\mathcal{J}}$  for the marginal distributions over source text and judges. We can marginalize over the source segments and judges to obtain a useful quantity:

$$\begin{aligned}
& P(\pi|s_1, s_2) \\
&= \sum_{x \in \mathcal{X}} \sum_{j \in \mathcal{J}} P_{\mathcal{X}}(x) \cdot P_{\mathcal{J}}(j) \cdot P(\pi|s_1, s_2, x, j)
\end{aligned}$$

We refer to this as the  $\langle P_{\mathcal{X}}, P_{\mathcal{J}} \rangle$ -*relative ability* of students  $s_1$  and  $s_2$ . By using different marginal distributions  $P_{\mathcal{X}}$ , we can specify what kinds of source text interest us (for instance,  $P_{\mathcal{X}}$  could focus most of its probability mass on German tweets). Similarly, by using different marginal distributions  $P_{\mathcal{J}}$ , we can specify what judges we want to impress (for instance,  $P_{\mathcal{J}}$  could focus all of its mass on one important corporate customer or evenly among all fluent bilingual speakers of a language pair).

With this machinery, we can express the purpose of a translation competition more clearly: to estimate the  $\langle P_{\mathcal{X}}, P_{\mathcal{J}} \rangle$ -*relative ability* of a set of students. In the case of WMT,  $P_{\mathcal{J}}$  presumably<sup>6</sup> defines a space of competent source-to-target bilingual speakers, while  $P_{\mathcal{X}}$  defines a space of newswire documents.

We’ll refer to an estimate of  $P(\pi|s_1, s_2)$  as a *preference model*. In other words, a preference model is a distribution  $Q(\pi|s_1, s_2)$ . Given a set of pairwise comparisons (e.g., Table 2), the challenge is to estimate a preference model  $Q(\pi|s_1, s_2)$  such that  $Q$  is “close” to  $P$ . For measuring distributional proximity, a natural choice is KL-divergence (Kullback and Leibler, 1951), but we cannot use it here because  $P$  is unknown.

Fortunately, if we have i.i.d. data drawn from  $P$ , then we can do the next best thing and compute the perplexity of preference model  $Q$  on this heldout test data. Let  $\mathcal{D}$  be a sequence of triples  $\langle s_1, s_2, \pi \rangle$  where the preferences  $\pi$  are i.i.d. samples from  $P(\pi|s_1, s_2)$ . The perplexity of preference model  $Q$  on test data  $\mathcal{D}$  is:

$$\text{perplexity}(Q|\mathcal{D}) = 2^{-\sum_{\langle s_1, s_2, \pi \rangle \in \mathcal{D}} \frac{1}{|\mathcal{D}|} \log_2 Q(\pi|s_1, s_2)}$$

How do we obtain such a test set from competition data? Recall that a WMT competition produces pairwise comparisons like those in Table 2.

<sup>6</sup>One could argue that it specifies a space of machine translation specialists, but likely these individuals are thought to be a representative sample of a broader community.

Let  $\mathcal{C}$  be the set of *comparisons*  $\langle s_1, s_2, x, j, \pi \rangle$  obtained from a translation competition. Competition data  $\mathcal{C}$  is not necessarily<sup>7</sup> sampled i.i.d. from  $P(s_1, s_2, x, j, \pi)$  because we may intentionally<sup>8</sup> bias data collection towards certain students, judges or source text. Also, because WMT elicits its data in batches (see Table 1), every segment  $x$  of source text appears in at least ten comparisons.

To create an appropriately-sized test set that closely resembles i.i.d. data, we isolate the subset  $\mathcal{C}'$  of comparisons whose source text appears in at most  $k$  comparisons, where  $k$  is the smallest positive integer such that  $|\mathcal{C}'| \geq 2000$ . We then create the test set  $\mathcal{D}$  from  $\mathcal{C}'$ :

$$\mathcal{D} = \{\langle s_1, s_2, \pi \rangle \mid \langle s_1, s_2, x, j, \pi \rangle \in \mathcal{C}'\}$$

We reserve the remaining comparisons for training preference models. Table 3 shows the resulting dataset sizes for each competition track.

Unlike with raw rankings, the claim that one preference model is better than another has testable implications. Given two competing models, we can train them on the same comparisons, and compare their perplexities on the test set. This gives us a quantitative<sup>9</sup> answer to the question of which is the better model. We can then publish a system ranking based on the most trustworthy preference model.

## 5 Baselines

Let's begin then, and create some simple preference models to serve as baselines.

### 5.1 Uniform

The simplest preference model is a uniform distribution over preferences, for any choice of students  $s_1, s_2$ :

$$Q(\pi|s_1, s_2) = \frac{1}{3} \quad \forall \pi \in \Pi$$

This will be our only model that does not require training data, and its perplexity on any test set will be 3 (i.e. equal to number of possible preferences).

### 5.2 Adjusted Uniform

Now suppose we have a set  $\mathcal{C}$  of comparisons available for training. Let  $\mathcal{C}_\pi \subseteq \mathcal{C}$  denote the subset of comparisons with preference  $\pi$ , and let

<sup>7</sup>In WMT, it certainly is not.

<sup>8</sup>To collect judge agreement statistics, for instance.

<sup>9</sup>As opposed to philosophical.

$\mathcal{C}(s_1, s_2)$  denote the subset comparing students  $s_1$  and  $s_2$ .

Perhaps the simplest thing we can do with the training data is to estimate the probability of ties (i.e. preference 0). We can then distribute the remaining probability mass uniformly among the other two preferences:

$$Q(\pi|s_1, s_2) = \begin{cases} \frac{|\mathcal{C}_0|}{|\mathcal{C}|} & \text{if } \pi = 0 \\ \frac{1 - \frac{|\mathcal{C}_0|}{|\mathcal{C}|}}{2} & \text{otherwise} \end{cases}$$

## 6 Simple Bayesian Models

### 6.1 Independent Pairs

Another simple model is the direct estimation of each relative ability  $P(\pi|s_1, s_2)$  independently. In other words, for each pair of students  $s_1$  and  $s_2$ , we estimate a separate preference distribution. The maximum likelihood estimate of each distribution would be:

$$Q(\pi|s_1, s_2) = \frac{|\mathcal{C}_\pi(s_1, s_2)| + |\mathcal{C}_{\hat{\pi}}(s_2, s_1)|}{|\mathcal{C}(s_1, s_2)| + |\mathcal{C}(s_2, s_1)|}$$

However the maximum likelihood estimate would test poorly, since any zero probability estimates for test set preferences would result in infinite perplexity. To make this model practical, we assume a symmetric Dirichlet prior with strength  $\alpha$  for each preference distribution. This gives us the following Bayesian estimate:

$$Q(\pi|s_1, s_2) = \frac{\alpha + |\mathcal{C}_\pi(s_1, s_2)| + |\mathcal{C}_{\hat{\pi}}(s_2, s_1)|}{3\alpha + |\mathcal{C}(s_1, s_2)| + |\mathcal{C}(s_2, s_1)|}$$

We call this the Independent Pairs preference model.

### 6.2 Independent Students

The Independent Pairs model makes a strong independence assumption. It assumes that even if we know that student A is much better than student B, and that student B is much better than student C, we can infer nothing about how student A will fare versus student C. Instead of directly estimating the relative ability  $P(\pi|s_1, s_2)$  of students  $s_1$  and  $s_2$ , we could instead try to estimate the *universal ability*  $P(\pi|s_1) = \sum_{s_2 \in \mathcal{S}} P(\pi|s_1, s_2) \cdot P(s_2|s_1)$  of each individual student  $s_1$  and then try to reconstruct the relative abilities from these estimates.

For the same reasons as before, we assume a symmetric Dirichlet prior with strength  $\alpha$  for each

preference distribution, which gives us the following Bayesian estimate:

$$Q(\pi|s_1) = \frac{\alpha + \sum_{s_2 \in \mathcal{S}} |\mathcal{C}_\pi(s_1, s_2)| + |\mathcal{C}_{\hat{\pi}}(s_2, s_1)|}{3\alpha + \sum_{s_2 \in \mathcal{S}} |\mathcal{C}(s_1, s_2)| + |\mathcal{C}(s_2, s_1)|}$$

The estimates  $Q(\pi|s_1)$  do not yet constitute a preference model. A downside of this approach is that there is no principled way to reconstruct a preference model from the universal ability estimates. We experiment with three ad-hoc reconstructions. The *asymmetric* reconstruction simply ignores any information we have about student  $s_2$ :

$$Q(\pi|s_1, s_2) = Q(\pi|s_1)$$

The *arithmetic* and *geometric* reconstructions compute an arithmetic/geometric average of the two universal abilities:

$$Q(\pi|s_1, s_2) = \frac{Q(\pi|s_1) + Q(\hat{\pi}|s_2)}{2}$$

$$Q(\pi|s_1, s_2) = [Q(\pi|s_1) * Q(\hat{\pi}|s_2)]^{\frac{1}{2}}$$

We respectively call these the (Asymmetric/Arithmetic/Geometric) Independent Students preference models. Notice the similarities between the universal ability estimates  $Q(\pi|s_1)$  and the BOJAR ranking heuristic. These three models are our attempt to render the BOJAR heuristic as preference models.

## 7 Item-Response Theoretic (IRT) Models

Let's revisit (Lopez, 2012)'s objection to the BOJAR ranking heuristic: "...couldn't a system still be penalized simply by being compared to [good systems] more frequently than its competitors?" The official WMT 2012 findings (Callison-Burch et al., 2012) echoes this concern in justifying the exclusion of reference translations from the 2012 competition:

[W]orkers have a very clear preference for reference translations, so including them unduly penalized systems that, through (un)luck of the draw, were pitted against the references more often.

Presuming the students are paired uniformly at random, this issue diminishes as more comparisons are elicited. But preference elicitation is expensive, so it makes sense to assess the relative ability of the students with as few elicitations as possible. Still, WMT 2012's decision to eliminate

references entirely is a bit of a draconian measure, a treatment of the symptom rather than the (perceived) disease. If our models cannot function in the presence of training data variation, then we should change the models, not the data. A model that only works when the students are all about the same level is not one we should rely on.

We experiment with a simple model that relaxes some independence assumptions made by previous models, in order to allow training data variation (e.g. who a student has been paired with) to influence the estimation of the student abilities. Figure 1(left) shows plate notation (Koller and Friedman, 2009) for the model's independence structure. First, each student's *ability* distribution is drawn from a common prior distribution. Then a number of translation *items* are generated. Each *item* is *authored* by a student and has a *quality* drawn from the student's *ability* distribution. Then a number of pairwise *comparisons* are generated. Each *comparison* has two *options*, each a translation *item*. The *quality* of each item is *observed* by a judge (possibly noisily) and then the judge states a *preference* by comparing the two *observations*.

We investigate two parameterizations of this model: Gaussian and categorical. Figure 1(right) shows an example of the Gaussian parameterization. The student ability distributions are Gaussians with a known standard deviation  $\sigma_a$ , drawn from a zero-mean Gaussian prior with known standard deviation  $\sigma_0$ . In the example, we show the ability distributions for students 6 (an above-average student, whose mean is 0.4) and 14 (a poor student, whose mean is -0.6). We also show an item authored by each student. Item 43 has a somewhat low quality of -0.3 (drawn from student 14's ability distribution), while item 205 is not student 6's best work (he produces a mean quality of 0.4), but still has a decent quality at 0.2. Comparison 1 pits these items against one another. A judge draws noise from a zero-mean Gaussian with known standard deviation  $\sigma_{obs}$ , then adds this to the item's actual quality to get an observed quality. For the first option (item 43), the judge draws a noise of -0.12 to observe a quality of -0.42 (worse than it actually is). For the second option (item 205), the judge draws a noise of 0.15 to observe a quality of 0.35 (better than it actually is). Finally, the judge compares the two observed qualities. If the absolute difference is lower than his decision

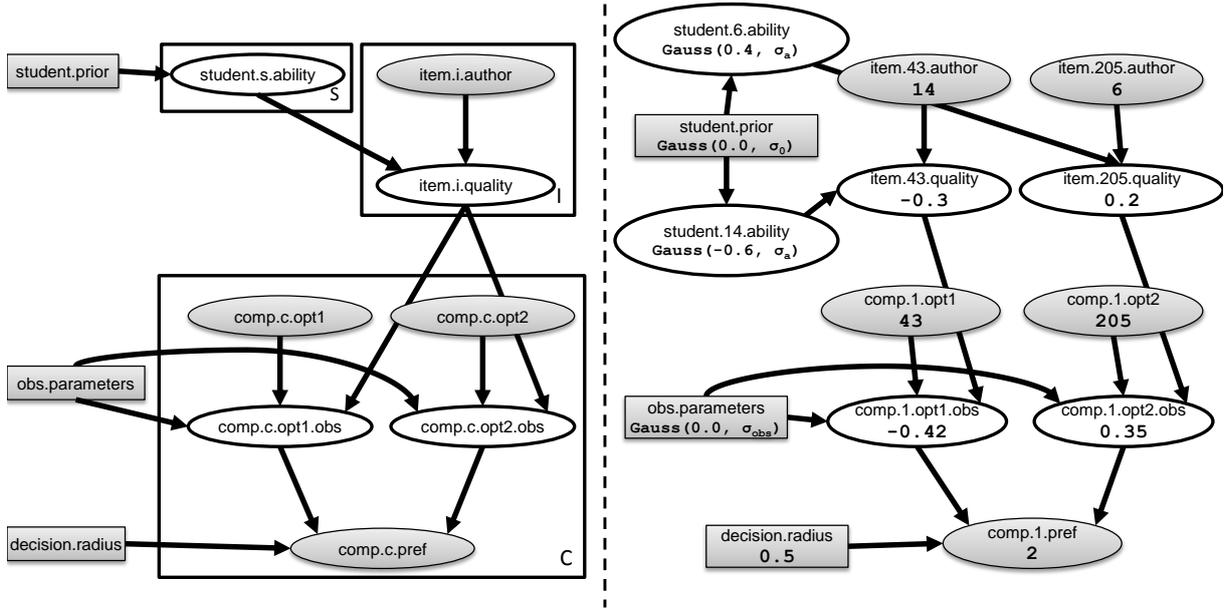

Figure 1: Plate notation (left) showing the independence structure of the IRT Models. Example instantiated subnetwork (right) for the Gaussian parameterization. Shaded rectangles are hyperparameters. Shaded ellipses are variables observable from a set of comparisons.

radius (which here is 0.5), then he states no preference (i.e. a preference of 0). Otherwise he prefers the item with the higher observed quality.

The categorical parameterization is similar to the Gaussian parameterization, with the following differences. Item quality is not continuous, but rather a member of the discrete set  $\{1, 2, \dots, \Lambda\}$ . The student ability distributions are categorical distributions over  $\{1, 2, \dots, \Lambda\}$ , and the student ability prior is a symmetric Dirichlet with strength  $\alpha_a$ . Finally, the observed quality is the item quality  $\lambda$  plus an integer-valued noise  $\nu \in \{1 - \lambda, \dots, \Lambda - \lambda\}$ . Noise  $\nu$  is drawn from a discretized zero-mean Gaussian with standard deviation  $\sigma_{obs}$ . Specifically,  $Pr(\nu)$  is proportional to the value of the probability density function of the zero-mean Gaussian  $\mathcal{N}(0, \sigma_{obs})$ .

We estimated the model parameters with Gibbs sampling (Geman and Geman, 1984). We found that Gibbs sampling converged quickly and consistently<sup>10</sup> for both parameterizations. Given the parameter estimates, we obtain a preference model  $Q(\pi|s_1, s_2)$  through the inference query:

$$Pr(\text{comp.c}'.\text{pref} = \pi \mid \begin{array}{l} \text{item.i}'.\text{author} = s_1, \\ \text{item.i}''.\text{author} = s_2, \\ \text{comp.c}'.\text{opt1} = i', \\ \text{comp.c}'.\text{opt2} = i'' \end{array})$$

<sup>10</sup>We ran 200 iterations with a burn-in of 50.

where  $c', i', i''$  are new comparison and item ids that do not appear in the training data.

We call these models Item-Response Theoretic (IRT) models, to acknowledge their roots in the psychometrics (Thurstone, 1927; Bradley and Terry, 1952; Luce, 1959) and item-response theory (Hambleton, 1991; van der Linden and Hambleton, 1996; Baker, 2001) literature. Item-response theory is the basis of modern testing theory and drives adaptive standardized tests like the Graduate Record Exam (GRE). In particular, the Gaussian parameterization of our IRT models strongly resembles<sup>11</sup> the Thurstone (Thurstone, 1927) and Bradley-Terry-Luce (Bradley and Terry, 1952; Luce, 1959) models of paired comparison and the 1PL normal-ogive and Rasch (Rasch, 1960) models of student testing. From the testing perspective, we can view each comparison as two students simultaneously posing a test question to the other: “Give me a translation of the source text which is better than mine.” The students can answer the question correctly, incorrectly, or they can provide a translation of analogous quality. An extra dimension of our models is judge noise, not a factor when modeling multiple-choice tests, for which the right answer is not subject to opinion.

<sup>11</sup>These models are not traditionally expressed using graphical models, although it is not unprecedented (Mislevy and Almond, 1997; Mislevy et al., 1999).

Table 3: Dataset sizes for each competition track (number of comparisons).

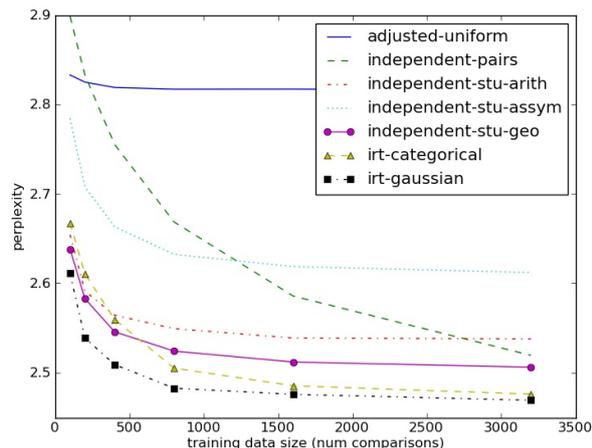

Figure 2: WMT10 model perplexities. The perplexity of the uniform preference model is 3.0 for all training sizes.

## 8 Experiments

We organized the competition data as described at the end of Section 4. To compare the preference models, we did the following:

- Randomly chose a subset of  $k$  comparisons from the training set, for  $k \in \{100, 200, 400, 800, 1600, 3200\}$ .<sup>12</sup>
- Trained the preference model on these comparisons.
- Evaluated the perplexity of the trained model on the test preferences, as described in Section 4.

For each model and training size, we averaged the perplexities from 5 trials of each competition track. We then plotted average perplexity as a function of training size. These graphs are shown

<sup>12</sup>If  $k$  was greater than the total number of training comparisons, then we took the entire set.

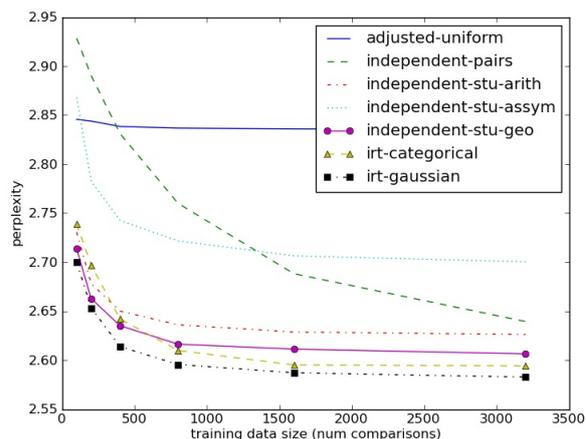

Figure 3: WMT11 model perplexities.

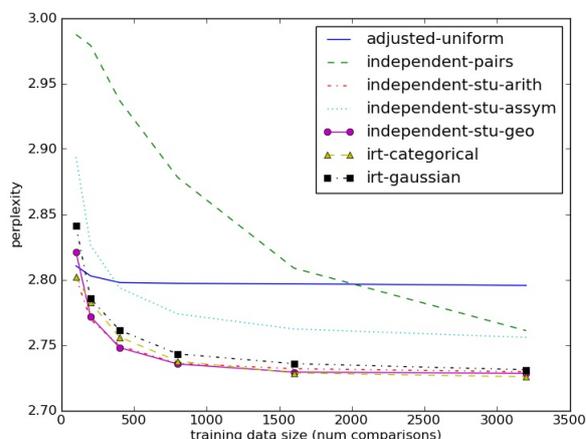

Figure 4: WMT12 model perplexities.

in Figure 2 (WMT10)<sup>13</sup>, and Figure 4 (WMT12). For WMT10 and WMT11, the best models were the IRT models, with the Gaussian parameterization converging the most rapidly and reaching the lowest perplexity. For WMT12, in which reference translations were excluded from the competition, four models were nearly indistinguishable: the two IRT models and the two averaged Independent Student models. This somewhat validates the organizers' decision to exclude the references, particularly given WMT's use of the BOJAR ranking heuristic (the nucleus of the Independent Student models) for its official rankings.

<sup>13</sup>Results for WMT10 exclude the German-English and English-German tracks, since we used these to tune our model hyperparameters. These were set as follows. The Dirichlet strength for each baseline was 1. For IRT-Gaussian:  $\sigma_0 = 1.0, \sigma_{obs} = 1.0, \sigma_a = 0.5$ , and the decision radius was 0.4. For IRT-Categorical:  $\Lambda = 8, \sigma_{obs} = 1.0, \alpha_a = 0.5$ , and the decision radius was 0.

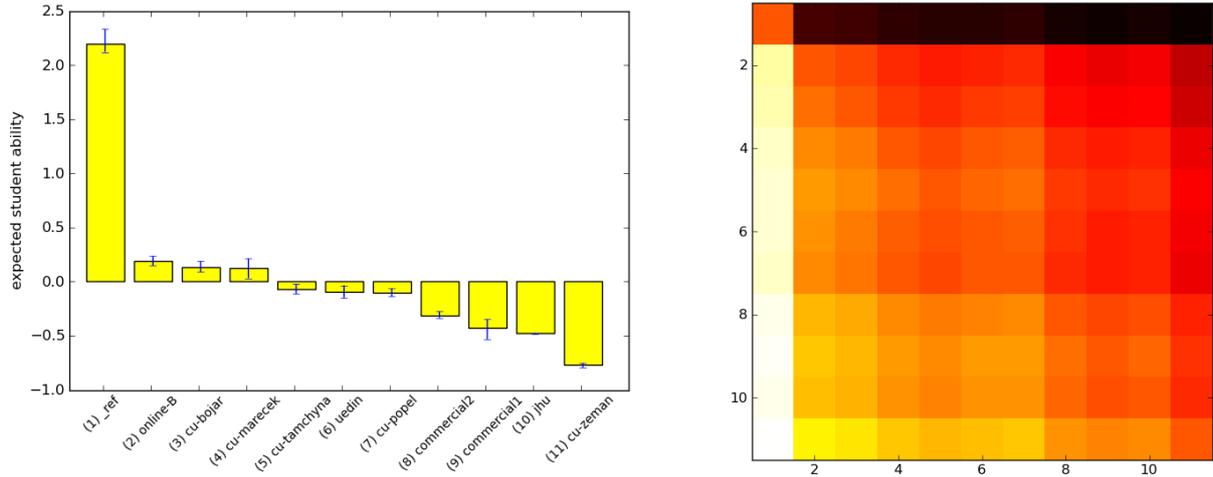

Figure 6: English-Czech WMT11 results (average of 5 trainings on 1600 comparisons). Error bars (left) indicate one stddev of the estimated ability means. In the heatmap (right), cell  $(s_1, s_2)$  is darker if preference model  $Q(\pi|s_1, s_2)$  skews in favor of student  $s_1$ , lighter if it skews in favor of student  $s_2$ .

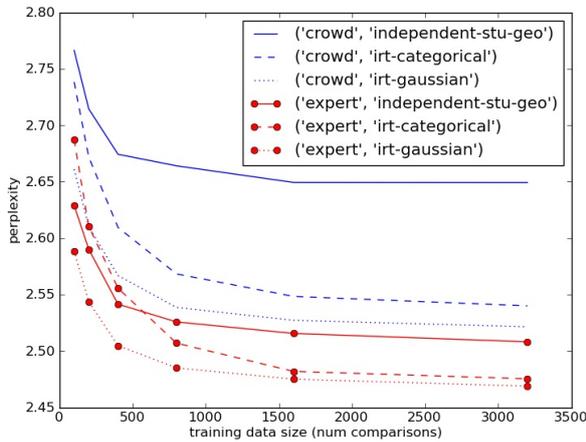

Figure 5: WMT10 model perplexities (crowd-sourced versus expert training).

The IRT models proved the most robust at handling judge noise. We repeated the WMT10 experiment using the same test sets, but using the unfiltered crowdsourced comparisons (rather than “expert”<sup>14</sup> comparisons) for training. Figure 5 shows the results. Whereas the crowdsourced noise considerably degraded the Geometric Independent Students model, the IRT models were remarkably robust. IRT-Gaussian in particular came close to replicating the performance of Geometric Independent Students trained on the much cleaner expert data. This is rather impressive, since the crowdsourced judges agree only 46.6% of the time, compared to a 65.8% agreement rate among

<sup>14</sup>I.e., machine translation specialists.

expert judges (Callison-Burch et al., 2010).

Another nice property of the IRT models is that they explicitly model student ability, so they yield a natural ranking. For training size 1600 of the WMT11 English-Czech track, Figure 6 (left) shows the mean student abilities learned by the IRT-Gaussian model. The error bars show one standard deviation of the ability means (recall that we performed 5 trials, each with a random training subset of size 1600). These results provide further insight into a case analyzed by (Lopez, 2012), which raised concern about the relative ordering of online-B, cu-bojar, and cu-marecek. According to IRT-Gaussian’s analysis of the data, these three students are so close in ability that any ordering is essentially arbitrary. Short of a full ranking, the analysis does suggest four strata. Viewing one of IRT-Gaussian’s induced preference models as a heatmap<sup>15</sup> (Figure 6, right), four bands are discernable. First, the reference sentences are clearly the darkest (best). Next come students 2-7, followed by the slightly lighter (weaker) students 8-10, followed by the lightest (weakest) student 11.

## 9 Conclusion

WMT has faced a crisis of confidence lately, with researchers raising (real and conjectured) issues with its analytical methodology. In this paper, we showed how WMT can restore confidence in

<sup>15</sup>In the heatmap, cell  $(s_1, s_2)$  is darker if preference model  $Q(\pi|s_1, s_2)$  skews in favor of student  $s_1$ , lighter if it skews in favor of student  $s_2$ .

its conclusions – by shifting the focus from *rankings* to *relative ability*. Estimates of relative ability (the expected head-to-head performance of system pairs over a probability space of judges and source text) can be empirically compared, granting substance to previously nebulous questions like:

1. **Is my analysis better than your analysis?**  
Rather than the current anecdotal approach to comparing competition analyses (e.g. presenting example rankings that seem somehow wrong), we can empirically compare the predictive power of the models on test data.
2. **How much of an impact does judge noise have on my conclusions?** We showed that judge noise can have a significant impact on the quality of our conclusions, if we use the wrong models. However, the IRT-Gaussian appears to be quite noise-tolerant, giving similar-quality conclusions on both expert and crowdsourced comparisons.
3. **How many comparisons should I elicit?** Many of our preference models (including IRT-Gaussian and Geometric Independent Students) are close to convergence at around 1000 comparisons. This suggests that we can elicit far fewer comparisons and still derive confident conclusions. This is the first time a concrete answer to this question has been provided.

Institute of Automation, Chinese Academy of Sciences, Beijing, China

{jjzhang, cqzong}@nlpr.ia.ac.cn

## Abstract

Currently, almost all of the statistical machine translation (SMT) models are trained with the parallel corpora in some specific domains. However, when it comes to a language pair or a different domain without any bilingual resources, the traditional SMT loses its power. Recently, some research works study the unsupervised SMT for inducing a simple word-based translation model from the monolingual corpora. It successfully bypasses the constraint of bitext for SMT and obtains a relatively promising result. In this paper, we take a step forward and propose a simple but effective method to induce a phrase-based model from the monolingual corpora given an automatically-induced translation lexicon or a manually-edited translation dictionary. We apply our method for the domain adaptation task and the extensive experiments show that our proposed method can substantially improve the translation quality.

## 1 Introduction

During the last decade, statistical machine translation has made great progress. Novel translation models, such as phrase-based models (Koehn et al., 2007), hierarchical phrase-based models (Chiang, 2007) and linguistically syntax-based models (Liu et al., 2006; Huang et al., 2006; Galley, 2006; Zhang et al., 2008; Chiang, 2010; Zhang et al., 2011; Zhai et al., 2011, 2012) have been proposed and achieved higher and higher translation performance. However, all of these state-of-the-art translation models rely on the parallel corpora to induce translation rules and estimate the corresponding parameters.

It is unfortunate that the parallel corpora are very expensive to collect and are usually not available for resource-poor languages and for many specific domains even in a resource-rich language pair.

Recently, more and more researchers concentrated on taking full advantage of the monolingual corpora in both source and target languages, and proposed methods for bilingual lexicon induction from non-parallel data (Rapp, 1995, 1999; Koehn and Knight, 2002; Haghighi et al., 2008; Daumé III and Jagarlamudi, 2011) and proposed unsupervised statistical machine translation (bilingual lexicon is a byproduct) with only monolingual corpora (Ravi and Knight, 2011; Nuhn et al., 2012; Dou and Knight, 2012).

In the bilingual lexicon induction (Koehn and Knight, 2002; Haghighi et al., 2008; Daumé III and Jagarlamudi, 2011), with the help of the orthographic and context features, researchers adopted an unsupervised method, such as canonical correlation analysis (CCA) model, to automatically induce the word translation pairs between two languages from non-parallel data only requiring that the monolingual data in each language are from a fairly comparable domain.

The unsupervised statistical machine translation method (Ravi and Knight, 2011; Nuhn et al., 2012; Dou and Knight, 2012) viewed the translation task as a decipherment problem and designed a generative model with the objective function to maximize the likelihood of the source language monolingual data. To tackle the large-scale vocabulary, they mainly considered the word-based model (e.g. IBM Model 3) and applied the Bayesian method with Gibbs sampling or slice sampling. Finally, they used the learned translation model directly to translate unseen data (Ravi and Knight, 2011; Nuhn et al., 2012) or incorporated the learned bilingual lexicon as a new in-domain translation resource into the phrase-based model which is trained with out-of-domain data to improve the domain adaptation performance in machine translation (Dou and Knight, 2012).

We can easily see that these unsupervised methods can only induce the word-based translation rules (bilingual lexicon) at present. It is a big challenge that whether we can induce phrase

Table 1: Examples of new translation knowledge learned with the proposed phrase pair induction method. For the three fields separated by “|||”, the first two are respectively Chinese and English phrase, and the last one is the word alignment between these two phrases.

level translation rules and learn a phrase-based model from the monolingual corpora.

In this paper, we focus on exploring this direction and propose a simple but effective method to induce the phrase-level translation rules from monolingual data. The main idea of our method is to divide the phrase-level translation rule induction into two steps: bilingual lexicon induction and phrase pair induction.

Since many researchers have studied the bilingual lexicon induction, in this paper, we mainly concentrate ourselves on phrase pair induction given a probabilistic bilingual lexicon and two in-domain large monolingual data (source and target language). In addition, we will further introduce how to refine the induced phrase pairs and estimate the parameters of the induced phrase pairs, such as four standard translation features and phrase reordering feature used in the conventional phrase-based models (Koehn et al., 2007). The induced phrase-based model will be used to help domain adaptation for machine translation.

In the rest of this paper, we first explain with examples to show what new translation knowledge can be learned with our proposed phrase pair induction method (Section 2), and then we introduce the approach for probabilistic bilingual lexicon acquisition in Section 3. In Section 4 and 5, we respectively present our method for phrase pair induction and introduce an approach for phrase pair refinement and parameter estimation. Section 6 will show the detailed experiments for the task of domain adaptation. We will introduce some related work in Section 7 and conclude this paper in Section 8.

## 2 What Can We Learn with Phrase Pair Induction?

Readers may doubt that if phrase pair induction is performed only using bilingual lexicon and monolingual data, what new translation knowledge can be learned?

The bilingual lexicon can only express the translation equivalence between source- and target-side word pair and has little ability to deal with word reordering and idiom translation. In contrast, phrase pair induction can make up for this deficiency to some extent. Furthermore, our method is able to learn some unknown word translations.

From the induced phrase pairs with our method, we have conducted a deep analysis and find that we can learn three kinds of new translation knowledge: 1) word reordering in a phrase pair; 2) idioms; and 3) unknown word translations. Table 1 gives examples for each of the three kinds. For the first example, the source and target phrase are extracted respectively from monolingual data, each word in the source phrase has a translation in the target phrase, but the word order is different. The word order encoded in a phrase pair is difficult to learn in a word-based SMT. In the second example, the *italic* source word corresponds to two target words (in *italic*), and the phrase pair is an idiom which cannot be learned from word-based SMT. In the third example, as we learn from the source and target monolingual text that the words around the *italic* ones are translations with each other, thus we cannot only extract a new phrase pair but also learn a translation pair of unknown words in *italic*.

## 3 Probabilistic Bilingual Lexicon Acquisition

In order to induce the phrase pairs from the in-domain monolingual data for domain adaptation, the probabilistic bilingual lexicon is essential.

In this paper, we acquire the probabilistic bilingual lexicon from two approaches: 1) build a bilingual lexicon from large-scale out-of-domain parallel data; 2) adopt a manually collected in-domain lexicon. This paper uses Chinese-to-English translation as a case study and electronic data is the in-domain data we focus on.

In Chinese-to-English translation, there are lots of parallel data on News. Here, we utilize about 2.08 million sentence pairs<sup>1</sup> in News domain to learn a probabilistic bilingual lexicon. Basically, we can use GIZA++ (Och, 2003) to get the probabilistic lexicon. However, the problem is that each source-side word associates too many possible translations which contain much noise. For instance, in the lexicon obtained with GIZA++, each source-side word has about 13 translations on average. The noise of the lexicon can influence the accuracy of the induced phrase pairs to a large extent. To learn a lexicon with a high precision, we follow Munteanu and Marcu (2006) to apply *Log-Likelihood-Ratios* (Dunning, 1993; Melamed, 2000; Moore, 2004a, 2004b) to estimate how strong the association is between a source-side word and its aligned target-side word. We employ the same algorithm used in (Munteanu and Marcu, 2006) which first use the GIZA++ (with grow-diag-final-and heuristic) to obtain the word alignment between source and target words, and then calculate the association strength between the aligned words. After using the log-likelihood-ratios algorithm<sup>2</sup>, we obtain a probabilistic bilingual lexicon with bidirectional translation probabilities from the out-of-domain data. In the final lexicon, the number of average translations is only 5. We call this lexicon *LLR-lex*.

In the electronic domain, we manually collected a lexicon which contains about 140k entries. It should be noted that there is no translation probability in this lexicon. In order to assign probabilities to each entry, we apply the *Corpus Translation Probability* which used in (Wu et al., 2008): given an in-domain source language monolingual data, we translate this data with the phrase-based model trained on the out-of-domain News data, the in-domain lexicon and the in-domain target language monolingual data (for language model estimation). With the source language data and its translation, we estimate the bidirectional translation probabilities for each entry in the original lexicon. For the entries whose translation probabilities are not estimated, we just assign a uniform probability. That is if a source word has  $n$  translations, then the translation probability of target word given the source word is  $1/n$ . We call this lexicon *Domain-lex*.

<sup>1</sup> LDC category numbers are: LDC2000T50, LDC2003E14, LDC2003E07, LDC2004T07, LDC2005T06, LDC2002L27, LDC2005T10 and LDC2005T34.

<sup>2</sup> Following Moore (2004b), we use the threshold 10 on LLR to filter out unlikely translations.

We combine *LLR-lex* and *Domain-lex* to obtain the final probabilistic bilingual lexicon for phrase pair induction.

## 4 Phrase Pair Induction Method

Given a probabilistic bilingual lexicon and two monolingual data, we present a simple but effective method for phrase pair induction in this section.

---

Input: Probabilistic bilingual lexicon  $V$  (each source word  $s$  maps a translation set  $V[s]$ )  
 Source language monolingual data  $S=\{s_n\} n=1\dots N$   
 Target language monolingual data  $T=\{t_m\} m=1\dots M$   
 Output: Phrase pairs  $P$

---

```

1: For each distinct source-side phrase  $s_i^j$  in  $S$ :
2:   If each  $s_k \in s_i^j$  in  $V$ :
3:     Collect  $V[s_k]_{k=i}^j$ 
4:     For each permutation  $s_i^{j'}$  of  $s_i^j$ :
5:       If  $t_{i'}^{j'}$  in  $T$ :  $\triangleright t_{k'} \in V[s_{k'}] k' \in [i, j]$ 
6:         Add phrase pair  $(s_i^j, t_{i'}^{j'})$  into  $P$ 

```

---

Figure 1: a naïve algorithm for phrase pair induction.

### 4.1 A Naïve Method

We first introduce a relatively naïve way to extract phrase pairs from the given resources. For a source phrase (word sequence), we can reorder the words in the phrase (permutation) first, and then obtain the target phrases with the bilingual lexicon (translation), and finally check if the target phrase is in the target monolingual data. The algorithm is given in Figure 1.

Figure 1 shows that the naïve algorithm is very easy to implement. However, the time complexity is too high. For each source phrase  $s_i^j$  (with  $(j-i+1)!$  permutations), suppose a source word has  $C$  translations on average and checking whether the target phrase  $t_{i'}^{j'}$  in  $T$  needs time  $O(|T|)$ , then, phrase pair induction for a single source phrase needs time  $O(C^{j-i+1}|T|(j-i+1)!)$ .

It is very time consuming. One may design smarter algorithms. For example, one can collect distinct  $n$ -grams from source and target monolingual data. Then, for a source-side phrase with length  $L$ , one can find the best translation candidate using the probabilistic bilingual lexicon from the target-side phrases with the same length  $L$ . The biggest disadvantage of these algorithms is that they can only induce phrase pair (with the

same length) encoding word reordering, but cannot learn phrase pairs in different length. Furthermore, they cannot learn idioms and unknown word translations from monolingual data. Obviously, these kind of approaches is not optimal.

## 4.2 Phrase Pair Induction with Inverted Index

In order to make the phrase pair induction both effective and efficient, we propose a method using inverted index data structure which is usually a central component of a typical search engine.

The inverted index is employed to represent the target language monolingual data. For a target language word, the inverted index not only records the sentence position in monolingual data, but also records the word position in a sentence. Some examples are shown in Table 2. By doing this, we do not need to iterate all the permutations of source language phrase  $s_i^j$  to explore possible phrase pairs encoding word reordering. Furthermore, it is possible to learn idiom translation and unknown word translations. We will elaborate how to induce phrase pairs with the help of inverted index.

Target Language Word	Position
communication	(2,5), (106,20), ..., (23022, 12)
...	...
zoom	(90,2), (280,21), ..., (90239,15)

Table 2: Some examples of inverted index for target language words, (2,5) means that “communication” occurs at the 5<sup>th</sup> word of the 2<sup>nd</sup> sentence in the target monolingual data.

The new algorithm for phrase pair induction is presented in Figure 2. Line 1 iterates all the distinct phrases in the source-side monolingual data. It can be implemented by collecting all the distinct n-grams in which n is the phrase length we are interested in (3 to 7 in this paper). For each distinct source-side phrase, Line 2-5 efficiently collects all the positions in the target monolingual data for the translations of each word in the source phrase. Line 6 sorts the positions so that we can easily find the position sequence belonging to a same sentence. Line 8-9 discards all the position sub-sequences that lack translations for more than one source-side words. That is to say we allow at most one unknown word in an induced phrase pair in order to make the induction more accurate. Line 10 and Line 12 is the core of this algorithm. We first define a constraint before detailing the algorithm.

---

Input: Probabilistic bilingual lexicon  $V$  (each source word  $s$  maps a translation set  $V[s]$ )  
Source language monolingual data  $S=\{s_n\} n=1\dots N$   
Inverted index representing target language monolingual data  $IMap$

---

Output: Phrase pairs  $P$

---

```

1: For each distinct source-side phrase  $s_i^j$  in  $S$ :
2:    $positionArray = []$ 
3:   For each  $s_k \in s_i^j$ :
4:     For each  $t \in V[s_k]$ :
5:       add  $IMap[t]$  into  $positionArray$ 
6:   Sort  $positionArray$ 
7:   For each sequence in a same sentence in  $positionArray$ :
8:     If more than 1 word in  $s_i^j$  has no trans in the seq:
9:       Discard this seq and continue
10:    Probability smoothing for single word gap
11:    For all continuous position sub-sequence:
12:      Find the one  $t_h^k$  with maximum probability
13:    Add phrase pair  $(s_i^j, t_h^k)$  into  $P$ 

```

---

Figure 2: Phrase pair induction using inverted index.

**Constraint:** we require that there exists at most one phrase in a target sentence that is the translation of the source-side phrase.

According to our analysis, it is not often to find that two phrases (length larger than 2) in a same sentence have the same meaning. Even if it happens, it is reasonable to keep the one with the highest probability. Given a position sequence belonging to a same sentence, Line 10 smoothes the probability of the single word gap according to the probabilities of the around words. Single word gap means that this word is not aligned but its left and right words are aligned with the words of the source-side phrase. Suppose the target sub-sequence is  $t_i \dots t_{i+r} \dots t_j$  and  $t_{i+r}$  is the only word that is not aligned with source-side words. We smooth the probability  $p(t_{i+r} | null)$  as follows:

$$p(t_{i+r} | null) = \begin{cases} \frac{\min\{p(t_i | s_i), p(t_j | s_j)\}}{2}, & \text{if } r=1 \text{ or } r+1=j \\ \frac{p(t_{i+r-1} | s_{i+r-1}) + p(t_{i+r+1} | s_{i+r+1})}{2}, & \text{otherwise} \end{cases} \quad (1)$$

The above formula means that if the left or the right side only has one word, then the smoothed probability is one half of the minimum of the probabilities of the two neighbors, otherwise the smoothed probability is the average of the probabilities of the two neighbors. This smoothing strategy encourages that if more words around the un-aligned word are translations of the source-side phrase, then the gap word is more likely to belong to the translations of the source-side phrase.

After probability smoothing of the single gap word, we are ready to extract the candidate translation of the source-side phrase. Similar with Line 9 in Figure 2, we further filter the target continuous phrase if more than one word in source-side phrase has no translation in this target phrase. After that, we just choose the continuous target phrase with the largest probability if two or more continuous target phrases exist in the same target sentence. The probability of a target-side phrase given the source-side phrase is computed similar to that of (Koehn et al., 2003) except that we impose length normalization:

$$p_{lex}(t|s,a) = \left[ \prod_{i=1}^n \frac{1}{|\{j|(i,j) \in a\}|} \sum_{\forall(i,j) \in a} p(t_i|s_j) \right]^{\frac{1}{n}} \quad (2)$$

where the alignment  $a$  is produced using probabilistic bilingual lexicon. If a target word in  $t$  is a gap word, we suppose there is a word alignment between the target gap word and the source-side *null*.

Similarly, we can compute the probability of source-side phrase given the target-side phrase  $p_{lex}(s|t,a)$ . Then, we find the target-side phrase which has the biggest value of  $p_{lex}(t|s,a) \cdot p_{lex}(s|t,a)$ . Line 13 in Figure 2 collects the induced phrase pairs.

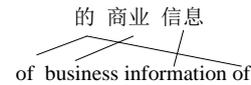

For the time complexity, it depends on the length of *positionArray*, since the time complexity of the core algorithm (Line 7-13) is proportional to the length of *positionArray*. If *positionArray* contains almost all the positions in the target monolingual data  $T$ , then the worst time complexity will be  $O(|T|\log|T|)$  (for array sort). However, we find in the target monolingual data (1 million sentences) that each distinct word happens 110 times on average. Then, for a source-side phrase with 7 words, the average length of *positionArray* will be 3850, since each source word has averagely 5 target translations (mentioned in Section 3). Therefore, the algorithm is relatively efficient in the average case.

## 5 Phrase Pair Refinement and Parameterization

### 5.1 Phrase Pair Refinement

Some of the phrase pairs induced in Section 4 may contain noise. According to our analysis, we find that the biggest problem is that in the target-side of the phrase pair, there are two or more identical words aligned to the same source-

side word. For example, we extract a phrase pair as follows:

In the above phrase pair, there are two words “of” in the target side and the first one is redundant. The phrase pair induction algorithm presented in Section 4 cannot deal with this situation. In this section, we propose a simple approach to handle this problem. For each entry in *LLR-lex*, such as (的, of), we can learn two kinds of information from the out-of-domain word-aligned sentence pairs: one is whether the target translation is before or after the translation of the preceding source-side word (Order); the other is whether the target translation is adjacent with the translation of the preceding source-side word (Adjacency). If the source-side word is the beginning of the phrase, we calculate the corresponding information with the succeeding word instead of the preceding word. For the entries in *Domain-lex*, we constrain that the target translation should be adjacent with the translations of its source-side neighbors and translation order is the same with the source-side words.

With the Order and Adjacency information, we first check the order information, and then check the adjacency information if the duplicates cannot be handled using order information. For example, since (的, of) is an entry in *LLR-lex* and we have learned that “of” is much more likely to be behind the translation of the succeeding word. Thus, the first word “of” can be discarded. This refinement can be applied before finding the phrase pair with maximum probability (Line 12 in Figure 2) so that the duplicate words do not affect the calculation of translation probability of phrase pair.

### 5.2 Translation Probability Estimation

It is well known that in the phrase-based SMT there are four translation probabilities and the reordering probability for each phrase pair.

The translation probabilities in the traditional phrase-based SMT include bidirectional phrase translation probabilities and bidirectional lexical weights. For the lexical weights, we can use the  $p_{lex}(s|t,a)$  and  $p_{lex}(t|s,a)$  computed in the above section without length normalization. However, for the phrase-level probability, we cannot use maximum likelihood estimation since the phrase pairs are not extracted from parallel sentences.

In this paper, we borrow and extend the idea of (Klementiev et al., 2012) to calculate the phrase-level translation probability with context information in source and target monolingual corpus. The value is calculated using a vector space model. With source and target vocabularies  $(s_1, s_2, \dots, s_N)$  and  $(t_1, t_2, \dots, t_M)$ , the source-side phrase  $s$  and target-side phrase  $t$  can be respectively represented in an  $N$ - and  $M$ -dimensional vector. The  $k$ -th component of  $s$ 's contextual vector is computed using the method of (Fung and Yee, 1998) as follows:

$$w_k = n_{s,k} \times (\log(n_{\max} / n_k) + 1) \quad (3)$$

where  $n_{s,k}$  and  $n_k$  denotes the number of times  $s_k$  occurs in the context of  $s$  and in the entire source language monolingual data, and  $n_{\max}$  is the maximum number of occurrence of any source-side word in the source language monolingual data. The  $k$ -th element of  $t$ 's vector can be computed with the same method. We finally normalize these vectors with  $L_2$ -norm.

With the  $s$ 's and  $t$ 's contextual vector representations, we calculate two similarities: 1) project  $s$ 's vector into target side  $\hat{t}$  with the lexical mapping  $p(t/s)$ , and then get the similarity by computing the cosine of two angles between  $t$ 's and  $\hat{t}$ 's vectors; 2) project  $t$ 's vector into source side  $\hat{s}$  with the lexical mapping  $p(s/t)$ , and then obtain the similarity between  $s$ 's and  $\hat{s}$ 's vectors. These two contextual similarities will serve as two phrase-level translation probabilities.

### 5.3 Reordering Probability Estimation

For the reordering probabilities of newly induced phrase pairs, we can also follow Klementiev et al. (2012) to estimate these probabilities using source and target monolingual data. The method is to calculate six probabilities for monotone, swap or discontinuous cases. For the phrase pair (的商业信息, business information of), we find a source sentence containing 的商业信息, and find a target sentence containing *business information of*. If there is another phrase pair  $(\bar{s}, \bar{t})$ ,  $\bar{t}$  exactly follows *business information of* and  $\bar{s}$  occurs in the same source sentence with 的商业信息, then we compare the position relationship between  $\bar{s}$  and 的商业信息. We increment the swap count if  $\bar{s}$  is just before 的商业信息. After counting, we finally use maximum likelihood estimation method to compute the reordering probabilities.

## 6 Related Work

As far as we know, few researchers study phrase pair induction from only monolingual data.

There are three research works that are most related with ours. One is using an in-domain probabilistic bilingual lexicon to extract sub-sentential parallel fragments from comparable corpora (Munteanu and Marcu, 2006; Quirk et al., 2007; Cettolo et al., 2010). Munteanu and Marcu (2006) first extract the candidate parallel sentences from the comparable corpora and further extract the accurate sub-sentential bilingual fragments from the candidate parallel sentences using the in-domain probabilistic bilingual lexicon. Compared with their work, our focus is to induce phrase pairs directly from monolingual data rather than comparable data. Thus, finding the candidate parallel sentences is not possible in our situation.

Another is to make full use of monolingual data with transductive learning (Ueffing et al., 2007; Schwenk, 2008; Wu et al., 2008; Bertoldi and Federico, 2009). For the target-side monolingual data, they just use it to train language model, and for the source-side monolingual data, they employ a baseline (word-based SMT or phrase-based SMT trained with small-scale bitext) to first translate the source sentences, combining the source sentence and its target translation as a bilingual sentence pair, and then train a new phrase-base SMT with these pseudo sentence pairs. This method cannot learn idiom translations and unknown word translations.

The third is to estimate the translation parameters and reordering parameters using monolingual data given the phrase pairs (Klementiev et al., 2012). Their work supposes the phrase pairs are already given and then corresponding parameters can be learned with monolingual data. Different from their work, we concentrate ourselves on inducing phrase pairs from monolingual data and then borrow some ideas from theirs for parameter estimation. Furthermore, we extend their contextual similarity between source and target phrases to both directions.

## 7 Experiments

### 7.1 Experimental Setup

Our purpose is to induce phrase pairs to improve translation quality for domain adaptation. We have introduced the out-of-domain data and the electronic in-domain lexicon in Section 3. Here we introduce other information about the in-

domain data. Besides the in-domain lexicon, we have collected respectively 1 million monolingual sentences in electronic area from the web. They are neither parallel nor comparable because we cannot even extract a small number of parallel sentence pairs from this monolingual data using the method of (Munteanu and Marcu, 2006). We further employ experts to translate 2000 Chinese electronic sentences into English. The first half is used as the tuning set (*elec1000-tune*) and the second half is employed as the testing set (*elec1000-test*).

We construct two kinds of phrase-based models using Moses (Koehn et al., 2007): one uses out-of-domain data and the other uses in-domain data. For the out-of-domain data, we build the phrase table and reordering table using the 2.08 million Chinese-to-English sentence pairs, and we use the SRILM toolkit (Stolcke, 2002) to train the 5-gram English language model with the target part of the parallel sentences and the Xinhua portion of the English Gigaword. For the in-domain electronic data, we first consider the lexicon as a phrase table in which we assign a constant 1.0 for each of the four probabilities, and then we combine this initial phrase table and the induced phrase pairs to form the new phrase table. The in-domain reordering table is created for the induced phrase pairs. An in-domain 5-gram English language model is trained with the target 1 million monolingual data.

We use BLEU (Papineni et al., 2002) score with shortest length penalty as the evaluation metric and apply the pairwise re-sampling approach (Koehn, 2004) to perform the significance test.

## 7.2 Experimental Results

In this section, we first conduct experiments to figure out how the translation performance degrades when the domain changes. To better illustrate the comparison, we first use News data to evaluate the NIST evaluation tests and then use the same News data to evaluate the electronic test sets. For the NIST evaluation, we employ Chinese-to-English NIST MT03 as the tuning set and NIST MT05 as the test set. Table 3 gives the results. It is obvious that, it is relatively high when using the News training data to evaluate the same News test set. However, when the test domain is changed, the translation performance decreases to a large extent.

Given the in-domain bilingual lexicon and two monolingual data, previous works also proposed

some good methods to explore the potential of the given data to improve the translation quality. Here, we implement their approaches and use them as our strong baseline. Wu et al. (2008) regards the in-domain lexicon with corpus translation probability as another phrase table and further use the in-domain language model besides the out-of-domain language model. Table 4 gives the results. We can see from the table that the domain lexicon is much helpful and significantly outperforms the baseline with more than 4.0 BLEU points. When it is enhanced with the in-domain language model, it can further improve the translation performance by more than 2.5 BLEU points. This method has made good use of in-domain lexicon and the target-side in-domain monolingual data, but it does not take full advantage of the in-domain source-side monolingual data.

In order to use source-side monolingual data, Ueffing et al. (2007), Schwenk (2008), Wu et al. (2008) and Bertoldi and Federico (2009) employed the transductive learning to first translate the source-side monolingual data using the best configuration (baseline+in-domain lexicon+in-domain language model) and obtain 1-best translation for each source-side sentence. With the source-side sentences and their translations, the new phrase table and reordering table are built. Then, these resources are added into the best configuration. The experimental results are presented in the last row of Table 4. From the results, we see that transductive learning can further improve the translation performance significantly by 0.6 BLEU points.

In transductive learning, in-domain lexicon and both-side monolingual data have been explored. However, this method does not take full advantage of both-side monolingual data because it uses source and target monolingual data individually. In our method, we explore fully the source and target monolingual data to induce translation equivalence on the phrase level. In order to make the phrase pair induction more efficient, we first sort all the sentences in the both-side monolingual data according to the word hit rate in the bilingual lexicon. Then, we conduct six sets of experiments respectively on the first 100k, 200k, 300k, 500k and whole 1m sentences. All the experiments are run based on the configuration with BLEU 13.41 in Table 4, and we call this configuration *BestConfig*. Note that the unknown words are only allowed if the source-side of a phrase pair has more than 3 words. Table 5 shows the results.

Training Data	Tune Data (NIST MT03)	Test Data (NIST MT05)
2.08M sentence pairs in News	35.79	34.26
	Tune Data (elec1000-tune)	Test Data (elec1000-test)
	7.93	6.69

Table 3: Experimental results using News training data to test NIST evaluation data and electronic data (numbers denote BLEU score points in percent).

Method	Tune (elec1000-tune)	Test (elec1000-test)
Baseline	7.93	6.69
baseline + in-domain lexicon	10.97	<b>10.87</b>
baseline + in-domain lexicon + in-domain language model	13.72	<b>13.41<sup>++</sup></b>
Transductive Learning	14.13	<b>14.01*</b>

Table 4: Experimental results using News training data, in-domain lexicon, language model and transductive learning. **Bold** figures mean that the results are statistically significant better than the baseline with  $p < 0.01$ , and “<sup>++</sup>” denotes the result is statistically significant better than *baseline+in-domain lexicon*. “\*” means that the result is statistically significant better than 13.41 with  $p < 0.05$ .

Method	Tune (BLEU %)	Test (BLEU %)
BestConfig	13.72	13.41
+phrase pair induction (100k)	14.23	<b>14.06</b>
+phrase pair induction (200k)	14.45	<b>14.24</b>
+phrase pair induction (300k)	14.76	<b>14.83<sup>++</sup></b>
+phrase pair induction (500k)	14.98	<b>15.16<sup>++</sup></b>
+phrase pair induction (1m)	15.11	<b>15.30<sup>++</sup></b>

Table 5: Experimental results of our phrase pair induction method. **Bold** figures denotes the corresponding method significantly outperform the BestConfig with  $p < 0.05$ . **Bold** and *Italic* figures means the results are significantly better than that of BestConfig with  $p < 0.01$ . “<sup>++</sup>” denotes that the corresponding approach performs significantly better than Transductive Learning with  $p < 0.01$ .

Method	Before Filtering	After Filtering
+phrase pair induction (100k)	72,615	8,724
+phrase pair induction (200k)	108,948	12,328
+phrase pair induction (300k)	136,529	17,505
+phrase pair induction (500k)	150,263	19,862
+phrase pair induction (1m)	169,172	21,486

Table 6: the number of phrase pairs induced with different size of monolingual data.

We can see from the table that our method obtains the best translation performance. When using the first 100k sentences for phrase pair induction, it obtains a significant improvement over the BestConfig by 0.65 BLEU points and can outperform the transductive learning method. When we use more monolingual data, the performance becomes even better. The method of phrase pair induction using 300k sentences performs quite well. It outperforms the BestConfig significantly with an improvement of 1.42 BLEU points and it also performs much better than transductive learning method with gains of 0.82 BLEU points. With the monolingual data larger

and larger, the gains become smaller and smaller because the word hit rate gets lower and lower. These experimental results empirically show the effectiveness of our proposed phrase pair induction method.

A question remains that how many new phrase pairs are induced with different size of monolingual data. Here, we give respectively the statistics before and after filtering with the 1000 test sentences. Table 6 shows the statistics. We can see from the table that lots of new phrase pairs can be induced since the source and target monolingual data is in the same domain. However, since the source and target monolingual data is

far from parallel, most of the phrase pairs are not long. For example, in the 108,948 distinct phrase pairs, we find that the phrase pair distribution according to source-side length is (3:50.6%, 4:35.6%, 5:3.3%, 6:9.8%, 7:0.7%). It is easy to see that the phrase pairs whose source-side length longer than 4 account for only a very small part.

## 8 Conclusion and Future Work

This paper proposes a simple but effective method to induce phrase pairs from monolingual data. Given the probabilistic bilingual lexicon and both-side monolingual data in the same domain, the method employs inverted index structure to represent the target-side monolingual data, and induce the translations for each distinct source-side phrase with the help of the bilingual lexicon. We further propose an approach to refine the result phrase pairs to make them more accurate. We also introduce how to estimate the translation and reordering parameters for the induced phrase pairs with monolingual data. Extensive experiments on domain adaptation have shown that our method can significantly outperform previous methods which also focus on exploring the in-domain lexicon and monolingual data.

However, through the analysis we find that our induced phrase pairs still contain some noise, such as the words in source- and target-side of the phrase pair are all aligned but the target-side phrase expresses the different meaning. Furthermore, our proposed method cannot learn expressions which are not lexical translations but are semantic ones. In the future, we will study further on these phenomena and propose new methods to handle these problems.

## Abstract

Words often gain new senses in new domains. Being able to automatically identify, from a corpus of monolingual text, which word *tokens* are being used in a previously unseen sense has applications to machine translation and other tasks sensitive to lexical semantics. We define a task, SENSESPOTTING, in which we build systems to spot tokens that have new senses in new domain text. Instead of difficult and expensive annotation, we build a gold-standard by leveraging cheaply available parallel corpora, targeting our approach to the problem of domain adaptation for machine translation. Our system is able to achieve F-measures of as much as 80%, when applied to word types it has *never seen before*. Our approach is based on a large set of novel features that capture varied aspects of how words change when used in new domains.

## 1 Introduction

As Magnini et al. (2002) observed, the domain of the text that a word occurs in is a useful signal for performing word sense disambiguation (e.g. in a text about finance, *bank* is likely to refer to a financial institution while in a text about geography, it is likely to refer to a *river bank*). However, in the classic WSD task, ambiguous word types and a set of possible senses are known in advance. In this work, we focus on the setting where we observe texts in two different domains and want to identify words in the second text that have a sense that did not appear in the first text, without any lexical knowledge in the new domain.

To illustrate the task, consider the French noun *rapport*. In the parliament domain, this means

	<i>état</i>	<i>rapport</i>	<i>régime</i>
Govt.	geo. state	report	(political) regime
Medical	state (mind) geo. state	report ratio	diet (political) regime
Science	geo. state	ratio report	(political) regime diet
Movies	geo. state	report	(political) regime diet

Table 1: Examples of French words and their most frequent senses (translations) in four domains.

(and is translated as) “report.” However, in moving to a medical or scientific domain, the word *gains a new sense*: “ratio”, which simply does not exist in the parliament domain. In a science domain, the “report” sense exists, but it is dominated about 12:1 by “ratio.” In a medical domain, the “report” sense remains dominant (about 2:1), but the new “ratio” sense appears frequently.

In this paper we define a new task that we call SENSESPOTTING. The goal of this task is to identify words in a new domain monolingual text that appeared in old domain text but which have a new, previously unseen sense<sup>1</sup>. We operate under the framework of phrase sense disambiguation (Carpuat and Wu, 2007), in which we take automatically align *parallel* data in an old domain to generate an initial old-domain sense inventory. This sense inventory provides the set of “known” word senses in the form of phrasal translations. Concrete examples are shown in Table 1. One of our key contributions is the development of a rich set of features based on monolingual text that are indicative of new word senses.

This work is driven by an application need. When machine translation (MT) systems are applied in a new domain, many errors are a result of: (1) previously unseen (OOV) source language words, or (2) source language words that appear with a new sense and which require new transla-

<sup>1</sup>All features, code, data and raw results are at: [github.com/hal3/IntrinsicPSDEvaluation](https://github.com/hal3/IntrinsicPSDEvaluation)

tions<sup>2</sup> (Carpuat et al., 2012). Given monolingual text in a new domain, OOVs are easy to identify, and their translations can be acquired using dictionary extraction techniques (Rapp, 1995; Fung and Yee, 1998; Schafer and Yarowsky, 2002; Schafer, 2006; Haghghi et al., 2008; Mausam et al., 2010; Daumé III and Jagarlamudi, 2011), or active learning (Bloodgood and Callison-Burch, 2010). However, previously seen (even frequent) words which require new translations are harder to spot.

Because our motivation is translation, one significant point of departure between our work and prior related work (§3) is that we focus on *word tokens*. That is, we are not interested *only* in the question of “has this known word (type) gained a new sense?”, but the much more specific question of “is this particular (token) *occurrence* of this known word being used in a new sense?” Note that for both the dictionary mining setting *and* the active learning setting, it is important to consider words in context when acquiring their translations.

## 2 Task Definition

Our task is defined by two data components. Details about their creation are in §5. First, we need an old-domain sense dictionary, extracted from French-English parallel text (in our case, parliamentary proceedings). Next, we need new-domain monolingual French text (we use medical text, scientific text and movie subtitle text). Given these two inputs, our challenge is to find tokens in the new-domain text that are being used in a new sense (w.r.t. the old-domain dictionary).

We assume that we have access to a small amount of new domain parallel “tuning data.” From this data, we can extract a small new domain dictionary (§5). By comparing this new domain dictionary to the old domain dictionary, we can identify which words have gained new senses. In this way, we turn the SENSESPOTTING problem into a supervised binary classification problem: an example is a French word in context (in the new domain monolingual text) and its label is positive when it is being used in a sense that did not exist in the old domain dictionary. In this task, the classifier is always making predictions on words

---

<sup>2</sup>Sense shifts do not always demand new translations; some ambiguities are preserved across languages. E.g., *fenêtre* can refer to a window of a building or on a monitor, but translates as “window” either way. Our experiments use bilingual data with an eye towards improving MT performance: we focus on words that demand new translations.

*outside* this tuning data on word types it *has never seen before!* From an applied perspective, the assumption of a small amount of parallel data in the new domain is reasonable: if we want an MT system for a new domain, we will likely have some data for system tuning and evaluation.

## 3 Related Work

While word senses have been studied extensively in lexical semantics, research has focused on word sense disambiguation, the task of disambiguating words in context given a predefined sense inventory (e.g., Agirre and Edmonds (2006)), and word sense induction, the task of learning sense inventories from text (e.g., Agirre and Soroa (2007)). In contrast, detecting novel senses has not received as much attention, and is typically addressed within word sense induction, rather than as a distinct SENSESPOTTING task. Novel sense detection has been mostly motivated by the study of language change over time. Most approaches model changes in co-occurrence patterns for *word types* when moving between corpora of old and modern language (Sagi et al., 2009; Cook and Stevenson, 2010; Gulordava and Baroni, 2011).

Since these type-based models do not capture polysemy in the new language, there have been a few attempts at detecting new senses at the token-level as in SENSESPOTTING. Lau et al. (2012) leverage a common framework to address sense induction and disambiguation based on topic models (Blei et al., 2003). Sense induction is framed as learning topic distributions for a word type, while disambiguation consists of assigning topics to word tokens. This model can interestingly be used to detect newly coined senses, which might co-exist with old senses in recent language. Baman and Crane (2011) use parallel Latin-English data to learn to disambiguate Latin words into English senses. New English translations are used as evidence that Latin words have shifted sense. In contrast, the SENSESPOTTING task consists of detecting when senses are unknown in parallel data.

Such novel sense induction methods require manually annotated datasets for the purpose of evaluation. This is an expensive process and therefore evaluation is typically conducted on a very small scale. In contrast, our SENSESPOTTING task leverages automatically word-aligned parallel corpora as a source of annotation for supervision during training and evaluation.

The impact of domain on novel senses has also received some attention. Most approaches operate at the *type*-level, thus capturing changes in the most frequent sense of a word when shifting domains (McCarthy et al., 2004; McCarthy et al., 2007; Erk, 2006; Chan and Ng, 2007). Chan and Ng (2007) notably show that detecting changes in predominant sense as modeled by domain sense priors can improve sense disambiguation, even after performing adaptation using active learning.

Finally, SENSESPOTTING has not been addressed directly in MT. There has been much interest in translation mining from parallel or comparable corpora for *unknown* words, where it is easy to identify which words need translations. In contrast, SENSESPOTTING detects when words have new senses and, thus, frequently a new translation. Work on active learning for machine translation has focused on collecting translations for longer unknown segments (e.g., Bloodgood and Callison-Burch (2010)). There has been some interest in detecting which phrases that are hard to translate for a given system (Mohit and Hwa, 2007), but difficulties can arise for many reasons: SENSESPOTTING focuses on a single problem.

## 4 New Sense Indicators

We define features over both *word types* and *word tokens*. In our classification setting, each instance consists of a French word token in context. Our *word type* features ignore this context and rely on statistics computed over our entire new domain corpus. In contrast, our *word token* features consider the context of the particular instance of the word. If it were the case that only one sense existed for all word tokens of a particular type within a single domain, we would expect our word type features to be able to spot new senses without the help of the word token features. However, in fact, even within a single domain, we find that often a word type is used with several senses, suggesting that word token features may also be useful.

### 4.1 Type-level Features

**Lexical Item Frequency Features** A very basic property of the new domain that we hope to capture is that word frequencies change, and such changes might be indicative of a domain shift. As such, we compute unigram log probabilities (via smoothed relative frequencies) of each word under consideration in the old domain and the new domain. We then add as features these two log

probabilities as well as their difference. These are our **Type:RelFreq** features.

**N-gram Probability Features** The goal of the **Type:NgramProb** feature is to capture the fact that “unusual contexts” might imply new senses. To capture this, we can look at the log probability of the word under consideration given its N-gram context, both according to an old-domain language model (call this  $\ell_{ng}^{old}$ ) and a new-domain language model (call this  $\ell_{ng}^{new}$ ). However, we do not simply want to capture unusual words, but words that are unlikely in context, so we also need to look at the respective unigram log probabilities:  $\ell_{ug}^{old}$  and  $\ell_{ug}^{new}$ . From these four values, we compute corpus-level (and therefore type-based) statistics of the new domain n-gram log probability ( $\ell_{ng}^{new}$ , the difference between the n-gram probabilities in each domain ( $\ell_{ng}^{new} - \ell_{ng}^{old}$ ), the difference between the n-gram and unigram probabilities in the new domain ( $\ell_{ng}^{new} - \ell_{ug}^{new}$ ), and finally the combined difference:  $\ell_{ng}^{new} - \ell_{ug}^{new} + \ell_{ug}^{old} - \ell_{ng}^{old}$ ). For each of these four values, we compute the following type-based statistics over the monolingual text: mean, standard deviation, minimum value, maximum value and sum. We use trigram models.

**Topic Model Feature** The intuition behind the topic model feature is that if a word’s distribution over topics changes when moving into a new domain, it is likely to also gain a new sense. For example, suppose that in our old domain, the French word *enceinte* is only used with the sense “wall,” but in our new domain, *enceinte* may have senses corresponding to either “wall” or to “pregnant.” We would expect to see this reflected in *enceinte*’s distribution over topics: the topic that places relatively high probabilities on words such as “bébé” (English “baby”) and *enfant* (English “child”) will also place a high probability on *enceinte* when trained on new domain data. In the old domain, however, we would not expect a similar topic (if it exists) to give a high probability to *enceinte*. Based on this intuition, for all words  $w$ , where  $T_o$  and  $T_n$  are the set of old and new topics and  $P_o$  and  $P_n$  are the old and new distributions defined over them, respectively, and  $cos$  is the cosine similarity between a pair of topics, we define the feature **Type:TopicSim**:  $\sum_{t \in T_n, t' \in T_o} P_n(t|w)P_o(t'|w)cos(t, t')$ . For a word  $w$ , the feature value will be high if, for each new domain topic  $t$  that places high probability on  $w$ , there is an old domain topic  $t'$  that

is similar to  $t$  and also places a high probability on  $w$ . Conversely, if no such topic exists, the score will be low, indicating the word has gained a new sense. We use the online LDA (Blei et al., 2003; Hoffman et al., 2010), implemented in <http://hunch.net/~vw/> to compute topics on the two domains separately. We use 100 topics.

**Context Feature** It is expected that words acquiring new senses will tend to neighbor different sets of words (e.g. different arguments, prepositions, parts of speech, etc.). Thus, we define an additional type level feature to be the ratio of the number of new domain n-grams (up to length three) that contain word  $w$  and which do not appear in the old domain to the total number of new domain n-grams containing  $w$ . With  $N_w$  indicating the set of n-grams in the new domain which contain  $w$ ,  $O_w$  indicating the set of n-grams in the old domain which contain  $w$ , and  $|N_w - O_w|$  indicating the n-grams which contain  $w$  and appear in the new but not the old domain, we define **Type:Context** as  $\frac{|N_w - O_w|}{|N_w|}$ . We do not count n-grams containing OOVs, as they may simply be instances of applying the same sense of a word to a new argument

## 4.2 Token-level Features

**N-gram Probability Features** Akin to the N-gram probability features at the type level (namely, **Token:NgramProb**), we compute the same values at the token level (new/old domain and unigram/trigram). Instead of computing statistics over the entire monolingual corpus, we use the instantaneous values of these features for the token under consideration. The six features we construct are: unigram (and trigram) log probabilities in the old domain, the new domain, and their difference.

**Context Features** Following the type-level n-gram feature, we define features for a particular word *token* based on its n-gram context. For token  $w_i$ , in position  $i$  in a given sentence, we consider its context words in a five word window:  $w_{i-2}$ ,  $w_{i-1}$ ,  $w_{i+1}$ , and  $w_{i+2}$ . For each of the four contextual words in positions  $p = \{-2, -1, 1, 2\}$ , relative to  $i$ , we define the following feature, **Token:CtxCnt**:  $\log(c_{w_p})$  where  $c_{w_p}$  is the number of times word  $w_p$  appeared in position  $p$  relative to  $w_i$  in the OLD-domain data. We also define a single feature which is the percent of the four contextual words which had been seen in the OLD-domain data, **Token:Ctx%**.

**Token-Level PSD Features** These features aim to capture generalized characteristics of a context.

Towards this end, first, we pose the problem as a phrase sense disambiguation (PSD) problem over the known sense inventory. Given a source word in a context, we train a classifier to predict the most likely target translation. The ground truth labels (target translation for a given source word) for this classifier are generated from the phrase table of the old domain data. We use the same set of features as in Carpuat and Wu (2007). Second, given a source word  $s$ , we use this classifier to compute the probability distribution of target translations ( $p(t|s)$ ). Subsequently, we use this probability distribution to define new features for the SENSESPOTTING task. The idea is that, if a word is used in one of the known senses then its context must have been seen previously and hence we hope that the PSD classifier outputs a spiky distribution. On the other hand, if the word takes a new sense then hopefully it is used in an unseen context resulting in the PSD classifier outputting an uniform distribution. Based on this intuition, we add the following features: **MaxProb** is the maximum probability of any target translation:  $\max_t p(t|s)$ . **Entropy** is the entropy of the probability distribution:  $-\sum_t p(t|s) \log p(t|s)$ . **Spread** is the difference between maximum and minimum probabilities of the probability distribution:  $(\max_t p(t|s) - \min_t p(t|s))$ . **Confusion** is the uncertainty in the most likely prediction given the source token:  $\frac{\text{median}_t p(t|s)}{\max_t p(t|s)}$ . The use of median in the numerator rather than the second best is motivated by the observation that, in most cases, top ranked translations are of the same sense but differ in morphology.

We train the PSD classifier in two modes: 1) a single global classifier that predicts the target translation given any source word; 2) a local classifier for each source word. When training the global PSD classifier, we include some lexical features that depend on the source word. For both modes, we use real valued and binned features giving rise to four families of features **Token:G-PSD**, **Token:G-PSDBin**, **Token:L-PSD** and **Token:L-PSDBin**.

**Prior vs. Posterior PSD Features** When the PSD classifier is trained in the second mode, i.e. one classifier per word type, we can define additional features based on the prior (with out the word context) and posterior (given the word's context) probability distributions output by the classifier, i.e.  $p_{\text{prior}}(t|s)$  and  $p_{\text{post}}(t|s)$  respec-

Domain	Sentences	Lang	Tokens	Types
Hansard	8,107,356	fr	161,695,309	191,501
		en	144,490,268	186,827
EMEA	472,231	fr	6,544,093	34,624
		en	5,904,296	29,663
Science	139,215	fr	4,292,620	117,669
		en	3,602,799	114,217
Subs	19,239,980	fr	154,952,432	361,584
		en	174,430,406	293,249

Table 2: Basic characteristics of the parallel data.

tively. We compute the following set of features referred to as **Token:PSDRatio**: **SameMax** checks if both the prior and posterior distributions have the same translation as the most likely translation. **SameMin** is same as the above feature but check if the least likely translation is same. **X-OR\_MinMax** is the exclusive-OR of **SameMax** and **SameMin** features. **KL** is the KL-divergence between the two distributions. Since KL-divergence is asymmetric, we use  $KL(p_{\text{prior}}||p_{\text{post.}})$  and  $KL(p_{\text{post.}}||p_{\text{prior}})$ . **MaxNorm** is the ratio of maximum probabilities in prior and posterior distributions. **SpreadNorm** is the ratio of spread of the prior and posterior distributions, where spread is the difference between maximum and minimum probabilities of the distribution as defined earlier. **ConfusionNorm** is the ratio of confusion of the prior and posterior distributions, where confusion is defined as earlier.

## 5 Data and Gold Standard

The first component of our task is a parallel corpus of old domain data, for which we use the French-English Hansard parliamentary proceedings (<http://www.parl.gc.ca>). From this, we extract an old domain sense dictionary, using the Moses MT framework (Koehn et al., 2007). This defines our old domain sense dictionary. For new domains, we use three sources: (1) the EMEA medical corpus (Tiedemann, 2009), (2) a corpus of scientific abstracts, and (3) a corpus of translated movie subtitles (Tiedemann, 2009). Basic statistics are shown in Table 2. In all parallel corpora, we normalize the English for American spelling.

To create the gold standard *truth*, we followed a lexical sample approach and collected a set of 300 “representative types” that are interesting to evaluate on, because they have multiple senses within a single domain or whose senses are likely to change in a new domain. We used a semi-automatic approach to identify representative types. We first used the phrase table from

	Parallel		Repr. Types	Repr. Tokens	% New Sense
	Sents	fr-tok			
EMEA	24k	270k	399	35,266	52.0%
Science	22k	681k	425	8,355	24.3%
Subs	36k	247k	388	22,598	43.4%

Table 3: Statistics about representative words and the size of the development sets. The columns show: the total amount of parallel development data (# of sentences and tokens in French), # of representative types that appear in this corpus, the corresponding # of tokens, and the percentage of these tokens that correspond to “new senses.”

the Moses output to rank phrases in each domain using TF-IDF scores with Okapi BM25 weighting. For each of the three new domains (EMEA, Science, and Subs), we found the intersection of phrases between the old and the new domain. We then looked at the different translations that each had in the phrase table and a French speaker selected a subset that have multiple senses.<sup>3</sup>

In practice, we limited our set almost entirely to source *words*, and included only a single multi-word phrase, *vue des enfants*, which usually translates as “for children” in the old domain but almost always translates as “sight of children” in the EMEA domain (as in “. . . should be kept out of *the sight of children*”). Nothing in the way we have defined, approached, or evaluated the SENSESPOTTING task is dependent on the use of representative words instead of longer representative phrases. We chose to consider mostly source language words for simplicity and because it was easier to identify good candidate words.

In addition to the manually chosen words, we also identified words where the translation with the highest lexical weight varied in different domains, with the intuition being that are the words that are likely to have acquired a new sense. The top 200 words from this were added to the manually selected representative words to form a list of 450. Table 3 shows some statistics about these words across our three test domains.

## 6 Experiments

### 6.1 Experimental setup

Our goal in evaluation is to be able to understand what our approach is realistically capable of. One challenge is that the distribution

<sup>3</sup>In order to create the *evaluation data*, we used both sides of the full parallel text; we do *not* use the English side of the parallel data for actually building systems.

of representative words is highly skewed.<sup>4</sup> We present results in terms of area under the ROC curve (AUC),<sup>5</sup> micro-averaged precision/recall/f-measure and macro-averaged precision/recall/f-measure. For macro-averaging, we compute a single confusion matrix over all the test data and determining P/R/F from that matrix. For micro-averaging, we compute a separate confusion matrix *for each word type* on the French side, compute P/R/F for each of these separately, and then average the results. (Thus, micro-F is not a function of micro-P and micro-R.) The AUC and macro-averaged scores give a sense of how well the system is doing on a type-level basis (essentially weighted by type frequency), while the micro-averaged scores give a sense as to how well the system is doing on individual types, not taking into account their frequencies.

For most of our results, we present standard deviations to help assess significance ( $\pm 2\sigma$  is roughly a 90% confidence interval). For our results, in which we use new-domain training data, we compute these results via 16-fold cross validation. The folds are split *across types so the system is never being tested on a word type that it has seen before*. We do this because it more closely resembles our application goals. We do 16-fold for convenience, because we divide the data into binary folds recursively (thus having a power-of-two is easier), with an attempt to roughly balance the size of the training sets in each fold (this is tricky because of the skewed nature of the data). This entire 16-fold cross-validation procedure is repeated 10 times and averages and standard deviations are over the 160 replicates.

We evaluate performance using our type-level features only, TYPEONLY, our token-level features only, TOKENONLY, and using both our type and our token level features, ALLFEATURES.

We compare our results with two baselines: RANDOM and CONSTANT. RANDOM predicts new-sense or not-new-sense randomly and with equal probability. CONSTANT always predicts new-sense, achieving 100% recall and a macro-level precision that is equal to the percent of representative words which do have a new sense, modulo cross-validation splits (see Table 3). Addi-

<sup>4</sup>The most frequent (*voie*) appears 3881 times; there are 60 singleton words on average across the three new domains.

<sup>5</sup>AUC is the probability that the classifier will assign a higher score to a randomly chosen positive example than to a randomly chosen negative example (Wikipedia, 2013).

tionally, we compare our results with a type-level oracle, TYPEORACLE. For all tokens of a given word type, the oracle predicts the majority label (new-sense or not-new-sense) for that word type. These results correspond to an upper bound for the TYPEONLY experiments.

## 6.2 Classification Setup

For all experiments, we use a linear classifier trained by stochastic gradient descent to optimize logistic loss. We also did some initial experiments on development data using boosted decision trees instead and other loss functions (hinge loss, squared loss), but they never performed as well. In all cases, we perform 20 passes over the training data, using development data to perform early stopping (considered at the end of each pass). We also use development data to tune a regularizer (either  $\ell_1$  or  $\ell_2$ ) and its regularization weight.<sup>6</sup> Finally, all real valued features are automatically bucketed into 10 consecutive buckets, each with (approximately) the same number of elements. Each learner uses a small amount of development data to tune a threshold on scores for predicting new-sense or not-a-new-sense, using macro F-measure as an objective.

## 6.3 Result Summary

Table 4 shows our results on the SENSESPOTTING task. Classifiers based on the features that we defined outperform both baselines in all macro-level evaluations for the SENSESPOTTING task. Using AUC as an evaluation metric, the TOKENONLY, TYPEONLY, and ALLFEATURES models performed best on EMEA, Science, and Subtitles data, respectively. Our token-level features perform particularly poorly on the Science and Subtitles data. Although the model trained on only those features achieves reasonable precision (72.59 and 70.00 on Science and Subs, respectively), its recall is very low (20.41 and 35.15), indicating that the model classifies many new-sense words as not-new-sense. Most of our token-level features capture the intuition that when a word token appears in new or infrequent contexts, it is likely to have gained a new sense. Our results indicate that this intuition was more fruitful for EMEA than for Science or Subs.

In contrast, the type-only features (TYPEONLY)

<sup>6</sup>We use <http://hunch.net/~vw/> version 7.1.2, and run it with the following arguments that affect learning behavior: `--exact_adaptive_norm --power_t 0.5`

Table 4: Complete SENSESPOTTING results for all domains. The scores are from cross-validation on a single domain; in all cases, higher is better. Two standard deviations of performance over the cross-validation are shown in small type. For all domains and metrics, the highest (not necessarily statistically significant) non-oracle results are bolded.

are relatively weak for predicting new senses on EMEA data but stronger on Subs (TYPEONLY AUC performance is higher than both baselines) and even stronger on Science data (TYPEONLY AUC and f-measure performance is higher than both baselines as well as the ALLFEATURES model). In our experience with the three datasets, we know that the Science data, which contains abstracts from a wide variety of scientific disciplines, is the most diverse, followed by the Subs data, and then EMEA, which mostly consists of text from drug labels and tends to be quite repetitive. Thus, it makes sense that type-level features would be the most informative for the least homogeneous dataset. Representative words in scientific text are likely to appear in variety of contexts, while in the EMEA data they may only appear in a few, making it easier to contrast them with the distributions observed in the old domain data.

For all domains, in micro-level evaluation, our models fail to outperform the CONSTANT baseline. Recall that the micro-level evaluation computes precision, recall, and f-measure for all word tokens of a given word type and then averages across word types. We observe that words that are less frequent in both the old and the new domains are more likely to have a new sense than more frequent words, which causes the CONSTANT base-

line to perform reasonably well. In contrast, it is more difficult for our models to make good predictions for less frequent words. A low frequency in the new domain makes type level features (estimated over only a few instances) noisy and unreliable. Similarly, a low frequency in the old domain makes the our token level features, which all contrast with old domain instances of the word type.

#### 6.4 Feature Ablation

In the previous section, we observed that (with one exception) both Type-level and Token-level features are useful in our task (in some cases, essential). In this section, we look at finer-grained feature distinctions through a process of feature ablation. In this setting, we begin with *all features* in a model and *remove* one feature at a time, always removing the feature that hurts performance least. For these experiments, we determine which feature to remove using AUC. Note that we’re actually able to beat (by 2-4 points AUC) the scores from Table 4 by removing features!

The results here are somewhat mixed. In EMEA and Science, one can actually get by (according to AUC) with very few features: just two (Type:NgramProband Type:Context) are sufficient to achieve optimal AUC scores. To get higher Macro-F scores requires nearly all the features, though this is partially due to the choice of

EMEA	AUC	MacF	Science	AUC	MacF	Subs	AUC	MacF

Table 6: Cross-domain test results on the SENSESPOTTING task. Two standard deviations are shown in small type. Only AUC, Macro-F and Micro-F are shown for brevity.

AUC as the measure on which to ablate. It’s quite clear that for Science, all the useful information is in the type-level features, a result that echoes what we saw in the previous section. While for EMEA and Subs, both type- and token-level features play a significant role. Considering the six most useful features in each domain, the ones that pop out as frequently most useful are the global PSD features, the ngram probability features (either type- or token-based), the relative frequency features and the context features.

## 6.5 Cross-Domain Training

One disadvantage to the previous method for evaluating the SENSESPOTTING task is that it requires parallel data in a new domain. Suppose we have *no* parallel data in the new domain at all, yet still want to attack the SENSESPOTTING task. One option is

to train a system on domains for which we *do* have parallel data, and then apply it in a new domain. This is precisely the setting we explore in this section. Now, instead of performing cross-validation in a single domain (for instance, Science), we take the union of *all* of the training data in the other domains (e.g., EMEA and Subs), train a classifier, and then apply it to Science. This classifier will almost certainly be worse than one trained on NEW (Science) but does not require *any* parallel data in that domain. (Hyperparameters are chosen by development data from the OLD union.)

The results of this experiment are shown in Table 6. We include results for TOKENONLY, TYPEONLY and ALLFEATURES; all of these are trained in the cross-domain setting. To ease comparison to the results that do not suffer from domain shift, we also present “XV-ALLFEATURES”, which are results copied from Table 4 in which parallel data from NEW is used. Overall, there is a drop of about 7.3% absolute in AUC, moving from XV-ALLFEATURES to ALLFEATURES, including a small improvement in Science (likely because Science is markedly smaller than Subs, and “more difficult” than EMEA with many word types).

## 6.6 Detecting Most Frequent Sense Changes

We define a second, related task: MOSTFREQUENSENSECHANGE. In this task, instead of predicting if a given word token has a sense which is brand new with respect to the old domain, we predict whether it is being used with a sense which is not the one that was observed *most frequently* in the old domain. In our EMEA, Science, and Subtitles data, 68.2%, 48.3%, and 69.6% of word tokens’ predominant sense changes.

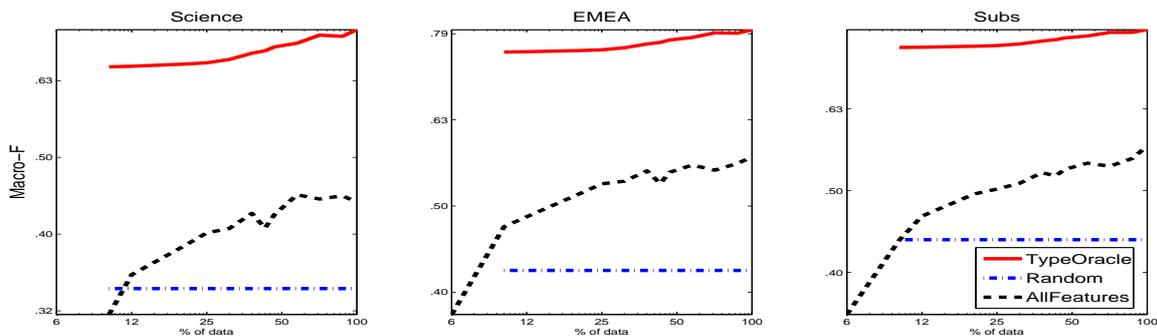

Figure 1: Learning curves for the three domains. X-axis is percent of data used, Y-axis is Macro-F score. Both axes are in log scale to show the fast rate of growth. A horizontal bar corresponding to random predictions, and the TYPEORACLE results are shown for comparison.

	AUC	Macro-F	Micro-F
<b>EMEA</b>

CONSTANT	50.00 ± 0.00	<b>65.21</b> ± 0.00	<b>73.22</b> ± 0.00
TYPEONLY	68.32 ± 1.05	54.70 ± 2.35	57.04 ± 1.52
TYPEORACLE	91.41 ± 0.00	86.71 ± 0.00	74.26 ± 0.00
TOKENONLY	<b>68.49</b> ± 0.59	62.76 ± 0.89	64.40 ± 1.08
ALLFEATURES	68.31 ± 0.93	<b>64.73</b> ± 1.93	<b>67.20</b> ± 1.65
<b>Subs</b>			
RANDOM	50.27 ± 0.27	56.93 ± 0.29	50.93 ± 1.11
CONSTANT	50.00 ± 0.00	<b>79.96</b> ± 0.00	<b>76.26</b> ± 0.00
TYPEONLY	<b>60.36</b> ± 0.90	67.78 ± 1.98	61.58 ± 1.78
TYPEORACLE	82.16 ± 0.00	87.96 ± 0.00	73.87 ± 0.00
TOKENONLY	59.49 ± 1.04	<b>77.79</b> ± 0.82	<b>73.51</b> ± 0.68
ALLFEATURES	54.97 ± 0.89	77.30 ± 1.58	72.29 ± 1.68

Table 7: Cross-validation results on the MOSTFREQSENSECHANGE task. Two standard deviations are shown in small type.

We use the same set of features and learning framework to generate and evaluate models for this task. While the SENSESPOTTING task has MT utility in suggesting which new domain words demand a new translation, the MOSTFREQSENSECHANGE task has utility in suggesting which words demand a new translation probability distribution when shifting to a new domain. Table 7 shows the results of our MOSTFREQSENSECHANGE task experiments.

Results on the MOSTFREQSENSECHANGE task are somewhat similar to those for the SENSESPOTTING task. Again, our models perform better under a macro-level evaluation than under a micro-level evaluation. However, in contrast to the SENSESPOTTING results, token-level features

perform quite well on their own for all domains. It makes sense that our token level features have a better chance of success on this task. The important comparison now is between a new domain token in context and the *majority* of the old domain tokens of the same word type. This comparison is likely to be more informative than when we are equally interested in identifying overlap between the current token and any old domain senses. Like the SENSESPOTTING results, when doing a micro-level evaluation, our models do not perform as well as the CONSTANT baseline, and, as before, we attribute this to data sparsity.

## 6.7 Learning Curves

All of the results presented so far use classifiers trained on instances of representative types (i.e. “representative tokens”) extracted from fairly large new domain parallel corpora (see Table 3), consisting of between 22 and 36 thousand parallel sentences, which yield between 8 and 35 thousand representative tokens. Although we expect some new domain parallel tuning data to be available in most MT settings, we would like to know how many representative types are required to achieve good performance on the SENSESPOTTING task. Figure 6.5 shows learning curves over the number of representative tokens that are used to train SENSESPOTTING classifiers. In fact, only about 25-50% of the data we used is really necessary to achieve the performance observed before.

## Abstract

We present BRAINSUP, an extensible framework for the generation of creative sentences in which users are able to force several words to appear in the sentences and to control the generation process across several semantic dimensions, namely *emotions*, *colors*, *domain relatedness* and *phonetic properties*. We evaluate its performance on a creative sentence generation task, showing its capability of generating well-formed, catchy and effective sentences that have all the good qualities of slogans produced by human copywriters.

## 1 Introduction

A variety of real-world scenarios involve talented and knowledgeable people in a time-consuming process to write creative, original sentences generated according to well-defined requisites. For instance, to advertise a new product it could be desirable to have its name appearing in a punchy sentence together with some keywords relevant for marketing, e.g. “fresh”, or “thirst” for the advertisement of a drink. Besides, it could be interesting to characterize the sentence with respect to a specific color, like “blue” to convey the idea of freshness, or to a color more related to the brand of the company, e.g. “red” for a new *Ferrari*. Moreover, making the slogan evoke “joy” or “satisfaction” could make the advertisement even more catchy for customers. On the other hand, there are many examples of provocative slogans in which copywriters try to impress their readers by suscitating strong negative feelings, as in the case of anti-smoke campaigns (e.g., “there are cooler ways to die than smoking” or “cancer cures smoking”), or the famous beer motto “*Guinness* is not good for

you”. As another scenario, creative sentence generation is also a useful teaching device. For example, the *keyword* or *linkword* method used for second language learning links the translation of a foreign (*target*) word to one or more keywords in the native language which are phonologically or lexically similar to the target word (Sagarra and Alba, 2006). To illustrate, for teaching the Italian word “tenda”, which means “curtain” in English, the learners are asked to imagine “rubbing a *tender* part of their leg with a *curtain*”. These words should co-occur in the same sentence, but constructing such sentences by hand can be a difficult and very time-consuming process. Özbal and Strapparava (2011), who attempted to automate the process, conclude that the inability to retrieve from the web a good sentence for all cases is a major bottleneck.

Although state of the art computational models of creativity often produce remarkable results, e.g., Manurung et al. (2008), Greene et al. (2010), Guerini et al. (2011), Colton et al. (2012) just to name a few, to our best knowledge there is no attempt to develop an unified framework for the generation of creative sentences in which users can control all the variables involved in the creative process to achieve the desired effect.

In this paper, we advocate the use of syntactic information to generate creative utterances by describing a methodology that accounts for lexical and phonetic constraints and multiple semantic dimensions at the same time. We present BRAINSUP, an extensible framework for creative sentence generation in which users can control all the parameters of the creative process, thus generating sentences that can be used for practical applications. First, users can define a set of keywords which must appear in the final sentence. Second, they can slant the output towards a spe-

Domain	Keywords	BRAINSUP output examples
coffee	waking, cup	Between waking and doing there is a wondrous cup.
coke	drink, exhaustion	The physical exhaustion wants the dark drink.
health	day, juice, sunshine	With juice and cereal the normal day becomes a summer sunshine.
beauty	kiss, lips	Passionate kiss, perfect lips. – Lips and eyes want the kiss.
mascara	drama, lash	Lash your drama to the stage. – A mighty drama, a biting lash.
pickle	crunch, bite	Crunch your bite to the top. – Crunch of a savage byte. – A large byte may crunch a little attention.
soap	skin, love, touch	A touch of love is worth a fortune of skin. – The touch of froth is the skin of love. – A skin of water is worth a touch of love.

Table 1: A selection of sentences automatically generated by BRAINSUP for specific domains.

cific *emotion*, *color* or *domain*. At the same time, they can require a sentence to include desired phonetic properties, such as *rhymes*, *alliteration* or *plosives*. The combination of these features allows for the generation of potentially catchy and memorable sentences by establishing connections between linguistic, emotional (LaBar and Cabeza, 2006), echoic and visual (Borman et al., 2005) memory, as exemplified by the system outputs showcased in Table 1. Other creative dimensions can easily be plugged in, due to the inherently modular structure of the system.

BRAINSUP supports the creative process by greedily exploring a huge solution space to produce completely novel utterances responding to user requisites. It exploits syntactic constraints to dramatically cut the size of the search space, thus making it possible to focus on the creative aspects of sentence generation.

## 2 Related work

Research in creative language generation has bloomed in recent years. In this section, we provide a necessarily succinct overview of a selection of the studies that most heavily inspired and influenced the development of BRAINSUP.

Humor generators are a notable class of systems exploring new venues in computational creativity (Binsted and Ritchie, 1997; McKay, 2002; Manurung et al., 2008). Valitutti et al. (2009) present an interactive system which generates humorous puns obtained through variation of famil-

iar expressions with word substitution. The variation takes place considering the phonetic distance and semantic constraints such as semantic similarity, semantic domain opposition and affective polarity difference. Possibly closer to slogan generation, Guerini et al. (2011) slant existing textual expressions to obtain more positively or negatively valenced versions using WordNet (Miller, 1995) semantic relations and SentiWordNet (Esuli and Sebastiani, 2006) annotations. Stock and Straparava (2006) generate acronyms based on lexical substitution via semantic field opposition, rhyme, rhythm and semantic relations. The model is limited to the generation of noun phrases.

Poetry generation systems face similar challenges to BRAINSUP as they struggle to combine semantic, lexical and phonetic features in a unified framework. Greene et al. (2010) describe a model for poetry generation in which users can control meter and rhyme scheme. Generation is modeled as a cascade of weighted Finite State Transducers that only accept strings conforming to the desired rhyming scheme. Toivanen et al. (2012) attempt to generate novel poems by replacing words in existing poetry with morphologically compatible words that are semantically related to a target domain. Content control and the inclusion of phonetic features are left as future work and syntactic information is not taken into account. The Electronic Text Composition project<sup>1</sup> is a corpus based approach to poetry generation which recursively combines automatically generated linguistic constituents into grammatical sentences. Colton et al. (2012) propose another data-driven approach to poetry generation based on simile transformation. The mood and theme of the poems are influenced by daily news. Constraints about phonetic properties of the selected words or their frequencies can be enforced during retrieval. Unlike these examples, BRAINSUP makes heavy use of syntactic information to enforce well-formed sentences and to constraint the search for a solution, and provides an extensible framework in which various forms of linguistic creativity can easily be incorporated.

Several slogan generators are available on the web<sup>2</sup>, but their capabilities are very limited as they can only replace single words or word sequences within existing slogan. This often results in syntactically incorrect outputs. Furthermore, they do not allow for other forms of user control.

### 3 Architecture of BRAINSUP

To effectively support the creative process with useful suggestions, we must be able to generate sentences conforming to the user needs. First of all, users can select the *target words* that need to appear in the sentence. In the context of second language learning, these might be the words that a learner must associate in order to expand her vocabulary. For slogan generation, the target words could be the key features of a product, or target-defining keywords that copywriters want to explicitly mention. On top of that, a user can characterize the generated sentences according to several dimensions, namely: 1) a specific semantic domain, e.g.: “sports” or “blankets”; 2) a specific emotion, e.g., “joy”, “anger” or just “negative”; 3) a specific color, e.g., “red” or “blue”; 4) a combination of phonetic properties of the words that will appear in the sentence, i.e., rhymes, alliterations and plosives. More formally, the *user input* is a tuple:  $U = \langle \mathbf{t}, \mathbf{d}, c, e, p, \mathbf{w} \rangle$ , where  $\mathbf{t}$  is the set of *target words*,  $\mathbf{d}$  is a set of words defining the target *domain*,  $c$  and  $p$  are, respectively, the *color* and the *emotion* towards which the user wants to slant the sentence,  $p$  represents the desired phonetic features, and  $\mathbf{w}$  is a set of *weights* that control the influence of each dimension on the generative process, as detailed in Section 3.3. For target and domain words, users can explicitly select one or more POSes to be considered, e.g., “drink/verb” or “drink/verb,noun”.

The sentence generation process is based on morpho-syntactic *patterns* which we automatically discover from a corpus of dependency parsed sentences  $\mathcal{P}$ . These patterns represent very general skeletons of well-formed sentences that we employ to generate creative sentences by only focusing on the lexical aspects of the process. Candidate fillers for each empty position (*slot*) in the patterns are chosen according to the lexical and syntactic constraints enforced by the dependency relations in the patterns. These constraints are learned from relation-head-modifier co-occurrence counts estimated from a dependency treebank  $\mathcal{L}$ . A beam search in the space of all possible lexicalizations of a syntactic pattern promotes the words with the highest likelihood of satisfying the user specification.

Algorithm 1 provides a high-level description of the creative sentence generation process. Here,  $\Theta$  is a set of meta-parameters that affect search complexity and running time of the algorithm, such as the minimum/maximum number of solutions to

---

**Algorithm 1** SentenceGeneration( $U, \Theta, \mathcal{P}, \mathcal{L}$ ):  $U$  is the user specification,  $\Theta$  is a set of meta-parameters;  $\mathcal{P}$  and  $\mathcal{L}$  are two dependency treebanks.

be generated, the maximum number of patterns to consider, or the maximum size of the generated sentences. CompatiblePatterns( $\cdot$ ) finds the most frequent syntactic patterns in  $\mathcal{P}$  that are compatible with the user specification, as explained in Section 3.1; FillInPattern( $\cdot$ ) carries out the beam search, and returns the best solutions generated for each pattern  $p$  given  $U$ . The algorithm terminates when at least a minimum number of solutions have been generated, or when all the compatible patterns have been exhausted. Finally, only the best among the generated solutions are shown to the user. More details about the search in the solution space are provided in Section 3.2.

#### 3.1 Pattern selection

We generate creative sentences starting from morpho-syntactic *patterns* which have been automatically learned from a large corpus  $\mathcal{P}$ . The choice of the corpus from which the patterns are extracted constitutes the first element of the creative sentence generation process, as different choices will generate sentences with different styles. For example, a corpus of slogans or punchlines can result in short, catchy and memorable sentences, whereas a corpus of simplified English would be a better choice to learn a second language or to address low reading level audiences.

A pattern is the syntactic skeleton of a class of sentences observed in  $\mathcal{P}$ . Within a pattern, a second element of creativity involves the selection of original combinations of words (*fillers*) that do not violate the grammaticality of the sentence. The patterns that we employ are automatic dependency trees from which all content-words have been removed, as exemplified in Figure 1. After selecting the target corpus, we parse all the sentences with the Stanford Parser (Klein and Man-

ning, 2003) and produce the patterns by stripping away all content words from the parses. Then, for each pattern we count how many times it has been observed in the corpus. Additionally, we keep track of what kind of empty *slots*, i.e., empty positions, are available in each pattern. For example, the pattern in Figure 1 can accommodate up to two singular nouns (NN), one plural noun (NNS), one adjective (JJ) and one verb in the past tense (VBD). This information is needed to select the patterns which are *compatible* with the target words  $\mathbf{t}$  in the user specification  $U$ . For example, this pattern is not compatible with  $\mathbf{t} = [\text{heading}/\text{VBG}, \text{edge}/\text{NN}]$  as the pattern does not have an empty slot for a gerundive verb, while it satisfies  $\mathbf{t} = [\text{heading}/\text{NN}, \text{edge}/\text{NN}]$  as it can accommodate the two singular nouns. While retrieving patterns, we also need to enforce that a pattern be not completely filled just by adding the target words  $\mathbf{t}$ , as under these conditions there would be no room to achieve any kind of creative effect. Therefore, we also require that the patterns retrieved by `CompatiblePatterns( $\cdot$ )` have more empty slots than the size of  $\mathbf{t}$ . The minimum and maximum number of excess slots in the pattern are two other meta-parameters controlled by  $\Theta$ . `CompatiblePatterns( $\cdot$ )` returns compatible patterns ordered by their frequency, i.e. when generating solutions the first patterns that are explored are the most frequently observed ones. In this way, we achieve the following two objectives: 1) we compensate for the unavoidable errors introduced by the automatic parser, as frequently observed parses are less likely to be the result of an erroneous interpretation of a sentence; and 2) we generate sentences that are most likely to be catchy and memorable, being based on syntactic constructs that are used more frequently. To avoid always selecting the same patterns for the same kinds of inputs, we add a small random component (also controlled by  $\Theta$ ) to the pattern sorting algorithm, thus allowing for sentences to be generated also from non-top ranked patterns.

### 3.2 Searching the solution space

With the compatible patterns selected, we can initiate a beam search in the space of all possible lexicalizations of the patterns, i.e., the space of all sentences that can be generated by respecting the syntactic constraints encoded by each pattern. The process starts with a syntactic pattern  $p$  containing only stop words, syntactic relations and morphologic constraints (i.e., part-of-speech

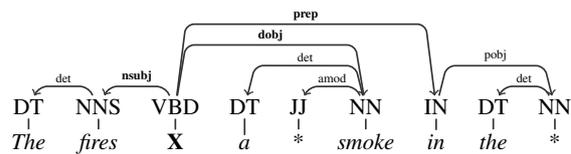

Figure 2: A partially lexicalized sentence with a highlighted empty slot marked with  $X$ . The relevant dependencies to fill in the slot are shown in boldface.

tags) for the empty slots. The search advances towards a complete solution by selecting an empty slot to fill and trying to place candidate fillers in the selected position. Each *partially lexicalized solution* is scored by a battery of scoring functions that compete to generate creative sentences respecting the user specification  $U$ , as explained in Section 3.3. The most promising solutions are extended by filling another slot, until completely lexicalized sentences, i.e., sentences without empty slots, are generated.

To limit the number of words that can occupy a given position in a sentence, we define a set of operators that return a list of candidate fillers for a slot solely based on syntactic clues. To achieve that, we analyze a large corpus of parsed sentences  $\mathcal{L}^3$  and store counts of observed *head-relation-modifier* ( $\langle h, r, m \rangle$ ) dependency relations. Let  $\tau_r(h)$  be an operator that, when applied to a head word  $h$  in a relation  $r$ , returns the set of words in  $\mathcal{L}$  which have been observed as modifiers for  $h$  in  $r$  with a specific POS. To simplify the notation, we assume that the relation  $r$  also carries along the POS of the head and modifier slots. As an example, with respect to the tree depicted in Figure 2,  $\tau_{\text{amod}}(\text{smoke})$  would return all the words with POS equal to “JJ” that have been observed as adjective modifiers for the singular noun “smoke”. We will refer to  $\tau_r(\cdot)$  as the *dependency operator* for  $r$ . For every  $\tau_r(\cdot)$ , we also define an *inverse dependency operator*  $\tau_r^{-1}(\cdot)$ , which returns the list of the possible heads in  $r$  when applied to a modifier word  $m$ . For instance, with respect to Figure 2,  $\tau_{\text{nsubj}}^{-1}(\text{fires})$  would return the set of verbs in the past tense of which “fires” as a plural noun can be a subject.

While filling in a given slot  $X$ , the dependency operators can be combined to obtain a list of words which are likely to occupy that position given the syntactic constraints induced by the structure of the pattern. Let  $W = \cup_i \{w_i\}$  be the set of words which are directly connected to the empty slot by

<sup>3</sup>Distinct from the corpus used for pattern selection,  $\mathcal{P}$ .

a dependency relation. Each word  $w_i$  implies a constraint that candidate fillers for  $X$  must satisfy. If  $w_i$  is the head of  $X$ , then a direct operator is used to retrieve a list of fillers that satisfy the  $i^{\text{th}}$  constraint. Conversely, if  $w_i$  is a modifier of  $X$ , an inverse operator is employed.

As an example, let us consider the partially completed sentence shown in Figure 2 having an empty slot marked with  $X$ . Here, the word “smoke” is a modifier for  $X$ , to which it is connected by a *doobj* relation. Therefore, we can exploit  $\tau_{\text{doobj}}^{-1}(\text{smoke})$  to obtain a ranked list of words that can occupy  $X$  according to this constraint. Similarly, the  $\tau_{\text{nsubj}}^{-1}(\text{fires})$  operator can be used to retrieve a list of verbs in the past tense that accept “fires” as *nsubj* modifier. Finally  $\tau_{\text{prep}}^{-1}(\text{in})$  can further restrict our options to verbs that accepts complements introduced by the preposition “in”. For example, the words “generated”, “produced”, “caused” or “formed” would be good candidates to fill in the slot considering all the previous constraints. More formally, we can define the set of candidate fillers for a slot  $X$ ,  $\mathcal{C}_X$ , as:  $\mathcal{C}_X = \tau_{\text{rh}_X}^{-1}(h_X) \cap (\bigcap_{w_i|w_i \in M_X} \tau_{r_{w_i,X}}(w_i))$ , where  $r_{w_i,X}$  is the type of relation between  $w_i$  and  $X$ ,  $M_X$  is the set of modifiers of  $X$  and  $h_X$  is the syntactic head of  $X$ .<sup>4</sup>

Concerning the order in which slots are filled, we start from those that have the highest number of dependencies (both head or modifiers) that have been already instantiated in the sentence, i.e., we start from the slots that are connected to the highest number of non-empty slots. In doing so we maximize the constraints that we can rely on when inserting a new word, and eventually generate more reliable outputs.

### 3.3 Filler selection and solution scoring

We have devised a set of *feature functions* that account for different aspects of the creative sentence generation process. By changing the weight  $\mathbf{w}$  of the feature functions in  $U$ , users can control the extent to which each creativity component will affect the sentence generation process, and tune the output of the system to better match their needs. As explained in the remainder of this section, feature functions are responsible for ranking the candidate slot fillers to be used during sentence generation and for selecting the best solutions to be

<sup>4</sup>An empty slot does not generate constraints for  $X$ . In addition, there might be cases in which it is not possible to find a filler that satisfies all the constraints at the same time. In such cases, all the fillers that satisfy the maximum number of constraints are considered.

---

**Algorithm 2** RankCandidates( $U, \mathbf{f}, c_1, c_2, s, X$ ):  $c_1$  and  $c_2$  are two candidate fillers for the slot  $X$  in the sentence  $s = [s_0, \dots, s_n]$ ;  $\mathbf{f}$  is the set of feature functions;  $U$  is the user specification.

---

```

 $\mathbf{s}^{c_1} \leftarrow \mathbf{s}, \mathbf{s}^{c_2} \leftarrow \mathbf{s}, \mathbf{s}^{c_1}[X] \leftarrow c_1, \mathbf{s}^{c_2}[X] \leftarrow c_2$ 
for all  $\mathbf{f} \in \text{SortFeatureFunctions}_{\Theta}(U, \mathbf{f})$  do
  if  $\mathbf{f}(\mathbf{s}^{c_1}, U) > \mathbf{f}(\mathbf{s}^{c_2}, U)$  then return  $c_1 \succ c_2$ 
  else if  $\mathbf{f}(\mathbf{s}^{c_1}, U) < \mathbf{f}(\mathbf{s}^{c_2}, U)$  then
    return  $c_1 \prec c_2$ 
return  $c_1 \equiv c_2$ 

```

---

shown to the users.

Algorithm 2 details the process of ranking candidate fillers. To compare two candidates  $c_1$  and  $c_2$  for the slot  $X$  in the sentence  $s$ , we first generate two sentences  $\mathbf{s}^{c_1}$  and  $\mathbf{s}^{c_2}$  in which the empty slot  $X$  is occupied by  $c_1$  and  $c_2$ , respectively. Then, we sort the feature functions based on their weights in descending order, and in turn we apply them to score the two sentences. As soon as we find a scorer for which one sentence is better than the other, we can take a decision about the ranking of the fillers. This approach makes it possible to establish a strict order of precedence among feature functions and to select fillers that have a highest chance of maximizing the user satisfaction.

Concerning the scoring of partial solutions and complete sentences, we adopt a simple linear combination of scoring functions. Let  $\mathbf{s}$  be a (partial) sentence,  $\mathbf{f} = [f_0, \dots, f_k]$  be the vector of scoring functions and  $\mathbf{w} = [w_0, \dots, w_k]$  the associated vector of weights in  $U$ . The overall score of  $\mathbf{s}$  is calculated as  $\text{score}(\mathbf{s}, U) = \sum_{i=0}^k w_i f_i(\mathbf{s}, U)$ . Solutions that do not contain all the required target words are discarded and not shown to the user.

Currently, the model employs the following 12 feature functions:

**Chromatic and emotional connotation.** The chromatic connotation of a sentence  $\mathbf{s} = [s_0, \dots, s_n]$  is computed as  $\mathbf{f}(\mathbf{s}, U) = \sum_{s_i} (\text{sim}(s_i, c) - \sum_{c_j \neq c} \text{sim}(s_i, c_j))$ , where  $c$  is the user selected target color and  $\text{sim}(s_i, c_j)$  is the degree of association between the word  $s_i$  and the color  $c_j$  as calculated by Mohammad (2011). All the words in the sentence which have an association with the target color  $c$  give a positive contribution, while those that are associated with a color  $c_i \neq c$  contribute negatively. Emotional connotation works exactly in the same way, but in this case word-emotion associations are taken from (Mohammad and Turney, 2010).

**Domain relatedness.** This feature function uses an LSA (Deerwester et al., 1990) vector space

model to measure the similarity between the words in the sentence and the target domain  $\mathbf{d}$  specified by the user. It is calculated as:  $f(\mathbf{s}, U) = \frac{\sum_{d_i} v(d_i) \cdot \sum_{s_i} v(s_i)}{\|\sum_{d_i} v(d_i)\| \cdot \|\sum_{s_i} v(s_i)\|}$  where  $v(\cdot)$  returns the representation of a word in the vector space.

**Semantic cohesion.** This feature behaves exactly like domain relatedness, with the only difference that it measures the similarity between the words in the sentence and the target words  $\mathbf{t}$ .

**Target-words scorer.** This feature function simply counts what fraction of the target words  $\mathbf{t}$  is present in a partial solution:  $f(\mathbf{s}, U) = (\sum_{s_i | s_i \in \mathbf{t}} 1) / |\mathbf{t}|$ . The target word scorer takes care of enforcing the presence of the target words in the sentences. Letting beam search find the best placement for the target words comes at no extra cost and results in a simple and elegant model.

**Phonetic features (plosives, alliteration and rhyme).** All the phonetic features are based on the phonetic representation of English words of the Carnegie Mellon University pronouncing dictionary (Lenzo, 1998). The plosives feature is calculated as the ratio between the number of plosive sounds in a sentence and the overall number of phonemes. For the alliteration scorer, we store the phonetic representation of each word in  $\mathbf{s}$  in a *trie* (i.e., *prefix tree*), and count how many times each node  $n_i$  of the trie (corresponding to a phoneme) is traversed. Let  $c_i$  be the value of the counts for  $n_i$ . The alliteration score is then calculated as  $f(\mathbf{s}, U) = (\sum_{i | c_i > 1} c_i) / \sum_i c_i$ . More simply put, we count how many of the phonetic prefixes of the words in the sentence are repeated, and then we normalize this value by the total number of phonemes in  $\mathbf{s}$ . The rhyme feature works exactly in the same way, with the only difference that we invert the phonetic representation of each word before adding it to the TRIE. Thus, we give higher scores to sentences in which several words share the same phonetic ending.

**Variety scorer.** This feature function promotes sentences that contain as many different words as possible. It is calculated as the number of distinct words in the sentence over the size of the sentence.

**Unusual-words scorer.** To increase the ability of the model to generate sentences containing non-trivial word associations, we may want to prefer solutions in which relatively uncommon words are employed. Inversely, we may want to lower lex-

ical complexity to generate sentences more appropriate for certain education or reading levels. We define  $c_i$  as the number of times each word  $s_i \in \mathbf{s}$  is observed in a corpus  $\mathcal{V}$ . Accordingly, the value of this feature is calculated as:  $f(\mathbf{s}, U) = (1/|\mathbf{s}|)(\sum_{s_i} 1/c_i)$ .

**N-gram likelihood.** This is simply the likelihood of a sentence estimated by an  $n$ -gram language model, to enforce the generation of well-formed word sequences. When a solution is not complete, in the computation we include only the sequences of contiguous words (i.e., not interrupted by empty slots) having length greater than or equal to the order of the  $n$ -gram model.

**Dependency likelihood.** This feature is related to the dependency operators introduced in Section 3.2 and it enforces sentences in which dependency chains are well formed. We estimate the probability of a modifier word  $m$  and its head  $h$  to be in the relation  $r$  as  $p_r(h, m) = c_r(h, m) / (\sum_{h_i} \sum_{m_i} c_r(h_i, m_i))$ , where  $c_r(\cdot)$  is the number of times that  $m$  depends on  $h$  in the dependency treebank  $\mathcal{L}$  and  $h_i, m_i$  are all the head/modifier pairs observed in  $\mathcal{L}$ . The dependency-likelihood of a sentence  $\mathbf{s}$  can then be calculated as  $f(\mathbf{s}, U) = \exp(\sum_{(h,m,r) \in r(\mathbf{s})} \log p_r(h, m))$ ,  $r(\mathbf{s})$  being the set of dependency relations in  $\mathbf{s}$ .

## 4 Evaluation

We evaluated our model on a creative sentence generation task. The objective of the evaluation is twofold: we wanted to demonstrate 1) the effectiveness of our approach for creative sentence generation, in general, and 2) the potential of BRAINSUP to support the brainstorming process behind slogan generation. To this end, the annotation template included one question asking the annotators to rate the quality of the generated sentences as slogans.

Five experienced annotators were asked to rate 432 creative sentences according to the following criteria, namely: 1) *Catchiness*: is the sentence attractive, catchy or memorable? [Yes/No] 2) *Humor*: is the sentence witty or humorous? [Yes/No]; 3) *Relatedness*: is the sentence semantically related to the target domain? [Yes/No]; 4) *Correctness*: is the sentence grammatically correct? [Ungrammatical/Slightly disfluent/Fluent]; 5) *Success*: could the sentence be a good slogan for the target domain? [As it is/With minor editing/No]. In these last two cases, the annotators

were instructed to select the middle option only in cases where the gap with a correct/successful sentence could be filled just by performing minor editing. The annotation form had no default values, and the annotators did not know how the evaluated sentences were generated, or whether they were the outcome of one or more systems.

We started by collecting slogans from an online repository of slogans<sup>5</sup>. Then, we randomly selected a subset of these slogans and for each of them we generated an input specification  $U$  for the system. We used the commercial domain of the advertised product as the target domain  $\mathbf{d}$ . Two or three content words appearing in each slogan were randomly selected as the target words  $\mathbf{t}$ . We did so to simulate the brainstorming phase behind the slogan generation process, where copywriters start with a set of relevant keywords to come up with a catchy slogan. In all cases, we set the target emotion to “positive” as we could not establish a generally valid criteria to associate a specific emotion to a product. Concerning chromatic slanting, for target domains having a strong chromatic correlation we allowed the system to slant the generated sentences accordingly. In the other cases, a random color association was selected. In this manner, we produced 10 tuples  $\langle \mathbf{t}, \mathbf{d}, c, e, p \rangle$ . Then, from each tuple we produced 5 complete user specifications by enabling or disabling different feature function combinations<sup>6</sup>. The four combinations of features are: **base**: Target-word scorer + N-gram likelihood + Dependency likelihood + Variety scorer + Unusual-words scorer + Semantic cohesion; **base+D**: all the scorers in *base* + Domain relatedness; **base+D+C**: all the scorers in *base+D* + Chromatic connotation; **base+D+E**: all the scorers in *base+D* + Emotional connotation; **base+D+P**: all the scorers in *base+D* + Phonetic features. For each of the resulting 50 input configurations, we generated up to 10 creative sentences. As the system could not generate exactly 10 solutions in all the cases, we ended up with a set of 432 items to annotate. The weights of the feature functions were set heuristically, due to the lack of an annotated dataset suitable to learn an opti-

<sup>5</sup>[http://www.tvacres.com/advertising\\_slogans.htm](http://www.tvacres.com/advertising_slogans.htm)

<sup>6</sup>An alternative strategy to keep the annotation effort under control would have been to generate fewer sentences from a larger number of inputs. We adopted the former setting since we regarded it as more similar to a brainstorming session, where the system proposes different alternatives to inspire human operators. Forcing BRAINSUP to only output one or two sentences would have limited its ability to explore and suggest potentially valuable outputs.

MC	Cat.	Hum.	Corr.	Rel.	Succ.	RND <sub>2</sub>	RND <sub>3</sub>
2	-	-	16.67	-	22.22	-	37.04
3	47.45	39.58	43.52	13.66	44.21	62.50	49.38
4	33.10	37.73	32.18	21.99	22.22	31.25	12.35
5	19.44	22.69	07.64	64.35	11.34	06.25	01.23

Table 2: Majority classes (%) for the five dimensions of the annotation.

mal weight configuration. We started by assigning the highest weight to the *Target Word* scorer (i.e., 1.0), followed by the *Variety* and *Unusual Word* scorers (0.99), the *Phonetic Features*, *Chromatic/Emotional Connotation* and *Semantic Cohesion* scorers (0.98) and finally the *Domain*, *N-gram* and *Dependency Likelihood* scorers (0.97). These settings allow us to enforce an order of precedence among the scorers during slot-filling, while giving them virtually equal relevance for solution ranking.

As discussed in Section 3 we use two different treebanks to learn the syntactic patterns ( $\mathcal{P}$ ) and the dependency operators ( $\mathcal{L}$ ). For these experiments, patterns were learned from a corpus of 16,000 proverbs (Mihalcea and Strapparava, 2006), which offers a good selection of short sentences with a good potential to be used for slogan generation. This choice seemed to be a good compromise as, to our best knowledge, there is no published slogan dataset with an adequate size. Besides, using existing slogans might have legal implications that we might not be aware of. Dependency operators were learned by dependency parsing the British National Corpus<sup>7</sup>. To reduce the amount of noise introduced by the automatic parses, we only considered sentences having less than 20 words. Furthermore, we only considered sentences in which all the content words are listed in WordNet (Miller, 1995) with the observed part of speech.<sup>8</sup> The LSA space used for the semantic feature functions was also learned on BNC data, but in this case no filtering was applied.

## 4.1 Results

To measure the agreement among the annotators, similarly to Mohammad (2011) and Ozbal and Strapparava (2012) we calculated the majority class for each dimension of the annotation task. A

<sup>7</sup><http://www.natcorp.ox.ac.uk/>

<sup>8</sup>Since the CMU pronouncing dictionary used by the phonetic scorers is based on the American pronunciation of words, we actually pre-processed the whole BNC by replacing all British-English words with their American-English counterparts. To this end, we used the mapping available at <http://wordlist.sourceforge.net/>.

	Cat.	Rel.	Hum.	Succ.	Corr.
Yes	67.59	93.98	12.73	32.41	64.35
Partly	-	-	-	23.15	31.71
No	32.41	06.02	87.27	44.44	03.94

Table 3: Majority decisions (%) for each annotation dimension.

majority class greater than or equal to 3 means that the absolute majority of the 5 annotators agreed on the same decision<sup>9</sup>. Table 2 shows the observed agreement for each dimension. The column labeled  $RND_2$  ( $RND_3$ ) shows the random agreement for a given number of annotators and a binary (ternary) decision. For example, all five annotators ( $MC=5$ ) agreed on the annotation of the catchiness of the slogans in 19.44% of the cases. The random chance of agreement for 5 annotators on the binary decision problem is 6.25%. The figures for  $MC \geq 4$  are generally high, confirming a good agreement among the annotators. The agreement on the relatedness of the slogans is especially high, with all 5 annotators taking the same decision in almost two cases out of three, i.e., 64.35%.

Table 3 lists the distribution of answers for each dimension in the cases where a decision can be taken by majority vote. The generated slogans are found to be catchy in more than 2/3 of the cases, (i.e., 67.59%), completely successful in 1/3 of the cases (32.41%) and completely correct in 2/3 of the cases (64.35%). These figures demonstrate that BRAINSUP is very effective in generating grammatical utterances that have all the appealing properties of a successful slogan. As for humor, the sentences are found to have this property in only 12.73% of cases. Even though the figure is not very high, we should also consider that BRAINSUP is not explicitly trying to generate amusing utterances. Concerning success, we should point out that in 23.15% of the cases the annotators have found that the generated slogans have the potential to be turned into successful ones only with minor editing. This is a very important piece of result, as it corroborates our claim that BRAINSUP can indeed be a valuable tool for copywriting, even when it does not manage to output a perfectly good sentence. Similar conclusions can be drawn concerning the correctness of the output, as in almost one third of the cases the slogans are

<sup>9</sup>For the binary decisions (i.e., catchiness, relatedness and humor), at least 3 annotators out of 5 must necessarily agree on the same option.

only affected by minor disfluencies.

The relatedness figure is especially high, as in almost 94% of the cases the majority of annotators found the slogans to be pertinent to the target domain. This result is not surprising, as all the slogans are generated by considering keywords that already exist in real slogans for the same domain. Anyhow, this is exactly the kind of setting in which we expect BRAINSUP to be employed, i.e., to support creative sentence generation starting from a good set of relevant keywords. Nonetheless, it is very encouraging to observe that the generation process does not deteriorate the positive impact of the input keywords.

We would also like to mention that in 63 cases (14.58%) the majority of the annotators have labeled the slogans favorably across all 5 dimensions. The examples listed in Table 1 are selected from this set. It is interesting to observe how the word associations established by BRAINSUP can result in pertinent yet unintentional rhetorical devices such as metaphors (“a summer sunshine”), puns (“lash your drama”) and personifications (“lips and eyes want”). Some examples show the effect of the phonetic features, e.g. plosives in “*passionate kiss, perfect lips*”, alliteration in “*the dark drink*” and rhyming in “lips and eyes want the kiss”. In some cases, the output of BRAINSUP seems to be governed by mysterious philosophical reasoning, as in the delicate examples generated for “soap”.

For comparison, Table 4 lists a selection of the examples that have been labeled as unsuccessful by the majority of raters. In some cases, BRAINSUP is improperly selecting attributes that highlight undesirable properties in the target domain, e.g., “A pleasant tasting, a *heady* wine”. To avoid similar errors, it would be necessary to reason about the valence of an attribute for a specific domain. In other cases, the  $N$ -gram and the Dependency Likelihood features may introduce phrases which are very cohesive but unrelated to the rest of the sentence, e.g., “Unscrupulous doctors smoke *armored units*”. Many of these errors could be solved by increasing the weight of the Semantic Cohesion and Domain Relatedness scorers. In other cases, such as “A sixth calorie may taste *an own good*” or “A *same sunshine* is fewer than a juice of day”, more sophisticated reasoning about syntactic and semantic relations in the output might be necessary in order to enforce the generation of sound and grammatical sentences.

We could not find a significant correlation be-

Domain	Keywords	BRAINSUP output examples
pleasure	wine, tasting	A pleasant tasting, a heady wine. – A fruity tasting may drink a sparkling wine.
healthy	day, juice, sunshine	Drink juice of your sunshine, and your weight will choose day of you. – A same sunshine is fewer than a juice of day.
cigarette	doctors, smoke	Unscrupulous doctors smoke armored units. – Doctors smoke no arrow.
mascara	drama, lash	The such drama is the lash.
soap	skin, love, touch	The touch of skin is the love of cacophony. – You love an own skin for a first touch.
coke	calorie, taste, good	A sixth calorie may taste an own good.
coffee	waking, cup	You cannot cup hands without waking some fats.

Table 4: Unsuccessful BRAINSUP outputs.

tween the input variables (e.g., presence or absence of phonetic features or chromatic slanting) and the outcome of the annotation, i.e. the system by and large produces correct, catchy, related and (at least potentially) successful outputs regardless of the specific input configurations. In this respect, it should be noted that we did not carry out any kind of optimization of the feature weights, which might be needed to obtain more heavily characterized sentences. Furthermore, to better appreciate the contribution of the individual features, comparative experiments in which the users evaluate the system before and after triggering a feature function might be necessary. Concerning the correlation among output dimensions, we only observed relatively high Spearman correlation between correctness and relatedness (0.65), and catchiness and success (0.68).

## 5 Conclusion

We have presented BRAINSUP, a novel system for creative sentence generation that allows users to control many aspects of the creativity process, from the presence of specific target words in the output, to the selection of a target domain, and to the injection of phonetic and semantic properties in the generated sentences. BRAINSUP makes heavy use of dependency parsed data and statistics collected from dependency treebanks to ensure the grammaticality of the generated sentences, and to trim the search space while seeking the sentences that maximize the user satisfaction.

The system has been designed as a supporting tool for a variety of real-world applications, from advertisement to entertainment and education, where at the very least it can be a valuable support for time-consuming and knowledge-intensive sentence generation needs. To demonstrate this point, we carried out an evaluation on a creative sentence generation benchmark showing that BRAINSUP can effectively produce catchy, memorable and successful sentences that have the potential to inspire the work of copywriters.

To our best knowledge, this is the first systematic attempt to build an extensible framework that allows for multi-dimensional creativity while at the same time relying on syntactic constraints to enforce grammaticality. In this regard, our approach is dual with respect to previous work based on lexical substitution, which suffers from limited expressivity and creativity latitude. In addition, by acquiring the lexicon and the sentence structure from two distinct corpora, we can guarantee that the sentences that we generate have never been observed. We believe that our contribution constitutes a valid starting point for other researchers to deal with unexplored dimensions of creativity.

As future work, we plan to use machine learning techniques to estimate optimal weights for the feature functions in different use cases. We would also like to consider syntactic clues while reasoning about semantic properties of the sentence, e.g., color and emotion associations, instead on relying solely on lexical semantics. Concerning the extension of the capabilities of BRAINSUP, we want to include common-sense knowledge and reasoning to profit from more sophisticated semantic relations and to inject humor on demand. Further tuning of BRAINSUP to build a dedicated system for slogan generation is also part of our future plans. After these improvements, we would like to conduct a more focused evaluation on slogan generation involving human copywriters and domain experts in an interactive setting.

We would like to conclude this paper with a pearl of BRAINSUP’s wisdom:

*It is wiser to believe in science  
than in everlasting love.*

## Abstract

We propose a joint inference algorithm for grammatical error correction. Different from most previous work where different error types are corrected independently, our proposed inference process considers all possible errors in a unified framework. We use integer linear programming (ILP) to model the inference process, which can easily incorporate both the power of existing error classifiers and prior knowledge on grammatical error correction. Experimental results on the Helping Our Own shared task show that our method is competitive with state-of-the-art systems.

## 1 Introduction

Grammatical error correction is an important task of natural language processing (NLP). It has many potential applications and may help millions of people who learn English as a second language (ESL). As a research field, it faces the challenge of processing ungrammatical language, which is different from other NLP tasks. The task has received much attention in recent years, and was the focus of two shared tasks on grammatical error correction in 2011 and 2012 (Dale and Kilgarriff, 2011; Dale et al., 2012).

To detect and correct grammatical errors, two different approaches are typically used — knowledge engineering or machine learning. The first relies on handcrafting a set of rules. For example, the superlative adjective *best* is preceded by the article *the*. In contrast, the machine learning approach formulates the task as a classification problem based on learning from training data. For example, an article classifier takes a noun phrase (NP) as input and predicts its article using class labels *a/an*, *the*, or  $\epsilon$  (no article).

Both approaches have their advantages and disadvantages. One can readily handcraft a set of

rules to incorporate various prior knowledge from grammar books and dictionaries, but rules often have exceptions and it is difficult to build rules for all grammatical errors. On the other hand, the machine learning approach can learn from texts written by ESL learners where grammatical errors have been annotated. However, training data may be noisy and classifiers may need prior knowledge to guide their predictions.

Another consideration in grammatical error correction is how to deal with multiple errors in an input sentence. Most previous work deals with errors individually: different classifiers (or rules) are developed for different types of errors (article classifier, preposition classifier, etc). Classifiers are then deployed independently. An example is a pipeline system, where each classifier takes the output of the previous classifier as its input and proposes corrections of one error type.

One problem of this pipeline approach is that the relations between errors are ignored. For example, assume that an input sentence contains *a cats*. An article classifier may propose to delete *a*, while a noun number classifier may propose to change *cats* to *cat*. A pipeline approach will choose one of the two corrections based purely on which error classifier is applied first. Another problem is that when applying a classifier, the surrounding words in the context are assumed to be correct, which is not true if grammatical errors appear close to each other in a sentence.

In this paper, we formulate grammatical error correction as a task suited for joint inference. Given an input sentence, different types of errors are jointly corrected as follows. For every possible error correction, we assign a score which measures how grammatical the resulting sentence is if the correction is accepted. We then choose a set of corrections which will result in a corrected sentence that is judged to be the most grammatical.

The inference problem is solved by integer lin-

ear programming (ILP). Variables of ILP are indicators of possible grammatical error corrections, the objective function aims to select the best set of corrections, and the constraints help to enforce a valid and grammatical output. Furthermore, ILP not only provides a method to solve the inference problem, but also allows for a natural integration of grammatical constraints into a machine learning approach. We will show that ILP fully utilizes individual error classifiers, while prior knowledge on grammatical error correction can be easily expressed using linear constraints. We evaluate our proposed ILP approach on the test data from the Helping Our Own (HOO) 2011 shared task (Dale and Kilgarriff, 2011). Experimental results show that the ILP formulation is competitive with state-of-the-art grammatical error correction systems.

The remainder of this paper is organized as follows. Section 2 gives the related work. Section 3 introduces a basic ILP formulation. Sections 4 and 5 improve the basic ILP formulation with more constraints and second order variables, respectively. Section 6 presents the experimental results. Section 7 concludes the paper.

## 2 Related Work

The knowledge engineering approach has been used in early grammatical error correction systems (Murata and Nagao, 1993; Bond et al., 1995; Bond and Ikehara, 1996; Heine, 1998). However, as noted by (Han et al., 2006), rules usually have exceptions, and it is hard to utilize corpus statistics in handcrafted rules. As such, the machine learning approach has become the dominant approach in grammatical error correction.

Previous work in the machine learning approach typically formulates the task as a classification problem. Article and preposition errors are the two main research topics (Knight and Chander, 1994; Han et al., 2006; Tetreault and Chodorow, 2008; Dahlmeier and Ng, 2011). Features used in classification include surrounding words, part-of-speech tags, language model scores (Gamon, 2010), and parse tree structures (Tetreault et al., 2010). Learning algorithms used include maximum entropy (Han et al., 2006; Tetreault and Chodorow, 2008), averaged perceptron, naïve Bayes (Rozovskaya and Roth, 2011), etc. Besides article and preposition errors, verb form errors also attract some attention recently (Liu et al., 2010; Tajiri et al., 2012).

Several research efforts have started to deal with correcting different errors in an integrated manner (Gamon, 2011; Park and Levy, 2011; Dahlmeier and Ng, 2012a). Gamon (2011) uses a high-order sequential labeling model to detect various errors. Park and Levy (2011) models grammatical error correction using a noisy channel model, where a predefined generative model produces correct sentences and errors are added through a noise model. The work of (Dahlmeier and Ng, 2012a) is probably the closest to our current work. It uses a beam-search decoder, which iteratively corrects an input sentence to arrive at the best corrected output. The difference between their work and our ILP approach is that the beam-search decoder returns an approximate solution to the original inference problem, while ILP returns an exact solution to an approximate inference problem.

Integer linear programming has been successfully applied to many NLP tasks, such as dependency parsing (Riedel and Clarke, 2006; Martins et al., 2009), semantic role labeling (Punyakanok et al., 2005), and event extraction (Riedel and McCallum, 2011).

## 3 Inference with First Order Variables

The inference problem for grammatical error correction can be stated as follows: “*Given an input sentence, choose a set of corrections which results in the best output sentence.*” In this paper, this problem will be expressed and solved by integer linear programming (ILP).

To express an NLP task in the framework of ILP requires the following steps:

1. Encode the output space of the NLP task using integer variables;
2. Express the inference objective as a linear objective function; and
3. Introduce problem-specific constraints to refine the feasible output space.

In the following sections, we follow the above formulation. For the grammatical error correction task, the variables in ILP are indicators of the corrections that a word needs, the objective function measures how grammatical the whole sentence is if some corrections are accepted, and the constraints guarantee that the corrections do not conflict with each other.

### 3.1 First Order Variables

Given an input sentence, the main question that a grammatical error correction system needs to answer is: *What corrections at which positions?* For example, is it reasonable to change the word *cats* to *cat* in the sentence *A cats sat on the mat?* Given the corrections at various positions in a sentence, the system can readily come up with the corrected sentence. Thus, a natural way to encode the output space of grammatical error correction requires information about sentence position, error type (e.g., noun number error), and correction (e.g., *cat*).

Suppose  $s$  is an input sentence, and  $|s|$  is its length (i.e., the number of words in  $s$ ). Define *first order variables*:

$$Z_{l,p}^k \in \{0, 1\}, \quad (1)$$

where

$p \in \{1, 2, \dots, |s|\}$  is a position in a sentence,

$l \in L$  is an error type,

$k \in \{1, 2, \dots, C(l)\}$  is a correction of type  $l$ .

$L$ : the set of error types,

$C(l)$ : the number of corrections for error type  $l$ .

If  $Z_{l,p}^k = 1$ , the word at position  $p$  should be corrected to  $k$  that is of error type  $l$ . Otherwise, the word at position  $p$  is not applicable for this correction. Deletion of a word is represented as  $k = \epsilon$ . For example,  $Z_{\text{Art},1}^a = 1$  means that the article (Art) at position 1 of the sentence should be  $a$ . If  $Z_{\text{Art},1}^a = 0$ , then the article should not be  $a$ . Table 1 contains the error types handled in this work, their possible corrections and applicable positions in a sentence.

### 3.2 The Objective Function

The objective of the inference problem is to find the best output sentence. However, there are exponentially many different combinations of corrections, and it is not possible to consider all combinations. Therefore, instead of solving the original inference problem, we will solve an approximate inference problem by introducing the following decomposable assumption: *Measuring the output quality of multiple corrections can be decomposed into measuring the quality of the individual corrections.*

Let  $s'$  be the resulting sentence if the correction  $Z_{l,p}^k$  is accepted for  $s$ , or for simplicity denoting

it as  $s \xrightarrow{Z_{l,p}^k} s'$ . Let  $w_{l,p,k} \in \mathbb{R}$ , measure how grammatical  $s'$  is. Define the objective function as

$$\max \sum_{l,p,k} w_{l,p,k} Z_{l,p}^k.$$

This linear objective function aims to select a set of  $Z_{l,p}^k$ , such that the sum of their weights is the largest among all possible candidate corrections, which in turn gives the most grammatical sentence under the decomposable assumption.

Although the decomposable assumption is a strong assumption, it performs well in practice, and one can relax the assumption by using higher order variables (see Section 5).

For an individual correction  $Z_{l,p}^k$ , we measure the quality of  $s'$  based on three factors:

1. The language model score  $h(s', \text{LM})$  of  $s'$  based on a large web corpus;

2. The confidence scores  $f(s', t)$  of classifiers, where  $t \in E$  and  $E$  is the set of classifiers. For example, an article classifier trained on well-written documents will score every article in  $s'$ , and measure the quality of  $s'$  from the perspective of an article “expert”.

3. The disagreement scores  $g(s', t)$  of classifiers, where  $t \in E$ . A disagreement score measures how ungrammatical  $s'$  is from the perspective of a classifier. Take the article classifier as an example. For each article instance in  $s'$ , the classifier computes the difference between the maximum confidence score among all possible choices of articles, and the confidence score of the observed article. This difference represents the disagreement on the observed article by the article classifier or “expert”. Define the maximum difference over all article instances in  $s'$  to be the article classifier disagreement score of  $s'$ . In general, this score is large if the sentence  $s'$  is more ungrammatical.

The weight  $w_{l,p,k}$  is a combination of these scores:

$$w_{l,p,k} = \nu_{\text{LM}} h(s', \text{LM}) + \sum_{t \in E} \lambda_t f(s', t) + \sum_{t \in E} \mu_t g(s', t), \quad (2)$$

where  $\nu_{\text{LM}}$ ,  $\lambda_t$ , and  $\mu_t$  are the coefficients.

### 3.3 Constraints

An observation on the objective function is that it is possible, for example, to set  $Z_{\text{Art},p}^a = 1$  and

Type $l$	Correction $k$	$C(l)$	Applicable	Variables
article	a, the, $\epsilon$	3	article or NP	$Z_{\text{Art},p}^a, Z_{\text{Art},p}^{\text{the}}, Z_{\text{Art},p}^\epsilon$
preposition	on, at, in, ...	confusion set	preposition	$Z_{\text{Prep},p}^{\text{on}}, Z_{\text{Prep},p}^{\text{at}}, Z_{\text{Prep},p}^{\text{in}}, \dots$
noun number	singular, plural	2	noun	$Z_{\text{Noun},p}^{\text{singular}}, Z_{\text{Noun},p}^{\text{plural}}$
punctuation	punctuation symbols	candidates	determined by rules	$Z_{\text{Punct},p}^{\text{original}}, Z_{\text{Punct},p}^{\text{cand1}}, Z_{\text{Punct},p}^{\text{cand2}}, \dots$
spelling	correctly spelled words	candidates	determined by a spell checker	$Z_{\text{Spell},p}^{\text{original}}, Z_{\text{Spell},p}^{\text{cand1}}, Z_{\text{Spell},p}^{\text{cand2}}, \dots$

Table 1: Error types and corrections. The *Applicable* column indicates which parts of a sentence are applicable to an error type. In the first row,  $\epsilon$  means deleting an article.

$Z_{\text{Art},p}^{\text{the}} = 1$ , which means there are two corrections *a* and *the* for the same sentence position  $p$ , but obviously only one article is allowed.

A simple constraint to avoid these conflicts is

$$\sum_k Z_{l,p}^k = 1, \quad \forall \text{ applicable } l, p$$

It reads as follows: for each error type  $l$ , only one output  $k$  is allowed at any applicable position  $p$  (note that  $Z_{l,p}^k$  is a Boolean variable).

Putting the variables, objective function, and constraints together, the ILP problem with respect to first order variables is as follows:

$$\max \sum_{l,p,k} w_{l,p,k} Z_{l,p}^k \quad (3)$$

$$\text{s.t. } \sum_k Z_{l,p}^k = 1, \quad \forall \text{ applicable } l, p \quad (4)$$

$$Z_{l,p}^k \in \{0, 1\} \quad (5)$$

The ILP problem is solved using `lp_solve`<sup>1</sup>, an integer linear programming solver based on the revised simplex method and the branch-and-bound method for integers.

### 3.4 An Illustrating Example

To illustrate the ILP formulation, consider an example input sentence  $s$ :

$$\text{A cats sat on the mat .} \quad (6)$$

First, the constraint (4) at position 1 is:

$$Z_{\text{Art},1}^a + Z_{\text{Art},1}^{\text{the}} + Z_{\text{Art},1}^\epsilon = 1,$$

which means only one article in  $\{a, \text{the}, \epsilon\}$  is selected.

<sup>1</sup><http://lpsolve.sourceforge.net/>

Next, to compute  $w_{l,p,k}$ , we collect language model score and confidence scores from the article (ART), preposition (PREP), and noun number (NOUN) classifier, i.e.,  $E = \{\text{ART}, \text{PREP}, \text{NOUN}\}$ .

The weight for  $Z_{\text{Noun},2}^{\text{singular}}$  is:

$$w_{\text{Noun},2,\text{singular}} = \nu_{\text{LM}} h(s', \text{LM}) + \lambda_{\text{ART}} f(s', \text{ART}) + \lambda_{\text{PREP}} f(s', \text{PREP}) + \lambda_{\text{NOUN}} f(s', \text{NOUN}) + \mu_{\text{ART}} g(s', \text{ART}) + \mu_{\text{PREP}} g(s', \text{PREP}) + \mu_{\text{NOUN}} g(s', \text{NOUN}).$$

where  $s \xrightarrow{Z_{\text{Noun},2}^{\text{singular}}} s' = \text{A cat sat on the mat .}$

The confidence score  $f(s', t)$  of classifier  $t$  is the average of the confidence scores of  $t$  on the applicable instances in  $s'$ .

For example, there are two article instances in  $s'$ , located at position 1 and 5 respectively, hence,

$$\begin{aligned} f(s', \text{ART}) &= \frac{1}{2} (f(s'[1], 1, \text{ART}) + f(s'[5], 5, \text{ART})) \\ &= \frac{1}{2} (f(a, 1, \text{ART}) + f(\text{the}, 5, \text{ART})). \end{aligned}$$

Here, the symbol  $f_t(s'[p], p, \text{ART})$  refers to the confidence score of the article classifier at position  $p$ , and  $s'[p]$  is the word at position  $p$  of  $s'$ .

Similarly, the disagreement score  $g(s', \text{ART})$  of the article classifier is

$$\begin{aligned} g(s', \text{ART}) &= \max(g_1, g_2) \\ g_1 &= \arg \max_k f(k, 1, \text{ART}) - f(a, 1, \text{ART}) \\ g_2 &= \arg \max_k f(k, 5, \text{ART}) - f(\text{the}, 5, \text{ART}) \end{aligned}$$

Putting them together, the weight for  $Z_{\text{Noun},2}^{\text{singular}}$  is:

$$\begin{aligned} w_{\text{Noun},2,\text{singular}} &= \nu_{\text{LM}} h(s', \text{LM}) \\ &+ \frac{\lambda_{\text{ART}}}{2} (f(a, 1, \text{ART}) + f(\text{the}, 5, \text{ART})) \\ &+ \lambda_{\text{PREP}} f(\text{on}, 4, \text{PREP}) \\ &+ \frac{\lambda_{\text{NOUN}}}{2} (f(\text{cat}, 2, \text{NOUN}) + f(\text{mat}, 6, \text{NOUN})) \\ &+ \mu_{\text{ART}} g(s', \text{ART}) \\ &+ \mu_{\text{PREP}} g(s', \text{PREP}) \\ &+ \mu_{\text{NOUN}} g(s', \text{NOUN}) \end{aligned}$$

Input	A	cats	sat	on	the	mat
Corrections	The, $\epsilon$	cat		at, in	a, $\epsilon$	mats
	$Z_{\text{Art},1}^a$	$Z_{\text{Noun},2}^{\text{singular}}$		$Z_{\text{Prep},4}^{\text{on}}$	$Z_{\text{Art},5}^a$	$Z_{\text{Noun},6}^{\text{singular}}$
Variables	$Z_{\text{Art},1}^{\text{the}}$	$Z_{\text{Noun},2}^{\text{plural}}$		$Z_{\text{Prep},4}^{\text{at}}$	$Z_{\text{Art},5}^{\text{the}}$	$Z_{\text{Noun},6}^{\text{plural}}$
	$Z_{\text{Art},1}^\epsilon$			$Z_{\text{Prep},4}^{\text{in}}$	$Z_{\text{Art},5}^\epsilon$	

Table 2: The possible corrections on example (6).

### 3.5 Complexity

The time complexity of ILP is determined by the number of variables and constraints. Assume that for each sentence position, at most  $K$  classifiers are applicable<sup>2</sup>. The number of variables is  $O(K|s|C(l^*))$ , where  $l^* = \arg \max_{l \in L} C(l)$ . The number of constraints is  $O(K|s|)$ .

## 4 Constraints for Prior Knowledge

### 4.1 Modification Count Constraints

In practice, we usually have some rough gauge of the quality of an input sentence. If an input sentence is mostly grammatical, the system is expected to make few corrections. This requirement can be easily satisfied by adding modification count constraints.

In this work, we constrain the number of modifications according to error types. For the error type  $l$ , a parameter  $N_l$  controls the number of modifications allowed for type  $l$ . For example, the modification count constraint for article corrections is

$$\sum_{p,k} Z_{\text{Art},p}^k \leq N_{\text{Art}}, \quad \text{where } k \neq s[p]. \quad (7)$$

The condition ensures that the correction  $k$  is different from the original word in the input sentence. Hence, the summation only counts real modifications. There are similar constraints for preposition, noun number, and spelling corrections:

$$\sum_{p,k} Z_{\text{Prep},p}^k \leq N_{\text{Prep}}, \quad \text{where } k \neq s[p], \quad (8)$$

$$\sum_{p,k} Z_{\text{Noun},p}^k \leq N_{\text{Noun}}, \quad \text{where } k \neq s[p], \quad (9)$$

$$\sum_{p,k} Z_{\text{Spell},p}^k \leq N_{\text{Spell}}, \quad \text{where } k \neq s[p]. \quad (10)$$

<sup>2</sup>In most cases,  $K = 1$ . An example of  $K > 1$  is a noun that requires changing the word form (between singular and plural) and inserting an article, for which  $K = 2$ .

### 4.2 Article-Noun Agreement Constraints

An advantage of the ILP formulation is that it is relatively easy to incorporate prior linguistic knowledge. We now take article-noun agreement as an example to illustrate how to encode such prior knowledge using linear constraints.

A noun in plural form cannot have *a* (or *an*) as its article. That two Boolean variables  $Z_1$  and  $Z_2$  are mutually exclusive can be handled using a simple inequality  $Z_1 + Z_2 \leq 1$ . Thus, the following inequality correctly enforces article-noun agreement:

$$Z_{\text{Art},p_1}^a + Z_{\text{Noun},p_2}^{\text{plural}} \leq 1, \quad (11)$$

where the article at  $p_1$  modifies the noun at  $p_2$ .

### 4.3 Dependency Relation Constraints

Another set of constraints involves dependency relations, including subject-verb relation and determiner-noun relation. Specifically, for a noun  $n$  at position  $p$ , we check the word  $w$  related to  $n$  via a child-parent or parent-child relation. If  $w$  belongs to a set of verbs or determiners (*are, were, these, all*) that takes a plural noun, then the noun  $n$  is required to be in plural form by adding the following constraint:

$$Z_{\text{Noun},p}^{\text{plural}} = 1. \quad (12)$$

Similarly, if a noun  $n$  at position  $p$  is required to be in singular form due to subject-verb relation or determiner-noun relation, we add the following constraint:

$$Z_{\text{Noun},p}^{\text{singular}} = 1. \quad (13)$$

## 5 Inference with Second Order Variables

### 5.1 Motivation and Definition

To relax the decomposable assumption in Section 3.2, instead of treating each correction separately, one can combine multiple corrections into a single correction by introducing higher order variables.

Consider the sentence *A cat sat on the mat.* When measuring the gain due to  $Z_{\text{Noun},2}^{\text{plural}} = 1$  (change *cat* to *cats*), the weight  $w_{\text{Noun},2,\text{plural}}$  is likely to be small since *A cats* will get a low language model score, a low article classifier confidence score, and a low noun number classifier confidence score. Similarly, the weight  $w_{\text{Art},1,\epsilon}$  of  $Z_{\text{Art},1}^\epsilon$  (delete article *A*) is also likely to be small because of the missing article. Thus, if one considers the two corrections separately, they are both unlikely to appear in the final corrected output.

However, the correction from *A cat sat on the mat.* to *Cats sat on the mat.* should be a reasonable candidate, especially if the context indicates that there are many cats (more than one) on the mat. Due to treating corrections separately, it is difficult to deal with multiple interacting corrections with only first order variables.

In order to include the correction  $\epsilon$  *Cats*, one can use a new set of variables, *second order variables*. To keep symbols clear, let  $Z = \{Z_u | Z_u = Z_{l,p}^k, \forall l, p, k\}$  be the set of first order variables, and  $w_u = w_{l,p,k}$  be the weight of  $Z_u = Z_{l,p}^k$ . Define a second order variable  $X_{u,v}$ :

$$X_{u,v} = Z_u \wedge Z_v, \quad (14)$$

where  $Z_u$  and  $Z_v$  are first order variables:

$$Z_u \triangleq Z_{l_1,p_1}^{k_1}, \quad Z_v \triangleq Z_{l_2,p_2}^{k_2}. \quad (15)$$

The definition of  $X_{u,v}$  states that a second order variable is set to 1 if and only if its two component first order variables are both set to 1. Thus, it combines two corrections into a single correction. In the above example, a second order variable is introduced:

$$X_{u,v} = Z_{\text{Art},1}^\epsilon \wedge Z_{\text{Noun},2}^{\text{plural}},$$

$$s \xrightarrow{X_{u,v}} s' = \text{Cats sat on the mat.}$$

Similar to first order variables, let  $w_{u,v}$  be the weight of  $X_{u,v}$ . Note that definition (2) only depends on the output sentence  $s'$ , and the weight of the second order variable  $w_{u,v}$  can be defined in the same way:

$$w_{u,v} = \nu_{\text{LM}} h(s', \text{LM}) + \sum_{t \in E} \lambda_t f(s', t) + \sum_{t \in E} \mu_t g(s', t). \quad (16)$$

## 5.2 ILP with Second Order Variables

A set of new constraints is needed to enforce consistency between the first and second order variables. These constraints are the linearization of definition (14) of  $X_{u,v}$ :

$$X_{u,v} = Z_u \wedge Z_v \Leftrightarrow \begin{cases} X_{u,v} \leq Z_u \\ X_{u,v} \leq Z_v \\ X_{u,v} \geq Z_u + Z_v - 1 \end{cases} \quad (17)$$

A new objective function combines the weights from both first and second order variables:

$$\max \sum_{l,p,k} w_{l,p,k} Z_{l,p}^k + \sum_{u,v} w_{u,v} X_{u,v}. \quad (18)$$

In our experiments, due to noisy data, some weights of second order variables are small, even if both of its first order variables have large weights and satisfy all prior knowledge constraints. They will affect ILP proposing good corrections. We find that the performance will be better if we change the weights of second order variables to  $w'_{u,v}$ , where

$$w'_{u,v} \triangleq \max\{w_{u,v}, w_u, w_v\}. \quad (19)$$

Putting them together, (20)-(25) is an ILP formulation using second order variables, where  $X$  is the set of all second order variables which will be explained in the next subsection.

$$\max \sum_{l,p,k} w_{l,p,k} Z_{l,p}^k + \sum_{u,v} w'_{u,v} X_{u,v} \quad (20)$$

$$\text{s.t. } \sum_k Z_{l,p}^k = 1, \quad \forall \text{ applicable } l, p \quad (21)$$

$$X_{u,v} \leq Z_u, \quad (22)$$

$$X_{u,v} \leq Z_v, \quad (23)$$

$$X_{u,v} \geq Z_u + Z_v - 1, \forall X_{u,v} \in X \quad (24)$$

$$X_{u,v}, Z_{l,p}^k \in \{0, 1\} \quad (25)$$

## 5.3 Complexity and Variable Selection

Using the notation in section 3.5, the number of second order variables is  $O(|Z|^2) = O(K^2 |s|^2 C(l^*)^2)$  and the number of constraints is  $O(K^2 |s|^2 C(l^*)^2)$ . More generally, for variables with higher order  $h \geq 2$ , the number of variables (and constraints) is  $O(K^h |s|^h C(l^*)^h)$ .

Note that both the number of variables and the number of constraints increase exponentially with increasing variable order. In practice, a small subset of second order variables is sufficient to

Data set	Sentences	Words	Edits
Dev set	939	22,808	1,264
Test set	722	18,790	1,057

Table 3: Overview of the HOO 2011 data sets. Corrections are called *edits* in the HOO 2011 shared task.

achieve good performance. For example, noun number corrections are only coupled with nearby article corrections, and have no connection with distant or other types of corrections.

In this work, we only introduce second order variables that combine article corrections and noun number corrections. Furthermore, we require that the article and the noun be in the same noun phrase. The set  $X$  of second order variables in Equation (24) is defined as follows:

$$X = \{X_{u,v} = Z_u \wedge Z_v | l_1 = \text{Art}, l_2 = \text{Noun}, s[p_1], s[p_2] \text{ are in the same noun phrase}\},$$

where  $l_1, l_2, p_1, p_2$  are taken from Equation (15).

## 6 Experiments

Our experiments mainly focus on two aspects: how our ILP approach performs compared to other grammatical error correction systems; and how the different constraints and the second order variables affect the ILP performance.

### 6.1 Evaluation Corpus and Metric

We follow the evaluation setup in the HOO 2011 shared task on grammatical error correction (Dale and Kilgarriff, 2011). The development set and test set in the shared task consist of conference and workshop papers taken from the Association for Computational Linguistics (ACL). Table 3 gives an overview of the data sets.

System performance is measured by precision, recall, and  $F$  measure:

$$P = \frac{\# \text{ true edits}}{\# \text{ system edits}}, R = \frac{\# \text{ true edits}}{\# \text{ gold edits}}, F = \frac{2PR}{P+R}. \quad (26)$$

The difficulty lies in how to generate the system edits from the system output. In the HOO 2011 shared task, participants can submit system edits directly or the corrected plain-text system output. In the latter case, the official HOO scorer will extract system edits based on the original (ungram-

matical) input text and the corrected system output text, using GNU Wdiff<sup>3</sup>.

Consider an input sentence *The data is similar with test set.* taken from (Dahlmeier and Ng, 2012a). The gold-standard edits are *with*  $\rightarrow$  *to* and  $\epsilon$   $\rightarrow$  *the*. That is, the grammatically correct sentence should be *The data is similar to the test set.* Suppose the corrected output of a system to be evaluated is exactly this perfectly corrected sentence *The data is similar to the test set.* However, the official HOO scorer using GNU Wdiff will automatically extract only one system edit *with*  $\rightarrow$  *to* for this system output. Since this single system edit does not match any of the two gold-standard edits, the HOO scorer returns an F measure of 0, even though the system output is perfectly correct.

In order to overcome this problem, the *Max-Match* ( $M^2$ ) scorer was proposed in (Dahlmeier and Ng, 2012b). Given a set of gold-standard edits, the original (ungrammatical) input text, and the corrected system output text, the  $M^2$  scorer searches for the system edits that have the largest overlap with the gold-standard edits. For the above example, the system edits automatically determined by the  $M^2$  scorer are identical to the gold-standard edits, resulting in an F measure of 1 as we would expect. We will use the  $M^2$  scorer in this paper to determine the best system edits. Once the system edits are found,  $P$ ,  $R$ , and  $F$  are computed using the standard definition (26).

### 6.2 ILP Configuration

#### 6.2.1 Variables

The first order variables are given in Table 1. If the indefinite article correction  $a$  is chosen, then the final choice between  $a$  and  $an$  is decided by a rule-based post-processing step. For each preposition error variable  $Z_{\text{prep},p}^k$ , the correction  $k$  is restricted to a pre-defined confusion set of prepositions which depends on the observed preposition at position  $p$ . For example, the confusion set of *on* is  $\{at, for, in, of\}$ . The list of prepositions corrected by our system is *about, among, at, by, for, in, into, of, on, over, to, under, with, and within*. Only selected positions in a sentence (determined by rules) undergo punctuation correction. The spelling correction candidates are given by a spell checker. We used GNU Aspell<sup>4</sup> in our work.

<sup>3</sup><http://www.gnu.org/software/wdiff/>

<sup>4</sup><http://aspell.net>

## 6.2.2 Weights

As described in Section 3.2, the weight of each variable is a linear combination of the language model score, three classifier confidence scores, and three classifier disagreement scores. We use the Web 1T 5-gram corpus (Brants and Franz, 2006) to compute the language model score for a sentence. Each of the three classifiers (article, preposition, and noun number) is trained with the multi-class confidence weighted algorithm (Cramer et al., 2009). The training data consists of all non-OCR papers in the ACL Anthology<sup>5</sup>, minus the documents that overlap with the HOO 2011 data set. The features used for the classifiers follow those in (Dahlmeier and Ng, 2012a), which include lexical and part-of-speech n-grams, lexical head words, web-scale n-gram counts, dependency heads and children, etc. Over 5 million training examples are extracted from the ACL Anthology for use as training data for the article and noun number classifiers, and over 1 million training examples for the preposition classifier.

Finally, the language model score, classifier confidence scores, and classifier disagreement scores are normalized to take values in  $[0, 1]$ , based on the HOO 2011 development data. We use the following values for the coefficients:  $\nu_{\text{LM}} = 1$  (language model);  $\lambda_t = 1$  (classifier confidence); and  $\mu_t = -1$  (classifier disagreement).

## 6.2.3 Constraints

In Section 4, three sets of constraints are introduced: modification count (MC), article-noun agreement (ANA), and dependency relation (DR) constraints. The values for the modification count parameters are set as follows:  $N_{\text{Art}} = 3$ ,  $N_{\text{Prep}} = 2$ ,  $N_{\text{Noun}} = 2$ , and  $N_{\text{Spell}} = 1$ .

## 6.3 Experimental Results

We compare our ILP approach with two other systems: the beam search decoder of (Dahlmeier and Ng, 2012a) which achieves the best published performance to date on the HOO 2011 data set, and UI Run1 (Rozovskaya et al., 2011) which achieves the best performance among all participating systems at the HOO 2011 shared task. The results are given in Table 4.

The HOO 2011 shared task provides two sets of gold-standard edits: the original gold-standard edits produced by the annotator, and the official gold-

System	Original			Official		
	P	R	F	P	R	F
UI Run1	40.86	11.21	17.59	54.61	14.57	23.00
Beam search	30.28	19.17	23.48	33.59	20.53	25.48
ILP	20.54	27.93	23.67	21.99	29.04	25.03

Table 4: Comparison of three grammatical error correction systems.

standard edits which incorporated corrections proposed by the HOO 2011 shared task participants. All three systems listed in Table 4 use the  $M^2$  scorer to extract system edits. The results of the beam search decoder and UI Run1 are taken from Table 2 of (Dahlmeier and Ng, 2012a).

Overall, ILP inference outperforms UI Run1 on both the original and official gold-standard edits, and the improvements are statistically significant at the level of significance 0.01. The performance of ILP inference is also competitive with the beam search decoder. The results indicate that a grammatical error correction system benefits from corrections made at a whole sentence level, and that joint correction of multiple error types achieves state-of-the-art performance.

Table 5 provides the comparison of the beam search decoder and ILP inference in detail. The main difference between the two is that, except for spelling errors, ILP inference gives higher recall than the beam search decoder, while its precision is lower. This indicates that ILP inference is more aggressive in proposing corrections.

Next, we evaluate ILP inference in different configurations. We only focus on article and noun number error types. Table 6 shows the performance of ILP in different configurations. From the results, MC and DR constraints improve precision, indicating that the two constraints can help to restrict the number of erroneous corrections. Including second order variables gives the best  $F$  measure, which supports our motivation for introducing higher order variables.

Adding article-noun agreement constraints (ANA) slightly decreases performance. By examining the output, we find that although the overall performance worsens slightly, the agreement requirement is satisfied. For example, for the input *We utilize search engine to . . .*, the output without ANA is *We utilize a search engines to . . .* but with ANA is *We utilize the search engines to . . .*, while the only gold edit inserts *a*.

## 7 Conclusion

In this paper, we model grammatical error correction as a joint inference problem. The inference problem is solved using integer linear programming. We provide three sets of constraints to incorporate additional linguistic knowledge, and introduce a further extension with second order variables. Experiments on the HOO 2011 shared task show that ILP inference achieves state-of-the-art performance on grammatical error correction.

# Text-Driven Toponym Resolution using Indirect Supervision

Michael Speriosu     Jason Baldrige

Department of Linguistics

University of Texas at Austin

Austin, TX 78712 USA

{speriosu, jbaldrid}@utexas.edu

## Abstract

Toponym resolvers identify the specific locations referred to by ambiguous place-names in text. Most resolvers are based on heuristics using spatial relationships between multiple toponyms in a document, or metadata such as population. This paper shows that text-driven disambiguation for toponyms is far more effective. We exploit document-level geotags to indirectly generate training instances for text classifiers for toponym resolution, and show that textual cues can be straightforwardly integrated with other commonly used ones. Results are given for both 19th century texts pertaining to the American Civil War and 20th century newswire articles.

## 1 Introduction

It has been estimated that at least half of the world's stored knowledge, both printed and digital, has geographic relevance, and that geographic information pervades many more aspects of humanity than previously thought (Petras, 2004; Skupin and Esperbé, 2011). Thus, there is value in connecting linguistic references to places (e.g. placenames) to formal references to places (coordinates) (Hill, 2006). Allowing for the querying and exploration of knowledge in a geographically informed way requires more powerful tools than a keyword-based search can provide, in part due to the ambiguity of toponyms (placenames).

Toponym resolution is the task of disambiguating toponyms in natural language contexts to geographic locations (Leidner, 2008). It plays an essential role in automated geographic indexing and information retrieval. This is useful for historical research that combines age-old geographic issues like territoriality with modern computational tools (Guldi, 2009), studies of the effect of histor-

ically recorded travel costs on the shaping of empires (Scheidel et al., 2012), and systems that convey the geographic content in news articles (Teitler et al., 2008; Sankaranarayanan et al., 2009) and microblogs (Gelernter and Mushegian, 2011).

Entity disambiguation systems such as those of Kulkarni et al. (2009) and Hoffart et al. (2011) disambiguate references to people and organizations as well as locations, but these systems do not take into account any features or measures unique to geography such as physical distance. Here we demonstrate the utility of incorporating distance measurements in toponym resolution systems.

Most work on toponym resolution relies on heuristics and hand-built rules. Some use simple rules based on information from a gazetteer, such as population or administrative level (city, state, country, etc.), resolving every instance of the same toponym type to the same location regardless of context (Ladra et al., 2008). Others use relationships between multiple toponyms in a context (local or whole document) and look for containment relationships, e.g. *London* and *England* occurring in the same paragraph or as the bigram *London, England* (Li et al., 2003; Amitay et al., 2004; Zong et al., 2005; Clough, 2005; Li, 2007; Volz et al., 2007; Jones et al., 2008; Buscaldi and Rosso, 2008; Grover et al., 2010). Still others first identify unambiguous toponyms and then disambiguate other toponyms based on geopolitical relationships with or distances to the unambiguous ones (Ding et al., 2000). Many favor resolutions of toponyms within a local context or document that cover a smaller geographic area over those that are more dispersed (Rauch et al., 2003; Leidner, 2008; Grover et al., 2010; Loureiro et al., 2011; Zhang et al., 2012). Roberts et al. (2010) use relationships learned between people, organizations, and locations from Wikipedia to aid in toponym resolution when such named entities are present, but do not exploit any other textual context.

Most of these approaches suffer from a major weakness: they rely primarily on spatial relationships and metadata about locations (e.g., population). As such, they often require nearby toponyms (including unambiguous or containing toponyms) to resolve ambiguous ones. This reliance can result in poor coverage when the required information is missing in the context or when a document mentions locations that are neither nearby geographically nor in a geopolitical relationship. There is a clear opportunity that most ignore: use non-toponym textual context. Spatially relevant words like *downtown* that are not explicit toponyms can be strong cues for resolution (Hollenstein and Purves, 2012). Furthermore, the connection between non-spatial words and locations has been successfully exploited in data-driven approaches to document geolocation (Eisenstein et al., 2010, 2011; Wing and Baldrige, 2011; Roller et al., 2012) and other tasks (Hao et al., 2010; Pang et al., 2011; Intagorn and Lerman, 2012; Hecht et al., 2012; Louwerse and Benesh, 2012; Adams and McKenzie, 2013).

In this paper, we learn resolvers that use all words in local or document context. For example, the word *lobster* appearing near the toponym *Portland* indicates the location is Portland in Maine rather than Oregon or Michigan. Essentially, we learn a text classifier per toponym. There are no massive collections of toponyms labeled with locations, so we train models indirectly using geo-tagged Wikipedia articles. Our results show these text classifiers are far more accurate than algorithms based on spatial proximity or metadata. Furthermore, they are straightforward to combine with such algorithms and lead to error reductions for documents that match those algorithms' assumptions.

Our primary focus is toponym resolution, so we evaluate on toponyms identified by human annotators. However, it is important to consider the utility of an end-to-end toponym identification and resolution system, so we also demonstrate that performance is still strong when toponyms are detected with a standard named entity recognizer.

We have implemented all the models discussed in this paper in an open source software package called Fieldspring, which is available on GitHub: <http://github.com/utcompling/fieldspring>. Explicit instructions are provided for preparing data and running code to reproduce our results.

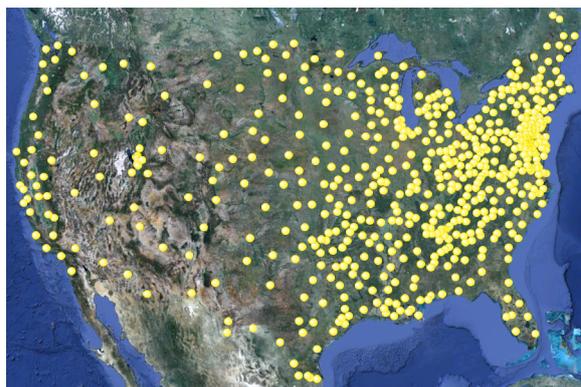

Figure 1: Points representing the United States.

## 2 Data

### 2.1 Gazetteer

Toponym resolvers need a gazetteer to obtain candidate locations for each toponym. Additionally, many gazetteers include other information such as population and geopolitical hierarchy information. We use GEONAMES, a freely available gazetteer containing over eight million entries worldwide.<sup>1</sup> Each location entry contains a name (sometimes more than one) and latitude/longitude coordinates. Entries also include the location's administrative level (e.g. city or state) and its position in the geopolitical hierarchy of countries, states, etc.

GEONAMES gives the locations of regional items like states, provinces, and countries as single points. This is clearly problematic when we seek connections between words and locations: e.g. we might learn that many words associated with the USA are connected to a point in Kansas. To get around this, we represent regional locations as a set of points derived from the gazetteer. Since regional locations are named in the entries for locations they contain, all locations contained in the region are extracted (in some cases over 100,000 of them) and then  $k$ -means is run to find a smaller set of spatial centroids. These act as a tractable proxy for the spatial extent of the entire region.  $k$  is set to the number of  $1^\circ$  by  $1^\circ$  grid cells covered by that region. Figure 1 shows the points computed for the United States.<sup>2</sup> A nice property of this representation is that it does not involve region shape files and the additional programming infrastructure they require.

<sup>1</sup>Downloaded April 16, 2013 from [www.geonames.org](http://www.geonames.org).

<sup>2</sup>The representation also contains three points each in Hawaii and Alaska not shown in Figure 1.

Table 1: Statistics of the corpora used for evaluation. Columns subscripted by *top* give figures for toponyms. The last two columns give the average number of candidate locations per toponym token and the number of candidate locations for the most ambiguous toponym.

A location for present purposes is thus a set of points on the earth’s surface. The distance between two locations is computed as the great circle distance between the closest pair of representative points, one from each location.

## 2.2 Toponym Resolution Corpora

We need corpora with toponyms identified and resolved by human annotators for evaluation. The TR-CONLL corpus (Leidner, 2008) contains 946 REUTERS news articles published in August 1996. It has about 204,000 words and articles range in length from a few hundred words to several thousand words. Each toponym in the corpus was identified and resolved by hand.<sup>3</sup> We place every third article into a test portion (TRC-TEST) and the rest in a development portion. Since our methods do not learn from explicitly labeled toponyms, we do not need a training set.

The Perseus Civil War and 19th Century American Collection (CWAR) contains 341 books (58 million words) written primarily about and during the American Civil War (Crane, 2000). Toponyms were annotated by a semi-automated process: a named entity recognizer identified toponyms, and then coordinates were assigned using simple rules and corrected by hand. We divide CWAR into development (CWAR-DEV) and test (CWAR-TEST) sets in the same way as TR-CONLL.

Table 1 gives statistics for both corpora, including the number and ambiguity of gold standard toponyms for both as well as NER identified to-

<sup>3</sup>We found several systematic types of errors in the original TR-CONLL corpus, such as coordinates being swapped for some locations and some longitudes being zero or the negative of their correct values. We repaired many of these errors, though some more idiosyncratic mistakes remain. We, along with Jochen Leidner, will release this updated version shortly and will link to it from our Fieldspring GitHub page.

ponyms for TR-CONLL.<sup>4</sup> We use the pre-trained English NER from the OpenNLP project.<sup>5</sup>

## 2.3 Geolocated Wikipedia Corpus

The GEOWIKI dataset contains over one million English articles from the February 11, 2012 dump of Wikipedia. Each article has human-annotated latitude/longitude coordinates. We divide the corpus into training (80%), development (10%), and test (10%) at random and perform preprocessing to remove markup in the same manner as Wing and Baldrige (2011). The training portion is used here to learn models for text-driven resolvers.

## 3 Toponym Resolvers

Given a set of toponyms provided via annotations or identified using NER, a resolver must select a candidate location for each toponym (or, in some cases, a resolver may abstain). Here, we describe baseline resolvers, a heuristic resolver based on the usual cues used in most toponym resolvers, and several text-driven resolvers. We also discuss combining heuristic and text-driven resolvers.

### 3.1 Baseline Resolvers

**RANDOM** For each toponym, the RANDOM resolver randomly selects a location from those associated in the gazetteer with that toponym.

**POPULATION** The POPULATION resolver selects the location with the greatest population for each toponym. It is generally quite effective, but when a toponym has several locations with large populations, it is often wrong. Also, it can only be used when such information is available, and it is

<sup>4</sup>States and countries are not annotated in CWAR, so we do not evaluate end-to-end using NER plus toponym resolution for it as there are many (falsely) false positives.

<sup>5</sup>[opennlp.apache.org](http://opennlp.apache.org)

less effective if the population statistics are from a time period different from that of the corpus.

### 3.2 SPIDER

Leidner (2008) describes two general and useful *minimality* properties of toponyms:

- *one sense per discourse*: multiple tokens of a toponym in the same text generally do not refer to different locations in the same text
- *spatial minimality*: different toponyms in a text tend refer to spatially near locations

Many toponym resolvers exploit these (Smith and Crane, 2001; Rauch et al., 2003; Leidner, 2008; Grover et al., 2010; Loureiro et al., 2011; Zhang et al., 2012). Here, we define SPIDER (Spatial Prominence via Iterative Distance Evaluation and Reweighting) as a strong representative of such textually unaware approaches. In addition to capturing both minimality properties, it also identifies the relative prominence of the locations for each toponym in a given corpus.

SPIDER resolves each toponym by finding the location for each that minimizes the sum distance to *all* locations for *all* other toponyms in the same document. On the first iteration, it tends to select locations that clump spatially: if *Paris* occurs with *Dallas*, it will choose Paris, Texas even though the topic may be a flight from Texas to France. Further iterations bring Paris, France into focus by capturing its prominence across the corpus. The key intuition is that most documents will discuss Paris, France and only a small portion of these mention places close to Paris, Texas; thus, Paris, France will be selected on the first iteration for many documents (though not for the *Dallas* document). SPIDER thus assigns each candidate location a weight (initialized to 1.0), which is re-estimated on each iteration. The adjusted distance between two locations is computed as the great circle distance divided by the product of the two locations’ weights. At the end of an iteration, each candidate location’s weight is updated to be the fraction of the times it was chosen times the number of candidates for that toponym. The weights are global, with one for each location in the gazetteer, so the same weight vector is used for each token of a given toponym on a given iteration.

For example, if after the first iteration Paris, France is chosen thrice, Paris, Texas once, and Paris, Arkansas never, the global weights of these locations are  $(3/4)*3=2.25$ ,  $(1/4)*3=.75$ , and

$(0/4)*3=0$ , respectively (assume, for the example, there are no other locations named *Paris*). The sum of the weights remains equal to the number of candidate locations. The updated weights are used on the next iteration, so Paris, France will seem “closer” since any distance computed to it is divided by a number greater than one. Paris, Texas will seem somewhat further away, and Paris, Arkansas infinitely far away. The algorithm continues for a fixed number of iterations or until the weights do not change more than some threshold. Here, we run SPIDER for 10 iterations; the weights have generally converged by this point.

When only one toponym is present in a document, we simply select the candidate with the greatest weight. When there is no such weight information, such as when the toponym does not co-occur with other toponyms anywhere in the corpus, we select a candidate at random.

SPIDER captures prominence, but we stress it is not our main innovation: its purpose is to be a benchmark for text-driven resolvers to beat.

### 3.3 Text-Driven Resolvers

The text-driven resolvers presented in this section all use local context windows, document context, or both, to inform disambiguation.

**TRIPDL** We use a document geolocator trained on GEOWIKI’s document location labels. Others—such as Smith and Crane (2001)—have estimated a document-level location to inform toponym resolution, but ours is the first we are aware of to use training data from a different domain to build a document geolocator that uses all words (not only toponyms) to estimate a document’s location. We use the document geolocation method of Wing and Baldrige (2011). It discretizes the earth’s surface into  $1^\circ$  by  $1^\circ$  grid cells and assigns Kullback-Liebler divergences to each cell given a document, based on language models learned for each cell from geolocated Wikipedia articles. We obtain the probability of a cell  $c$  given a document  $d$  by the standard method of exponentiating the negative KL-divergence and normalizing these values over all cells:

$$P(c|d) = \frac{\exp(-KL(c, d))}{\sum_{c'} \exp(-KL(c', d))}$$

This distribution is used for all toponyms  $t$  in  $d$  to define distributions  $P_{DL}(l|t, d)$  over candidate

locations of  $t$  in document  $d$  to be the portion of  $P(c|d)$  consistent with the  $t$ 's candidate locations:

$$P_{DL}(l|t, d) = \frac{P(c_l|d)}{\sum_{l' \in G(t)} P(c_{l'}|d)}$$

where  $G(t)$  is the set of the locations for  $t$  in the gazetteer, and  $c_l$  is the cell containing  $l$ . TRIPDL (Toponym Resolution Informed by Predicted Document Locations) chooses the location that maximizes  $P_{DL}$ .

**WISTR** While TRIPDL uses an off-the-shelf document geolocator to capture the geographic gist of a document, WISTR (Wikipedia Indirectly Supervised Toponym Resolver) instead directly targets each toponym. It learns text classifiers based on local context window features trained on instances automatically extracted from GEOWIKI.

To create the indirectly supervised training data for WISTR, the OpenNLP named entity recognizer detects toponyms in GEOWIKI, and candidate locations for each toponym are retrieved from GEONAMES. Each toponym with a location within 10km of the document location is considered a mention of that location. For example, the *Empire State Building* Wikipedia article has a human-provided location label of (40.75,-73.99). The toponym *New York* is mentioned several times in the article, and GEONAMES lists a *New York* at (40.71,-74.01). These points are 4.8km apart, so each mention of *New York* in the document is considered a reference to New York City.

Next, context windows  $w$  of twenty words to each side of each toponym are extracted as features. The label for a training instance is the candidate location closest to the document location. We extract 1,489,428 such instances for toponyms relevant to our evaluation corpora. These instances are used to train logistic regression classifiers  $P(l|t, w)$  for location  $l$  and toponym  $t$ . To disambiguate a new toponym, WISTR chooses the location that maximizes this probability.

Few such probabilistic toponym resolvers exist in the literature. Li (2007) builds a probability distribution over locations for each toponym, but still relies on nearby toponyms that could refer to regions that contain that toponym and requires hand construction of distributions. Other learning approaches to toponym resolution (e.g. Smith and Mann (2003)) require explicit unambiguous mentions like *Portland, Maine* to construct training instances, while our data gathering methodol-

ogy does not make such an assumption. Overell and Ruger (2008) and Overell (2009) only use nearby toponyms as features. Mani et al. (2010) and Qin et al. (2010) use other word types but only in a local context, and they require toponym-labeled training data. Our approach makes use of all words in local and document context and requires no explicitly labeled toponym tokens.

**TRAWL** We bring TRIPDL, WISTR, and standard toponym resolution cues about administrative levels together with TRAWL (Toponym Resolution via Administrative levels and Wikipedia Locations). The general form of a probabilistic resolver that utilizes such information to select a location  $\hat{l}$  for a toponym  $t$  in document  $d$  may be defined as

$$\hat{l} = \arg \max_l P(l, a_l|t, d).$$

where  $a_l$  is the administrative level (country, state, city) for  $l$  in the gazetteer. This captures the fact that countries (like Sudan) tend to be referred to more often than small cities (like Sudan, Texas). The above term is simplified as follows:

$$\begin{aligned} P(l, a_l|t, d) &= P(a_l|t, d)P(l|a_l, t, d) \\ &\approx P(a_l|t)P(l|t, d) \end{aligned}$$

where we approximate the administrative level prediction as independent of the document, and the location as independent of administrative level. The latter term is then expressed as a linear combination of the local context (WISTR) and the document context (TRIPDL):

$$P(l|t, d) = \lambda_t P(l|t, c_t) + (1-\lambda_t) P_{DL}(l|t, d).$$

$\lambda_t$ , the weight of the local context distribution, is set according to the confidence that a prediction based on local context is correct:

$$\lambda_t = \frac{f(t)}{f(t)+C},$$

where  $f(t)$  is the fraction of training instances of toponym  $t$  of all instances extracted from GEOWIKI.  $C$  is set experimentally;  $C=.0001$  was the optimal value for CWAR-DEV. Intuitively, the larger  $C$  is, the greater  $f(t)$  must be for the local context to be trusted over the document context.

We define  $P(a|t)$ , the administrative level component, to be the fraction of representative points for a location  $\hat{l}$  out of the number of representatives points for all candidate locations  $l \in t$ ,

$$\frac{\|R_{\hat{l}}\|}{\sum_{l' \in t} \|R_{l'}\|}$$

where  $\|R_l\|$  is the number of representative points of  $l$ . This boosts states and countries since higher probability is assigned to locations with more points (and cities have just one point).

Taken together, the above definitions yield the TRAWL resolver, which selects the optimal candidate location  $\hat{l}$  according to

$$\hat{l} = \arg \max_l P(a_i|t)(\lambda_t P(l|t, c_t) + (1-\lambda_t)P_{DL}(l|t, d)).$$

### 3.4 Combining Resolvers and Backoff

SPIDER begins with uniform weights for each candidate location of each toponym. WISTR and TRAWL both output distributions over these locations based on outside knowledge sources, and can be used as more informed initializations of SPIDER than the uniform ones. We call these combinations WISTR+SPIDER and TRAWL+SPIDER.<sup>6</sup>

WISTR fails to predict when encountering a toponym it has not seen in the training data, and TRIPDL fails when a toponym only has locations in cells with no probability mass. TRAWL fails when both of these are true. In these cases, we select the candidate location geographically closest to the most likely cell according to TRIPDL’s  $P(c|d)$  distribution.

### 3.5 Document Size

For SPIDER, runtime is quadratic in the size of documents, so breaking up documents vastly reduces runtime. It also restricts the minimality heuristic—appropriately—to smaller spans of text. For resolvers that take into account the surrounding document when determining how to resolve a toponym, such as TRIPDL and TRAWL, it can often be beneficial to divide documents into smaller subdocuments in order to get a better estimate of the overall geographic prominence of the text surrounding a toponym, but at a more coarse-grained level than the local context models provide. For these reasons, we simply divide each book in the CWAR corpus into small subdocuments of at most 20 sentences.

## 4 Evaluation

Many prior efforts use a simple accuracy metric: the fraction of toponyms whose predicted location

<sup>6</sup>We scale each toponym’s distribution as output by WISTR or TRAWL by the number of candidate locations for that toponym, since the total weight for each toponym in SPIDER is the number of candidate locations, not 1.

is the same as the gold location. Such a metric can be problematic, however. The gazetteer used by a resolver may not contain, for a given toponym, a location whose latitude and longitude *exactly* match the gold label for the toponym (Leidner, 2008). Also, some errors are worse than others, e.g. predicting a toponym’s location to be on the other side of the world versus predicting it to be a different city in the same country—accuracy does not reflect this difference.

We choose a metric that instead measures the distance between the correct and predicted location for each toponym and compute the mean and median of all such error distances. This is used in document geolocation work (Eisenstein et al., 2010, 2011; Wing and Baldrige, 2011; Roller et al., 2012) and is related to the root mean squared distance metric discussed by Leidner (2008).

It is important to understand performance on plain text (without gold toponyms), which is the typical use case for applications using toponym resolvers. Both the accuracy metric and the error-distance metric encounter problems when the set of predicted toponyms is not the same as the set of gold toponyms (regardless of locations), e.g. when a named entity recognizer is used to identify toponyms. In this case, we can use precision and recall, where a true positive is defined as the prediction of a correctly identified toponym’s location to be as close as possible to its gold label, given the gazetteer used. False positives occur when the NER incorrectly predicts a toponym, and false negatives occur when it fails to predict a toponym identified by the annotator. When a correctly identified toponym receives an incorrect location prediction, this counts as both a false negative and a false positive. We primarily present results from experiments with gold toponyms but include an accuracy measure for comparability with results from experiments run on plain text with a named entity recognizer. This accuracy metric simply computes the fraction of toponyms that were resolved as close as possible to their gold label given the gazetteer.

## 5 Results

Table 2 gives the performance of the resolvers on the TR-CONLL and CWAR test sets when gold toponyms are used. Values for RANDOM and SPIDER are averaged over three trials. The ORACLE row gives results when the candidate

Resolver	TRC-TEST			CWAR-TEST

WISTR	279	<b>22.6</b>	<b>82.3</b>	855	<b>0.0</b>	69.1
WISTR+SPIDER <sub>10</sub>	430	23.1	81.8	201	<b>0.0</b>	<b>85.9</b>
TRAWL	235	<b>22.6</b>	81.4	945	<b>0.0</b>	67.8
TRAWL+SPIDER <sub>10</sub>	297	23.1	80.7	<b>148</b>	<b>0.0</b>	78.2

Table 2: Accuracy and error distance metrics on test sets with gold toponyms.

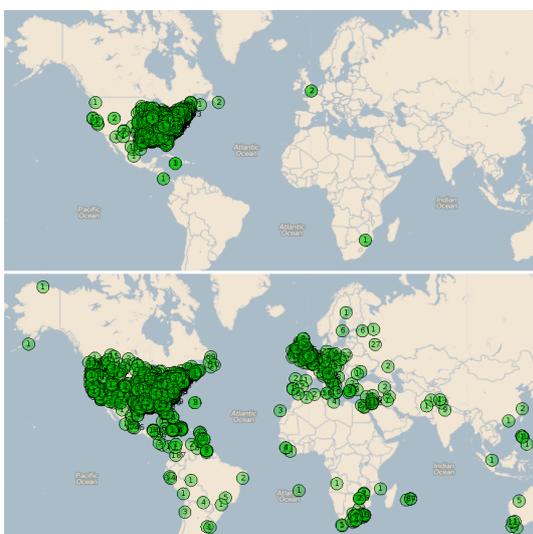

Figure 2: Visualization of how SPIDER clumps most predicted locations in the same region (above), on the CWAR-DEV corpus. TRAWL’s output (below) is much more dispersed.

from GEONAMES closest to the annotated location is always selected. The ORACLE mean and median error values on TR-CONLL are nonzero due to errors in the annotations and inconsistencies stemming from the fact that coordinates from GEONAMES were not used in the annotation of TR-CONLL.

On both datasets, SPIDER achieves errors and accuracies much better than RANDOM, validating the intuition that authors tend to discuss places near each other more often than not, while some locations are more prominent in a given corpus despite violating the minimality heuristic. The text-driven resolvers vastly outperform SPIDER, showing the effectiveness of textual cues for toponym resolution.

The local context resolver WISTR is very effective: it has the highest accuracy for TR-CONLL, though two other text-based resolvers also beat the challenging POPULATION baseline’s accuracy. TRAWL achieves a better mean distance metric for TR-CONLL, and when used to seed SPIDER, it obtains the lowest mean error on CWAR by a large margin. SPIDER seeded with WISTR achieves the highest accuracy on CWAR. The overall geographic scope of CWAR, a collection of documents about the American Civil War, is much smaller than that of TR-CONLL (articles about international events). This makes toponym resolution easier overall (especially error distances) for minimality resolvers like SPIDER, which primarily seek tightly clustered sets of locations. This behavior is quite clear in visualizations of predicted locations such as Figure 2.

On the CWAR dataset, POPULATION performs relatively poorly, demonstrating the fragility of population-based decisions for working with historical corpora. (Also, we note that POPULATION is not a resolver *per se* since it only ever predicts one location for a given toponym, regardless of context.)

Table 3 gives results on TRC-TEST when NER-identified toponyms are used. In this case, the ORACLE results are less than 100% due to the limitations of the NER, and represent the best possible results given the NER we used.

When resolvers are run on NER-identified toponyms, the text-driven resolvers that use local context again easily beat SPIDER. WISTR achieves the best performance. The named entity recognizer is likely better at detecting common toponyms than rare toponyms due to the na-

Resolver	P	R	F
ORACLE	82.6	59.9	69.4
RANDOM	25.1	18.2	21.1
POPULATION	71.6	51.9	60.2
SPIDER <sub>10</sub>	40.5	29.4	34.1
TRIPDL	51.8	37.5	43.5
WISTR	<b>73.9</b>	<b>53.6</b>	<b>62.1</b>
WISTR+SPIDER <sub>10</sub>	73.2	53.1	61.5
TRAWL	72.5	52.5	60.9
TRAWL+SPIDER <sub>10</sub>	72.0	52.2	60.5

Table 3: Precision, recall, and F-score of resolvers on TRC-TEST with NER-identified toponyms.

ture of its training data, and many more local context training instances were extracted from common toponyms than from rare ones in Wikipedia. Thus, our model that uses *only* these local context models does best when running on NER-identified toponyms. We also measured the mean and median error distance for toponyms correctly identified by the named entity recognizer, and found that they tended to be 50-200km worse than for gold toponyms. This also makes sense given the named entity recognizer’s tendency to detect common toponyms: common toponyms tend to be more ambiguous than others.

Results on TR-CONLL indicate much higher performance than the resolvers presented by Leidner (2008), whose F-scores do not exceed 36.5% with either gold or NER toponyms.<sup>7</sup> TRC-TEST is a subset of the documents Leidner uses (he did not split development and test data), but the results still come from overlapping data. The most direct comparison is SPIDER’s F-score of 39.7% compared to his LSW03 algorithm’s 35.6% (both are minimality resolvers). However, our evaluation is more penalized since SPIDER loses precision for NER’s false positives (Jack London as a location) while Leidner only evaluated on actual locations. It thus seems fair to conclude that the text-driven classifiers, with F-scores in the mid-50’s, are much more accurate on the corpus than previous work.

## 6 Error Analysis

Table 4 shows the ten toponyms that caused the greatest total error distances from TRC-DEV with gold toponyms when resolved by TRAWL, the resolver that achieves the lowest mean error on that

<sup>7</sup>Leidner (2008) reports precision, recall, and F-score values even with gold toponyms, since his resolvers can abstain.

dataset among all our resolvers.

*Washington*, the toponym contributing the most total error, is a typical example of a toponym that is difficult to resolve, as there are two very prominent locations within the United States with the name. Choosing one when the other is correct results in an error of over 4000 kilometers. This occurs, for example, when TRAWL chooses Washington state in the phrase *Israel’s ambassador to Washington*, where more knowledge about the status of Washington, D.C. as the political center of the United States (e.g. in the form of more or better contextual training instances) could overturn the administrative level component’s preference for states.

An instance of *California* in a baseball-related news article is incorrectly predicted to be the town California, Pennsylvania. The context is: *...New York starter Jimmy Key left the game in the first inning after Seattle shortstop Alex Rodriguez lined a shot off his left elbow. The Yankees have lost 12 of their last 19 games and their lead in the AL East over Baltimore fell to five games. At California, Tim Wakefield pitched a six-hitter for his third complete game of the season and Mo Vaughn and Troy O’Leary hit solo home runs in the second inning as the surging Boston Red Sox won their third straight 4-1 over the California Angels. Boston has won seven of eight and is 20-6...* The presence of many east coast cues—both toponym and otherwise—make it unsurprising that the resolver would predict California, Pennsylvania despite the administrative level component’s heavier weighting of the state.

The average errors for the toponyms *Australia* and *Russia* are fairly small and stem from differences in how countries are represented across different gazetteers, not true incorrect predictions.

Table 5 shows the toponyms with the greatest errors from CWAR-DEV with gold toponyms when resolved by WISTR+SPIDER. *Rome* is sometimes predicted as cities in Italy and other parts of Europe rather than Rome, Georgia, though it correctly selects the city in Georgia more often than not due to SPIDER’s preference for tightly clumped sets of locations. *Mexico*, however, frequently gets incorrectly selected as a city in Maryland near many other locations in the corpus when TRAWL’s administrative level component is not present. Many other of the toponyms contributing to the total error such as *Jackson* and *Lexington* are

Toponym	N	Mean	Total
Washington	25	3229	80717
Gaza	12	5936	71234
California	8	5475	43797
Montana	3	11635	34905

simply the result of many American towns sharing the same names and a lack of clear disambiguating context.

## 7 Conclusion

Our text-driven resolvers prove highly effective for both modern day newswire texts and 19th century texts pertaining to the Civil War. They easily outperform standard minimality toponym resolvers, but can also be combined with them. This strategy works particularly well when predicting toponyms on a corpus with relatively restricted geographic extents. Performance remains good when resolving toponyms identified automatically, indicating that end-to-end systems based on our models may improve the experience of digital humanities scholars interested in finding and visualizing toponyms in large corpora.

## Acknowledgements

We thank: the three anonymous reviewers, Grant DeLozier, and the UT Austin Natural Language Learning reading group, for their helpful feedback; Ben Wing, for his document geolocation software; Jochen Leidner, for providing the TR-CONLL corpus as well as feedback on earlier versions of this paper; and Scott Nesbit, for providing the annotations for the CWAR corpus. This research was supported by a grant from the Morris Memorial Trust Fund of the New York Community Trust.

## Abstract

As a paratactic language, sentence-level argument extraction in Chinese suffers much from the frequent occurrence of ellipsis with regard to inter-sentence arguments. To resolve such problem, this paper proposes a novel global argument inference model to explore specific relationships, such as *Coreference*, *Sequence* and *Parallel*, among relevant event mentions to recover those inter-sentence arguments in the sentence, discourse and document layers which represent the cohesion of an event or a topic. Evaluation on the ACE 2005 Chinese corpus justifies the effectiveness of our global argument inference model over a state-of-the-art baseline.

## 1 Introduction

The task of event extraction is to recognize event mentions of a predefined event type and their arguments (participants and attributes). Generally, it can be divided into two subtasks: trigger extraction, which aims to identify trigger/event mentions and determine their event type, and argument extraction, which aims to extract various arguments of a specific event and assign the roles to them. In this paper, we focus on argument extraction in Chinese event extraction. While most of previous studies in Chinese event extraction deal with Chinese trigger extraction (e.g., Chen and Ji, 2009a; Qin et al., 2010; Li et al., 2012a, 2012b), there are only a few on Chinese argument extraction (e.g., Tan et al., 2008; Chen and Ji, 2009b). Following previous studies, we divide argument extraction into two components, argument identification

and role determination, where the former recognizes the arguments in a specific event mention and the latter classifies these arguments by roles.

With regard to methodology, most of previous studies on argument extraction recast it as a Semantic Role Labeling (SRL) task and focus on intra-sentence information to identify the arguments and their roles. However, argument extraction is much different from SRL in the sense that, while the relationship between a predicate and its arguments in SRL can be mainly decided from the syntactic structure, the relationship between an event trigger and its arguments are more semantics-based, especially in Chinese, as a paratactic (e.g., discourse-driven and pro-drop) language with the wide spread of ellipsis and the open flexible sentence structure. Therefore, some arguments of a specific event mention are far away from the trigger and how to recover those inter-sentence arguments becomes a challenging issue in Chinese argument extraction. Consider the following discourse (from ACE 2005 Chinese corpus) as a sample:

D1: 巴勒斯坦自治政府否认和加沙走廊 20 号清晨造成两名以色列人**丧生(E1)**的**炸弹攻击(E2)**事件有关...表示将对这起**攻击(E3)**事件展开调查。(The Palestinian National Authority denied any involvement in the **bomb attack (E2)** occurred in the Gaza Strip on the morning of the 20th, which **killed (E1) two Israelites**. ... They claimed that they will be investigating this **attack (E3)**.) - From CBS20001120.1000.0823

In above discourse, there are three event mentions, one *kill* (E1) and two *Attack* (E2, E3). While it is relatively easy to identify 20 号清晨 (morning of 20th), 加沙走廊 (Gaza Strip) and 炸弹 (bomb) as the *Time*, *Place* and *Instrument* roles in E2 by a sentence-based argument

extractor, it is really challenging to recognize these entities as the arguments of its corefered mention E3 since to reduce redundancy in a Chinese discourse, the later Chinese sentences omit many of these entities already mentioned in previous sentences. Similarly, it is hard to recognize 两名以色列人 (two Israelites) as the *Target* role for event mention E2 and identify 炸弹 (bomb) as the *Instrument* role for event mention E1. An alternative way is to employ various relationships among relevant event mentions in a discourse to infer those inter-sentence arguments.

The contributions of this paper are:

- 1) We propose a novel global argument inference model, in which various kinds of event relations are involved to infer more arguments on their semantic relations.
- 2) Different from Liao and Grishman (2010) and Hong et al. (2011), which only consider document-level consistency, we propose a more fine-grained consistency model to enforce the consistency in the sentence, discourse and document layers.
- 3) We incorporate argument semantics into our global argument inference model to unify the semantics of the event and its arguments.

The rest of this paper is organized as follows. Section 2 overviews the related work. Section 3 describes a state-of-the-art Chinese argument extraction system as the baseline. Section 4 introduces our global model in inferring those inter-sentence arguments. Section 5 reports experimental results and gives deep analysis. Finally, we conclude our work in Section 6.

## 2 Related Work

Almost all the existing studies on argument extraction concern English. While some apply pattern-based approaches (e.g., Riloff, 1996; Califf and Mooney, 2003; Patwardhan and Riloff, 2007; Chambers and Jurafsky, 2011), the others use machine learning-based approaches (e.g., Grishman et al., 2005; Ahn, 2006; Patwardhan and Riloff, 2009; Lu and Roth, 2012), most of which rely on various kinds of features in the context of a sentence. In comparison, there are only a few studies exploring inter-sentence information or argument semantics (e.g., Liao and Grishman, 2010; Hong et al., 2011; Huang and Riloff, 2011, 2012).

Compared with the tremendous work on English event extraction, there are only a few studies (e.g., Tan et al., 2008; Chen and Ji, 2009b;

Fu et al., 2010; Qin et al., 2010; Li et al., 2012) on Chinese event extraction with focus on either feature engineering or trigger expansion, under the same framework as English trigger identification. In addition, there are only very few of them focusing on Chinese argument extraction and almost all aim to feature engineering and are based on sentence-level information and recast this task as an SRL-style task. Tan et al. (2008) introduce multiple levels of patterns to improve the coverage in Chinese argument classification. Chen and Ji (2009b) apply various kinds of lexical, syntactic and semantic features to address the special issues in Chinese argument extraction. Fu et al. (2010) use a feature weighting scheme to re-weight various features for Chinese argument extraction. Li et al. (2012b) introduce more refined features to the system of Chen and Ji (2009b) as their baseline.

Specially, several studies have successfully incorporated cross-document or document-level information and argument semantics into event extraction, most of them focused on English.

Yangarber et al. (2007) apply a cross-document inference mechanism to refine local extraction results for the disease name, location and start/end time. Mann (2007) proposes some constraints on relationship rescoring to impose the discourse consistency on the CEO's personal information. Chambers and Jurafsky (2008) propose a narrative event chain which are partially ordered sets of event mentions centered around a common protagonist and this chain can represent the relationship among the relevant event mentions in a document.

Ji and Grishman (2008) employ a rule-based approach to propagate consistent triggers and arguments across topic-related documents. Liao and Grishman (2010) mainly focus on employing the cross-event consistency information to improve sentence-level trigger extraction and they also propose an inference method to infer the arguments following role consistency in a document. Hong et al. (2011) employ the background information to divide an entity type into more cohesive subtypes to create the bridge between two entities and then infer arguments and their roles using cross-entity inference on the subtypes of entities. Huang and Riloff (2012) propose a sequentially structured sentence classifier which uses lexical associations and discourse relations across sentences to identify event-related document contexts and then apply it to recognize arguments and their roles on the relation among triggers and arguments.

### 3 Baseline

In the task of event extraction as defined in ACE evaluations, an event is defined as a specific occurrence involving participants (e.g., *Person, Attacker, Agent, Defendant*) and attributes (e.g., *Place, Time*). Commonly, an event mention is triggered via a word (trigger) in a phrase or sentence which clearly expresses the occurrence of a specific event. The arguments are the entity mentions involved in an event mention with a specific role, the relation of an argument to an event where it participates. Hence, extracting an event consists of four basic steps, identifying an event trigger, determining its event type, identifying involved arguments (participants and attributes) and determining their roles.

As the baseline, we choose a state-of-the-art Chinese event extraction system, as described in Li et al. (2012b), which consists of four typical components: trigger identification, event type determination, argument identification and role determination. In their system, the former two components, trigger identification and event type determination, are processed in a joint model, where the latter two components are run in a pipeline way. Besides, the Maximum-Entropy (ME) model is employed to train individual component classifiers for above four components.

This paper focuses on argument identification and role determination. In order to provide a stronger baseline, we introduce more refined features in such two components, besides those adopted in Li et al. (2012b). Following is a list of features adopted in our baseline.

- 1) Basic features: trigger, POS (Part Of Speech) of the trigger, event type, head word of the entity, entity type, entity subtype;
- 2) Neighbouring features: left neighbouring word of the entity + its POS, right neighbour word of the entity + its POS, left neighbour word of the trigger + its POS, right neighbour word of the trigger + its POS;
- 3) Dependency features: dependency path from the entity to the trigger, depth of the dependency path;
- 4) Syntactic features: path from the trigger to the entity, difference of the depths of the trigger and entity, place of the entity (before trigger or after trigger), depth of the path from the trigger to the entity, siblings of the entity;
- 5) Semantic features: semantic role of the entity tagged by an SRL tool (e.g., *ARG0, ARG1*) (Li et al., 2010), sememe of trigger in Hownet (Dong and Dong, 2006).

### 4 Inferring Inter-Sentence Arguments on Relevant Event Mentions

In this paper, a global argument inference model is proposed to infer those inter-sentence arguments and their roles, incorporating with semantic relations between relevant event mention pairs and argument semantics.

#### 4.1 Motivation

It's well-known that Chinese is a paratactic language, with an open flexible sentence structure and often omits the subject or the object, while English is a hypotactic language with a strict sentence structure and emphasizes on cohesion between clauses. Hence, there are two issues in Chinese argument extraction, associated with its nature of the paratactic language.

The first is that many arguments of an event mention are out of the event mention scope since ellipsis is a common phenomenon in Chinese. We call them inter-sentence arguments in this paper. Table 1 gives the statistics of intra-sentence and inter-sentence arguments in the ACE 2005 Chinese corpus and it shows that 20.8% of the arguments are inter-sentence ones while this figure is less than 1% of the ACE 2005 English corpus. The main reason of that difference is that some Chinese arguments are omitted in the same sentence of the trigger since Chinese is a paratactic language with the wide spread of ellipsis. Besides, a Chinese sentence does not always end with a full stop. In particular, a comma is used frequently as the stop sign of a sentence in Chinese. We detect sentence boundaries, relying on both full stop and comma signs, since in a Chinese document, comma can be also used to sign the end of a sentence. In particular, we detect sentence boundaries on full stop, exclamatory mark and question mark firstly. Then, we identify the sentence boundaries on comma, using a binary classifier with a set of lexical and constituent-based syntactic features, similar to Xue and Yang (2010).

Category	Number
#Arguments	8032
#Inter-sentence	1673(20.8%)
#Intra-sentence	6359(79.2%)

Table 1. Statistics: Chinese argument extraction with regard to intra- sentence and inter-sentence arguments.

The second issue is that the Chinese word order in a sentence is rather agile for the open

flexible sentence structure. Hence, different word orders can often express the same semantics. For example, a *Die* event mention “Three person died in this accident.” can be expressed in many different orders in Chinese, such as “在事故中三人死亡。”, “事故中死亡三人。”, “三人在事故中死亡。”, etc.

In a word, above two issues indicate that syntactic feature-based approaches are limited in identifying Chinese arguments and it will lead to low recall in argument identification. Therefore, employing those high level information to capture the semantic relation, not only the syntactic structure, between the trigger and its long distance arguments is the key to improve the performance of the Chinese argument identification. Unfortunately, it is really hard to find their direct relations since they always appear in different clauses or sentences. An alternative way is to link the different event mentions with their predicates (triggers) and use the trigger as a bridge to connect the arguments to the trigger in another event mention indirectly. Hence, the semantic relations among event mentions are helpful to be a bridge to identify those inter-sentence arguments.

## 4.2 Relations of Event Mention Pairs

In a discourse, most event mentions are surrounding a specific topic. It's obvious that those mentions have the intrinsic relationships to reveal the essential structure of a discourse. Those relevant semantics-based relations are helpful to infer the arguments for a specific trigger mention when the syntactic relations in Chinese argument extraction are not as effective as that in English. In this paper, we divide the relations among relevant event mentions into three categories: *Coreference*, *Sequence* and *Parallel*.

An event may have more than one mention in a document and *coreference* event mentions refer to the same event, as same as the definition in the ACE evaluations. Those *coreference* event mentions always have the same arguments and roles. Therefore, employing this relation can infer the arguments of an event mention from their *Coreference* ones. For example, we can recover the *Time*, *Place* and *Instrument* for E3 via its *Coreference* mention E2 in discourse D1, mentioned in Section 1.

Li et al. (2012a) find out that sometimes two trigger mentions are within a Chinese word whose morphological structure is *Coordination*.

Take the following sentence as a sample:

D2: 一名 17 岁的少年劫持一辆巴士, **刺(E4)死(E5)** 一名妇女。(A 12-year-old younger hijacked a bus and then **stabbed (E4)** a woman to **death (E5)**.) - From ZBN20001218.0400.0005

In D2, 刺死 (stab a person to death) is a trigger with the *Coordination* structure and can be divided into two single-morpheme words 刺 (stab) and 死 (die) while the former triggers an *Attack* event and the latter refers to a *Die* one. It's interesting that they share all arguments in this sentence. The relation between those event mentions whose triggers merge a Chinese word or share the subject and the object are *Parallel*. For the errors in the syntactic parsing, the second single-morpheme trigger is often assigned a wrong tag (e.g., NN, JJ) and this leads to the errors in the argument extraction. Therefore, inferring the arguments of the second single-morpheme trigger from that of the first one based on *Parallel* relation is also an available way to recover arguments.

Like that the topic is an axis in a discourse, the relations among those relevant event mentions with the different types is the bone to link them into a narration. There are a few studies on using the event relations in NLP (e.g., summarization (Li et al., 2006), learning narrative event chains (Chambers and Jurafsky, 2007)) to ensure its effectiveness. In this paper, we define two types of *Sequence* relations of relevant event mentions: *Cause* and *Temporal* for their high probabilities of sharing arguments.

The *Cause* relation between the event mentions are similar to that in the Penn Discourse TreeBank 2.0 (Prasad et al., 2008). For example, an *Attack* event often is the cause of an *Die* or *Injure* event. Our *Temporal* relation is limited to those mentions with the same or relevant event types (e.g., *Transport* and *Arrest*) for the high probabilities of sharing arguments. Take the following discourse as a sample:

D3: 这批战俘离开(E6)阿尔及利亚西部城市廷杜夫前往(E7)摩洛哥西南部城市阿加迪尔。(These prisoners left (E6) Tindouf, a western city of Algeria, and went (E7) to Agadir, a southwestern city of Morocco.) - From Xin20001215.2000.0158

In D3, there are two *Transport* mentions and it is natural to infer 阿加迪尔 (Agadir) as the *Destination* role of E6 and 廷杜夫 (Tindouf) as the *Origin* role of E7 via their *Sequence* relation.

### 4.3 Identifying Relations of Event Mention Pairs

Currently, there are only few studies focusing on such area (e.g., Ahn, 2006; Chamber and Jurafsky, 2007; Huang and Riloff, 2012; Do et al., 2012) and their approaches cannot be introduced to our system directly for the language nature and the different goal. We try to achieve a higher accuracy in this stage so that our argument inference can recover more true arguments.

Inspired by Li and Zhou (2012), we also use the morphological structure to identify the *Parallel* relation. Two parallel event mentions with the adjacent trigger mentions  $w_1$  and  $w_2$  must satisfy follows two conditions:

1)  $Morph(w_1, w_2)$  is *Coordination*

2)  $HM(w_1) \in T_i, HM(w_2) \in T_j \quad i \neq j$

where  $Morph(w_1, w_2)$  is a function to recognize the morphological structure of joint word  $w_1 w_2$ ,  $HM(w_i)$  is to identify the head morpheme<sup>1</sup> in word  $w_i$  and  $T_i$  is the set of the head morphemes with  $i$ th event type. These constraints are enlightened by the fact that only Chinese words with *Coordination* structure can be divided into two new words and each word can trigger an event with the different event type<sup>2</sup>. The implementation of  $Morph(w_1, w_2)$  and  $HM(w)$  are described in Li and Zhou (2012).

The *Coreference* relation is divided into two types: *Noun-based Coreference (NC)* and *Event-based Coreference (EC)* while the former always uses a verbal noun to refer to an event mentioned in current or previous sentence and the latter is that an event is mentioned twice or more actually. For example, the relation between E2 and E3 in D1 is *NC* while the trigger of E3 is only a verbal noun without any direct arguments and it refers to E2.

We adopt a simple rule to recognize those *NC* relations: for each event mention whose trigger is a noun and doesn't act as the subject/object, we regard their relation as *NC* if there is another event mention with the same trigger in current or previous sentence.

Inspired by Ahn (2006), we use the following conditions to infer the *EC* relations between two event mentions with the same event type:

- 1) Their trigger mentions refer to the same trigger;
- 2) They have at least one same or similar

<sup>1</sup> It acts as the governing semantic element in a Chinese word.

<sup>2</sup> If they have the same event type, they will be regarded as a single event mention.

subject/object;

- 3) The score of cosine similarity of two event mentions is more than a threshold<sup>3</sup>.

Finally, for the *Sequence* relation, instead of identifying and classifying the relations clearly and correctly, our goal is to identify whether there are relevant event mentions in a long sentence or two adjacent short sentences who share arguments. Algorithm 1 illustrates a knowledge-based approach to identify the *Sequence* event relation in a discourse for any two trigger mentions  $tri_1$  and  $tri_2$  as follows:

---

#### Algorithm 1

---

```
1: input:  $tri_1$  and  $tri_2$  and their type  $et_1$  and  $et_2$ 
2: output: whether their relation is Sequence
3: begin
4:    $hm_1 \leftarrow HM(tri_1); hm_2 \leftarrow HM(tri_2)$ 
5:    $MP \leftarrow FindAllMP(hm_1, et_1, hm_2, et_2)$ 
6:   for any  $mp_i$  in  $MP$ 
7:     if  $ShareArg(mp_i)$  is true then
8:       return true // Sequence
9:     end if
10:  end for
11:  return false
12: end
```

---

In algorithm 1,  $HM(tri)$  is to identify the head morpheme in trigger  $tri$  and  $FindAllMP(hm_1, et_1, hm_2, et_2)$  is to find all event mention pairs in the training set which satisfy the condition that their head morphemes are  $hm_1$  and  $hm_2$ , and their event types are  $et_1$  and  $et_2$  respectively. Besides,  $ShareArg(mp_i)$  is used to identify whether the event mention pair  $mp_i$  sharing at least one argument. In this algorithm, since the relations on the event types are too coarse, we introduce a more fine-gained *Sequence* relation both on the event types and the head morphemes of the triggers which can divide an event type into many subtypes on the head morpheme. Li and Zhou (2012) have ensured the effectiveness of using head morpheme to infer the triggers and our experiment results also show it is helpful for identifying relevant event mentions which aims to the higher accuracy.

### 4.4 Global Argument Inference Model

Our global argument inference model is composed of two steps: 1) training two sentence-based classifiers: argument identifier (AI) and role determiner (RD) that estimate the score of a candidate acts as an argument and belongs to a

<sup>3</sup> The threshold is tuned to 0.78 on the training set.

specific role following Section 3. 2) Using the scores of two classifiers and the event relations in a sentence, a discourse or a document, we perform global optimization to infer those missing or long distance arguments and their roles.

To incorporate those event relations with our global argument inference model, we regard a document as a tree and divide it into three layers: document, discourse and sentence. A document is composed of a set of the discourses while a discourse contains three sentences. Since almost all arguments (~98%) of a specific event mention in the ACE 2005 Chinese corpus appear in the sentence containing the specific event mention and its two adjacent sentences (previous and next sentences), we only consider these three sentences as a discourse to simplify the process of identifying the scope of a discourse.

We incorporate different event relations into our model on the different layer and the goal of our global argument inference model is to achieve the maximized scores over a document on its three layers and two classifiers: AI and RD. The score of document  $D$  is defined as

$$\hat{D} = \arg \max_{X,Y} (\alpha \sum_{I_i \in D} \sum_{S_{<i,j>} \in I_i} \sum_{T_{<i,j,k>} \in S_{<i,j>}} \sum_{A_Z \in T_{<i,j,k>}} \sum_{(1)} (f_I(E_Z)X_Z + (1-f_I(E_Z))(1-X_Z))$$

$$+ (1-\alpha) \sum_{I_i \in D} \sum_{S_{<i,j>} \in I_i} \sum_{T_{<i,j,k>} \in S_{<i,j>}} \sum_{A_Z \in T_{<i,j,k>}} \sum_{m \in R} \sum_{(2)} (f_D(E_Z, R_m)Y_{<Z,m>} + (1-f_D(E_Z, R_m))(1-Y_{<Z,m>}))$$

$$s.t. \quad X_Z \in \{0,1\} \quad (2)$$

$$Y_{<Z,m>} \in \{0,1\} \quad (3)$$

$$X_Z \geq Y_{<Z,m>} \quad \forall m \in R \quad (4)$$

$$X_Z = \sum_{m \in R} Y_{<Z,m>} \quad (5)$$

where  $I_i$  is the  $i$ th discourses in document  $D$ ;  $S_{<i,j>}$  is the  $j$ th sentences in discourse  $I_i$ ;  $T_{<i,j,k>}$  is the  $k$ th event mentions in sentence  $S_{<i,j>}$ ;  $A_{<i,j,k,l>}$  is the  $l$ th candidate arguments in event mention  $T_{<i,j,k>}$ ;  $Z$  is used to denote  $<i,j,k,l>$ ;  $f_I(E_Z)$  is the score of AI identifying entity mention  $E_Z$  as an argument, where  $E_Z$  is the  $l$ th entity of the  $k$ th event mention of the  $j$ th sentence of the  $i$ th discourse in document  $D$ .  $f_D(E_Z, R_m)$  is the score of RD assigning role  $R_m$  to argument  $E_Z$ . Finally,  $X_Z$  and  $Y_{<Z,m>}$  are the indicators denoting whether entity  $E_Z$  is an argument and whether the role  $R_m$  is assigned to entity  $E_Z$  respectively. Besides, Eq. 4 and Eq. 5 are the inferences to enforce that:

- 1) if an entity belongs to a role, it must be an argument;
- 2) if a entity is an argument of a specific event mention, it must have a role.

**Parallel relation:** Sentence-based optimization is used to incorporate the *Parallel* relation of two event mentions into our model and they share all arguments in a sentence. Since different event type may have different role set, each role in a specific event should be mapped to the corresponding role in its *Parallel* event when they have the different event type. For example, the argument “一名 17 岁的少年” (A 12-year-old younger) in D2 acts as the *Attacker* role in the *Attack* event and the *Agent* role in the *Die* event. We learn those role-pairs from the training set and Table 2 shows part of the role relations learning from the training set.

Event type pair	Role pair
Attack-Die	Attacker-Agent; Target-Victim;...
Injure-Die	Agent-Agent; Victim-Victim;...
Transport-Demonstrate	Artifact-Entity; Destination-Place;...

Table 2. Part of role-pairs for those event mention pairs with *Parallel* relation.

To infer the arguments and their roles on the *Parallel* relation, we enforce the consistency on the role-pair as follows:

$$Y_{<i,j,k,l,m>} = Y_{<i,j,k',l',m'>} \quad (6)$$

$$\forall I_i \in D \wedge S_{<i,j>} \in I_i \wedge T_{<i,j,k>} \in S_{<i,j>} \wedge T_{<i,j,k'>} \in S_{<i,j>} \wedge A_{<i,j,k,l>} \in T_{<i,j,k>} \wedge A_{<i,j,k',l'>} \in T_{<i,j,k'>} \wedge <m,m'> \in RP_{et_h \times et_{h'}} \wedge E_{<i,j,k,l>} = E_{<i,j,k',l'>}$$

where  $RP_{et_h \times et_{h'}}$  is the set of role-pairs between two *Parallel* event mention  $et_h$  and  $et_{h'}$  and  $E_{<i,j,k,l>} = E_{<i,j,k',l'>}$  means they refer to the same entity mention. With the transitivity between the indicators  $X$  and  $Y$ , Eq. 6 also enforces the consistency on  $X_{<i,j,k,l>}$  and  $X_{<i,j,k',l'>}$ .

**Coreference relation:** Since the *NC* and *EC* relation between two event mentions are different in the event expression, we introduce the discourse-based optimization for the former and document-based optimization for the latter.

For two *NC* mentions, we ensure that the succeeding mentions can inherit the arguments from the previous one. To enforce this consistency, we just replace all  $f_I(E_Z)$  and  $f_D(E_Z, R_m)$  of the succeeding event mention with that of the previous one, since the previous one have the more context information.

As for two *EC* event mentions, algorithm 2 shows how to create the constraints for our

global argument inference model to infer arguments and roles.

---

### Algorithm 2

---

1: **input:** two event mentions  $T, T'$  and their arguments set  $A$  and  $A'$   
2: **output:** the constraints set  $C$   
3: **begin**  
4:   **for** each argument  $a$  in  $A$  **do**  
5:      $a' \leftarrow \text{FindSim}(a)$   
6:     **if**  $a' \neq \emptyset$  **then**  
7:        $C \leftarrow C \cup \text{Consistency}(Y_a, Y_{a'})$   
8:     **end if**  
9:   **end for**  
10: **end**

---

In algorithm 2, the function  $\text{FindSim}(a)$  is used to find a similar candidate argument  $a'$  in  $A'$  for  $a$ . If it's found, we enforce the consistency of argument  $a$  and  $a'$  in the role by using  $\text{Consistency}(Y_a, Y_{a'})$  where  $Y_a$  and  $Y_{a'}$  are the indicators in Eq. 1. To evaluate the similarity between two candidates  $a$  and  $a'$ , we regard them as similar ones when they are the same word or in the same entity coreference chain. We use a coreference resolution tool to construct the entity coreference chains, as described in Kong et al (2010).

**Sequence relation:** For any two event mentions in a discourse, we use the event type pair with their head morphemes (e.g., *Attack: 炸 (burst) - Die: 死 (die)*, *Trial-Hearing: 审 (trial) - Sentence: 判 (sentence)*) to search the training set and then obtain the probabilities of sharing the arguments as mentioned in algorithm 1. We denoted  $\text{Pro}_{\langle et, et', HM(tri), HM(tri'), R_m, R_m' \rangle}$  as the probability of the trigger mentions  $tri$  and  $tri'$  (their event types are  $et$  and  $et'$  respectively.) sharing an argument whose roles are  $R_m$  and  $R_m'$  respectively. We propose following discourse-based constraint to enforce the consistency between the roles of two arguments, which are related semantically, temporally, causally or conditionally, based on the probability of sharing an argument and the absolute value of the difference between the scores of RD:

$$\begin{aligned}
Y_{\langle i, j, k, l, m \rangle} &= Y_{\langle i, j', k', l', m' \rangle} \\
\forall i \in D \wedge S_{\langle i, j \rangle}, S_{\langle i, j' \rangle} \in I_i \wedge T_{\langle i, j, k \rangle} \in S_{\langle i, j \rangle} \\
&\wedge T_{\langle i, j', k' \rangle} \in S_{\langle i, j' \rangle} \wedge m, m' \in R \wedge E_{\langle i, j, k, l \rangle} = E_{\langle i, j', k', l' \rangle} \\
&\wedge \text{Pro}_{\langle et, et', HM(tri), HM(tri'), R_m, R_m' \rangle} > \delta \wedge \\
&\left| f_D(E_{\langle i, j, k, l \rangle}, R_m) - f_D(E_{\langle i, j', k', l' \rangle}, R_m') \right| > \lambda
\end{aligned} \quad (7)$$

where  $\delta$  and  $\lambda$  are the thresholds learned from the

development set;  $tri$  and  $tri'$  are triggers of  $k$ th and  $k'$ th event mention whose event types are  $et$  and  $et'$  in  $S_{\langle i, j \rangle}$  and  $S_{\langle i, j' \rangle}$  respectively.

## 4.5 Incorporating Argument Semantics into Global Argument Inference Model

We also introduce the argument semantics, which represent the semantic relations of argument-argument pair, argument-role pair and argument-trigger pair, to reflect the cohesion inside an event. Hong et al. (2011) found out that there is a strong argument and role consistency in the ACE 2005 English corpus. Those consistencies also occur in Chinese and they reveal the relation between the trigger and its arguments, and also explore the relation between the argument and its role. Besides, those entities act as non-argument also have the consistency with high probabilities.

To let the global argument inference model combine those knowledges of argument semantics, we compute the prior probabilities  $P(X_{\langle i, j \rangle} = 1)$  and  $P(Y_{\langle i, j, m \rangle} = 1)$  that entity  $en_j$  occurs in a specific event type  $et_i$  as an argument and its role is  $R_m$  respectively. To overcome the sparsity of the entities, we cluster those entities into more cohesive subtype following Hong et al. (2011). Hence, following the independence assumptions described by Berant et al. (2011), we modify the  $f_I(E_Z)$  and  $f_D(E_Z, R_m)$  in Eq. 1 as follows:

$$f_I(E_Z) = \log \frac{P(X_Z = 1 | F_Z)P(X_Z = 1)}{(1 - P(X_Z = 1 | F_Z))P(X_Z = 0)} \quad (8)$$

$$f_D(E_Z, R_m) = \log \frac{P(Y_{\langle Z, m \rangle} = 1 | F_{\langle Z, m \rangle})P(X_{\langle Z, m \rangle} = 1)}{(1 - P(X_{\langle Z, m \rangle} = 1 | F_{\langle Z, m \rangle}))P(X_{\langle Z, m \rangle} = 0)} \quad (9)$$

where  $P(X_Z = 1 | F_Z)$  and  $P(Y_{\langle Z, m \rangle} = 1 | F_{\langle Z, m \rangle})$  are the probabilities from the AI and AD respectively while  $F_Z$  and  $F_{\langle Z, m \rangle}$  are the feature vectors. Besides,  $P(X_{\langle Z, m \rangle} = 1)$  and  $P(X_Z = 1)$  are the prior probabilities learning from the training set.

## 5 Experimentation

In this section, we first describe the experimental settings and the baseline, and then evaluate our global argument inference model incorporating with relevant event mentions and argument semantics to infer arguments and their roles.

### 5.1 Experimental Settings and Baseline

For fair comparison, we adopt the same experimental settings as the state-of-the-art event extraction system (Li et al. 2012b) and all the

evaluations are experimented on the ACE 2005 Chinese corpus. We randomly select 567 documents as the training set and the remaining 66 documents as the test set. Besides, we reserve 33 documents in the training set as the development set and use the ground truth entities, times and values for our training and testing. As for evaluation, we also follow the standards as defined in Li et al. (2012b). Finally, all the sentences in the corpus are divided into words using a Chinese word segmentation tool (*ICTCLAS*)<sup>1</sup> with all entities annotated in the corpus kept. We use *Berkeley Parser*<sup>2</sup> and *Stanford Parser*<sup>3</sup> to create the constituent and dependency parse trees. Besides, the ME tool (*Maxent*)<sup>4</sup> is employed to train individual component classifiers and *lp\_solver*<sup>5</sup> is used to construct our global argument inference model.

Besides, all the experiments on argument extraction are done on the output of the trigger extraction system as described in Li et al. (2012b). Table 3 shows the performance of the baseline trigger extraction system and Line 1 in Table 4 illustrates the results of argument identification and role determination based on this system.

Trigger identification			Event type determination		
P(%)	R(%)	F1	P(%)	R(%)	F1
74.4	71.9	73.1	71.4	68.9	70.2

Table 3. Performance of the baseline on trigger identification and event type determination.

## 5.2 Inferring Arguments on Relevant Event Mentions and Argument Semantics

We develop a baseline system as mentioned in Section 3 and Line 2 in Table 4 shows that it slightly improves the F1-measure by 0.9% over Li et al. (2012b) due to the incorporation of more refined features. This result indicates the limitation of syntactic-based feature engineering.

Before evaluating our global argument inference model, we should identify the event relations between two mentions in a sentence, a discourse or a document. The experimental results show that the accuracies of identifying *NC*, *EC*, *Parallel* and *Sequence* relation are 80.0%, 72.4%, 88.5% and 87.7% respectively. Those results ensure that our simple methods are

effective. Our statistics on the development set shows almost 65% of the event mentions are involved in those *Coreference*, *Parallel* and *Sequence* relations, which occupy 63%, 50%, 9% respectively<sup>6</sup>. Most of the exceptions are isolated event mentions.

System	Argument identification			Argument role determination		
	P(%)	R(%)	F1	P(%)	R(%)	F1
Li et al.(2012b)	59.1	57.2	58.1	55.8	52.1	53.9
Baseline	60.5	57.6	59.0	55.7	53.0	54.4
BIM	59.3	60.1	59.7	54.4	55.2	54.8
BIM+RE	60.2	65.6	62.8	55.0	60.0	57.4
BIM+RE+AS	<b>62.9</b>	<b>66.1</b>	<b>64.4</b>	<b>57.2</b>	<b>60.2</b>	<b>58.7</b>

Table 4. Performance comparison of argument extraction on argument identification and role determination.

Once the classifier AI and RD are trained, we would like to apply our global argument inference model to infer more inter-sentence arguments and roles. To achieve an optimal solution, we formulate the global inference problem as an Integer Linear Program (ILP), which leads to maximize the objective function. ILP is a mathematical method for constraint-based inference to find the optimal values for a set of variables that maximize an objective function in satisfying a certain number of constraints. In the literature, ILP has been widely used in many NLP applications (e.g., Barzilay and Lapata, 2006; Do et al., 2012; Li et al., 2012b).

For our systems, we firstly evaluate the performance of our basic global argument inference model (BIM) with the Eq. 2–5 which enforce the consistency on AI and RD and then introduce the inference on the relevant event mentions (RE) and argument semantics (AS) to BIM. Table 4 shows their results and we can find out that:

- 1) BIM only slightly improves the performance in F1-measure, as the result of more increase in recall (R) than decrease in precision (P). This suggests that those constraints just enforcing the consistency on AI and RD is not effective enough to infer more arguments.
- 2) Compared to the BIM, our model BIM+RE enhances the performance of argument identification and role determination by 3.1% and 2.6% improvement in F1-measure respectively. This suggests the effectiveness

<sup>1</sup> <http://ictclas.org/>

<sup>2</sup> <http://code.google.com/p/berkeleyparser/>

<sup>3</sup> <http://nlp.stanford.edu/software/lex-parser.shtml>

<sup>4</sup> <http://mallet.cs.umass.edu/>

<sup>5</sup> <http://lpsolve.sourceforge.net/5.5/>

<sup>6</sup> 20% of the mentions belongs to both *Coreference* and *Sequence* relations.

of our global argument inference model on the relevant event mentions to infer inter-sentence arguments. Table 5 shows the contributions of the different event relations while the *Sequence* relation gains the highest improvement of argument identification and role determination in F1-measure respectively.

Constraint	Argument identification			Argument role determination		
	P(%)	R(%)	F1	P(%)	R(%)	F1
BIM	59.3	60.1	59.7	54.4	55.2	54.8
+Parallel	<b>+0.6</b>	+0.7	+0.6	+0.4	+0.6	+0.5
+NC	+0.0	+0.8	+0.4	-0.2	+0.6	+0.2
+EC	<b>+0.6</b>	+1.2	+0.9	<b>+0.5</b>	+1.0	+0.7
+ Sequence	-0.3	<b>+2.8</b>	<b>+1.2</b>	-0.2	<b>+2.6</b>	<b>+1.1</b>

Table 5. Contributions of different event relations on argument identification and role determination. (Incremental)

- 3) Our model BIM+ER+AS gains 1.6% improvement for argument identification, and 1.3% for role determination. The results ensure that argument semantics not only can improve the performance of argument identification, but also is helpful to assign a correct role to an argument in role determination.

Table 3 shows 25.6% of trigger mentions introduced into argument extraction are pseudo ones. If we use the golden trigger extraction, our exploration shows that the precision and recall of argument identification can be up to 78.6% and 88.3% respectively. Table 6 shows the performance comparison of argument extraction on AI and RD given golden trigger extraction. Compared to the Baseline, our system improves the performance of argument identification and role determination by 6.4% and 5.8% improvement in F1-measure respectively, largely due to the dramatic increase in recall of 10.9% and 10.4%.

System	Argument identification			Argument role determination		
	P(%)	R(%)	F1	P(%)	R(%)	F1
Baseline	76.2	77.4	76.8	70.4	72.0	71.2
Model2	<b>78.6</b>	<b>88.3</b>	<b>83.2</b>	<b>72.3</b>	<b>82.4</b>	<b>77.0</b>

Table 6. Performance comparison of argument identification and type determination. (Golden trigger extraction)

### 5.3 Discussion

The initiation of our paper is that syntactic features play an important role in current machine learning-based approaches for English

event extraction, however, their effectiveness is much reduced in Chinese. So the improvement of our model for English event extraction is much less than that of Chinese. However, our model can be an effective complement of the sentence-level English argument extraction systems since the performance of argument extraction is still low in English and using discourse-level information is a way to improve its performance, especially for those event mentions whose arguments spread in complex sentences.

Moreover, our exploration shows that our global argument inference model can mine those arguments within a long distance which are unannotated as arguments of a special event mention in the corpus since the annotators just tagged arguments in a narrow scope or omitted a few arguments. Actually, they are the true ones to our knowledge and are more than 30.6% of those pseudo arguments inferred by our model. This ensures that our global argument inference model and those relations among event mentions is helpful to argument extraction.

## 6 Conclusion

In this paper we propose a global argument inference model to extract those inter-sentence arguments due to the nature of Chinese that it is a discourse-driven pro-drop language with the wide spread of ellipsis and the open flexible sentence structure. In particular, we incorporate various kinds of event relations and the argument semantics into the model in the sentence, discourse and document layers which represent the cohesion of an event or a topic. The experimental results ensure that our global argument inference model outperforms the state-of-the-art system.

In future work, we will focus on introducing more semantic information and cross-document information into the global argument inference model to improve the performance of argument extraction.

# Fine-grained Semantic Typing of Emerging Entities

Ndapandula Nakashole, Tomasz Tylenda, Gerhard Weikum

Max Planck Institute for Informatics  
Saarbrücken, Germany

{nnakasho,tylenda,weikum}@mpi-inf.mpg.de

## Abstract

Methods for information extraction (IE) and knowledge base (KB) construction have been intensively studied. However, a largely under-explored case is tapping into highly dynamic sources like news streams and social media, where new entities are continuously emerging. In this paper, we present a method for discovering and semantically typing newly emerging out-of-KB entities, thus improving the freshness and recall of ontology-based IE and improving the precision and semantic rigor of open IE. Our method is based on a probabilistic model that feeds weights into integer linear programs that leverage type signatures of relational phrases and type correlation or disjointness constraints. Our experimental evaluation, based on crowd-sourced user studies, show our method performing significantly better than prior work.

## 1 Introduction

A large number of knowledge base (KB) construction projects have recently emerged. Prominent examples include Freebase (Bollacker 2008) which powers the Google Knowledge Graph, ConceptNet (Havasi 2007), YAGO (Suchanek 2007), and others. These KBs contain many millions of entities, organized in hundreds to hundred thousands of semantic classes, and hundred millions of relational facts between entities. However, despite these impressive advances, there are still major limitations regarding coverage and freshness. Most KB projects focus on entities that appear in Wikipedia (or other reference collections such as IMDB), and very few have tried to gather entities “in the long tail” beyond prominent sources. Vir-

tuallly all projects miss out on newly emerging entities that appear only in the latest news or social media. For example, the Greenlandic singer Nive Nielsen has gained attention only recently and is not included in any KB (a former Wikipedia article was removed because it “does not indicate the importance or significance of the subject”), and the resignation of BBC director Entwistle is a recently new entity (of type event).

**Goal.** Our goal in this paper is to discover emerging entities of this kind on the fly as they become noteworthy in news and social-media streams. A similar theme is pursued in research on *open information extraction (open IE)* (Banko 2007; Fader 2011; Talukdar 2010; Venetis 2011; Wu 2012), which yields higher recall compared to ontology-style KB construction with canonicalized and semantically typed entities organized in prespecified classes. However, state-of-the-art open IE methods extract all noun phrases that are likely to denote entities. These phrases are not canonicalized, so the same entity may appear under many different names, e.g., “Mr. Entwistle”, “George Entwistle”, “the BBC director”, “BBC head Entwistle”, and so on. This is a problem because names and titles are ambiguous, and this hampers precise search and concise results.

Our aim is for all recognized and newly discovered entities to be semantically interpretable by having *fine-grained types* that connect them to KB classes. The expectation is that this will boost the disambiguation of known entity names and the grouping of new entities, and will also strengthen the extraction of relational facts about entities. For informative knowledge, new entities must be typed in a fine-grained manner (e.g., guitar player, blues band, concert, as opposed to crude types like person, organization, event).

Strictly speaking, the new entities that we cap-

ture are *typed noun phrases*. We do not attempt any cross-document co-reference resolution, as this would hardly work with the long-tail nature and sparse observations of emerging entities. Therefore, our setting resembles the established task of fine-grained typing for noun phrases (Fleischmann 2002), with the difference being that we disregard common nouns and phrases for prominent in-KB entities and instead exclusively focus on the difficult case of phrases that likely denote new entities. The baselines to which we compare our method are state-of-the-art methods for noun-phrase typing (Lin 2012; Yosef 2012).

**Contribution.** The solution presented in this paper, called PEARL, leverages a repository of relational patterns that are organized in a type-signature taxonomy. More specifically, we harness the PATTY collection consisting of more than 300,000 typed paraphrases (Nakashole 2012). An example of PATTY’s expressive phrases is:  $\langle \text{musician} \rangle * \text{cover} * \langle \text{song} \rangle$  for a musician performing someone else’s song. When extracting noun phrases, PEARL also collects the co-occurring PATTY phrases. The type signatures of the relational phrases are cues for the type of the entity denoted by the noun phrase. For example, an entity named Snoop Dogg that frequently co-occurs with the  $\langle \text{singer} \rangle * \text{distinctive voice in} * \langle \text{song} \rangle$  pattern is likely to be a singer. Moreover, if one entity in a relational triple is in the KB and can be properly disambiguated (e.g., a singer), we can use a partially bound pattern to infer the type of the other entity (e.g., a song) with higher confidence.

In this line of reasoning, we also leverage the common situation that many input sentences contain one entity registered in the KB and one novel or unknown entity. Known entities are recognized and mapped to the KB using a recent tool for named entity disambiguation (Hoffart 2011). For cleaning out false hypotheses among the type candidates for a new entity, we devised probabilistic models and an integer linear program that considers incompatibilities and correlations among entity types.

In summary, our contribution in this paper is a model for discovering and ontologically typing out-of-KB entities, using a fine-grained type system and harnessing relational paraphrases with type signatures for probabilistic weight computa-

tion. Crowdsourced quality assessments demonstrate the accuracy of our model.

## 2 Detection of New Entities

To detect noun phrases that potentially refer to entities, we apply a part-of-speech tagger to the input text. For a given noun phrase, there are four possibilities: *a)* The noun phrase refers to a general concept (a class or abstract concept), not an individual entity. *b)* The noun phrase is a known entity that can be directly mapped to the knowledge base. *c)* The noun phrase is a new name for a known entity. *d)* The noun phrase is a new entity not known to the knowledge base at all. In this paper, our focus is on case d); all other cases are out of the scope of this paper.

We use an extensive dictionary of surface forms for in-KB entities (Hoffart 2012), to determine if a name or phrase refers to a known entity. If a phrase does not have any match in the dictionary, we assume that it refers to a new entity. To decide if a noun phrase is a true entity (i.e., an individual entity that is a member of one or more lexical classes) or a non-entity (i.e., a common noun phrase that denotes a class or a general concept), we base the decision on the following hypothesis (inspired by and generalizing (Bunescu 2006): A given noun phrase, not known to the knowledge base, is a true entity if its headword is singular and is consistently capitalized (i.e., always spelled with the first letter in upper case).

## 3 Typing Emerging Entities

To deduce types for new entities we propose to align new entities along the type signatures of patterns they occur with. In this manner we use the patterns to suggest types for the entities they occur with. In particular, we infer entity types from pattern type signatures. Our approach builds on the following hypothesis:

### Hypothesis 3.1 (Type Alignment Hypothesis)

*For a given pattern such as  $\langle \text{actor} \rangle$ ’s character in  $\langle \text{movie} \rangle$ , we assume that an entity pair  $(x, y)$  frequently occurring with the pattern in text implies that  $x$  and  $y$  are of the types  $\langle \text{actor} \rangle$  and  $\langle \text{movie} \rangle$ , respectively.*

**Challenges and Objective.** While the type alignment hypothesis works as a starting point, it introduces false positives. Such false positives stem

from the challenges of polysemy, fuzzy pattern matches, and incorrect paths between entities. With polysemy, the same lexico-syntactic pattern can have different type signatures. For example, the following are three different patterns:  $\langle \text{singer} \rangle \text{released} \langle \text{album} \rangle$ ,  $\langle \text{music\_band} \rangle \text{released} \langle \text{album} \rangle$ ,  $\langle \text{company} \rangle \text{released} \langle \text{product} \rangle$ . For an entity pair  $(x, y)$  occurring with the pattern “released”,  $x$  can be one of three different types.

We cannot expect that the phrases we extract in text will be exact matches of the typed relational patterns learned by PATTY. Therefore, for better recall, we must accept fuzzy matches. Quite often however, the extracted phrase matches multiple relational patterns to various degrees. Each of the matched relational patterns has its own type signature. The type signatures of the various matched patterns can be incompatible with one another.

The problem of incorrect paths between entities emerges when a pair of entities occurring in the same sentence do not stand in a true subject-object relation. Dependency parsing does not adequately solve the issue. Web sources contain a plethora of sentences that are not well-formed. Such sentences mislead the dependency parser to extract wrong dependencies.

Our solution takes into account polysemy, fuzzy matches, as well as issues stemming from potential incorrect-path limitations. We define and solve the following optimization problem:

**Definition 1 (Type Inference Optimization)**

*Given all the candidate types for  $x$ , find the best types or “strongly supported” types for  $x$ . The final solution must satisfy type disjointness constraints. Type disjointness constraints are constraints that indicate that, semantically, a pair of types cannot apply to the same entity at the same time. For example, a  $\langle \text{university} \rangle$  cannot be a  $\langle \text{person} \rangle$ .*

We also study a relaxation of type disjointness constraints through the use of type correlation constraints. Our task is therefore twofold: first, generate candidate types for new entities; second, find the best types for each new entity among its candidate types.

**4 Candidate Types for Entities**

For a given entity, candidate types are types that can potentially be assigned to that entity, based on

the entity’s co-occurrences with typed relational patterns.

**Definition 2 (Candidate Type)** *Given a new entity  $x$  which occurs with a number of patterns  $p_1, p_2, \dots, p_n$ , where each pattern  $p_i$  has a type signature with a domain and a range: if  $x$  occurs on the left of  $p_i$ , we pick the domain of  $p_i$  as a candidate type for  $x$ ; if  $x$  occurs on the right of  $p_i$ , we pick the range of  $p_i$  as a candidate type for  $x$ .*

For each candidate type, we compute confidence weights. Ideally, if an entity occurs with a pattern which is highly specific to a given type then the candidate type should have high confidence. For example “is married to” is more specific to people than “expelled from”. A *person* can be expelled from an *organization* but a *country* can also be expelled from an *organization* such as NATO. There are various ways to compute weights for *candidate types*. We first introduce a uniform weight approach and then present a method for computing more informative weights.

**4.1 Uniform Weights**

We are given a new entity  $x$  which occurs with phrases  $(x \text{ phrase}_1 y_1), (x \text{ phrase}_2 y_2), \dots, (x \text{ phrase}_n y_n)$ . Suppose these occurrences lead to the facts  $(x, p_1, y_1), (x, p_2, y_2), \dots, (x, p_n, y_n)$ . The  $p_i$ s are the *typed relational patterns* extracted by PATTY. The facts are generated by matching *phrases* to relational patterns with type signatures. The type signature of a pattern is denoted by:

$$\text{sig}(p_i) = (\text{domain}(p_i), \text{range}(p_i))$$

We allow fuzzy matches, hence each fact comes with a match score. This is the similarity degree between the phrase observed in text and the typed relational pattern.

**Definition 3 (Fuzzy Match Score)** *Suppose we observe the surface string:  $(x \text{ phrase } y)$  which leads to the fact:  $x, p_i, y$ . The fuzzy match similarity score is:  $\text{sim}(\text{phrase}, p_i)$ , where similarity is the  $n$ -gram Jaccard similarity between the phrase and the typed pattern.*

The confidence that  $x$  is of type *domain* is defined as follows:

**Definition 4 (Candidate Type Confidence)**

*For a given observation  $(x \text{ phrase } y)$ , where*

phrase matches patterns  $p_1, \dots, p_n$ , with domains  $d_1, \dots, d_b$  which are possibly the same:

$$\text{typeConf}(x, \text{phrase}, d) = \sum_{\{p_i: \text{domain}(p_i)=d\}} (\text{sim}(\text{phrase}, p_i))$$

Observe that this sums up over all patterns that match the phrase.

To compute the final confidence for  $\text{typeConf}(x, \text{domain})$ , we aggregate the confidences over all phrases occurring with  $x$ .

**Definition 5 (Aggregate Confidence)** For a set of observations  $(x, \text{phrase}_1, y_1), (x, \text{phrase}_2, y_2), \dots, (x, \text{phrase}_n, y_n)$ , the aggregate candidate type confidence is given by:

$$\begin{aligned} \text{aggTypeConf}(x, d) &= \sum_{\text{phrase}_i} \text{typeConf}(x, \text{phrase}_i, d) \\ &= \sum_{\text{phrase}_i} \sum_{\{p_j: \text{domain}(p_j)=d\}} (\text{sim}(\text{phrase}_i, p_j)) \end{aligned}$$

The confidence for the range  $\text{typeConf}(x, \text{range})$  is computed analogously. All confidence weights are normalized to values in  $[0, 1]$ .

The limitation of the uniform weight approach is that each pattern is considered equally good for suggesting candidate types. Thus this approach does not take into account the intuition that an entity occurring with a pattern which is highly specific to a given type is a stronger signal that the entity is of the type suggested. Our next approach addresses this limitation.

## 4.2 Co-occurrence Likelihood Weight Computation

We devise a likelihood model for computing weights for entity candidate types. Central to this model is the estimation of the likelihood of a given type occurring with a given pattern.

Suppose using PATTY methods we mined a typed relational pattern  $\langle t_1 \rangle p \langle t_2 \rangle$ . Suppose that we now encounter a new entity pair  $(x, y)$  occurring with a phrase that matches  $p$ . We can compute the likelihood of  $x$  and  $y$  being of types  $t_1$  and  $t_2$ , respectively, from the likelihood of  $p$  co-occurring with entities of types  $t_1, t_2$ . Therefore we are interested in the type-pattern likelihood, defined as follows:

**Definition 6 (Type-Pattern Likelihood)** The likelihood of  $p$  co-occurring with an entity pair  $(x, y)$  of the types  $(t_1, t_2)$  is given by:

$$P[t_1, t_2|p] \quad (1)$$

where  $t_1$  and  $t_2$  are the types of the arguments observed with  $p$  from a corpus such as Wikipedia.  $P[t_1, t_2|p]$  is expanded as follows:

$$P[t_1, t_2|p] = \frac{P[t_1, t_2, p]}{P[p]} \quad (2)$$

The expressions on the right-hand side of Equation 2 can be directly estimated from a corpus. We use Wikipedia (English), for corpus-based estimations.  $P[t_1, t_2, p]$  is the relative occurrence frequency of the typed pattern among all entity-pattern-entity triples in a corpus (e.g., the fraction of  $\langle \text{musician} \rangle$  plays  $\langle \text{song} \rangle$  among all triples).  $P[p]$  is the relative occurrence frequency of the untyped pattern (e.g., plays) regardless of the argument types. For example, this sums up over both  $\langle \text{musician} \rangle$  plays  $\langle \text{song} \rangle$  occurrences and  $\langle \text{actor} \rangle$  plays  $\langle \text{fictional character} \rangle$ . If we observe a fact where one argument name can be easily disambiguated to a knowledge-base entity so that its type is known, and the other argument is considered to be an out-of-knowledge-base entity, we condition the joint probability of  $t_1, p$ , and  $t_2$  in a different way:

**Definition 7 (Conditional Type-Pattern Likelihood)**

The likelihood of an entity of type  $t_1$  occurring with a pattern  $p$  and an entity of type  $t_2$  is given by:

$$P[t_1|t_2, p] = \frac{P[t_1, t_2, p]}{P[p, t_2]} \quad (3)$$

where the  $P[p, t_2]$  is the relative occurrence frequency of a partial triple, for example,  $\langle * \rangle$  plays  $\langle \text{song} \rangle$ .

Observe that all numbers refer to occurrence frequencies. For example,  $P[t_1, p, t_2]$  is a fraction of the total number of triples in a corpus.

Multiple patterns can suggest the same type for an entity. Therefore, the weight of the assertion that  $y$  is of type  $t$ , is the total support strength from all phrases that suggest type  $t$  for  $y$ .

**Definition 8 (Aggregate Likelihood)** The aggregate likelihood candidate type confidence is given

by:

$$\text{typeConf}(x, \text{domain}) = \sum_{\text{phrase}_i} \sum_{p_j} \left( \text{sim}(\text{phrase}_i, p_j) * \Upsilon \right)$$

Where  $\Upsilon = P[t_1, t_2|p]$  or  $P[t_1|t_2, p]$  or  $P[t_2|t_1, p]$

The confidence weights are normalized to values in  $[0, 1]$ . So far we have presented a way of generating a number of *weighted candidate types* for  $x$ . In the next step we pick the best types for an entity among all its candidate types.

### 4.3 Integer Linear Program Formulation

Given a set of *weighted candidate types*, our goal is to pick a compatible subset of types for  $x$ . The additional asset that we leverage here is the compatibility of types: how likely is it that an entity belongs to both type  $t_i$  and type  $t_j$ . Some types are mutually exclusive, for example, the type *location* rules out *person* and, at finer levels, *city* rules out *river* and *building*, and so on. Our approach harnesses these kinds of constraints. Our solution is formalized as an Integer Linear Program (ILP). We have candidate types for  $x$ :  $t_1, \dots, t_n$ . First, we define a decision variable  $T_i$  for each candidate type  $i = 1, \dots, n$ . These are binary variables:  $T_i = 1$  means type  $t_i$  is selected to be included in the set of types for  $x$ ,  $T_i = 0$  means we discard type  $t_i$  for  $x$ .

In the following we develop two variants of this approach: a “hard” ILP with rigorous disjointness constraints, and a “soft” ILP which considers type correlations.

**“Hard” ILP with Type Disjointness Constraints.** We infer type disjointness constraints from the YAGO2 knowledge base using occurrence statistics. Types with no overlap in entities or insignificant overlap below a specified threshold are considered disjoint. Notice that this introduces *hard constraints* whereby selecting one type of a disjoint pair rules out the second type. We define type disjointness constraints  $T_i + T_j \leq 1$  for all disjoint pairs  $t_i, t_j$  (e.g. person-artifact, movie-book, city-country, etc.). The ILP is defined as follows:

#### objective

$$\max \sum_i T_i \times w_i$$

#### type disjointness constraint

$$\forall (t_i, t_j)_{\text{disjoint}} T_i + T_j \leq 1$$

The weights  $w_i$  are the aggregated likelihoods as specified in Definition 8.

**“Soft” ILP with Type Correlations.** In many cases, two types are not really mutually exclusive in the strict sense, but the likelihood that an entity belongs to both types is very low. For example, few drummers are also singers. Conversely, certain type combinations are boosted if they are strongly correlated. An example is guitar players and electric guitar players. Our second ILP considers such soft constraints. To this end, we precompute *Pearson correlation* coefficients for all type pairs  $(t_i, t_j)$  based on co-occurrences of types for the same entities. These values  $v_{ij} \in [-1, 1]$  are used as weights in the objective function of the ILP. We additionally introduce pair-wise decision variables  $Y_{ij}$ , set to 1 if the entity at hand belongs to both types  $t_i$  and  $t_j$ , and 0 otherwise. This coupling between the  $Y_{ij}$  variables and the  $T_i, T_j$  variables is enforced by specific constraints. For the objective function, we choose a linear combination of per-type evidence, using weights  $w_i$  as before, and the type-compatibility measure, using weights  $v_{ij}$ . The ILP with correlations is defined as follows:

#### objective

$$\max \alpha \sum_i T_i \times w_i + (1 - \alpha) \sum_{ij} Y_{ij} \times v_{ij}$$

#### type correlation constraints

$$\forall_{i,j} Y_{ij} + 1 \geq T_i + T_j$$

$$\forall_{i,j} Y_{ij} \leq T_i$$

$$\forall_{i,j} Y_{ij} \leq T_j$$

Note that both ILP variants need to be solved per entity, not over all entities together. The “soft” ILP has a size quadratic in the number of candidate types, but this is still a tractable input for modern solvers. We use the Gurobi software package to compute the solutions for the ILP’s. With this design, PEARL can efficiently handle a typical news article in less than a second, and is well geared for keeping up with high-rate content streams in real time. For both the “hard” and “soft” variants of the ILP, the solution is the best types for entity  $x$  satisfying the constraints.

## 5 Evaluation

To define a suitable corpus of test data, we obtained a stream of news documents by subscribing to *Google News* RSS feeds for a few topics over a six-month period (April 2012 – September 2012). This produced 318,434 documents. The topics we subscribed to are: *Angela Merkel, Barack Obama, Business, Entertainment, Hillary Clinton, Joe Biden, Mitt Romney, Newt Gingrich, Rick Santorum, SciTech and Top News*. All our experiments were carried out on this data. The type system used is that of YAGO2, which is derived from WordNet. Human evaluations were carried out on Amazon Mechanical Turk (MTurk), which is a platform for crowd-sourcing tasks that require human input. Tasks on MTurk are small questionnaires consisting of a description and a set of questions.

**Baselines.** We compared PEARL against two state-of-the-art baselines: **i). NNPLB** (No Noun Phrase Left Behind), is the method presented in (Lin 2012), based on the propagation of types for known entities through salient patterns occurring with both known and unknown entities. We implemented the algorithm in (Lin 2012) in our framework, using the relational patterns of PATTY (Nakashole 2012) for comparability. For assessment we sampled from the top-5 highest ranked types for each entity. In our experiments, our implementation of NNPLB achieved precision values comparable to those reported in (Lin 2012). **ii). HYENA** (Hierarchical tYpe classification for Entity NAmes), the method of (Yosef 2012), based on a feature-rich classifier for fine-grained, hierarchical type tagging. This is a state-of-the-art representative of similar methods such as (Rahman 2010; Ling 2012).

**Evaluation Task.** To evaluate the quality of types assigned to emerging entities, we presented turkers with sentences from the news tagged with out-of-KB entities and the types inferred by the methods under test. The turkers task was to assess the correctness of types assigned to an entity mention. To make it easy to understand the task for the turkers, we combined the extracted entity and type into a sentence. For example if PEARL inferred that Brussels Summit is an political event, we generate and present the sentence: *Brussels Summit is an event*. We allowed four possible assessment val-

ues: *a) Very good* output corresponds to a perfect result. *b) Good* output exhibits minor errors. For instance, the description *G20 Summit is an organization* is wrong, because the summit is an event, but G20 is indeed an organization. The problem in this example is incorrect segmentation of a named entity. *c) Wrong* for incorrect types (e.g., *Brussels Summit is a politician*). *d) Not sure / do not know* for other cases.

**Comparing PEARL to Baselines.** Per method, turkers evaluated 105 entity-type pair test samples. We first sampled among out-of-KB entities that were mentioned frequently in the news corpus: in at least 20 different news articles. Each test sample was given to 3 different turkers for assessment. Since the turkers did not always agree if the type for a sample is good or not, we aggregate their answers. We use voting to decide whether the type was assigned correctly to an entity. We consider the following voting variants: i) majority “very good” or “good”, a conservative notion of precision:  $\text{precision}_{lower}$ . ii) at least one “very good” or “good”, a liberal notion of precision:  $\text{precision}_{upper}$ . Table 1 shows precision for PEARL-hard, PEARL-soft, NNPLB, and HYENA, with a 0.9-confidence Wilson score interval (Brown 2001). PEARL-hard outperformed PEARL-soft and also both baselines. HYENA’s relatively poor performance can be attributed to the fact that its features are mainly syntactic such as bi-grams and part-of-speech tags. Web data is challenging, it has a lot of variations in syntactic formulations. This introduces a fair amount of ambiguity which can easily mislead syntactic features. Leveraging semantic features as done by PEARL could improve HYENA’s performance. While the NNPLB method performs better than HYENA, in comparison to PEARL-hard, there is room for improvement. Like HYENA, NNPLB assigns negatively correlated types to the same entity. This limitation could be addressed by applying PEARL’s ILPs and probabilistic weights to the candidate types suggested by NNPLB.

To compute inter-judge agreement we calculated Fleiss’ kappa and Cohen’s kappa  $\kappa$ , which are standard measures. The usual assumption for Fleiss’  $\kappa$  is that labels are categorical, so that each disagreement counts the same. This is not the case in our settings, where different labels may indicate partial agreement (“good”, “very good”). There-

	Precision <sub>lower</sub>	Precision <sub>upper</sub>
PEARL-hard	<b>0.77</b> ±0.08	<b>0.88</b> ±0.06
PEARL-soft	0.53±0.09	0.77±0.09
HYENA	0.26±0.08	0.56±0.09
NNPLB	0.46±0.09	0.68±0.09

Table 1: Comparison of PEARL to baselines.

$\kappa$	<i>Fleiss</i>	<i>Cohen</i>
	0.34	0.45

Table 2: Lower bound estimations for inter-judge agreement kappa: Fleiss’  $\kappa$  & adapted Cohen’s  $\kappa$ .

fore the  $\kappa$  values in Table 2 are lower-bound estimates of agreement in our experiments; the “true agreement” seems higher. Nevertheless, the observed Fleiss  $\kappa$  values show that the task was fairly clear to the turkers; values  $> 0.2$  are generally considered as acceptable (Landis 1977). Cohen’s  $\kappa$  is also not directly applicable to our setting. We approximated it by finding pairs of judges who assessed a significant number of the same entity-type pairs.

	Precision <sub>lower</sub>	Precision <sub>upper</sub>
Freq. mentions	0.77±0.08	0.88±0.06
All mentions	0.65±0.09	0.77±0.08

Table 3: PEARL-hard performance on a sample of frequent entities (mention frequency  $\geq 20$ ) and on a sample of entities of all mention frequencies.

**Mention Frequencies.** We also studied PEARL-hard’s performance on entities of different mention frequencies. The results are shown in Table 3. Frequently mentioned entities provide PEARL with more evidence as they potentially occur with more patterns. Therefore, as expected, precision when sampling over all entities drops a bit. For such infrequent entities, PEARL does not have enough evidence for reliable type assignments.

**Variations of PEARL.** To quantify how various aspects of our approach affect performance, we studied a few variations. The first method is the full PEARL-hard. The second method is PEARL with no ILP (denoted No ILP), only using the probabilistic model. The third variation is PEARL without probabilistic weights (denoted Uniform

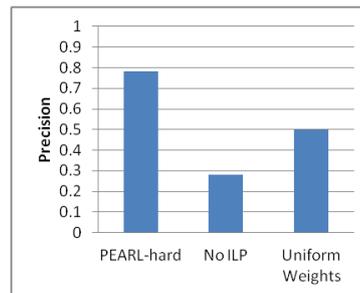

Figure 1: Variations of the PEARL method.

Weights). From Figure 1, it is clear that both the ILP and the weighting model contribute significantly to PEARL’s ability to make precise type assignments. Sample results from PEARL-hard are shown in Table 4.

**NDCG.** For a given entity mention  $e$ , an entity-typing system returns a ranked list of types  $\{t_1, t_2, \dots, t_n\}$ . We evaluated ranking quality using the top-5 ranks for each method. These assessments were aggregated into the normalized discounted cumulative gain (NDCG), a widely used measure for ranking quality. The NDCG values obtained are 0.53, 0.16, and 0.16, for PEARL-hard, HYENA, and NNPLB, respectively. PEARL clearly outperforms the baselines on ranking quality, too.

## 6 Related Work

Tagging mentions of named entities with lexical types has been pursued in previous work. Most well-known is the Stanford named entity recognition (NER) tagger (Finkel 2005) which assigns coarse-grained types like person, organization, location, and other to noun phrases that are likely to denote entities. There is fairly little work on fine-grained typing, notable results being (Fleischmann 2002; Rahman 2010; Ling 2012; Yosef 2012). These methods consider type taxonomies similar to the one used for PEARL, consisting of several hundreds of fine-grained types. All methods use trained classifiers over a variety of linguistic features, most importantly, words and bigrams with part-of-speech tags in a mention and in the textual context preceding and following the mention. In addition, the method of (Yosef 2012) (HYENA) utilizes a big gazetteer of per-type words that occur in Wikipedia anchor texts. This method outperforms earlier techniques on a variety of test

cases; hence it served as one of our baselines.

Closely related to our work is the recent approach of (Lin 2012) (NNPLB) for predicting types for out-of-KB entities. Noun phrases in the subject role in a large collection of fact triples are heuristically linked to Freebase entities. This yields type information for the linked mentions. For unlinkable entities the NNPLB method (inspired by (Kozareva 2011)) picks types based on co-occurrence with salient relational patterns by propagating types of linked entities to unlinkable entities that occur with the same patterns. Unlike PEARL, NNPLB does not attempt to resolve inconsistencies among the predicted types. In contrast, PEARL uses an ILP with type disjointness and correlation constraints to solve and penalize such inconsistencies. NNPLB uses untyped patterns, whereas PEARL harnesses patterns with type signatures. Furthermore, PEARL computes weights for candidate types based on patterns and type signatures. Weight computations in NNPLB are only based on patterns. NNPLB only assigns types to entities that appear in the subject role of a pattern. This means that entities in the object role are not typed at all. In contrast, PEARL infers types for entities in both the subject and object role.

Type disjointness constraints have been studied for other tasks in information extraction (Carlson 2010; Suchanek 2009), but using different formulations.

## 7 Conclusion

This paper addressed the problem of detecting and semantically typing newly emerging entities, to support the life-cycle of large knowledge bases. Our solution, PEARL, draws on a collection of semantically typed patterns for binary relations. PEARL feeds probabilistic evidence derived from

occurrences of such patterns into two kinds of ILPs, considering type disjointness or type correlations. This leads to highly accurate type predictions, significantly better than previous methods, as our crowdsourcing-based evaluation showed.

## Abstract

Relation Extraction (RE) is the task of extracting semantic relationships between entities in text. Recent studies on relation extraction are mostly supervised. The clear drawback of supervised methods is the need of training data: labeled data is expensive to obtain, and there is often a mismatch between the training data and the data the system will be applied to. This is the problem of *domain adaptation*. In this paper, we propose to combine (i) term generalization approaches such as word clustering and latent semantic analysis (LSA) and (ii) structured kernels to improve the adaptability of relation extractors to new text genres/domains. The empirical evaluation on ACE 2005 domains shows that a suitable combination of syntax and lexical generalization is very promising for domain adaptation.

## 1 Introduction

Relation extraction is the task of extracting semantic relationships between entities in text, e.g. to detect an employment relationship between the person *Larry Page* and the company *Google* in the following text snippet: *Google CEO Larry Page holds a press announcement at its headquarters in New York on May 21, 2012*. Recent studies on relation extraction have shown that supervised approaches based on either feature or kernel methods achieve state-of-the-art accuracy (Zelenko et al., 2002; Culotta and Sorensen, 2004;

Zhang et al., 2005; Zhou et al., 2005; Zhang et al., 2006; Bunescu, 2007; Nguyen et al., 2009; Chan and Roth, 2010; Sun et al., 2011). However, the clear drawback of supervised methods is the need of training data, which can slow down the delivery of commercial applications in new domains: labeled data is expensive to obtain, and there is often a mismatch between the training data and the data the system will be applied to. Approaches that can cope with domain changes are essential. This is the problem of domain adaptation (DA) or transfer learning (TL). Technically, domain adaptation addresses the problem of learning when the assumption of independent and identically distributed (i.i.d.) samples is violated. Domain adaptation has been studied extensively during the last couple of years for various NLP tasks, e.g. two shared tasks have been organized on domain adaptation for dependency parsing (Nivre et al., 2007; Petrov and McDonald, 2012). Results were mixed, thus it is still a very active research area.

However, to the best of our knowledge, there is almost no work on adapting relation extraction (RE) systems to new domains.<sup>1</sup> There are some prior studies on the related tasks of *multi-task transfer learning* (Xu et al., 2008; Jiang, 2009) and *distant supervision* (Mintz et al., 2009), which are clearly related but different: the former is the problem of how to transfer knowledge from old to new relation types, while distant supervision tries to learn new relations from unlabeled text by exploiting weak-supervision in the form of a knowledge resource (e.g. Freebase). We assume the same relation types but a shift in the underlying

\* The first author was affiliated with the Department of Computer Science and Information Engineering of the University of Trento (Povo, Italy) during the design of the models, experiments and writing of the paper.

<sup>1</sup>Besides an unpublished manuscript of a student project, but it is not clear what data was used. <http://tinyurl.com/bn2hdwk>

data distribution. Weak supervision is a promising approach to improve a relation extraction system, especially to increase its coverage in terms of types of relations covered. In this paper we examine the related issue of changes in the underlying data distribution, while keeping the relations fixed. Even a weakly supervised system is expected to perform well when applied to any kind of text (other domain/genre), thus ideally, we believe that combining domain adaptation with weak supervision is the way to go in the future. This study is a first step towards this.

We focus on *unsupervised* domain adaptation, i.e. no labeled target data. Moreover, we consider a particular domain adaptation setting: *single-system DA*, i.e. learning a single system able to cope with different but related domains. Most studies on DA so far have focused on building a specialized system for every specific target domain, e.g. Blitzer et al. (2006). In contrast, the goal here is to build a single system that can robustly handle several domains, which is in line with the setup of the recent shared task on parsing the web (Petrov and McDonald, 2012). Participants were asked to build a single system that can robustly parse all domains (reviews, weblogs, answers, emails, newsgroups), rather than to build several domain-specific systems. We consider this as a shift in what was considered domain adaptation in the past (adapt from source to a specific target) and what can be considered a somewhat different recent view of DA, that became widespread since 2011/2012. The latter assumes that the target domain(s) is/are not really known in advance. In this setup, the domain adaptation problem boils down to finding a more robust system (Søgaard and Johannsen, 2012), i.e. one wants to build a system that can robustly handle any kind of data.

We propose to combine (i) term generalization approaches and (ii) structured kernels to improve the performance of a relation extractor on new domains. Previous studies have shown that lexical and syntactic features are both very important (Zhang et al., 2006). We combine structural features with lexical information generalized by clusters or similarity. Given the complexity of feature engineering, we exploit kernel methods (Shawe-Taylor and Cristianini, 2004). We encode word clusters or similarity in tree kernels, which, in turn, produce spaces of tree fragments. For example, “president”, “vice-president” and “Texas”,

“US”, are terms indicating an employment relation between a person and a location. Rather than only matching the surface string of words, lexical similarity enables *soft* matches between similar words in convolution tree kernels. In the empirical evaluation on Automatic Content Extraction (ACE) data, we evaluate the impact of convolution tree kernels embedding lexical semantic similarities. The latter is derived in two ways with: (a) Brown word clustering (Brown et al., 1992); and (b) Latent Semantic Analysis (LSA). We first show that our system aligns well with the state of the art on the ACE 2004 benchmark. Then, we test our RE system on the ACE 2005 data, which exploits kernels, structures and similarities for domain adaptation. The results show that combining the huge space of tree fragments generalized at the lexical level provides an effective model for adapting RE systems to new domains.

## 2 Semantic Syntactic Tree Kernels

In kernel-based methods, both learning and classification only depend on the inner product between instances. Kernel functions can be efficiently and implicitly computed by exploiting the dual formulation:  $\sum_{i=1..l} y_i \alpha_i \phi(o_i) \phi(o) + b = 0$ , where  $o_i$  and  $o$  are two objects,  $\phi$  is a mapping from an object to a feature vector  $\vec{x}_i$  and  $\phi(o_i) \phi(o) = K(o_i, o)$  is a kernel function implicitly defining such a mapping. In case of structural kernels,  $K$  determines the shape of the substructures describing the objects. Commonly used kernels in NLP are string kernels (Lodhi et al., 2002) and tree kernels (Moschitti, 2006; Moschitti, 2008).

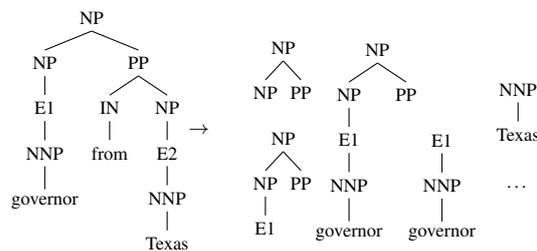

Figure 1: Syntactic tree kernel (STK).

Syntactic tree kernels (Collins and Duffy, 2001) compute the similarity between two trees  $T_1$  and  $T_2$  by counting common sub-trees (cf. Figure 1), without enumerating the whole fragment space. However, if two trees have similar substructures that employ different though related terminal nodes, they will not be matched. This is

clearly a limitation. For instance, the fragments corresponding to `governor` from `Texas` and `head` of `Maryland` are intuitively semantically related and should obtain a higher match when compared to `mother` of `them`.

Semantic syntactic tree kernels (Bloehdorn and Moschitti, 2007a; Bloehdorn and Moschitti, 2007b; Croce et al., 2011) provide one way to address this problem by introducing similarity  $\sigma$  that allows *soft matches* between words and, consequently, between fragments containing them. Let  $N_1$  and  $N_2$  be the set of nodes in  $T_1$  and  $T_2$ , respectively. Moreover, let  $I_i(n)$  be an indicator variable that is 1 if subtree  $i$  is rooted at  $n$  and 0 otherwise. The syntactic semantic convolution kernel  $TK_\sigma$  (Bloehdorn and Moschitti, 2007b) over  $T_1$  and  $T_2$  is computed as  $TK_\sigma(T_1, T_2) = \sum_{n_1 \in N_1, n_2 \in N_2} \Delta_\sigma(n_1, n_2)$  where  $\Delta_\sigma(n_1, n_2) = \sum_{n_1 \in N_1} \sum_{n_2 \in N_2} \sum_i I_i(n_1) I_i(n_2)$  is computed efficiently using the following recursive definition: i) If the nodes  $n_1$  and  $n_2$  are either different or have different number of children then  $\Delta_\sigma(n_1, n_2) = 0$ ; else ii) If  $n_1$  and  $n_2$  are pre-terminals then  $\Delta_\sigma(n_1, n_2) = \lambda \prod_{j=1}^{nc(n_1)} \Delta_\sigma(ch(n_1, j), ch(n_2, j))$ , where  $\sigma$  measures the similarity between the corresponding children of  $n_1$  and  $n_2$ ; iii) If  $n_1$  and  $n_2$  have identical children:  $\Delta_\sigma(n_1, n_2) = \lambda \prod_{j=1}^{nc(n_1)} (1 + \Delta_\sigma(ch(n_1, j), ch(n_2, j)))$ ; else  $\Delta_\sigma(n_1, n_2) = 0$ .  $TK_\sigma$  combines generalized lexical with structural information: it allows matching tree fragments that have the same syntactic structure but differ in their terminals. After introducing related work, we will discuss computational structures for RE and their extension with semantic similarity.

### 3 Related Work

Semantic syntactic tree kernels have been previously used for question classification (Bloehdorn and Moschitti, 2007a; Bloehdorn and Moschitti, 2007b; Croce et al., 2011). These kernels have not yet been studied for either domain adaptation or RE. Brown clusters were studied previously for feature-based approaches to RE (Sun et al., 2011; Chan and Roth, 2010), but they were not yet evaluated in kernels. Thus, we present a novel application of semantic syntactic tree kernels and Brown clusters for domain adaptation of tree-kernel based relation extraction.

Regarding domain adaptation, several methods have been proposed, ranging from instance

weighting (Jiang and Zhai, 2007) to approaches that change the feature representation (Daumé III, 2007) or try to exploit pivot features to find a generalized shared representation between domains (Blitzer et al., 2006). The easy-adapt approach presented in Daumé III (2007) assumes the supervised adaptation setting and is thus not applicable here. Structural correspondence learning (Blitzer et al., 2006) exploits unlabeled data from both source and target domain to find correspondences among features from different domains. These correspondences are then integrated as new features in the labeled data of the source domain. The key to SCL is to exploit pivot features to automatically identify feature correspondences, and as such is applicable to feature-based approaches but not in our case since we do not assume availability of target domain data. Instead, we apply a similar idea where we exploit an entire unlabeled corpus as pivot, and compare our approach to *instance weighting* (Jiang and Zhai, 2007).

Instance weighting is a method for domain adaptation in which instance-dependent weights are assigned to the loss function that is minimized during the training process. Let  $l(x, y, \theta)$  be some loss function. Then, as shown in Jiang and Zhai (2007), the loss function can be weighted by  $\beta_i l(x, y, \theta)$ , such that  $\beta_i = \frac{P_t(x_i)}{P_s(x_i)}$ , where  $P_s$  and  $P_t$  are the source and target distributions, respectively. Huang et al. (2007) present an application of instance weighting to support vector machines by minimizing the following re-weighted function:  $\min_{\theta, \xi} \frac{1}{2} \|\theta\|^2 + C \sum_{i=1}^m \beta_i \xi_i$ . Finding a good weight function is non-trivial (Jiang and Zhai, 2007) and several approximations have been evaluated in the past, e.g. Søgaard and Haulrich (2011) use a bigram-based text classifier to discriminate between domains. We will use a binary classifier trained on RE instance representations.

### 4 Computational Structures for RE

A common way to represent a constituency-based relation instance is the PET (path-enclosed-tree), the smallest subtree including the two target entities (Zhang et al., 2006). This is basically the former structure PAF<sup>2</sup> (predicate argument feature) defined in Moschitti (2004) for the extraction of predicate argument relations. The syntactic rep-

<sup>2</sup>It is the smallest subtree enclosing the predicate and one of its argument node.

resentation used by Zhang et al. (2006) (we will refer to it as PET Zhang) is the PET with enriched entity information: e.g. E1-NAM-PER, including entity type (PER, GPE, LOC, ORG) and mention type (NAM, NOM, PRO, PRE: name, nominal, pronominal or premodifier). An alternative kernel that does not use syntactic information is the Bag-of-Words (BOW) kernel, where a single root node is added above the terminals. Note that in this BOW kernel we actually mark target entities with E1/E2. Therefore, our BOW kernel can be considered an enriched BOW model. If we do not mark target entities, performance drops considerably, as discussed later.

As shown by Zhang et al. (2006), including gold-standard information on entity and mention type substantially improves relation extraction performance. We will use this gold information also in Section 6.1 to show that our system aligns well to the state of the art on the ACE 2004 benchmark. However, in a realistic setting this information is not available or noisy. In fact, as we discuss later, excluding gold entity information decreases system performance considerably. In the case of porting a system to new domains entity information will be unreliable or missing. Therefore, in our domain adaptation experiments on the ACE 2005 data (Section 6.3) we will not rely on this gold information but rather train a system using PET (target mentions only marked with E1/E2 and no gold entity label).<sup>3</sup>

#### 4.1 Syntactic Semantic Structures

Combining syntax with semantics has a clear advantage: it generalizes lexical information encapsulated in syntactic parse trees, while at the same time syntax guides semantics in order to obtain an effective semantic similarity. In fact, lexical information is highly affected by data-sparseness, thus tree kernels combined with semantic information created from additional resources should provide a way to obtain a more robust system.

We exploit this idea here for domain adaptation (DA): if words are generalized by semantic similarity  $LS$ , then in a hypothetical world changing  $LS$  such that it reflects the target domain would

<sup>3</sup>In a setup where gold label info is included, the impact of similarity-based methods is limited – gold information seems to predominate. We argue that whenever gold data is not available, distributional semantics paired with kernels can be useful to improve generalization and complement missing gold info.

allow the system to perform better in the target domain. The question remains how to establish a link between the semantic similarity in the source and target domain. We propose to use an entire unlabeled corpus as pivot: this corpus must be general enough to encapsulate the source and target domains of interest. The idea is to (i) learn semantic similarity between words on the pivot corpus and (ii) use tree kernels embedding such a similarity to learn a RE system on the source, which allows to generalize to the new target domain. This reasoning is related to Structural Correspondence Learning (SCL) (Blitzer et al., 2006). In SCL, a representation shared across domains is learned by exploiting pivot features, where a set of pivot features has to be selected (usually a few thousands). In our case *pivots* are words that co-occur with the target words in a large unlabeled corpus and are thus implicitly represented in the similarity matrix. Thus, in contrast to SCL, we do not need to select a set of pivot features but rather rely on the distributional hypothesis to infer a semantic similarity from a large unlabeled corpus. Then, this similarity is incorporated into the tree kernel that provides the necessary restriction for an effective semantic similarity calculation. One peculiarity of our work is that we exploit a large amount of general data, i.e. data gathered from the web, which is a different but also more challenging scenario than the general unsupervised DA setting where domain specific data is available. We study two ways for term generalization in tree kernels: Brown words clusters and Latent Semantic Analysis (LSA), both briefly described next.

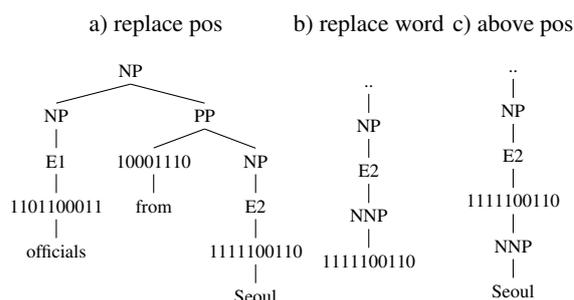

Figure 2: Integrating Brown cluster information

The Brown algorithm (Brown et al., 1992) is a hierarchical agglomerative hard-clustering algorithm. The path from the root of the tree down to a leaf node is represented compactly as a bitstring. By cutting the hierarchy at different levels one can obtain different granularities of word clusters. We

evaluate different ways to integrate cluster information into tree kernels, some of which are illustrated in Figure 2.

For LSA, we compute term similarity functions following the *distributional hypothesis* (Harris, 1964), i.e. the meaning of a word can be described by the set of textual contexts in which it appears. The original word-by-word context matrix  $M$  is decomposed through Singular Value Decomposition (SVD) (Golub and Kahan, 1965), where  $M$  is approximated by  $U_l S_l V_l^T$ . This approximation supplies a way to project a generic term  $w_i$  into the  $l$ -dimensional space using  $W = U_l S_l^{1/2}$ , where each row corresponds to the vectors  $\vec{w}_i$ . Given two words  $w_1$  and  $w_2$ , the term similarity function  $\sigma$  is estimated as the cosine similarity between the corresponding projections  $\vec{w}_1, \vec{w}_2$  and used in the kernel as described in Section 2.

## 5 Experimental Setup

We treat relation extraction as a multi-class classification problem and use SVM-light-TK<sup>4</sup> to train the binary classifiers. The output of the classifiers is combined using the one-vs-all approach. We modified the SVM-light-TK package to include the semantic tree kernels and instance weighting. The entire software package is publicly available.<sup>5</sup> For the SVMs, we use the same parameters as Zhang et al. (2006):  $\lambda = 0.4, c = 2.4$  using the Collins Kernel (Collins and Duffy, 2001). The precision/recall trade-off parameter for the *none* class was found on held-out data:  $j = 0.2$ . Evaluation metrics are standard micro average Precision, Recall and balanced Fscore (F1). To compute statistical significance, we use the approximate randomization test (Noreen, 1989).<sup>6</sup> In all our experiments, we model argument order of the relations explicitly. Thus, for instance for the 7 coarse ACE 2004 relations, we build 14 coarse-grained classifiers (two for each coarse ACE 2004 relation type except for PER-SOC, which is symmetric, and one classifier for the *none* relation).

**Data** We use two datasets. To compare our model against the state of the art we use the *ACE 2004* data. It contains 348 documents and 4,374 positive relation instances. To generate the training data, we follow prior studies and extract an instance for every pair of mentions in the same

sentence, which are separated by no more than three other mentions (Zhang et al., 2006; Sun et al., 2011). After data preprocessing, we obtained 4,327 positive and 39,120 negative instances.

ACE 2005	docs	sents	ASL	relations
nw+bn	298	5029	18.8	3562
bc	52	2267	16.3	1297
cts	34	2696	15.3	603
wl	114	1697	22.6	677

Table 1: Overview of the ACE 2005 data.

For the domain adaptation experiments we use the *ACE 2005* corpus. An overview of the data is given in Table 1. Note that this data is different from ACE 2004: it covers different years (ACE 2004: texts from 2001-2002; ACE 2005: 2003-2005). Moreover, the annotation guidelines have changed (for example, ACE 2005 contains no discourse relation, some relation (sub)types have changed/moved, and care must be taken for differences in SGM markup, etc.).

More importantly, the ACE 2005 corpus covers additional domains: weblogs, telephone conversation, usenet and broadcast conversation. In the experiments, we use news (the union of nw and bn) as source domain, and weblogs (wl), telephone conversations (cts) and broadcast conversation (bc) as target domains.<sup>7</sup> We take half of bc as only target development set, and leave the remaining data and domains for final testing (since they are already small, cf. Table 1). To get a feeling of how these domains differ, Figure 3 depicts the distribution of relations in each domain and Table 2 provides the most frequent out-of-vocabulary words together with their percentage.

**Lexical Similarity and Clustering** We applied LSA to ukWaC (Baroni et al., 2009), a 2 billion word corpus constructed from the Web<sup>8</sup> using the *s-space* toolkit.<sup>9</sup> Dimensionality reduction was performed using SVD with 250 dimensions, following (Croce et al., 2011). The co-occurrence matrix was transformed by *tfidf*. For the Brown word clusters, we used Percy Liang’s implementation<sup>10</sup> of the Brown clustering algorithm (Liang, 2005). We incorporate cluster information by us-

<sup>7</sup>We did not consider the usenet subpart, since it is among the smaller domains and data-preprocessing was difficult.

bc (24%)	insurance, unintelligible, malpractice, ph, clip, colonel, crosstalk
cts (34%)	uh, Yeah, um, eh, mhm, uh-huh, ~, ah, mm, th, plo, topic, y, workplace
wl (49%)	title, Starbucks, Well, blog, !!, werkheiser, undefeated, poor, shit

Table 2: For each domain the percentage of target domain words (types) that are unseen in the source together with the most frequent OOV words.

ing the 10-bit cluster prefix (Sun et al., 2011; Chan and Roth, 2010). For the domain adaptation experiments, we use ukWaC corpus-induced clusters as bridge between domains. We limited the vocabulary to that in ACE 2005, which are approximately 16k words. Following previous work, we left case intact in the corpus and induced 1,000 word clusters from words appearing at least 100 times.<sup>11</sup>

**DA baseline** We compare our approach to instance weighting (Jiang and Zhai, 2007). We modified SVM-light-TK such that it takes a parameter vector  $\beta_i, \dots, \beta_m$  as input, where each  $\beta_i$  represents the relative *importance* of example  $i$  with respect to the target domain (Huang et al., 2007; Widmer, 2008). To estimate the importance weights, we train a binary classifier that distinguishes between source and target domain instances. We consider the union of the three target domains as target data. To train the classifier, the source instances are marked as negative and the target instances are marked as positive. Then, this classi-

Polynomial composite	K,yes	72.6	67.7	70.1

Table 3: Comparison to previous work on the 7 relations of ACE 2004. K: kernel-based; F: feature-based; yes/no: models argument order explicitly.

fier is applied to the source data. To obtain the weights  $\beta_i$ , we convert the SVM scores into posterior probabilities by training a sigmoid using the modified Platt algorithm (Lin et al., 2007).<sup>12</sup>

## 6 Results

### 6.1 Alignment to Prior Work

Although most prior studies performed 5-fold cross-validation on ACE 2004, it is often not clear whether the partitioning has been done on the instance or on the document level. Moreover, it is often not stated whether argument order is modeled explicitly, making it difficult to compare system performance. Citing Wang (2008), “We feel that there is a sense of increasing confusion down this line of research”. To ease comparison for future research we use the same 5-fold split on the document level as Sun et al. (2011)<sup>13</sup> and make our system publicly available (see Section 5).

Table 3 shows that our system (bottom) aligns well with the state of the art. Our best system (composite kernel with polynomial expansion) reaches an F1 of 70.1, which aligns well to the 70.4 of Sun et al. (2011) that use the same data-split. This is slightly behind that of Zhang (2006); the reason might be threefold: i) different data partitioning; ii) different pre-processing; iii) they incorporate features from additional sources, i.e. a phrase chunker, dependency parser and semantic resources (Zhou et al., 2005) (we have on average 9 features/instance, they use 40). Since we focus on evaluating the impact of semantic similarity in tree kernels, we think our system is very competitive. Removing gold entity and mention

<sup>12</sup>Other weightings/normalizations (like LDA) didn’t improve the results; best was to take the posteriors and add  $c$ .

<sup>13</sup>[http://cs.nyu.edu/~asun/pub/ACL11\\_CVFileList.txt](http://cs.nyu.edu/~asun/pub/ACL11_CVFileList.txt)

information results in a significant F1 drop from 66.3% to 54.2%. However, in a realistic setting we do not have gold entity info available, especially not in the case when we apply the system to *any kind of text*. Thus, in the domain adaptation setup we assume entity boundaries given but not their label. Clearly, evaluating the approach on predicted mentions, e.g. Giuliano et al. (2007), is another important dimension, however, out of the scope of the current paper.

## 6.2 Tree Kernels with Brown Word Clusters

To evaluate the effectiveness of Brown word clusters in tree kernels, we evaluated different instance representations (cf. Figure 2) on the ACE 2005 development set. Table 4 shows the results.

bc-dev	P	R	F1
baseline	52.2	41.7	46.4
replace word	49.7	38.6	43.4
replace pos	56.3	41.9	<b>48.0</b>
replace pos only mentions	55.3	41.6	47.5
above word	54.5	42.2	47.6
above pos	55.8	41.1	47.3

Table 4: Brown clusters in tree kernels (cf. Fig 2).

To summarize, we found: i) it is generally a bad idea to dismiss lexical information completely, i.e. replacing or ignoring terminals harms performance; ii) the best way to incorporate Brown clusters is to replace the Pos tag with the cluster bitstring; iii) marking all words is generally better than only mentions; this is in contrast to Sun et al. (2011) who found that in their feature-based system it was better to add cluster information to entity mentions only. As we will discuss, the combination of syntax and semantics exploited in this novel kernel avoids the necessity of restricting cluster information to mentions only.

## 6.3 Semantic Tree Kernels for DA

To evaluate the effectiveness of the proposed kernels across domains, we use the ACE 2005 data as testbed. Following standard practices on ACE 2004, the newswire (nw) and broadcast news (bn) data from ACE 2005 are considered training data (labeled source domain). The test data consists of three targets: broadcast conversation, telephone conversation, weblogs. As we want to build a single system that is able to handle heterogeneous data, we do not assume that there is further unlabeled

domain-specific data, but we assume to have a large unlabeled corpus (ukWaC) at our disposal to improve the generalizability of our models.

Table 5 presents the results. In the first three rows we see the performance of the baseline models (PET, BOW and BOW without marking). In-domain (col 1): when evaluated on the same domain the system was trained on (nw+bn, 5-fold cross-validation). Out-of-domain performance (cols 2-4): the system evaluated on the targets, namely broadcast conversation (bc), telephone conversation (cts) and weblogs (wl). While the system achieves a performance of 46.0 F1 within its own domain, the performance drops to 45.3, 43.4 and 34.0 F1 on the target domains, respectively. The BOW kernel that disregards syntax is often less effective (row 2). We see also the effect of target entity marking: the BOW kernel without entity marking performs substantially worse (row 3). For the remaining experiments we use the BOW kernel with entity marking.

Rows 4 and 5 of Table 5 show the effect of using instance weighting for the PET baseline. Two models are shown: they differ in whether PET or BOW was used as instance representation for training the discriminative classifier. Instance weighting shows mixed results: it helps slightly on the weblogs domain, but does not help on broadcast conversation and telephone conversations. Interestingly, the two models used to obtain the weights perform similarly, despite the fact that their performance differs (F1: 70.5 BOW, 73.5 PET); it turns out that the correlation between the weights is high (+0.82).

The next part (rows 6-9) shows the effect of enriching the syntactic structures with either Brown word clusters or LSA. The Brown cluster kernel applied to PET (P\_WC) improves performance over the baseline over *all* target domains. The same holds also for the lexical semantic kernel based on LSA (P\_LSA), however, to only two out of three domains. This suggests that the two kernels capture different information and a combined kernel might be effective. More importantly, the table shows the effect of adding Brown clusters or LSA semantics to the BOW kernel: it can actually hurt performance, sometimes to a small but other times to a considerably degree. For instance, WC applied to PET achieves an F1 of 47.0 (baseline: 45.3) on the bc domain, while applied to BOW it hurts performance significantly, i.e. it drops from

<b>Baseline:</b>	<b>nw+bn (in-dom.)</b>			<b>bc</b>			<b>cts</b>			<b>wl</b>

Table 5: In-domain (first column) and out-of-domain performance (columns two to four) on ACE 2005. PET and BOW are abbreviated by P and B, respectively. If not specified BOW is *marked*.

45.0 to 41.2. This is also the case for LSA applied to the BOW kernel, which drops to 41.9. On the cts domain this is less pronounced. Only on the weblogs domain B\_LSA achieves a minor improvement (from 32.7 to 33.0). In general, distributional semantics constrained by syntax (i.e. combined with PET) can be effectively exploited, while if applied ‘blindly’ – without the guide of syntax (i.e. BOW) – performance might drop, often considerably. We believe that the semantic information does not help the BOW kernel as there is no syntactic information that constrains the application of the noisy source, as opposed to the case with the PET kernel.

As the two semantically enriched kernels, PET\_LSA and PET\_WC, seem to capture different information we use composite kernels (rows 10-11): the baseline kernel (PET) summed with the lexical semantic kernels. As we can see, results improve further: for instance on the bc test set, PET\_WC reaches an F1 of 47.0, while combined with PET (PET+PET\_WC) this improves to 48.3. Adding also PET\_LSA results in the best performance and our final system (last row): the composite kernel (PET+PET\_WC+PET\_LSA) reaches an F1 of 48.5, 43.6 and 37.8 on the target domains, respectively, i.e. with an absolute improvement of: +3.2%, +0.2% and +3.8%, respectively. Two out of three improvements are significant at  $p < 0.05$  (indicated by † in Table 5). Moreover, the system also improved in its own domain (first column),

therefore having achieved robustness.

By performing an error analysis we found that, for instance, the Brown clusters help to generalize locations and professions. For example, the baseline incorrectly considered ‘Dutch filmmaker’ in a PART-WHOLE relation, while our system correctly predicted GEN-AFF(filmmaker,Dutch). ‘Filmmaker’ does not appear in the source, however ‘Dutch citizen’ does. Both ‘citizen’ and ‘filmmaker’ appear in the same cluster, thereby helping the system to recover the correct relation.

<b>Relation:</b>	<b>bc</b>		<b>cts</b>		<b>wl</b>	
	BL	SYS	BL	SYS	BL	SYS
PART-WHOLE	37.8	<b>43.1</b>	<b>59.3</b>	52.3	30.5	<b>36.3</b>
ORG-AFF	60.7	<b>62.9</b>	35.5	<b>42.3</b>	41.0	<b>42.0</b>
PHYS	35.3	<b>37.6</b>	25.4	<b>28.7</b>	25.2	<b>26.9</b>
ART	20.8	<b>37.9</b>	34.5	<b>43.5</b>	26.5	<b>40.3</b>
GEN-AFF	30.1	<b>33.0</b>	16.8	<b>18.6</b>	21.6	<b>28.1</b>
PER-SOC	74.1	<b>74.2</b>	<b>66.3</b>	63.1	42.6	<b>48.0</b>
$\mu$ average	45.3	<b>48.5</b>	43.4	<b>43.6</b>	34.0	<b>37.8</b>

Table 6: F1 per coarse relation type (ACE 2005). SYS is the final model, i.e. last row (PET+PET\_WC+PET\_LSA) of Table 5.

Furthermore, Table 6 provides the performance breakdown per relation for the baseline (BL) and our best system (SYS). The table shows that our system is able to improve F1 on *all* relations for the broadcast and weblogs data. On most relations, this is also the case for the telephone (cts) data, although the overall improvement is not significant. Most errors were made on the PER-SOC

relation, which constitutes the largest portion of cts (cf. Figure 3). As shown in the same figure, the relation distribution of the cts domain is also rather different from the source. This conversation data is a very hard domain, with a lot of disfluencies and spoken language patterns. We believe it is more distant from the other domains, especially from the unlabeled collection, thus other approaches might be more appropriate, e.g. domain identification (Dredze et al., 2010).

## 7 Conclusions and Future Work

We proposed syntactic tree kernels enriched by lexical semantic similarity to tackle the portability of a relation extractor to different domains. The results of diverse kernels exploiting (i) Brown clustering and (ii) LSA show that a suitable combination of syntax and lexical generalization is very promising for domain adaptation. The proposed system is able to improve performance significantly on two out of three target domains (up to 8% relative improvement). We compared it to instance weighting, which gave only modest or no improvements. Brown clusters remained unexplored for kernel-based approaches. We saw that adding cluster information blindly might actually hurt performance. In contrast, adding lexical information combined with syntax can help to improve performance: the syntactic structure enriched with lexical information provides a feature space where syntax constrains lexical similarity obtained from unlabeled data. Thus, semantic syntactic tree kernels appear to be a suitable mechanism to adequately trade off the two kinds of information. In future we plan to extend the evaluation to predicted mentions, which necessarily includes a careful evaluation of pre-processing components, as well as evaluating the approach on other semantic tasks.

## Acknowledgments

We would like to thank Min Zhang for discussions on his prior work as well as the anonymous reviewers for their valuable feedback. The research described in this paper has been supported by the European Community's Seventh Framework Programme (FP7/2007-2013) under the grant #288024: LIMOSINE – Linguistically Motivated Semantic aggregation engiNes.

## Abstract

Word-final /t/-deletion refers to a common phenomenon in spoken English where words such as /wɛst/ “west” are pronounced as [wɛs] “wes” in certain contexts. Phonological variation like this is common in naturally occurring speech. Current computational models of unsupervised word segmentation usually assume idealized input that is devoid of these kinds of variation. We extend a non-parametric model of word segmentation by adding phonological rules that map from underlying forms to surface forms to produce a mathematically well-defined joint model as a first step towards handling variation and segmentation in a single model. We analyse how our model handles /t/-deletion on a large corpus of transcribed speech, and show that the joint model can perform word segmentation and recover underlying /t/s. We find that Bigram dependencies are important for performing well on real data and for learning appropriate deletion probabilities for different contexts.<sup>1</sup>

## 1 Introduction

Computational models of word segmentation try to solve one of the first problems language learners have to face: breaking an unsegmented stream of sound segments into individual words. Currently, most such models assume that the input consists of sequences of phonemes with no pronunciation variation across different occurrences of the same word type. In this paper we describe

<sup>1</sup>The implementation of our model as well as scripts to prepare the data will be made available at <http://web.science.mq.edu.au/~bborschi>. We can't release our version of the Buckeye Corpus (Pitt et al., 2007) directly because of licensing issues.

an extension of the Bayesian models of Goldwater et al. (2009) that incorporates phonological rules to “explain away” surface variation. As a concrete example, we focus on word-final /t/-deletion in English, although our approach is not limited to this case. We choose /t/-deletion because it is a very common and well-studied phenomenon (see Coetzee (2004, Chapter 5) for a review) and segmental deletion is an interesting test-case for our architecture. Recent work has found that /t/-deletion (among other things) is indeed common in child-directed speech (CDS) and, importantly, that its distribution is similar to that in adult-directed speech (ADS) (Dilley et al., to appear). This justifies our using ADS to evaluate our model, as discussed below.

Our experiments are consistent with longstanding and recent findings in linguistics, in particular that /t/-deletion heavily depends on the immediate context and that models ignoring context work poorly on real data. We also examine how well our models identify the probability of /t/-deletion in different contexts. We find that models that capture bigram dependencies between underlying forms provide considerably more accurate estimates of those probabilities than corresponding unigram or “bag of words” models of underlying forms.

In section 2 we discuss related work on handling variation in computational models and on /t/-deletion. Section 3 describes our computational model and section 4 discusses its performance for recovering deleted /t/s. We look at both a situation where word boundaries are pre-specified and only inference for underlying forms has to be performed; and the problem of jointly finding the word boundaries and recovering deleted underlying /t/s. Section 5 discusses our findings, and section 6 concludes with directions for further research.

## 2 Background and related work

The work of Elsner et al. (2012) is most closely related to our goal of building a model that handles variation. They propose a pipe-line architecture involving two separate generative models, one for word-segmentation and one for phonological variation. They model the mapping to surface forms using a probabilistic finite-state transducer. This allows their architecture to handle virtually arbitrary pronunciation variation. However, as they point out, combining the segmentation and the variation model into one joint model is not straight-forward and usual inference procedures are infeasible, which requires the use of several heuristics. We pursue an alternative research strategy here, starting with a single well-studied example of phonological variation. This permits us to develop a joint generative model for both word segmentation and variation which we plan to extend to handle more phenomena in future work.

An earlier work that is close to the spirit of our approach is Naradowsky and Goldwater (2009), who learn spelling rules jointly with a simple stem-suffix model of English verb morphology. Their model, however, doesn't naturally extend to the segmentation of entire utterances.

*/t/-deletion* has received a lot of attention within linguistics, and we point the interested reader to Coetzee (2004, Chapter 5) for a thorough review. Briefly, the phenomenon is as follows: word-final instances of */t/* may undergo deletion in natural speech, such that */west/* “west” is actually pronounced as *[wes]* “wes”.<sup>2</sup> While the frequency of this phenomenon varies across social and dialectal groups, within groups it has been found to be robust, and the probability of deletion depends on its phonological context: a */t/* is more likely to be dropped when followed by a consonant than a vowel or a pause, and it is more likely to be dropped when following a consonant than a vowel as well. We point out two recent publications that are of direct relevance to our research. Dilley et al. (to appear) study word-final variation in stop consonants in CDS, the kind of input we ideally would like to evaluate our models on. They find that “infants largely experience statistical distributions of non-canonical consonantal pronunciation variants [including deletion] that mirror those experienced by adults.” This both directly establishes the need

<sup>2</sup>Following the convention in phonology, we give underlying forms within “/.../” and surface forms within “[...]”.

for computational models to handle this dimension of variation, and justifies our choice of using ADS for evaluation, as mentioned above.

Coetzee and Kawahara (2013) provide a computational study of (among other things) */t/-deletion* within the framework of Harmonic Grammar. They do not aim for a joint model that also handles word segmentation, however, and rather than training their model on an actual corpus, they evaluate on constructed lists of examples, mimicking frequencies of real data. Overall, our findings agree with theirs, in particular that capturing the probability of deletion in different contexts does not automatically result in good performance for recovering individual deleted */t/s*. We will come back to this point in our discussion at the end of the paper.

## 3 The computational model

Our models build on the Unigram and the Bigram model introduced in Goldwater et al. (2009). Figure 1 shows the graphical model for our joint Bigram model (the Unigram case is trivially recovered by generating the  $U_{i,j}$ s directly from  $L$  rather than from  $L_{U_{i,j-1}}$ ). Figure 2 gives the mathematical description of the graphical model and Table 1 provides a key to the variables of our model.

The model generates a latent sequence of *underlying word-tokens*  $U_1, \dots, U_n$ . Each word token is itself a non-empty sequence of segments or phonemes, and each  $U_j$  corresponds to an underlying word form, prior to the application of any phonological rule. This generative process is repeated for each utterance  $i$ , leading to multiple utterances of the form  $U_{i,1}, \dots, U_{i,n_i}$  where  $n_i$  is the number of words in the  $i^{th}$  utterance, and  $U_{i,j}$  is the  $j^{th}$  word in the  $i^{th}$  utterance. Each utterance is padded by an observed utterance boundary symbol  $\$$  to the left and to the right, hence  $U_{i,0} = U_{i,n_i+1} = \$$ .<sup>3</sup> Each  $U_{i,j+1}$  is generated conditionally on its predecessor  $U_{i,j}$  from  $L_{U_{i,j}}$ , as shown in the first row of the lower plate in Figure 1. Each  $L_w$  is a distribution over the possible words that can follow a token of  $w$  and  $L$  is a global distribution over possible words, used as back-off for all  $L_w$ . Just as in Goldwater et al. (2009),  $L$  is drawn from a Dirichlet Process (DP) with base distribution  $B$  and concentration

<sup>3</sup>Each utterance terminates as soon as a  $\$$  is generated, thus determining the number of words  $n_i$  in the  $i^{th}$  utterance. See Goldwater et al. (2009) for discussion.

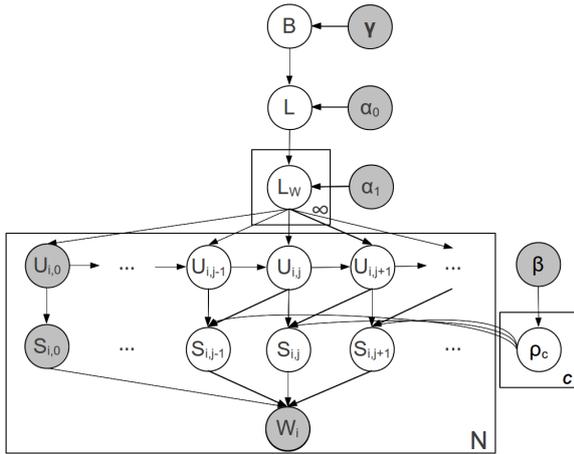

Figure 1: The graphical model for our joint model of word-final /t/-deletion and Bigram word segmentation. The corresponding mathematical description is given in Figure 2. The generative process mimics the intuitively plausible idea of generating underlying forms from some kind of syntactic model (here, a Bigram language model) and then mapping the underlying form to an observed surface-form through the application of a phonological rule component, here represented by the collection of rule probabilities  $\rho_c$ .

parameter  $\alpha_0$ , and the word type specific distributions  $L_w$  are drawn from a  $DP(L, \alpha_1)$ , resulting in a hierarchical DP model (Teh et al., 2006). The base distribution  $B$  functions as a lexical generator, defining a prior distribution over possible words. In principle,  $B$  can incorporate arbitrary prior knowledge about possible words, for example syllable structure (cf. Johnson (2008)). Inspired by Norris et al. (1997), we use a simpler possible word constraint that only rules out sequences that lack a vowel (see Figure 3). While this is clearly a simplification it is a plausible assumption for English data.

Instead of generating the observed sequence of segments  $W$  directly by concatenating the underlying forms as in Goldwater et al. (2009), we map each  $U_{i,j}$  to a corresponding surface-form  $S_{i,j}$  by a probabilistic rule component  $P_R$ . The values over which the  $S_{i,j}$  range are determined by the available phonological processes. In the

$$\begin{aligned}
 L \mid \gamma, \alpha_0 &\sim DP(\alpha_0, B(\cdot \mid \gamma)) \\
 L_w \mid L, \alpha_1 &\sim DP(\alpha_1, L) \\
 \rho_c \mid \beta &\sim Beta(1, 1) \\
 U_{i,0} &= \$ \\
 S_{i,0} &= \$ \\
 U_{i,j+1} \mid U_{i,j}, L_{U_{i,j}} &\sim L_{U_{i,j}} \\
 S_{i,j} \mid U_{i,j}, U_{i,j+1}, \rho &= P_R(\cdot \mid U_{i,j}, U_{i,j+1}) \\
 W_i \mid S_{i,1}, \dots, S_{i,n_i} &= CAT(S_{i,0}, \dots, S_{i,n_i})
 \end{aligned}$$

Figure 2: Mathematical description of our joint Bigram model. The lexical generator  $B(\cdot \mid \gamma)$  is specified in Figure 3 and  $P_R$  is explained in the text below. CAT stands for concatenation without word-boundaries,  $n_i$  refers to the number of words in utterance  $i$ .

Variable	Explanation
$B$	base distribution over possible words
$L$	back-off distribution over words
$L_w$	distribution over words following $w$
$U_{i,j}$	underlying form, a word
$S_{i,j}$	surface realization of $U_{i,j}$ , a word
$\rho_c$	/t/-deletion probability in context $c$
$W_i$	observed segments for $i^{th}$ utterance

Table 1: Key for the variables in Figure 1 and Figure 2. See Figure 3 for the definition of  $B$ .

model we study here, the phonological processes only include a rule for deleting word-final /t/s but in principle,  $P_R$  can be used to encode a wide variety of phonological rules. Here,  $S_{i,j} \in \{U_{i,j}, \text{DELFF}(U_{i,j})\}$  if  $U_{i,j}$  ends in a /t/, and  $S_{i,j} = U_{i,j}$  otherwise, where  $\text{DELFF}(u)$  refers to the same word as  $u$  except that it lacks  $u$ 's final segment.

We look at three kinds of contexts on which a rule's probability of applying depends:

1. a *uniform* context that applies to every word-final position
2. a *right* context that also considers the following segment
3. a *left-right* context that additionally takes the preceding segment into account

For each possible context  $c$  there is a probability  $\rho_c$  which stands for the probability of the rule applying in this context. Writing

$$\gamma \sim \text{Dir}(\langle 0.01, \dots, 0.01 \rangle)$$

$$B(w = x_{1:n} | \gamma) = \begin{cases} \frac{[\prod_{i=1}^n \gamma_{x_i}] \gamma_{\#}}{Z} & \text{if } V(w) \\ 0.0 & \text{if } \neg V(w) \end{cases}$$

Figure 3: Lexical generator with possible word-constraint for words in  $\Sigma^+$ ,  $\Sigma$  being the alphabet of available phonemes.  $x_{1:n}$  is a sequence of elements of  $\Sigma$  of length  $n$ .  $\gamma$  is a probability vector of length  $|\Sigma| + 1$  drawn from a sparse Dirichlet prior, giving the probability for each phoneme and the special word-boundary symbol  $\#$ . The predicate  $V$  holds of all sequences containing at least one vowel.  $Z$  is a normalization constant that adjusts for the mass assigned to the empty and non-possible words.

contexts in the notation familiar from generative phonology (Chomsky and Halle, 1968), our model can be seen as implementing the following rules under the different assumptions:<sup>4</sup>

$$\begin{array}{ll} \text{uniform} & /t/ \rightarrow \emptyset \quad / \text{ \_\_\_\_\_\_}]_{\text{word}} \\ \text{right} & /t/ \rightarrow \emptyset \quad / \text{ \_\_\_\_\_\_}]_{\text{word}} \beta \\ \text{left-right} & /t/ \rightarrow \emptyset \quad / \alpha \text{ \_\_\_\_\_\_}]_{\text{word}} \beta \end{array}$$

We let  $\beta$  range over  $V(\text{owel})$ ,  $C(\text{onsonant})$  and  $\$$  (utterance-boundary), and  $\alpha$  over  $V$  and  $C$ . We define a function  $\text{CONT}$  that maps a pair of adjacent underlying forms  $U_{i,j}, U_{i,j+1}$  to the context of the final segment of  $U_{i,j}$ . For example,  $\text{CONT}(/w\text{est}/, /e\text{v}/)$  returns “ $C \text{ \_\_\_\_\_\_}]_{\text{word}} V$ ” in the *left-right* setting, or simply “ $\text{ \_\_\_\_\_\_}]_{\text{word}}$ ” in the *uniform* setting.  $\text{CONT}$  returns a special  $\text{NOT}$  context if  $U_{i,j}$  doesn’t end in a  $/t/$ . We stipulate that  $\rho_{\text{NOT}} = 0.0$ . Then we can define  $P_R$  as follows:

$$P_R(\text{DELFINAL}(u) | u, r) = \rho_{\text{CONT}(u,r)}$$

$$P_R(u | u, r) = 1 - \rho_{\text{CONT}(u,r)}$$

Depending on the context setting used, our model includes one (*uniform*), three (*right*) or six (*left-right*)  $/t/$ -deletion probabilities  $\rho_c$ . We place a uniform Beta prior on each of those so as to learn their values in the  $\text{LEARN-}\rho$  experiments below.

Finally, the observed unsegmented utterances  $W_i$  are generated by concatenating all  $S_{i,j}$  using the function  $\text{CAT}$ .

We briefly comment on the central intuition of this model, i.e. why it can infer underlying

<sup>4</sup>For *right* there are three and for *left-right* six different rules, one for every instantiation of the context-template.

from surface forms. Bayesian word segmentation models try to compactly represent the observed data in terms of a small set of units (word types) and a short analysis (a small number of word tokens). Phonological rules such as  $/t/$ -deletion can “explain away” an observed surface type such as  $[w\text{es}]$  in terms of the underlying type  $/w\text{est}/$  which is independently needed for surface tokens of  $[w\text{est}]$ . Thus, the  $/t/ \rightarrow \emptyset$  rule makes possible a smaller lexicon for a given number of surface tokens. Obviously, human learners have access to additional cues, such as the meaning of words, knowledge of phonological similarity between segments and so forth. One of the advantages of an explicitly defined generative model such as ours is that it is straight-forward to gradually extend it by adding more cues, as we point out in the discussion.

### 3.1 Inference

Just as for the Goldwater et al. (2009) segmentation models, exact inference is infeasible for our joint model. We extend the collapsed Gibbs breakpoint-sampler described in Goldwater et al. (2009) to perform inference for our extended models. We refer the reader to their paper for additional details such as how to calculate the Bigram probabilities in Figure 4. Here we focus on the required changes to the sampler so as to perform inference under our richer model. We consider the case of a single surface string  $W$ , so we drop the  $i$ -index in the following discussion.

Knowing  $W$ , the problem is to recover the underlying forms  $U_1, \dots, U_n$  and the surface forms  $S_1, \dots, S_n$  for unknown  $n$ . A major insight in Goldwater’s work is that rather than sampling over the latent variables in the model directly (the number of which we don’t even know), we can instead perform Gibbs sampling over a set of boundary variables  $b_1, \dots, b_{|W|-1}$  that jointly determine the values for our variables of interest where  $|W|$  is the length of the surface string  $W$ . For our model, each  $b_j \in \{0, 1, t\}$ , where  $b_j = 0$  indicates absence of a word boundary,  $b_j = 1$  indicates presence of a boundary and  $b_j = t$  indicates presence of a boundary with a preceding underlying  $/t/$ . The relation between the  $b_j$  and the  $S_1, \dots, S_n$  and  $U_1, \dots, U_n$  is illustrated in Figure 5. The required sampling equations are given in Figure 4.

$$P(b_j = 0 \mid \mathbf{b}^{-j}) \propto P(w_{12,u} \mid w_{l,u}, \mathbf{b}^{-j}) \times P_r(w_{12,s} \mid w_{12,u}, w_{r,u}) \times P(w_{r,u} \mid w_{12,u}, \mathbf{b}^{-j} \oplus \langle w_{l,u}, w_{12,u} \rangle) \quad (1)$$

$$P(b_j = t \mid \mathbf{b}^{-j}) \propto P(w_{1,t} \mid w_{l,u}, \mathbf{b}^{-j}) \times P_r(w_{1,s} \mid w_{1,t}, w_{2,u}) \times P(w_{2,u} \mid w_{1,t}, \mathbf{b}^{-j} \oplus \langle w_{l,u}, w_{1,t} \rangle) \\ \times P_r(w_{2,s} \mid w_{2,u}, w_{r,u}) \times P(w_{r,u} \mid w_{2,u}, \mathbf{b}^{-j} \oplus \langle w_{l,u}, w_{1,t} \rangle \oplus \langle w_{1,t}, w_{2,u} \rangle) \quad (2)$$

$$P(b_j = 1 \mid \mathbf{b}^{-j}) \propto P(w_{1,s} \mid w_{l,u}, \mathbf{b}^{-j}) \times P_r(w_{1,s} \mid w_{1,s}, w_{2,u}) \times P(w_{2,u} \mid w_{1,s}, \mathbf{b}^{-j} \oplus \langle w_{l,u}, w_{1,s} \rangle) \\ \times P_r(w_{2,s} \mid w_{2,u}, w_{r,u}) \times P(w_{r,u} \mid w_{2,u}, \mathbf{b}^{-j} \oplus \langle w_{l,u}, w_{1,s} \rangle \oplus \langle w_{1,s}, w_{2,u} \rangle) \quad (3)$$

Figure 4: Sampling equations for our Gibbs sampler, see figure 5 for illustration.  $b_j = 0$  corresponds to no boundary at this position,  $b_j = t$  to a boundary with a preceeding underlying  $/t/$  and  $b_j = 1$  to a boundary with no additional underlying  $/t/$ . We use  $\mathbf{b}^{-j}$  for the statistics determined by all but the  $j^{\text{th}}$  position and  $\mathbf{b}^{-j} \oplus \langle r, l \rangle$  for these statistics plus an additional count of the bigram  $\langle r, l \rangle$ .  $P(w \mid l, \mathbf{b})$  refers to the bigram probability of  $\langle l, w \rangle$  given the the statistics  $\mathbf{b}$ ; we refer the reader to Goldwater et al. (2009) for the details of calculating these bigram probabilities and details about the required statistics for the collapsed sampler.  $P_R$  is defined in the text.

<i>underlying</i>	I	h	i	t	i	t	\$
<i>surface</i>	I	h	i	i	t	\$	
<i>boundaries</i>							
<i>observed</i>	I	h	i	i	t	\$	

Figure 5: The relation between the observed sequence of segments (bottom), the boundary variables  $b_1, \dots, b_{|W|-1}$  the Gibbs sampler operates over (in squares), the latent sequence of surface forms and the latent sequence of underlying forms. When sampling a new value for  $b_3 = t$ , the different word-variables in figure 4 are:  $w_{12,u}=w_{12,s}=hiit$ ,  $w_{1,t}=hit$  and  $w_{1,s}=hi$ ,  $w_{2,u}=w_{2,s}=it$ ,  $w_{l,u}=I$ ,  $w_{r,u}=\$$ . Note that we need a boundary variable at the end of the utterance as there might be an *underlying*  $/t/$  at this position as well. The final boundary variable is set to 1, not  $t$ , because the  $/t/$  in *it* is observed.

## 4 Experiments

### 4.1 The data

We are interested in how well our model handles  $/t/$ -deletion in real data. Ideally, we'd evaluate it on CDS but as of now, we know of no available large enough corpus of accurately hand-transcribed CDS. Instead, we used the Buckeye Corpus (Pitt et al., 2007) for our experiments, a large ADS corpus of interviews with English speakers that have been transcribed with relatively fine phonetic detail, with  $/t/$ -deletion among the things manually annotated. Pointing to the recent work by Dilley et al. (to appear) we want to emphasize that the statistical distribution of  $/t/$ -deletion has been found to be similar for ADS and

orthographic	I don't intend to
transcript	/aɪ r oʊ n i n t ε n d ə/
idealized	/aɪ d oʊ n t i n t ε n d t ə/
t-drop	/aɪ d oʊ n i n t ε n d t ə/

Figure 6: An example fragment from the Buckeye-corpus in orthographic form, the fine transcript available in the Buckeye corpus, a fully idealized pronunciation with canonical dictionary pronunciations and our version of the data with dropped  $/t/$ s.

CDS, at least for read speech.

We automatically derived a corpus of 285,792 word tokens across 48,795 utterances from the Buckeye Corpus by collecting utterances across all interviews and heuristically splitting utterances at speaker-turn changes and indicated silences. The Buckeye corpus lists for each word token a manually transcribed pronunciation in context as well as its canonical pronunciation as given in a pronouncing dictionary. As input to our model, we use the canonical pronunciation unless the pronunciation in context indicates that the final  $/t/$  has been deleted in which case we also delete the final  $/t/$  of the canonical pronunciation Figure 6 shows an example from the Buckeye Corpus, indicating how the original data, a fully idealized version and our derived input that takes into account  $/t/$ -deletions looks like.

Overall,  $/t/$ -deletion is a quite frequent phenomenon with roughly 29% of all underlying  $/t/$ s being dropped. The probabilities become more peaked when looking at finer context; see Table 3 for the empirical distribution of  $/t/$ -dropping for the six different contexts of the *left-right* setting.

## 4.2 Recovering deleted /t/s, given word boundaries

In this set of experiments we are interested in how well our model recovers /t/s when it is provided with the gold word boundaries. This allows us to investigate the strength of the statistical signal for the deletion rule without confounding it with the word segmentation performance, and to see how the different contextual settings *uniform*, *right* and *left-right* handle the data. Concretely, for the example in Figure 6 this means that we tell the model that there are boundaries between /aɪ/, /down/, /ɪntend/, /tu/ and /liv/ but we don’t tell it whether or not these words end in an underlying /t/. Even in this simple example, there are 5 possible positions for the model to posit an underlying /t/. We evaluate the model in terms of F-score, the harmonic mean of recall (the fraction of underlying /t/s the model correctly recovered) and precision (the fraction of underlying /t/s the model predicted that were correct).

In these experiments, we ran a total of 2500 iterations with a burnin of 2000. We collect samples with a lag of 10 for the last 500 iterations and perform *maximum marginal decoding* over these samples (Johnson and Goldwater, 2009), as well as running two chains so as to get an idea of the variance.<sup>5</sup>

We are also interested in how well the model can infer the rule probabilities from the data, that is, whether it can learn values for the different  $\rho_c$  parameters. We compare two settings, one where we perform inference for these parameters assuming a uniform Beta prior on each  $\rho_c$  (LEARN- $\rho$ ) and one where we provide the model with the empirical probabilities for each  $\rho_c$  as estimated off the gold-data (GOLD- $\rho$ ), e.g., for the *uniform* condition 0.29. The results are shown in Table 2.

Best performance for both the Unigram and the Bigram model in the GOLD- $\rho$  condition is achieved under the *left-right* setting, in line with the standard analyses of /t/-deletion as primarily being determined by the preceding and the following context. For the LEARN- $\rho$  condition, the Bigram model still performs best in the *left-right* setting but the Unigram model’s performance drops

<sup>5</sup>As manually setting the hyper-parameters for the DPs in our model proved to be complicated and may be objected to on principled grounds, we perform inference for them under a vague gamma prior, as suggested by Teh et al. (2006) and Johnson and Goldwater (2009), using our own implementation of a slice-sampler (Neal, 2003).

		<i>uniform</i>	<i>right</i>	<i>left-right</i>
Unigram	LEARN- $\rho$	56.52	39.28	23.59
	GOLD- $\rho$	62.08	60.80	66.15
Bigram	LEARN- $\rho$	60.85	62.98	77.76
	GOLD- $\rho$	69.06	69.98	73.45

Table 2: F-score of recovered /t/s with known word boundaries on real data for the three different context settings, averaged over two runs (all standard errors below 2%). Note how the Unigram model always suffers in the LEARN- $\rho$  condition whereas the Bigram model’s performance is actually best for LEARN- $\rho$  in the *left-right* setting.

	C_C	C_V	C_\$	V_C	V_V	V_\$
empirical	0.62	0.42	0.36	0.23	0.15	0.07
Unigram	0.41	0.33	0.17	0.07	0.05	0.00
Bigram	0.70	0.58	0.43	0.17	0.13	0.06

Table 3: Inferred rule-probabilities for different contexts in the *left-right* setting from one of the runs. “C\_C” stands for the context where the deleted /t/ is preceded and followed by a consonant, “V\_\$” stands for the context where it is preceded by a vowel and followed by the utterance boundary. Note how the Unigram model severely under-estimates and the Bigram model slightly over-estimates the probabilities.

in all settings and is now worst in the *left-right* and best in the *uniform* setting.

In fact, comparing the inferred probabilities to the “ground truth” indicates that the Bigram model estimates the true probabilities more accurately than the Unigram model, as illustrated in Table 3 for the *left-right* setting. The Bigram model somewhat overestimates the probability for all post-consonantal contexts but the Unigram model severely underestimates the probability of /t/-deletion across all contexts.

## 4.3 Artificial data experiments

To test our Gibbs sampling inference procedure, we ran it on artificial data generated according to the model itself. If our inference procedure fails to recover the underlying /t/s accurately in this setting, we should not expect it to work well on actual data. We generated our artificial data as follows. We transformed the sequence of canonical pronunciations in the Buckeye corpus (which we take to be underlying forms here) by randomly deleting final /t/s using empirical probabilities as shown in Table 3 to generate a sequence of artificial surface forms that serve as input to our models. We

		uniform	right	left-right
Unigram	LEARN- $\rho$	94.35	23.55 (+)	63.06
	GOLD- $\rho$	94.45	94.20	91.83
Bigram	LEARN- $\rho$	92.72	91.64	88.48
	GOLD- $\rho$	92.88	92.33	89.32

Table 4: F-score of /t/-recovery with known word boundaries on artificial data, each condition tested on data that corresponds to the assumption, averaged over two runs (standard errors less than 2% except (+) = 3.68%).

	Unigram	Bigram
LEARN- $\rho$	33.58	55.64
GOLD- $\rho$	55.92	57.62

Table 5: /t/-recovery F-scores when performing joint word segmentation in the *left-right* setting, averaged over two runs (standard errors less than 2%). See Table 6 for the corresponding segmentation F-scores.

did this for all three context settings, always estimating the deletion probability for each context from the gold-standard. The results of these experiments are given in table 4. Interestingly, performance on these artificial data is considerably better than on the real data. In particular the Bigram model is able to get consistently high F-scores for both the LEARN- $\rho$  and the GOLD- $\rho$  setting. For the Unigram model, we again observe the severe drop in the LEARN- $\rho$  setting for the *right* and *left-right* settings although it does remarkably well in the *uniform* setting, and performs well across all settings in the GOLD- $\rho$  condition. We take this to show that our inference algorithm is in fact working as expected.

#### 4.4 Segmentation experiments

Finally, we are also interested to learn how well we can do word segmentation and underlying /t/-recovery jointly. Again, we look at both the LEARN- $\rho$  and GOLD- $\rho$  conditions but focus on the *left-right* setting as this worked best in the experiments above. For these experiments, we perform simulated annealing throughout the initial 2000 iterations, gradually cooling the temperature from 5 to 1, following the observation by Goldwater et al. (2009) that without annealing, the Bigram model gets stuck in sub-optimal parts of the solution space early on. During the annealing stage, we prevent the model from performing inference

for underlying /t/s so that the annealing stage can be seen as an elaborate initialisation scheme, and we perform joint inference for the remaining 500 iterations, evaluating on the last sample and averaging over two runs. As neither the Unigram nor the Bigram model performs “perfect” word segmentation, we expect to see a degradation in /t/-recovery performance and this is what we find indeed. To give an impression of the impact of /t/-deletion, we also report numbers for running only the segmentation model on the Buckeye data with no deleted /t/s and on the data with deleted /t/s. The /t/-recovery scores are given in Table 5 and segmentation scores in Table 6. Again the Unigram model’s /t/-recovery score degrades dramatically in the LEARN- $\rho$  condition. Looking at the segmentation performance this isn’t too surprising: the Unigram model’s poorer token F-score, the standard measure of segmentation performance on a word token level, suggests that it misses many more boundaries than the Bigram model to begin with and, consequently, can’t recover any potential underlying /t/s at these boundaries. Also note that in the GOLD- $\rho$  condition, our joint Bigram model performs almost as well on data with /t/-deletions as the word segmentation model on data that includes no variation at all.

The generally worse performance of handling variation as measured by /t/-recovery F-score when performing joint segmentation is consistent with the finding of Elsner et al. (2012) who report considerable performance drops for their phonological learner when working with induced boundaries (note, however, that their model does not perform joint inference, rather the induced boundaries are given to their phonological learner as ground-truth).

## 5 Discussion

There are two interesting findings from our experiments. First of all, we find a much larger difference between the Unigram and the Bigram model in the LEARN- $\rho$  condition than in the GOLD- $\rho$  condition. We suggest that this is due to the Unigram model’s lack of dependencies between underlying forms, depriving it of an important source of evidence. Bigram dependencies provide additional evidence for underlying /t/ that are deleted on the surface, and because the Bigram model identifies these underlying /t/ more accurately, it can also estimate the /t/ deletion probability more accurately.

	Unigram	Bigram
LEARN- $\rho$	54.53	72.55 (2.3%)
GOLD- $\rho$	54.51	73.18
NO- $\rho$	54.61	70.12
NO-VAR	54.12	73.99

Table 6: Word segmentation F-scores for the /t/-recovery F-scores in Table 5 averaged over two runs (standard errors less than 2% unless given). NO- $\rho$  are scores for running just the word segmentation model with no /t/-deletion rule on the data that includes /t/-deletion, NO-VAR for running just the word segmentation model on the data with no /t/-deletions.

For example, /t/ dropping in “don’t you” yields surface forms “don you”. Because the word bigram probability  $P(\text{you} \mid \text{don’t})$  is high, the bigram model prefers to analyse surface “don” as underlying “don’t”. The Unigram model does not have access to word bigram information so the underlying forms it posits are less accurate (as shown in Table 2), and hence the estimate of the /t/-deletion probability is also less accurate. When the probabilities of deletion are pre-specified the Unigram model performs better but still considerably worse than the Bigram model when the word boundaries are known, suggesting the importance of non-phonological contextual effects that the Bigram model but not the Unigram model can capture. This suggests that for example word predictability in context might be an important factor contributing to /t/-deletion.

The other striking finding is the considerable drop in performance between running on naturalistic and artificially created data. This suggests that the natural distribution of /t/-deletion is much more complex than can be captured by statistics over the phonological contexts we examined. Following Guy (1991), a finer-grained distinction for the preceding segments might address this problem.

Yet another suggestion comes from the recent work in Coetzee and Kawahara (2013) who claim that “[a] model that accounts perfectly for the overall rate of application of some variable process therefore does not necessarily account very well for the actual application of the process to individual words.” They argue that in particular the extremely high deletion rates typical of high frequency items aren’t accurately captured when the

deletion probability is estimated across all types. A look at the error patterns of our model on a sample from the Bigram model in the LEARN- $\rho$  setting on the naturalistic data suggests that this is in fact a problem. For example, the word “just” has an extremely high rate of deletion with  $\frac{1746}{2442} = 0.71\%$ . While many tokens of “jus” are “explained away” through predicting underlying /t/s, the (literally) extra-ordinary frequency of “jus”-tokens lets our model still posit it as an underlying form, although with a much dampened frequency (of the 1746 surface tokens, 1081 are analysed as being realizations of an underlying “just”).

The /t/-recovery performance drop when performing joint word segmentation isn’t surprising as even the Bigram model doesn’t deliver a very high-quality segmentation to begin with, leading to both sparsity (through missed word-boundaries) and potential noise (through misplaced word-boundaries). Using a more realistic generative process for the underlying forms, for example an Adaptor Grammar (Johnson et al., 2007), could address this shortcoming in future work without changing the overall architecture of the model although novel inference algorithms might be required.

## 6 Conclusion and outlook

We presented a joint model for word segmentation and the learning of phonological rule probabilities from a corpus of transcribed speech. We find that our Bigram model reaches 77% /t/-recovery F-score when run with knowledge of true word-boundaries and when it can make use of both the preceding and the following phonological context, and that unlike the Unigram model it is able to learn the probability of /t/-deletion in different contexts. When performing joint word segmentation on the Buckeye corpus, our Bigram model reaches around above 55% F-score for recovering deleted /t/s with a word segmentation F-score of around 72% which is 2% better than running a Bigram model that does not model /t/-deletion.

We identified additional factors that might help handling /t/-deletion and similar phenomena. A major advantage of our generative model is the ease and transparency with which its assumptions can be modified and extended. For future work we plan to incorporate into our model richer phonological contexts, item- and frequency-specific probabilities and more direct use of word

predictability. We also plan to extend our model to handle additional phenomena, an obvious candidate being /d/-deletion.

Also, the two-level architecture we present is not limited to the mapping being defined in terms of rules rather than constraints in the spirit of Optimality Theory (Prince and Smolensky, 2004); we plan to explore this alternative path as well in future work.

To conclude, we presented a model that provides a clean framework to test the usefulness of different factors for word segmentation and handling phonological variation in a controlled manner.

# Compositional-ly Derived Representations of Morphologically Complex Words in Distributional Semantics

Angeliki Lazaridou and Marco Marelli and Roberto Zamparelli and Marco Baroni

Center for Mind/Brain Sciences (University of Trento, Italy)

first.last@unitn.it

## Abstract

Speakers of a language can construct an unlimited number of new words through morphological derivation. This is a major cause of data sparseness for corpus-based approaches to lexical semantics, such as distributional semantic models of word meaning. We adapt compositional methods originally developed for phrases to the task of deriving the distributional meaning of morphologically complex words from their parts. Semantic representations constructed in this way beat a strong baseline and can be of higher quality than representations directly constructed from corpus data. Our results constitute a novel evaluation of the proposed composition methods, in which the *full additive* model achieves the best performance, and demonstrate the usefulness of a compositional morphology component in distributional semantics.

## 1 Introduction

Effective ways to represent word meaning are needed in many branches of natural language processing. In the last decades, corpus-based methods have achieved some degree of success in modeling lexical semantics. Distributional semantic models (DSMs) in particular represent the meaning of a word by a vector, the dimensions of which encode corpus-extracted co-occurrence statistics, under the assumption that words that are semantically similar will occur in similar contexts (Turney and Pantel, 2010). Reliable distributional vectors can only be extracted for words that occur in many contexts in the corpus. Not surprisingly, there is a strong correlation between word frequency and vector quality (Bullinaria and Levy, 2007), and since most words occur only once even in very large corpora (Baroni, 2009), DSMs suffer data sparseness.

While word rarity has many sources, one of the most common and systematic ones is the high *productivity* of morphological derivation processes, whereby an unlimited number of new words can be constructed by adding affixes to existing stems (Baayen, 2005; Bauer, 2001; Plag, 1999).<sup>1</sup> For example, in the multi-billion-word corpus we introduce below, perfectly reasonable derived forms such as *lexicalizable* or *affixless* never occur. Even without considering the theoretically infinite number of possible derived nonce words, and restricting ourselves instead to words that are already listed in dictionaries, complex forms cover a high portion of the lexicon. For example, morphologically complex forms account for 55% of the lemmas in the CELEX English database (see Section 4.1 below). In most of these cases (80% according to our corpus) the stem is more frequent than the complex form (e.g., the stem *build* occurs 15 times more often than the derived form *rebuild*, and the latter is certainly not an unusual derived form).

DSMs ignore derivational morphology altogether. Consequently, they cannot provide meaningful representations for new derived forms, nor can they harness the systematic relation existing between stems and derivations (any English speaker can infer that *rebuild* is to *build again*, whether they are familiar with the prefixed form or not) in order to mitigate derived-form sparseness problems. A simple way to handle derivational mor-

---

<sup>1</sup>Morphological *derivation* constructs new words (in the sense of lemmas) from existing lexical items (*resource+ful*→*resourceful*). In this work, we do not treat *inflectional* morphology, pertaining to affixes that encode grammatical features such as number or tense (*dog+s*). We use *morpheme* for any component of a word (*resource* and *-ful* are both morphemes). We use *stem* for the lexical item that constitutes the base of derivation (*resource*) and *affix* (*prefix* or *suffix*) for the element attached to the stem to derive the new form (*-ful*). In English, stems are typically independent words, affixes *bound* morphemes, i.e., they cannot stand alone. Note that a stem can in turn be morphologically derived, e.g., *point+less* in *pointless+ly*. Finally, we use *morphologically complex* as synonymous with *derived*.

phology would be to identify the stem of rare derived words and use its distributional vector as a proxy to derived-form meaning.<sup>2</sup> The meaning of *rebuild* is not that far from that of *build*, so the latter might provide a reasonable surrogate. Still, something is clearly lost (if the author of a text felt the need to use the derived form, the stem was not fully appropriate), and sometimes the jump in meaning can be quite dramatic (*resourceless* and *resource* mean very different things!).

In the past few years there has been much interest in how DSMs can scale up to represent the meaning of larger chunks of text such as phrases or even sentences. Trying to represent the meaning of arbitrarily long constructions by directly collecting co-occurrence statistics is obviously ineffective and thus methods have been developed to derive the meaning of larger constructions as a function of the meaning of their constituents (Baroni and Zamparelli, 2010; Coecke et al., 2010; Mitchell and Lapata, 2008; Mitchell and Lapata, 2010; Socher et al., 2012). *Compositional* distributional semantic models (cDSMs) of word units aim at handling, compositionally, the high productivity of phrases and consequent data sparseness. It is natural to hypothesize that the same methods can be applied to morphology to derive the meaning of complex words from the meaning of their parts: For example, instead of harvesting a *rebuild* vector directly from the corpus, the latter could be constructed from the distributional representations of *re-* and *build*. Besides alleviating data sparseness problems, a system of this sort, that automatically induces the semantic contents of morphological processes, would also be of tremendous theoretical interest, given that the semantics of derivation is a central and challenging topic in linguistic morphology (Dowty, 1979; Lieber, 2004).

In this paper, we explore, for the first time (except for the proof-of-concept study in Guevara (2009)), the application of cDSMs to derivational morphology. We adapt a number of composition methods from the literature to the morphological setting, and we show that some of these methods can provide better distributional representations of derived forms than either those directly harvested from a large corpus, or those obtained by using the stem as a proxy to derived-form meaning. Our

---

<sup>2</sup>Of course, spotting and segmenting complex words is a big research topic unto itself (Beesley and Karttunen, 2000; Black et al., 1991; Sproat, 1992), and one we completely sidestep here.

results suggest that exploiting morphology could improve the quality of DSMs in general, extend the range of tasks that cDSMs can successfully model and support the development of new ways to test their performance.

## 2 Related work

Morphological induction systems use corpus-based methods to decide if two words are morphologically related and/or to segment words into morphemes (Dreyer and Eisner, 2011; Goldsmith, 2001; Goldwater and McClosky, 2005; Goldwater, 2006; Naradowsky and Goldwater, 2009; Wicentowski, 2004). Morphological induction has recently received considerable attention since morphological analysis can mitigate data sparseness in domains such as parsing and machine translation (Goldberg and Tsarfaty, 2008; Lee, 2004). Among the cues that have been exploited there is distributional similarity among morphologically related words (Schone and Jurafsky, 2000; Yarowsky and Wicentowski, 2000). Our work, however, differs substantially from this track of research. We do not aim at segmenting morphological complex words or identifying paradigms. Our goal is to automatically construct, given distributional representations of stems and affixes, semantic representations for the derived words containing those stems and affixes. A morphological induction system, given *rebuild*, will segment it into *re-* and *build* (possibly using distributional similarity between the words as a cue). Our system, given *re-* and *build*, predicts the (distributional semantic) meaning of *rebuild*.

Another emerging line of research uses distributional semantics to model human intuitions about the semantic transparency of morphologically derived or compound expressions and how these impact various lexical processing tasks (Kuperman, 2009; Wang et al., 2012). Although these works exploit vectors representing complex forms, they do not attempt to generate them compositionally.

The only similar study we are aware of is that of Guevara (2009). Guevara found a systematic geometric relation between corpus-based vectors of derived forms sharing an affix and their stems, and used this finding to motivate the composition method we term *lexfunc* below. However, unlike us, he did not test alternative models, and he only presented a qualitative analysis of the trajectories triggered by composition with various affixes.

### 3 Composition methods

Distributional semantic models (DSMs), also known as vector-space models, semantic spaces, or by the names of famous incarnations such as Latent Semantic Analysis or Topic Models, approximate the meaning of words with vectors that record their patterns of co-occurrence with corpus context features (often, other words). There is an extensive literature on how to develop such models and on their evaluation. Recent surveys include Clark (2012), Erk (2012) and Turney and Pantel (2010). We focus here on compositional DSMs (cDSMs). Since the very inception of distributional semantics, there have been attempts to compose meanings for sentences and larger passages (Landauer and Dumais, 1997), but interest in compositional DSMs has skyrocketed in the last few years, particularly since the influential work of Mitchell and Lapata (2008; 2009; 2010). For the current study, we have reimplemented and adapted to the morphological setting all cDSMs we are aware of, excluding the tensor-product-based models that Mitchell and Lapata (2010) have shown to be empirically disappointing and the models of Socher and colleagues (Socher et al., 2011; Socher et al., 2012), that require complex optimization procedures whose adaptation to morphology we leave to future work.

Mitchell and Lapata proposed a set of simple and effective models in which the composed vectors are obtained through component-wise operations on the constituent vectors. Given input vectors  $\mathbf{u}$  and  $\mathbf{v}$ , the multiplicative model (**mult**) returns a composed vector  $\mathbf{c}$  with:  $c_i = u_i v_i$ . In the weighted additive model (**wadd**), the composed vector is a weighted sum of the two input vectors:  $\mathbf{c} = \alpha \mathbf{u} + \beta \mathbf{v}$ , where  $\alpha$  and  $\beta$  are two scalars. In the **dilation** model, the output vector is obtained by first decomposing one of the input vectors, say  $\mathbf{v}$ , into a vector parallel to  $\mathbf{u}$  and an orthogonal vector. Following this, the parallel vector is dilated by a factor  $\lambda$  before re-combining. This results in:  $\mathbf{c} = (\lambda - 1)\langle \mathbf{u}, \mathbf{v} \rangle \mathbf{u} + \langle \mathbf{u}, \mathbf{u} \rangle \mathbf{v}$ .

Guevara (2010) and Zanzotto et al. (2010) propose the full additive model (**fulladd**), where the two vectors to be added are pre-multiplied by weight matrices:  $\mathbf{c} = \mathbf{A}\mathbf{u} + \mathbf{B}\mathbf{v}$

Since the Mitchell and Lapata and *fulladd* models were developed for phrase composition, the two input vectors were taken to be, very straightforwardly, the vectors of the two words to be com-

posed into the phrase of interest. In morphological derivation, at least one of the items to be composed (the affix) is a bound morpheme. In our adaptation of these composition models, we build bound morpheme vectors by accumulating the contexts in which a set of derived words containing the relevant morphemes occur, e.g., the *re-* vector aggregates co-occurrences of *redo*, *remake*, *retry*, etc.

Baroni and Zamparelli (2010) and Coecke et al. (2010) take inspiration from formal semantics to characterize composition in terms of function application, where the distributional representation of one element in a composition (the *functor*) is not a vector but a function. Given that linear functions can be expressed by matrices and their application by matrix-by-vector multiplication, in this *lexical function* (**lexfunc**) model, the functor is represented by a matrix  $\mathbf{U}$  to be multiplied with the argument vector  $\mathbf{v}$ :  $\mathbf{c} = \mathbf{U}\mathbf{v}$ . In the case of morphology, it is natural to treat bound affixes as functions over stems, since affixes encode the systematic semantic patterns we intend to capture. Unlike the other composition methods, *lexfunc* does not require the construction of distributional vectors for affixes. A matrix representation for every affix is instead induced directly from examples of stems and the corresponding derived forms, in line with the intuition that every affix corresponds to a different pattern of change of the stem meaning.

Finally, as already discussed in the Introduction, performing no composition at all but using the stem vector as a surrogate of the derived form is a reasonable strategy. We saw that morphologically derived words tend to appear less frequently than their stems, and in many cases the meanings are close. Consequently, we expect a **stem-only** “composition” method to be a strong baseline in the morphological setting.

## 4 Experimental setup

### 4.1 Morphological data

We obtained a list of stem/derived-form pairs from the CELEX English Lexical Database, a widely used 100K-lemma lexicon containing, among other things, information about the derivational structure of words (Baayen et al., 1995). For each derivational affix present in CELEX, we extracted from the database the full list of stem/derived pairs matching its most common part-of-speech signature (e.g., for *-er* we only considered pairs

Affix	Stem/Der. POS	Training Items	HQ/Tot. Test Items	Avg. SDR
-able	verb/adj	177	30/50	5.96
-al	noun/adj	245	41/50	5.88
-er	verb/noun	824	33/50	5.51
-ful	noun/adj	53	42/50	6.11

Table 1: Derivational morphology dataset

having a verbal stem and nominal derived form). Since CELEX was populated by semi-automated morphological analysis, it includes forms that are probably not synchronically related to their stems, such as *crypt+ic* or *re+form*. However, we did not manually intervene on the pairs, since we are interested in training and testing our methods in realistic, noisy conditions. In particular, the need to pre-process corpora to determine which forms are “opaque”, and should thus be bypassed by our systems, would greatly reduce their usefulness. Pairs in which either word occurred less than 20 times in our source corpus (described in Section 4.2 below) were filtered out and, in our final dataset, we only considered the 18 affixes (3 prefixes and 15 suffixes) with at least 100 pairs meeting this condition. We randomly chose 50 stem/derived pairs (900 in total) as test data. The remaining data were used as training items to estimate the parameters of the composition methods. Table 1 summarizes various characteristics of the dataset<sup>3</sup> (the last two columns of the table are explained in the next paragraphs).

**Annotation of quality of test vectors** The quality of the corpus-based vectors representing derived test items was determined by collecting human semantic similarity judgments in a crowdsourcing survey. In particular, we use the similarity of a vector to its nearest neighbors (NNs) as a proxy measure of quality. The underlying assump-

<sup>3</sup>Available from <http://clic.cimec.unitn.it/composes>

tion is that a vector, in order to be a good representation of the meaning of the corresponding word, should lie in a region of semantic space populated by intuitively similar meanings, e.g., we are more likely to have captured the meaning of *car* if the NN of its vector is the *automobile* vector rather than *potato*. Therefore, to measure the quality of a given vector, we can look at the average similarity score provided by humans when comparing this very vector with its own NNs.

All 900 derived vectors from the test set were matched with their three closest NNs in our semantic space (see Section 4.2), thus producing a set of 2,700 word pairs. These pairs were administered to CrowdFlower users,<sup>4</sup> who were asked to judge the relatedness of the two meanings on a 7-point scale (higher for more related). In order to ensure that participants were committed to the task and exclude non-proficient English speakers, we used 60 control pairs as gold standard, consisting of either perfect synonyms or completely unrelated words. We obtained 30 judgments for each derived form (10 judgments for each of 3 neighbor comparisons), with mean participant agreement of 58%. These ratings were averaged item-wise, resulting in a Gaussian distribution with a mean of 3.79 and a standard deviation of 1.31. Finally, each test item was marked as high-quality (HQ) if its derived form received an average score of at least 3, as low-quality (LQ) otherwise. Table 1 reports the proportion of HQ test items for each affix, and Table 2 reports some examples of HQ and LQ items with the corresponding NNs. It is worth observing that the NNs of the LQ items, while not as relevant as the HQ ones, are hardly random.

**Annotation of similarity between stem and derived forms** Derived forms differ in terms of how far their meaning is with respect to that of their stem. Certain morphological processes have systematically more impact than others on meaning: For example, the adjectival prefix *in-* negates the meaning of the stem, whereas *-ly* has the sole function to convert an adjective into an adverb. But the very same affix can affect different stems in different ways. For example, *remelt* means little more than to *melt again*, but *rethink* has subtler implications of changing one’s way to look at a problem, and while one of the senses of *cycling* is present in *recycle*, it takes some effort to see their relation.

<sup>4</sup><http://www.crowdflower.com>

Affix	Type	Derived form	Neighbors
-ist	HQ	transcendentalist	mythologist, futurist, theosophist
	LQ	florist	Harrod, wholesaler, stockist
-ity	HQ	publicity	publicise, press, publicize
	LQ	sparsity	dissimilarity, contiguity, perceptibility
-ment	HQ	advertisement	advert, promotional, advertising
	LQ	inducement	litigant, contractually, voluntarily
in-	HQ	inaccurate	misleading, incorrect, erroneous
	LQ	inoperable	metastasis, colorectal, biopsy
re-	HQ	recapture	retake, besiege, capture
	LQ	rename	defunct, officially, merge

Table 2: Examples of HQ and LQ derived vectors with their NNs

We conducted a separate crowdsourcing study where participants were asked to rate the 900 test stem/derived pairs for the strength of their semantic relationship on a 7-point scale. We followed a procedure similar to the one described for quality measurement; 7 judgments were collected for each pair. Participants’ agreement was at 60%. The last column of Table 1 reports the average stem/derived relatedness (**SDR**) for the various affixes. Note that the affixes with systematically lower SDR are those carrying a negative meaning (*in-*, *un-*, *-less*), whereas those with highest SDR do little more than changing the POS of the stem (*-ion*, *-ly*, *-ness*). Among specific pairs with very low relatedness we encounter *hand/handy*, *bear/bearable* and *active/activist*, whereas *compulsory/compulsorily*, *shameless/shamelessness* and *chaos/chaotic* have high SDR. Since the distribution of the average ratings was negatively skewed (mean rating: 5.52, standard deviation: 1.26),<sup>5</sup> we took 5 as the rating threshold to classify items as having high (**HR**) or low (**LR**) relatedness to their stems.

## 4.2 Distributional semantic space<sup>6</sup>

We use as our source corpus the concatenation of ukWaC, the English Wikipedia (2009 dump) and the BNC,<sup>7</sup> for a total of about 2.8 billion tokens. We collect co-occurrence statistics for the top 20K content words (adjectives, adverbs, nouns, verbs)

<sup>5</sup>The negative skew is not surprising, as derived forms must have some relation to their stems!

<sup>6</sup>Most steps of the semantic space construction and composition pipelines were implemented using the DISSECT toolkit: <https://github.com/composes-toolkit/dissect>.

<sup>7</sup><http://wacky.sslmit.unibo.it>, <http://en.wikipedia.org>, <http://www.natcorp.ox.ac.uk>

in lemma format, plus any item from the morphological dataset described above that was below this rank. The top 20K content words also constitute our context elements. We use a standard bag-of-words approach, counting collocates in a narrow 2-word before-and-after window. We apply (non-negative) Pointwise Mutual Information as weighting scheme and dimensionality reduction by Non-negative Matrix Factorization, setting the number of reduced-space dimensions to 350. These settings are chosen without tuning, and are based on previous experiments where they produced high-quality semantic spaces (Boleda et al., 2013; Bullinaria and Levy, 2007).

## 4.3 Implementation of composition methods

All composition methods except *mult* and *stem* have weights to be estimated (e.g., the  $\lambda$  parameter of *dilation* or the affix matrices of *lexfunc*). We adopt the estimation strategy proposed by Guevara (2010) and Baroni and Zamparelli (2010), namely we pick parameter values that optimize the mapping between stem and derived vectors directly extracted from the corpus. To learn, say, a *lexfunc* matrix representing the prefix *re-*, we extract vectors of  $V/reV$  pairs that occur with sufficient frequency (*visit/revisit*, *think/rethink*...). We then use least-squares methods to find weights for the *re-* matrix that minimize the distance between each *reV* vector generated by the model given the input  $V$  and the corresponding corpus-observed derived vector (e.g., we try to make the model-predicted *re+visit* vector as similar as possible to the corpus-extracted one). This is a general estimation approach that does not require task-specific hand-labeled data, and for which simple analytical solutions of the least-squares error prob-

lem exist for all our composition methods. We use only the training items from Section 4.1 for estimation. Note that, unlike the test items, these have not been annotated for quality, so we are adopting an unsupervised (no manual labeling) but noisy estimation method.<sup>8</sup>

For the *lexfunc* model, we use the training items separately to obtain weight matrices representing each affix, whereas for the other models all training data are used together to globally derive single sets of affix and stem weights. For the *wadd* model, the learning process results in  $0.16 \times \text{affix} + 0.33 \times \text{stem}$ , i.e., the affix contributes only half of its mass to the composition of the derived form. For *dilation*, we stretch the stem (i.e.,  $\mathbf{v}$  of the dilation equation is the stem vector), since it should provide richer contents than the affix to the derived meaning. We found that, on average across the training pairs, *dilation* weighted the stem 20 times more heavily than the affix ( $0.05 \times \text{affix} + 1 \times \text{stem}$ ). We then expect that the *dilation* model will have similar performance to the baseline *stem* model, as confirmed below.<sup>9</sup>

For all methods, vectors were normalized before composing both in training and in generation.

## 5 Experiment 1: approximating high-quality corpus-extracted vectors

The first experiment investigates to what extent composition models can approximate high-quality (HQ) corpus-extracted vectors representing derived forms. Note that since the test items were excluded from training, we are simulating a scenario in which composition models must generate representations for nonce derived forms.

Cosine similarity between model-generated and corpus-extracted vectors were computed for all models, including the *stem* baseline (i.e., cosine between stem and derived form). The first row of Table 3 reports mean similarities. The *stem* method sets the level of performance relatively high, confirming its soundness. Indeed, the parameter-free *mult* model performs below the baseline.<sup>10</sup> As expected, *dilation* performs simi-

<sup>8</sup>More accurately, we relied on semi-manual CELEX information to identify derived forms. A further step towards a fully knowledge-free system would be to pre-process the corpus with an unsupervised morphological induction system to extract stem/derived pairs.

<sup>9</sup>The other models have thousands of weights to be estimated, so we cannot summarize the outcome of parameter estimation here.

<sup>10</sup>This result does not necessarily contradict those of

	<i>stem</i>	<i>mult</i>	<i>dil.</i>	<i>wadd</i>	<i>fulladd</i>	<i>lexfunc</i>
<b>All</b>	0.47	0.39	0.48	0.50	0.56	0.54
<b>HR</b>	0.52	0.43	0.53	0.55	0.61	0.58
<b>LR</b>	0.32	0.28	0.33	0.38	0.41	0.42

Table 3: Mean similarity of composed vectors to high-quality corpus-extracted derived-form vectors, for all as well as high- (HR) and low-relatedness (LR) test items

larly to the baseline, while *wadd* outperforms it, although the effect does not reach significance ( $p=.06$ ).<sup>11</sup> Both *fulladd* and *lexfunc* perform significantly better than *stem* ( $p < .001$ ). *Lexfunc* provides a flexible way to account for affixation, since it models it directly as a function mapping from and onto word vectors, without requiring a vector representation of bound affixes. The reason at the base of its good performance is thus quite straightforward. On the other hand, it is surprising that a simple representation of bound affixes (i.e., as vectors aggregating the contexts of words containing them) can work so well, at least when used in conjunction with the granular dimension-by-dimension weights assigned by the *fulladd* method. We hypothesize that these aggregated contexts, by providing information about the set of stems an affix combines with, capture the shared semantic features that the affix operates on.

When the meaning of the derived form is far from that of its stem, the *stem* baseline should no longer constitute a suitable surrogate of derived-form meaning. The LR cases (see Section 4.1 above) are thus crucial to understand how well composition methods capture not only stem meaning, but also affix-triggered semantics. The HR and LR rows of Table 3 present the results for the respective test subsets. As expected, the *stem* approach undergoes a strong drop when performance is measured on LR items. At the other extreme, *fulladd* and *lexfunc*, while also finding the LR cases more difficult, still clearly outperform the baseline ( $p < .001$ ), confirming that they capture the meaning of derived forms beyond what their stems contribute to it. The effect of *wadd*, again, approaches significance when compared to the baseline ( $p = .05$ ). Very encouragingly, both

Mitchell and Lapata and others who found *mult* to be highly competitive. Due to differences in co-occurrence weighting schemes (we use a logarithmically scaled measure, they do not), their multiplicative model is closer to our additive one.

<sup>11</sup>Significance assessed by means of Tukey Honestly Significant Difference tests (Abdi and Williams, 2010)

	<i>stem</i>	<i>mult</i>	<i>wadd</i>	<i>dil.</i>	<i>fulladd</i>	<i>lexfunc</i>
<b>-less</b>	0.22	0.23	0.30	0.24	0.38	0.44
<b>in-</b>	0.39	0.34	0.45	0.40	0.47	0.45
<b>un-</b>	0.33	0.33	0.41	0.34	0.44	0.46

Table 4: Mean similarity of composed vectors to high-quality corpus-extracted derived-form vectors with negative affixes

*fulladd* and *lexfunc* significantly outperform *stem* also in the HR subset ( $p < .001$ ). That is, the models provide better approximations of derived forms even when the stem itself should already be a good surrogate. The difference between the two models is not significant.

We noted in Section 4.1 that forms containing the “negative” affixes *-less*, *un-* and *in-* received on average low SDR scores, since negation impacts meaning more drastically than other operations. Table 4 reports the performance of the models on these affixes. Indeed, the *stem* baseline performs quite poorly, whereas *fulladd*, *lexfunc* and, to a lesser extent, *wadd* are quite effective in this condition as well, all performing greatly above the baseline. These results are intriguing in light of the fact that modeling negation is a challenging task for DSMs (Mohammad et al., 2013) as well as cDSMs (Preller and Sadrzadeh, 2011). To the extent that our best methods have captured the negating function of a prefix such as *in-*, they might be applied to tasks such as recognizing lexical opposites, or even simple forms of syntactic negation (modeling *inoperable* is just a short step away from modeling *not operable* compositionally).

## 6 Experiment 2: Comparing the quality of corpus-extracted and compositionally generated words

The first experiment simulated the scenario in which derived forms are not in our corpus, so that directly extracting their representation from it is not an option. The second experiment tests if compositionally-derived representations can be better than those extracted directly from the corpus when the latter is a possible strategy (i.e., the derived forms are attested in the source corpus). To this purpose, we focused on those 277 test items that were judged as low-quality (LQ, see Section 4.1), which are presumably more challenging to generate, and where the compositional route could be most useful.

We evaluated the derived forms generated by

	<i>corpus</i>	<i>stem</i>	<i>wadd</i>	<i>fulladd</i>	<i>lexfunc</i>
<b>All</b>	2.28	3.26	4.12	3.99	3.09
<b>HR</b>	2.29	3.56	4.48	4.31	3.31
<b>LR</b>	2.22	2.48	3.14	3.12	2.52

Table 5: Average quality ratings of derived vectors

Target	Model	Neighbors
florist	<i>wadd</i>	flora, fauna, ecosystem
	<i>fulladd</i>	flora, fauna, egologist
	<i>lexfunc</i>	ornithologist, naturalist, botanist
sparsity	<i>wadd</i>	sparse, sparsely, dense
	<i>fulladd</i>	sparse, sparseness, angularity
	<i>lexfunc</i>	fragility, angularity, smallness
inducement	<i>wadd</i>	induce, inhibit, inhibition
	<i>fulladd</i>	induce, inhibition, mediate
	<i>lexfunc</i>	impairment, cerebral, ocular
inoperable	<i>wadd</i>	operable, palliation, biopsy
	<i>fulladd</i>	operable, inoperative, ventilator
	<i>lexfunc</i>	inoperative, unavoidably, flaw
rename	<i>wadd</i>	name, later, namesake
	<i>fulladd</i>	name, namesake, later
	<i>lexfunc</i>	temporarily, reinstate, thereafter

Table 6: Examples of model-predicted neighbors for words with LQ corpus-extracted vectors

the models that performed best in the first experiment (*fulladd*, *lexfunc* and *wadd*), as well as the *stem* baseline, by means of another crowdsourcing study. We followed the same procedure used to assess the quality of corpus-extracted vectors, that is, we asked judges to rate the relatedness of the target forms to their NNs (we obtained on average 29 responses per form).

The first line of Table 5 reports the average quality (on a 7-point scale) of the representations of the derived forms as produced by the models and baseline, as well as of the corpus-harvested ones (*corpus* column). All compositional models produce representations that are of significantly higher quality ( $p < .001$ ) than the corpus-based ones. The effect is also evident in qualitative terms. Table 6 presents the NNs predicted by the three compositional methods for the same LQ test items whose corpus-based NNs are presented in Table 2. These results indicate that morpheme composition is an effective solution when the quality of corpus-extracted derived forms is low (and the previous experiment showed that, when their quality is high, composition can at least approximate corpus-based vectors).

With respect to Experiment 1, we obtain a different ranking of the models, with *lexfunc* being outperformed by both *wadd* and *fulladd* ( $p < .001$ ), that are statistically indistinguishable. The *wadd*

composition is dominated by the stem, and by looking at the examples in Table 6 we notice that both this model and *fulladd* tend to feature the stem as NN (100% of the cases for *wadd*, 73% for *fulladd* in the complete test set). The question thus arises as to whether the good performance of these composition techniques is simply due to the fact that they produce derived forms that are near their stems, with no added semantic value from the affix (a “stemploitation” strategy).

However, the stemploitation hypothesis is dispelled by the observation that both models significantly outperform the *stem* baseline ( $p < .001$ ), despite the fact that the latter, again, has good performance, significantly outperforming the corpus-derived vectors ( $p < .001$ ). Thus, we confirm that compositional models provide higher quality vectors that are capturing the meaning of derived forms beyond the information provided by the stem.

Indeed, if we focus on the third row of Table 5, reporting performance on low stem-derived relatedness (LR) items (annotated as described in Section 4.1), *fulladd* and *wadd* still significantly outperform the corpus representations ( $p < .001$ ), whereas the quality of the *stem* representations of LR items is not significantly different from that of the corpus-derived ones. Interestingly, *lexfunc* displays the smallest drop in performance when restricting evaluation to LR items; however, since it does not significantly outperform the LQ corpus representations, this is arguably due to a floor effect.

## 7 Conclusion and future work

We investigated to what extent cDSMs can generate effective meaning representations of complex words through morpheme composition. Several state-of-the-art composition models were adapted and evaluated on this novel task. Our results suggest that morpheme composition can indeed provide high-quality vectors for complex forms, improving both on vectors directly extracted from the corpus and on a stem-backoff strategy. This result is of practical importance for distributional semantics, as it paves the way to address one of the main causes of data sparseness, and it confirms the usefulness of the compositional approach in a new domain. Overall, *fulladd* emerged as the best performing model, with both *lexfunc* and the simple *wadd* approach constituting strong rivals. The ef-

fectiveness of the best models extended also to the challenging cases where the meaning of derived forms is far from that of the stem, including negative affixes.

The *fulladd* method requires a vector representation for bound morphemes. A first direction for future work will thus be to investigate which aspects of the meaning of bound morphemes are captured by our current simple-minded approach to populating their vectors, and to explore alternative ways to construct them, seeing if they further improve *fulladd* performance.

A natural extension of our research is to address morpheme composition and morphological induction jointly, trying to model the intuition that good candidate morphemes should have coherent semantic representations. Relatedly, in the current setting we generate complex forms from their parts. We want to investigate the inverse route, namely “de-composing” complex words to derive representations of their stems, especially for cases where the complex words are more frequent (e.g. *comfort/comfortable*).

We would also like to apply composition to inflectional morphology (that currently lies outside the scope of distributional semantics), to capture the nuances of meaning that, for example, distinguish singular and plural nouns (consider, e.g., the difference between the mass singular *tea* and the plural *teas*, which coerces the noun into a count interpretation (Katz and Zamparelli, 2012)).

Finally, in our current setup we focus on a single composition step, e.g., we derive the meaning of *inoperable* by composing the morphemes *in-* and *operable*. But *operable* is in turn composed of *operate* and *-able*. In the future, we will explore recursive morpheme composition, especially since we would like to apply these methods to more complex morphological systems (e.g., agglutinative languages) where multiple morphemes are the norm.

# Unsupervised Consonant-Vowel Prediction over Hundreds of Languages

Young-Bum Kim and Benjamin Snyder

University of Wisconsin-Madison  
{ybkim,bsnyder}@cs.wisc.edu

## Abstract

In this paper, we present a solution to one aspect of the decipherment task: the prediction of consonants and vowels for an unknown language and alphabet. Adopting a classical Bayesian perspective, we perform posterior inference over hundreds of languages, leveraging knowledge of known languages and alphabets to uncover general linguistic patterns of typologically coherent language clusters. We achieve average accuracy in the unsupervised consonant/vowel prediction task of 99% across 503 languages. We further show that our methodology can be used to predict more fine-grained phonetic distinctions. On a three-way classification task between vowels, nasals, and non-nasal consonants, our model yields unsupervised accuracy of 89% across the same set of languages.

## 1 Introduction

Over the past centuries, dozens of lost languages have been deciphered through the painstaking work of scholars, often after decades of slow progress and dead ends. However, several important writing systems and languages remain undeciphered to this day.

In this paper, we present a successful solution to one aspect of the decipherment puzzle: automatically identifying basic phonetic properties of letters in an unknown alphabetic writing system. Our key idea is to use knowledge of the phonetic regularities encoded in known language vocabularies to automatically build a universal probabilistic model to successfully decode new languages.

Our approach adopts a classical Bayesian perspective. We assume that each language has an unobserved set of parameters explaining its

observed vocabulary. We further assume that each language-specific set of parameters was itself drawn from an unobserved common prior, shared across a cluster of typologically related languages. In turn, each cluster derives its parameters from a universal prior common to all language groups. This approach allows us to mix together data from languages with various levels of observations and perform joint posterior inference over unobserved variables of interest.

At the bottom layer (see Figure 1), our model assumes a language-specific data generating HMM over words in the language vocabulary. Each word is modeled as an emitted sequence of characters, depending on a corresponding Markov sequence of phonetic tags. Since individual letters are highly constrained in their range of phonetic values, we make the assumption of one-tag-per-observation-type (e.g. a single letter is constrained to be always a consonant or always a vowel across all words in a language).

Going one layer up, we posit that the language-specific HMM parameters are themselves drawn from informative, non-symmetric distributions representing a typologically coherent language grouping. By applying the model to a mix of languages with observed and unobserved phonetic sequences, the cluster-level distributions can be inferred and help guide prediction for unknown languages and alphabets.

We apply this approach to two small decipherment tasks:

1. predicting whether individual characters in an unknown alphabet and language represent vowels or consonants, and
2. predicting whether individual characters in an unknown alphabet and language represent vowels, nasals, or non-nasal consonants.

For both tasks, our approach yields considerable

success. We experiment with a data set consisting of vocabularies of 503 languages from around the world, written in a mix of Latin, Cyrillic, and Greek alphabets. In turn for each language, we consider it and its alphabet “unobserved” — we hide the graphic and phonetic properties of the symbols — while treating the vocabularies of the remaining languages as fully observed with phonetic tags on each of the letters.

On average, over these 503 leave-one-language-out scenarios, our model predicts consonant/vowel distinctions with 99% accuracy. In the more challenging task of vowel/nasal/non-nasal prediction, our model achieves average accuracy over 89%.

## 2 Related Work

The most direct precedent to the present work is a section in Knight et al. (2006) on universal phonetic decipherment. They build a trigram HMM with three hidden states, corresponding to consonants, vowels, and spaces. As in our model, individual characters are treated as the observed emissions of the hidden states. In contrast to the present work, they allow letters to be emitted by multiple states.

Their experiments show that the HMM trained with EM successfully clusters Spanish letters into consonants and vowels. They further design a more sophisticated finite-state model, based on linguistic universals regarding syllable structure and sonority. Experiments with the second model indicate that it can distinguish sonorous consonants (such as n, m, l, r) from non-sonorous consonants in Spanish. An advantage of the linguistically structured model is that its predictions do not require an additional mapping step from uninterpreted hidden states to linguistic categories, as they do with the HMM.

Our model and experiments can be viewed as complementary to the work of Knight et al., while also extending it to hundreds of languages. We use the simple HMM with EM as our baseline. In lieu of a linguistically designed model structure, we choose an empirical approach, allowing posterior inference over hundreds of known languages to guide the model’s decisions for the unknown script and language.

In this sense, our model bears some similarity to the decipherment model of Snyder et al. (2010), which used knowledge of a related language (Hebrew) in an elaborate Bayesian framework to de-

cipher the ancient language of Ugaritic. While the aim of the present work is more modest (discovering very basic phonetic properties of letters) it is also more widely applicable, as we don’t require detailed analysis of a known related language.

Other recent work has employed a similar perspective for tying learning across languages. Naseem et al. (2009) use a non-parametric Bayesian model over parallel text to jointly learn part-of-speech taggers across 8 languages, while Cohen and Smith (2009) develop a shared logistic normal prior to couple multilingual learning even in the absence of parallel text. In similar veins, Berg-Kirkpatrick and Klein (2010) develop hierarchically tied grammar priors over languages within the same family, and Bouchard-Côté et al. (2013) develop a probabilistic model of sound change using data from 637 Austronesian languages.

In our own previous work, we have developed the idea that *supervised* knowledge of some number of languages can help guide the unsupervised induction of linguistic structure, even in the absence of parallel text (Kim et al., 2011; Kim and Snyder, 2012)<sup>1</sup>. In the latter work we also tackled the problem of unsupervised phonemic prediction for unknown languages by using textual regularities of known languages. However, we assumed that the target language was written in a known (Latin) alphabet, greatly reducing the difficulty of the prediction task. In our present case, we assume no knowledge of any relationship between the writing system of the target language and known languages, other than that they are all alphabetic in nature.

Finally, we note some similarities of our model to some ideas proposed in other contexts. We make the assumption that each observation type (letter) occurs with only one hidden state (consonant or vowel). Similar constraints have been developed for part-of-speech tagging (Lee et al., 2010; Christodoulopoulos et al., 2011), and the power of type-based sampling has been demonstrated, even in the absence of explicit model constraints (Liang et al., 2010).

## 3 Model

Our generative Bayesian model over the observed vocabularies of hundreds of languages is

---

<sup>1</sup>We note that similar ideas were simultaneously proposed by other researchers (Cohen et al., 2011).

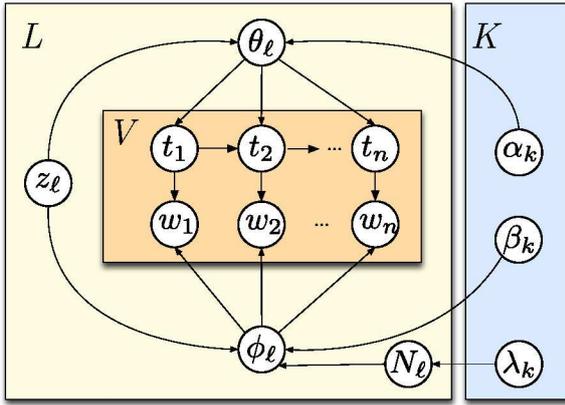

Figure 1: Graphical representation of our model. We have  $K$  language clusters,  $L$  languages, and  $V$  words in each language.

presented in Figure 1 and Algorithms 1, 2, and 3. We present a running commentary on the generative process from the bottom up, starting with Algorithm 3.

### 3.1 Data Generation

At the data generation stage (Algorithm 3), our model resembles an HMM. At each time step  $i$ , a tag  $t_i$  is selected according to a language-specific transition distribution  $\phi$ , indexed by the previous tag  $t_{i-1}$ . We note that in practice, we implemented a trigram version of the model,<sup>2</sup> but we present the bigram version here for notational clarity. We assume that our tagset includes phonetic categories of interest (such as consonant, vowel, nasal, etc) as well as a special tag to denote the boundaries between words.

An observation index  $j \in 1 \dots N_{\ell, t_i}$  is then drawn from the language-specific emission distribution  $\phi$ , indexed by the current tag  $t_i$ .  $N_{\ell, t_i}$  denotes the number of observation types associated with tag  $t_i$  in language  $\ell$ . Finally, we assume the existence of a deterministic function `orth` which maps each tag's observation indices to unique orthographic character symbols. This ensures that each observed character type corresponds to an observation index in exactly one tag category.

### 3.2 Language Generation

At the next stage up (Algorithm 2), we consider the generation of all language-specific parameters. This process begins by selecting a language cluster assignment  $z_\ell$  uniformly. The language cluster

<sup>2</sup>where the transition distribution is indexed by the previous *two* tags

---

#### Algorithm 1 Cluster Generation

---

```

for each cluster  $k \in 1 \dots K$  do
  for each tag  $t \in 1 \dots T$  do
    // emission Dirichlet parameter
     $\beta_{k,t} \sim \text{Unif}[0, 500]$ 

    // type-count Poisson parameter
     $\lambda_{k,t} \sim \text{Gamma}(g_1, g_2)$ 

    // transition Dirichlet parameters
    for each tag  $t'$  do
       $\alpha_{k,t,t'} \sim \text{Unif}[0, 500]$ 

```

---

---

#### Algorithm 2 Language Generation

---

```

for each language  $\ell$  do
  // draw cluster assignment
  cluster  $z_\ell \sim \text{Unif}[1 \dots K]$ 

  for each tag  $t$  do
    // generate tag type-count
     $N_{\ell,t} \sim \text{Poisson}(\lambda_{z_\ell,t})$ 

    // generate emission multinomial
     $\phi_{\ell,t,1} \dots \phi_{\ell,t,N_{\ell,t}} \sim \text{SymmDir}(\beta_{z_\ell,t})$ 

    // generate transition multinomial
     $\theta_{\ell,t,1} \dots \theta_{\ell,t,T} \sim \text{Dir}(\alpha_{z_\ell,t,1} \dots \alpha_{z_\ell,t,T})$ 

```

---

---

#### Algorithm 3 Data Generation

---

```

for each language  $\ell$  do
  for each position  $i$  do
    // transition to new tag token
     $t_i | t_{i-1} \sim \text{Cat}(\theta_{\ell,t_{i-1},1} \dots \theta_{\ell,t_{i-1},T})$ 

    // emit observation index token
     $j | t_i \sim \text{Cat}(\phi_{\ell,t_i,1} \dots \phi_{\ell,t_i,N_{\ell,t_i}})$ 

    // transcribe index token as character
     $w_i \leftarrow \text{orth}(\ell, j, t_i)$ 

```

---

provides priors over the HMM parameters. These priors include:

1. Poisson distributions over the number of observation types  $N_{\ell,t}$  associated with tag  $t$ ,
2. Dirichlet priors over transition distributions  $\theta$ , and
3. Dirichlet priors over emission distributions  $\phi$ .

For example, the cluster Poisson parameter over vowel observation types might be  $\lambda = 9$  (indicating 9 vowel letters on average for the cluster), while the parameter over consonant observation types might be  $\lambda = 20$  (indicating 20 consonant letters on average). These priors will be distinct for each language cluster and serve to characterize its general linguistic and typological properties.

We pause at this point to review the Dirichlet distribution in more detail. A  $k$ -dimensional Dirichlet with parameters  $\alpha_1 \dots \alpha_k$  defines a distribution over the  $k - 1$  simplex with the following density:

$$f(\theta_1 \dots \theta_k | \alpha_1 \dots \alpha_k) \propto \prod_i \theta_i^{\alpha_i - 1}$$

where  $\alpha_i > 0$ ,  $\theta_i > 0$ , and  $\sum_i \theta_i = 1$ . The Dirichlet serves as the *conjugate prior* for the Multinomial, meaning that the posterior  $\theta_1 \dots \theta_k | X_1 \dots X_n$  is again distributed as a Dirichlet (with updated parameters). It is instructive to reparameterize the Dirichlet with  $k + 1$  parameters:

$$f(\theta_1 \dots \theta_k | \alpha_0, \alpha'_1 \dots \alpha'_k) \propto \prod_i \theta_i^{\alpha_0 \alpha'_i - 1}$$

where  $\alpha_0 = \sum_i \alpha_i$ , and  $\alpha'_i = \alpha_i / \alpha_0$ . In this parameterization, we have  $\mathbb{E}[\theta_i] = \alpha'_i$ . In other words, the parameters  $\alpha'_i$  give the mean of the distribution, and  $\alpha_0$  gives the *precision* of the distribution. For large  $\alpha_0 \gg k$ , the distribution is highly peaked around the mean (conversely, when  $\alpha_0 \ll k$ , the mean lies in a valley).

Thus, the Dirichlet parameters of a language cluster characterize both the average HMMs of individual languages within the cluster, as well as how much we expect the HMMs to vary from the mean. In the case of emission distributions, we assume symmetric Dirichlet priors — i.e. one-parameter Dirichlets with densities given by  $f(\theta_1 \dots \theta_k | \beta) \propto \prod_i \theta_i^{\beta - 1}$ . This assumption is necessary, as we have no way to identify characters across languages in the decipherment scenario, and even the number of consonants and vowels (and thus multinomial/Dirichlet dimensions) can vary across the languages of a cluster. Thus, the mean of these Dirichlets will always be a uniform emission distribution. The single Dirichlet emission parameter per cluster will specify whether this mean is on a peak (large  $\beta$ ) or in a valley (small  $\beta$ ). In other words, it will control the expected *sparsity* of the resulting per-language emission multinomials.

In contrast, the transition Dirichlet parameters may be asymmetric, and thus very specific and informative. For example, one cluster may have the property that CCC consonant clusters are exceedingly rare across all its languages. This property would be expressed by a very small mean  $\alpha'_{\text{CCC}} \ll 1$  but large precision  $\alpha_0$ . Later we shall see examples of learned transition Dirichlet parameters.

### 3.3 Cluster Generation

The generation of the cluster parameters (Algorithm 1) defines the highest layer of priors for our model. As Dirichlets lack a standard conjugate prior, we simply use uniform priors over the interval  $[0, 500]$ . For the cluster Poisson parameters, we use conjugate Gamma distributions with vague priors.<sup>3</sup>

## 4 Inference

In this section we detail the inference procedure we followed to make predictions under our model. We run the procedure over data from 503 languages, assuming that all languages but one have observed character and tag sequences:  $w_1, w_2, \dots, t_1, t_2, \dots$ . Since each character type  $w$  is assumed to have a single tag category, this is equivalent to observing the character token sequence along with a character-type-to-tag mapping  $t_w$ . For the target language, we observe only character token sequence  $w_1, w_2, \dots$ .

We assume fixed and known parameter values only at the cluster generation level. Unobserved variables include (i) the cluster parameters  $\alpha, \beta, \lambda$ , (ii) the cluster assignments  $\mathbf{z}$ , (iii) the per-language HMM parameters  $\theta, \phi$  for all languages, and (iv) for the target language, the tag tokens  $t_1, t_2, \dots$  — or equivalently the character-type-to-tag mappings  $t_w$  — along with the observation type-counts  $N_t$ .

### 4.1 Monte Carlo Approximation

Our goal in inference is to predict the most likely tag  $t_{w,\ell}$  for each character type  $w$  in our target language  $\ell$  according to the posterior:

$$f(t_{w,\ell} | \mathbf{w}, \mathbf{t}_{-\ell}) = \int f(\mathbf{t}_\ell, \mathbf{z}, \alpha, \beta | \mathbf{w}, \mathbf{t}_{-\ell}) d\Theta \quad (1)$$

<sup>3</sup>(1,19) for consonants, (1,10) for vowels, (0.2, 15) for nasals, and (1,16) for non-nasal consonants.

where  $\Theta = (\mathbf{t}_{-w,\ell}, \mathbf{z}, \alpha, \beta)$ ,  $\mathbf{w}$  are the observed character sequences for all languages,  $\mathbf{t}_{-\ell}$  are the character-to-tag mappings for the observed languages,  $\mathbf{z}$  are the language-to-cluster assignments, and  $\alpha$  and  $\beta$  are all the cluster-level transition and emission Dirichlet parameters.

Sampling values  $(\mathbf{t}_\ell, \mathbf{z}, \alpha, \beta)_{n=1}^N$  from the integrand in Equation 1 allows us to perform the standard Monte Carlo approximation:

$$f(t_{w,\ell} = t \mid \mathbf{w}, \mathbf{t}_{-\ell}) \approx N^{-1} \sum_{n=1}^N \mathbb{I}(t_{w,\ell} = t \text{ in sample } n) \quad (2)$$

To maximize the Monte Carlo posterior, we simply take the most commonly sampled tag value for character type  $w$  in language  $\ell$ . Note that we leave out the language-level HMM parameters  $(\theta, \phi)$  as well as the cluster-level Poisson parameters  $\lambda$  from Equation 1 (and thus our sample space), as we can analytically integrate them out in our sampling equations.

## 4.2 Gibbs Sampling

To sample values  $(\mathbf{t}_\ell, \mathbf{z}, \alpha, \beta)$  from their posterior (the integrand of Equation 1), we use Gibbs sampling, a Monte Carlo technique that constructs a Markov chain over a high-dimensional sample space by iteratively sampling each variable conditioned on the currently drawn sample values for the others, starting from a random initialization. The Markov chain converges to an equilibrium distribution which is in fact the desired joint density (Geman and Geman, 1984). We now sketch the sampling equations for each of our sampled variables.

### Sampling $t_{w,\ell}$

To sample the tag assignment to character  $w$  in language  $\ell$ , we need to compute:

$$f(t_{w,\ell} \mid \mathbf{w}, \mathbf{t}_{-w,\ell}, \mathbf{t}_{-\ell}, \mathbf{z}, \alpha, \beta) \quad (3)$$

$$\propto f(\mathbf{w}_\ell, \mathbf{t}_\ell, N_\ell \mid \alpha_k, \beta_k, \mathbf{N}_{k-\ell}) \quad (4)$$

where  $N_\ell$  are the types-per-tag counts implied by the mapping  $\mathbf{t}_\ell$ ,  $k$  is the current cluster assignment for the target language ( $z_\ell = k$ ),  $\alpha_k$  and  $\beta_k$  are the cluster parameters, and  $\mathbf{N}_{k-\ell}$  are the types-per-tag counts for all languages currently assigned to the cluster, *other* than language  $\ell$ .

Applying the chain rule along with our model's conditional independence structure, we can further

re-write Equation 4 as a product of three terms:

$$f(N_\ell \mid \mathbf{N}_{k-\ell}) \quad (5)$$

$$f(t_1, t_2, \dots \mid \alpha_k) \quad (6)$$

$$f(w_1, w_2, \dots \mid N_\ell, t_1, t_2, \dots, \beta_k) \quad (7)$$

The first term is the posterior predictive distribution for the Poisson-Gamma compound distribution and is easy to derive. The second term is the tag transition predictive distribution given Dirichlet hyperparameters, yielding a familiar Polya urn scheme form. Removing terms that don't depend on the tag assignment  $t_{\ell,w}$  gives us:

$$\frac{\prod_{t,t'} (\alpha_{k,t,t'} + n(t,t'))^{[n'(t,t')]} \prod_t (\sum_{t'} \alpha_{k,t,t'} + n(t))^{[n'(t)]}}$$

where  $n(t)$  and  $n(t,t')$  are, respectively, unigram and bigram tag counts *excluding* those containing character  $w$ . Conversely,  $n'(t)$  and  $n'(t,t')$  are, respectively, unigram and bigram tag counts *including* those containing character  $w$ . The notation  $a^{[n]}$  denotes the ascending factorial:  $a(a+1) \cdots (a+n-1)$ . Finally, we tackle the third term, Equation 7, corresponding to the predictive distribution of emission observations given Dirichlet hyperparameters. Again, removing constant terms gives us:

$$\frac{\beta_{k,t}^{[n(w)]}}{\prod_{t'} N_{\ell,t'} \beta_{k,t'}^{[n'(t')]}}$$

where  $n(w)$  is the unigram count of character  $w$ , and  $n'(t')$  is the unigram count of tag  $t'$ , over all characters tokens (including  $w$ ).

### Sampling $\alpha_{k,t,t'}$

To sample the Dirichlet hyperparameter for cluster  $k$  and transition  $t \rightarrow t'$ , we need to compute:

$$\begin{aligned} f(\alpha_{k,t,t'} \mid \mathbf{t}, \mathbf{z}) \\ \propto f(\mathbf{t}, \mathbf{z} \mid \alpha_{z,t,t'}) \\ = f(\mathbf{t}_k \mid \alpha_{z,t,t'}) \end{aligned}$$

where  $\mathbf{t}_k$  are the tag sequences for all languages currently assigned to cluster  $k$ . This term is a predictive distribution of the multinomial-Dirichlet compound when the observations are grouped into *multiple* multinomials all with the same prior. Rather than inefficiently computing a product of Polya urn schemes (with many repeated ascending

factorials with the same base), we group common terms together and calculate:

$$\frac{\prod_{j=1}^n (\alpha_{k,t,t'} + k)^{n(j,k,t,t')}}{\prod_{j=1}^n (\sum_{t''} \alpha_{k,t,t''} + k)^{n(j,k,t)}}$$

where  $n(j, k, t)$  and  $n(j, k, t, t')$  are the numbers of languages currently assigned to cluster  $k$  which have *more than*  $j$  occurrences of unigram ( $t$ ) and bigram ( $t, t'$ ), respectively.

This gives us an efficient way to compute unnormalized posterior densities for  $\alpha$ . However, we need to sample from these distributions, not just compute them. To do so, we turn to slice sampling (Neal, 2003), a simple yet effective auxiliary variable scheme for sampling values from unnormalized but otherwise computable densities.

The key idea is to supplement the variable  $x$ , distributed according to unnormalized density  $\tilde{p}(x)$ , with a second variable  $u$  with joint density defined as  $p(x, u) \propto \mathbb{I}(u < \tilde{p}(x))$ . It is easy to see that  $\tilde{p}(x) \propto \int p(x, u) du$ . We then iteratively sample  $u|x$  and  $x|u$ , both of which are distributed uniformly across appropriately bounded intervals. Our implementation follows the pseudocode given in Mackay (2003).

### Sampling $\beta_{k,t}$

To sample the Dirichlet hyperparameter for cluster  $k$  and tag  $t$  we need to compute:

$$\begin{aligned} f(\beta_{k,t} | \mathbf{t}, \mathbf{w}, \mathbf{z}, \mathbf{N}) \\ \propto f(\mathbf{w} | \mathbf{t}, \mathbf{z}, \beta_{k,t}, \mathbf{N}) \\ \propto f(\mathbf{w}_k | \mathbf{t}_k, \beta_{k,t}, \mathbf{N}_k) \end{aligned}$$

where, as before,  $\mathbf{t}_k$  are the tag sequences for languages assigned to cluster  $k$ ,  $\mathbf{N}_k$  are the tag observation type-counts for languages assigned to the cluster, and likewise  $\mathbf{w}_k$  are the character sequences of all languages in the cluster. Again, we have the predictive distribution of the multinomial-Dirichlet compound with multiple grouped observations. We can apply the same trick as above to group terms in the ascending factorials for efficient computation. As before, we use slice sampling for obtaining samples.

### Sampling $z_\ell$

Finally, we consider sampling the cluster assignment  $z_\ell$  for each language  $\ell$ . We calculate:

$$\begin{aligned} f(z_\ell = k | \mathbf{w}, \mathbf{t}, \mathbf{N}, \mathbf{z}_{-\ell}, \alpha, \beta) \\ \propto f(\mathbf{w}_\ell, \mathbf{t}_\ell, N_\ell | \alpha_k, \beta_k, \mathbf{N}_{k-\ell}) \\ = f(N_\ell | \mathbf{N}_{k-\ell}) f(\mathbf{t}_\ell | \alpha_k) f(\mathbf{w}_\ell | \mathbf{t}_\ell, N_\ell, \beta_k) \end{aligned}$$

The three terms correspond to (1) a standard predictive distributions for the Poisson-gamma compound and (2) the standard predictive distributions for the transition and emission multinomial-Dirichlet compounds.

## 5 Experiments

To test our model, we apply it to a corpus of 503 languages for two decipherment tasks. In both cases, we will assume no knowledge of our target language or its writing system, other than that it is alphabetic in nature. At the same time, we will assume basic phonetic knowledge of the writing systems of the other 502 languages. For our first task, we will predict whether each character type is a consonant or a vowel. In the second task, we further subdivide the consonants into two major categories: the nasal consonants, and the non-nasal consonants. Nasal consonants are known to be perceptually very salient and are unique in being high frequency consonants in all known languages.

### 5.1 Data

Our data is drawn from online electronic translations of the Bible (<http://www.bible.is>, <http://www.crosswire.org/index.jsp>, and <http://www.biblegateway.com>). We have identified translations covering 503 distinct languages employing alphabetic writing systems. Most of these languages (476) use variants of the Latin alphabet, a few (26) use Cyrillic, and one uses the Greek alphabet. As Table 1 indicates, the languages cover a very diverse set of families and geographic regions, with Niger-Congo languages being the largest represented family.<sup>4</sup> Of these languages, 30 are either language isolates, or sole members of their language family in our data set.

For our experiments, we extracted unique word types occurring at least 5 times from the downloaded Bible texts. We manually identified vowel, nasal, and non-nasal character types. Since the letter ‘‘y’’ can frequently represent both a consonant and vowel, we exclude it from our evaluation. On average, the resulting vocabularies contain 2,388 unique words, with 19 consonant characters, two 2 nasal characters, and 9 vowels. We include the data as part of the paper.

<sup>4</sup>In fact, the Niger-Congo grouping is often considered the largest language family in the world in terms of distinct member languages.

## 5.2 Baselines and Model Variants

As our baseline, we consider the trigram HMM model of Knight et al. (2006), trained with EM. In all experiments, we run 10 random restarts of EM, and pick the prediction with highest likelihood. We map the induced tags to the gold-standard tag categories (1-1 mapping) in the way that maximizes accuracy.

We then consider three variants of our model. The simplest version, SYMM, disregards all information from other languages, using simple symmetric hyperparameters on the transition and emission Dirichlet priors (all hyperparameters set to 1). This allows us to assess the performance of

	Model	Cons vs Vowel	C vs V vs N
All	EM	93.37	74.59
	SYMM	95.99	80.72
	MERGE	97.14	86.13
	CLUST	<b>98.85</b>	<b>89.37</b>
Isolates	EM	94.50	74.53
	SYMM	96.18	78.13
	MERGE	97.66	86.47
	CLUST	<b>98.55</b>	<b>89.07</b>
Non-Latin	EM	92.93	78.26
	SYMM	95.90	79.04
	MERGE	96.06	83.78
	CLUST	<b>97.03</b>	<b>85.79</b>

Table 2: Average accuracy for EM baseline and model variants across 503 languages. **First panel:** results on all languages. **Second panel:** results for 30 isolate and singleton languages. **Third panel:** results for 27 non-Latin alphabet languages (Cyrillic and Greek). Standard Deviations across languages are about 2%.

our Gibbs sampling inference method for the type-based HMM, even in the absence of multilingual priors.

We next consider a variant of our model, MERGE, that assumes that *all* languages reside in a single cluster. This allows knowledge from the other languages to affect our tag posteriors in a generic, language-neutral way.

Finally, we consider the full version of our model, CLUST, with 20 language clusters. By allowing for the division of languages into smaller groupings, we hope to learn more specific parameters tailored for typologically coherent clusters of languages.

## 6 Results

The results of our experiments are shown in Table 2. In all cases, we report token-level accuracy (i.e. frequent characters count more than infrequent characters), and results are macro-averaged over the 503 languages. Variance across languages is quite low: the standard deviations are about 2 percentage points.

For the consonant vs. vowel prediction task, all tested models perform well. Our baseline, the EM-based HMM, achieves 93.4% accuracy. Simply using our Gibbs sampler with symmetric priors boosts the performance up to 96%. Performance

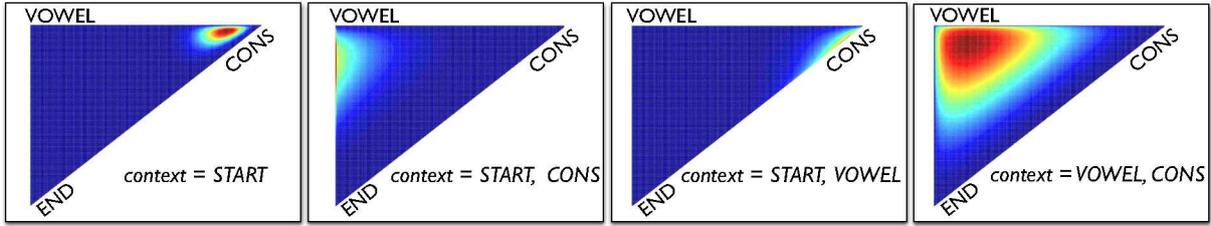

Figure 2: Inferred transition Dirichlet distributions for trigram MERGE model. Heat plots indicate Dirichlet densities over the 2-simplex.

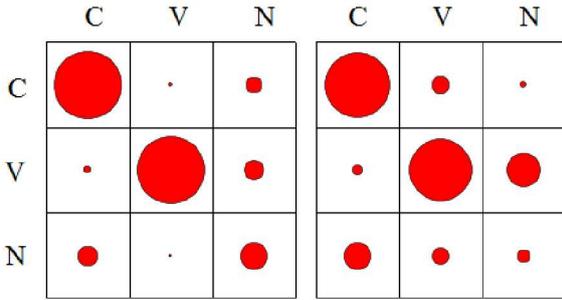

Figure 3: Confusion matrix for CLUST (left) and EM (right). Rows show true values, columns show predicted values. Size of blobs are proportional to counts.

increases again when we condition on other languages (MERGE), and we observe nearly 99% accuracy when allowing languages to cluster.

In the three-way nasal vs. non-nasal consonant vs. vowel prediction task, EM does not fare particularly well, only achieving 75% accuracy. As before, we see increasing performance gains for our model variants, culminating in almost 90% accuracy when the language clustering is used. The relatively weak performance of EM in this case should not be surprising: there is no *a priori* reason to expect any particular three-way classification to be the most salient clustering of letters from the perspective of EM. In contrast, our empirical multilingual approach allows the language-specific tag predictions to be guided by whatever values are set for the other, observed, languages.

We note that although a post-hoc mapping from inferred tags to true tags is necessary for both EM and SYMM, this is not the case for the final two variants of our model. Both MERGE and CLUST break symmetries over tags by way of the asymmetric posterior over transition Dirichlet parameters. Thus the reported accuracies are obtained without the need for any additional tag mappings.

Figure 2 further breaks down results for languages without any other related language in our collection. These include 9 language isolates and 21 singleton languages acting as sole representatives of their families. In addition, we show results for the 27 languages which employ non-Latin alphabets (26 Cyrillic and one Greek). Both of these scenarios are likely to occur in cases of lost language decipherment. We see similar results and trends, with somewhat lower performance in both cases.

## 7 Analysis

To further compare our model to the EM baseline, we show confusion matrices for the three-way classification task in Figure 3. We can immediately see that EM had considerable difficulty making nasal predictions. Most true nasals (third row) are assigned to the regular consonant category, and apparently EM mostly used the additional tag as a way to further subcategorize vowels. In contrast, our model does fairly well with nasals: most actual nasals are assigned to the nasal category (third row), while the plurality of nasal predictions are indeed true nasals (third column).

Next we examine the transition Dirichlet hyperparameters learned by our model. For the MERGE model, we infer a posterior over parameters shared by all 503 languages in our data set. Figure 2 shows MAP estimates of four of the Dirichlets governing transition probabilities from various contexts. As we can see, the learned hyperparameters yield highly asymmetric priors over transition distributions. Most languages like to start words with consonants, and after an initial consonant or vowel prefer to switch to the opposite category. In contrast, after a vowel-consonant sequence, languages can vary significantly in terms of the category favored next.

Figure 4 shows MAP transition Dirichlet hyperparameters of the CLUST model, when trained

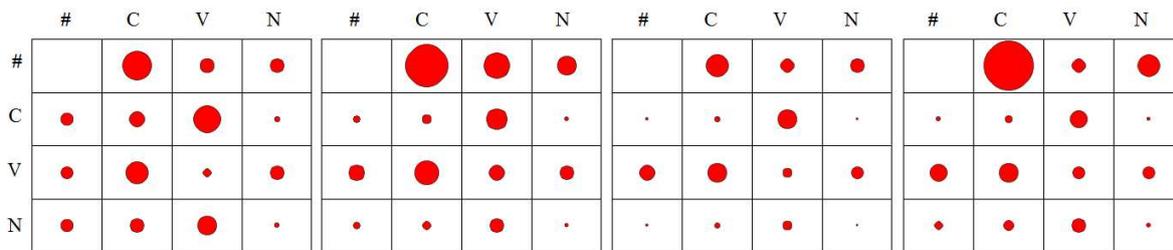

Figure 4: Inferred Dirichlet transition hyperparameters for bigram CLUST on three-way classification task with four latent clusters. Row gives starting state, column gives target state. Size of red blobs are proportional to magnitude of corresponding hyperparameters.

	0.91	22	0.53
	0.71	21	1.51
	0.24	17	3.06

Table 3: Plurality language families across 20 clusters. The columns indicate portion of languages in the plurality family, number of languages, and entropy over families.

with a bigram HMM with four language clusters. Examining just the first row, we see that the languages are partially grouped by their preference for the initial tag of words. All clusters favor languages which prefer initial consonants, though this preference is most weakly expressed in cluster 3. In contrast, both clusters 2 and 4 have very dominant tendencies towards consonant-initial languages, but differ in the relative weight given to languages preferring either vowels or nasals initially.

Finally, we examine the relationship between the induced clusters and language families in Table 3, for the trigram consonant vs. vowel CLUST model with 20 clusters. We see that for about half the clusters, there is a majority language family, most often Niger-Congo. We also observe distinctive clusters devoted to Austronesian and Quechuan languages. The largest two clusters are rather indistinct, without any single language family achieving more than 24% of the total.

## 8 Conclusion

In this paper, we presented a successful solution to one aspect of the decipherment task: the prediction of consonants and vowels for an unknown language and alphabet. Adopting a classical Bayesian perspective, we develop a model that performs posterior inference over hundreds of languages, leveraging knowledge of known languages to uncover general linguistic patterns of typologically coherent language clusters. Using this model, we automatically distinguish between consonant and vowel characters with nearly 99% accuracy across 503 languages. We further experimented on a three-way classification task involving nasal characters, achieving nearly 90% accuracy.

Future work will take us in several new directions: first, we would like to move beyond the assumption of an alphabetic writing system so that we can apply our method to undeciphered syllabic scripts such as Linear A. We would also like to extend our methods to achieve finer-grained resolution of phonetic properties beyond nasals, consonants, and vowels.

# Improving Text Simplification Language Modeling Using Unsimplified Text Data

David Kauchak

Middlebury College

Middlebury, VT 05753

dkauchak@middlebury.edu

## Abstract

In this paper we examine language modeling for text simplification. Unlike some text-to-text translation tasks, text simplification is a monolingual translation task allowing for text in both the input and output domain to be used for training the language model. We explore the relationship between normal English and simplified English and compare language models trained on varying amounts of text from each. We evaluate the models intrinsically with perplexity and extrinsically on the lexical simplification task from SemEval 2012. We find that a combined model using both simplified and normal English data achieves a 23% improvement in perplexity and a 24% improvement on the lexical simplification task over a model trained only on simple data. Post-hoc analysis shows that the additional unsimplified data provides better coverage for unseen and rare  $n$ -grams.

## 1 Introduction

An important component of many text-to-text translation systems is the language model which predicts the likelihood of a text sequence being produced in the output language. In some problem domains, such as machine translation, the translation is between two distinct languages and the language model can only be trained on data in the output language. However, some problem domains (e.g. text compression, text simplification and summarization) can be viewed as monolingual translation tasks, translating between text variations within a single language. In these monolingual problems, text *could* be used from both the input and output domain to train a language model. In this paper, we investigate this possibility for text

simplification where both simplified English text and normal English text are available for training a simple English language model.

Table 1 shows the  $n$ -gram overlap proportions in a sentence aligned data set of 137K sentence pairs from aligning Simple English Wikipedia and English Wikipedia articles (Coster and Kauchak, 2011a).<sup>1</sup> The data highlights two conflicting views: does the benefit of additional data outweigh the problem of the source of the data? Throughout the rest of this paper we refer to sentences/articles/text from English Wikipedia as *normal* and sentences/articles/text from Simple English Wikipedia as *simple*.

On the one hand, there is a strong correspondence between the simple and normal data. At the word level 96% of the simple words are found in the normal corpus and even for  $n$ -grams as large as 5, more than half of the  $n$ -grams can be found in the normal text. In addition, the normal text does represent English text and contains many  $n$ -grams not seen in the simple corpus. This extra information may help with data sparsity, providing better estimates for rare and unseen  $n$ -grams.

On the other hand, there is still only modest overlap between the sentences for longer  $n$ -grams, particularly given that the corpus is sentence-aligned and that 27% of the sentence pairs in this aligned data set are identical. If the word distributions were very similar between simple and normal text, then the overlap proportions between the two languages would be similar regardless of which direction the comparison is made. Instead, we see that the normal text has more varied language and contains more  $n$ -grams. Previous research has also shown other differences between simple and normal data sources that could impact language model performance including average number of syllables, reading

<sup>1</sup><http://www.cs.middlebury.edu/~dkauchak/simplification>

<i>n</i> -gram size:	1	2	3	4	5
simple in normal	0.96	0.80	0.68	0.61	0.55
normal in simple	0.87	0.68	0.58	0.51	0.46

Table 1: The proportion of *n*-grams that overlap in a corpus of 137K sentence-aligned pairs from Simple English Wikipedia and English Wikipedia.

complexity, and grammatical complexity (Napoles and Dredze, 2010; Zhu et al., 2010; Coster and Kauchak, 2011b). In addition, for some monolingual translation domains, it has been argued that it is not appropriate to train a language model using data from the input domain (Turner and Charniak, 2005).

Although this question arises in other monolingual translation domains, text simplification represents an ideal problem area for analysis. First, simplified text data is available in reasonable quantities. Simple English Wikipedia contains more than 60K articles written in simplified English. This is not the case for all monolingual translation tasks (Knight and Marcu, 2002; Cohn and Lapata, 2009). Second, the quantity of simple text data available is still limited. After pre-processing, the 60K articles represents less than half a million sentences which is orders of magnitude smaller than the amount of normal English data available (for example the English Gigaword corpus (David Graff, 2003)). Finally, many recent text simplification systems have utilized language models trained only on simplified data (Zhu et al., 2010; Woodsend and Lapata, 2011; Coster and Kauchak, 2011a; Wubben et al., 2012); improvements in simple language modeling could translate into improvements for these systems.

## 2 Related Work

If we view the normal data as out-of-domain data, then the problem of combining simple and normal data is similar to the language model domain adaption problem (Suzuki and Gao, 2005), in particular *cross-domain adaptation* (Bellegarda, 2004) where a domain-specific model is improved by incorporating additional general data. Adaptation techniques have been shown to improve language modeling performance based on perplexity (Rosenfeld, 1996) and in application areas such as speech transcription (Bacchiani and Roark, 2003) and machine translation (Zhao et al., 2004), though no previous research has examined the lan-

guage model domain adaptation problem for text simplification. Pan and Yang (2010) provide a survey on the related problem of domain adaptation for machine learning (also referred to as “transfer learning”), which utilizes similar techniques. In this paper, we explore some basic adaptation techniques, however this paper is not a comparison of domain adaptation techniques for language modeling. Our goal is more general: to examine the relationship between simple and normal data and determine whether normal data is helpful. Previous domain adaptation research is complementary to our experiments and could be explored in the future for additional performance improvements.

Simple language models play a role in a variety of text simplification applications. Many recent statistical simplification techniques build upon models from machine translation and utilize a simple language model during simplification/decoding both in English (Zhu et al., 2010; Woodsend and Lapata, 2011; Coster and Kauchak, 2011a; Wubben et al., 2012) and in other languages (Specia, 2010). Simple English language models have also been used as predictive features in other simplification sub-problems such as lexical simplification (Specia et al., 2012) and predicting text simplicity (Eickhoff et al., 2010).

Due to data scarcity, little research has been done on language modeling in other monolingual translation domains. For text compression, most systems are trained on uncompressed data since the largest text compression data sets contain only a few thousand sentences (Knight and Marcu, 2002; Galley and McKeown, 2007; Cohn and Lapata, 2009; Nomoto, 2009). Similarly for summarization, systems that have employed language models trained only on unsummarized text (Banko et al., 2000; Daume and Marcu, 2002).

## 3 Corpus

We collected a data set from English Wikipedia and Simple English Wikipedia with the former representing normal English and the latter simple English. Simple English Wikipedia has been previously used for many text simplification approaches (Zhu et al., 2010; Yatskar et al., 2010; Biran et al., 2011; Coster and Kauchak, 2011a; Woodsend and Lapata, 2011; Wubben et al., 2012) and has been shown to be simpler than normal English Wikipedia by both automatic measures and human perception (Coster and Kauchak, 2011b;

	simple	normal
sentences	385K	2540K
words	7.15M	64.7M
vocab size	78K	307K

Table 2: Summary counts for the simple-normal article aligned data set consisting of 60K article pairs.

Woodsend and Lapata, 2011). We downloaded **all** articles from Simple English Wikipedia then removed stubs, navigation pages and any article that consisted of a single sentence, resulting in 60K simple articles.

To partially normalize for content and source differences we generated a document aligned corpus for our experiments. We extracted the corresponding 60K normal articles from English Wikipedia based on the article title to represent the normal data. We held out 2K article pairs for use as a testing set in our experiments. The extracted data set is available for download online.<sup>2</sup>

Table 2 shows count statistics for the collected data set. Although the simple and normal data contain the same number of articles, because normal articles tend to be longer and contain more content, the normal side is an order of magnitude larger.

## 4 Language Model Evaluation: Perplexity

To analyze the impact of data source on simple English language modeling, we trained language models on varying amounts of simple data, normal data, and a combination of the two. For our first task, we evaluated these language models using perplexity based on how well they modeled the simple side of the held-out data.

### 4.1 Experimental Setup

We used trigram language models with interpolated Kneser-Kney discounting trained using the SRI language modeling toolkit (Stolcke, 2002). To ensure comparability, all models were closed vocabulary with the same vocabulary set based on the words that occurred in the simple side of the training corpus, though similar results were seen for other vocabulary choices. We generated different models by varying the size and type of training

<sup>2</sup><http://www.cs.middlebury.edu/~dkauchak/simplification>

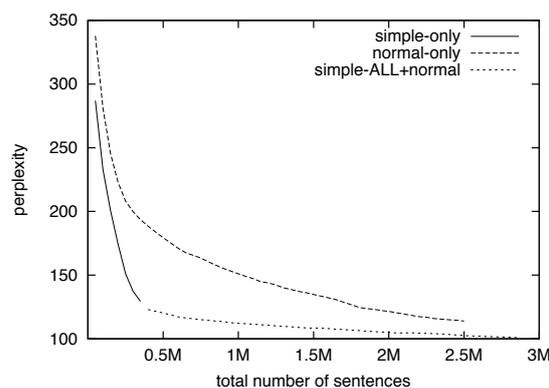

Figure 1: Language model perplexities on the held-out test data for models trained on increasing amounts of data.

data:

- **simple-only**: simple sentences only
- **normal-only**: normal sentences only
- **simple- $X$ +normal**:  $X$  simple sentences combined with a varying number of normal sentences

To evaluate the language models we calculated the model *perplexity* (Chen et al., 1998) on the simple side of the held-out data. The test set consisted of 2K simple English articles with 7,799 simple sentences and 179K words. Perplexity measures how likely a model finds a test set, with lower scores indicating better performance.

### 4.2 Perplexity Results

Figure 1 shows the language model perplexities for the three types of models for increasing amounts of training data. As expected, when trained on the same amount of data, the language models trained on simple data perform significantly better than language models trained on normal data. In addition, as we increase the amount of data, the simple-only model improves more than the normal-only model.

However, the results also show that the normal data does have some benefit. The perplexity for the *simple-ALL+normal* model, which starts with *all* available simple data, continues to improve as normal data is added resulting in a 23% improvement over the model trained with only simple data (from a perplexity of 129 down to 100). Even by itself the normal data does have value. The normal-only model achieves a slightly better perplexity than the simple-only model, though only by utilizing an order of magnitude more data.

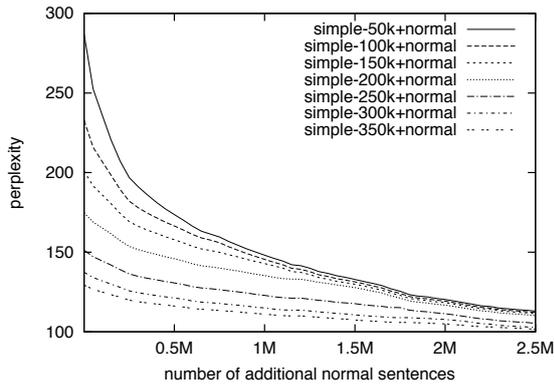

Figure 2: Language model perplexities for combined simple-normal models. Each line represents a model trained on a different amount of simple data as normal data is added.

To better understand how the amount of simple and normal data impacts perplexity, Figure 2 shows perplexity scores for models trained on varying amounts of simple data as we add increasing amounts of normal data. We again see that normal data is beneficial; regardless of the amount of simple data, adding normal data improves perplexity. This improvement is most beneficial when simple data is limited. Models trained on less simple data achieved larger performance increases than those models trained on more simple data.

Figure 2 also shows again that simple data is more valuable than normal data. For example, the simple-only model trained on 250K sentences achieves a perplexity of approximately 150. To achieve this same perplexity level starting with 200K simple sentences requires an additional 300K normal sentences, or starting with 100K simple sentences an additional 850K normal sentences.

### 4.3 Language Model Adaptation

In the experiments above, we generated the language models by treating the simple and normal data as one combined corpus. This approach has the benefit of simplicity, however, better performance for combining related corpora has been seen by domain adaptation techniques which combine the data in more structured ways (Bacchiani and Roark, 2003). *Our goal for this paper is not to explore domain adaptation techniques, but to determine if normal data is useful for the simple language modeling task.* However, to provide another dimension for comparison and to understand

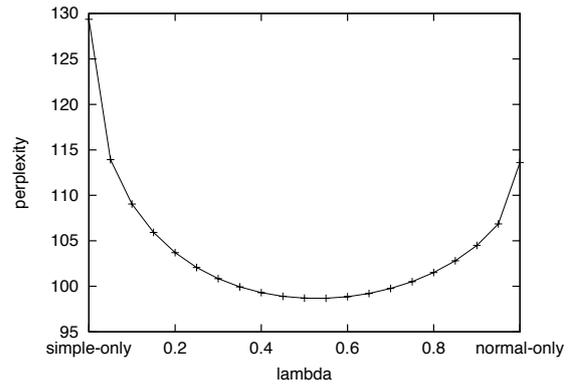

Figure 3: Perplexity scores for a linearly interpolated model between the simple-only model and the normal-only model for varying lambda values.

if domain adaptation techniques may be useful, we also investigated a linearly interpolated language model.

A linearly interpolated language model combines the probabilities of two or more language models as a weighted sum. In our case, the interpolated model combines the simple model estimate,  $p_s(w_i|w_{i-2}, w_{i-1})$ , and the normal model estimate,  $p_n(w_i|w_{i-2}, w_{i-1})$ , linearly (Jelinek and Mercer, 1980; Hsu, 2007):

$$p_{interpolated}(w_i|w_{i-2}, w_{i-1}) = \lambda p_n(w_i|w_{i-2}, w_{i-1}) + (1 - \lambda) p_s(w_i|w_{i-2}, w_{i-1})$$

where  $0 \leq \lambda \leq 1$ .

Figure 3 shows perplexity scores for varying lambda values ranging from the simple-only model on the left with  $\lambda = 0$  to the normal-only model on the right with  $\lambda = 1$ . As with the previous experiments, adding normal data improves perplexity. In fact, with a lambda of 0.5 (equal weight between the models) the performance is slightly better than the aggregate approaches above with a perplexity of 98. The results also highlight the balance between simple and normal data; normal data is not as good as simple data and adding too much of it can cause the results to degrade.

## 5 Language Model Evaluation: Lexical Simplification

Currently, no automated methods exist for evaluating sentence-level or document-level text simplification systems and manual evaluation is time-consuming, expensive and has not been validated. Because of these evaluation challenges, we chose to evaluate the language models extrinsi-

Word:	<i>tight</i>
Context:	With the physical market as <b>tight</b> as it has been in memory, silver could fly at any time.
Candidates:	constricted, pressurised, low, high-strung, tight
Human ranking:	tight, low, constricted, pressurised, high-strung

Figure 4: A lexical substitution example from the SemEval 2012 data set.

cally based on the lexical simplification task from SemEval 2012 (Specia et al., 2012).

Lexical simplification is a sub-problem of the general text simplification problem (Chandrasekar and Srinivas, 1997); a sentence is simplified by substituting words or phrases in the sentence with “simpler” variations. Lexical simplification approaches have been shown to improve the readability of texts (Urano, 2000; Leroy et al., 2012), are useful in domains such as medical texts where major content changes are restricted, and they may be useful as a pre- or post-processing step for general simplification systems.

## 5.1 Experimental Setup

Examples from the lexical simplification data set from SemEval 2012 consist of three parts:  $w$ , the word to be simplified;  $s_1, \dots, s_{i-1}, w, s_{i+1}, \dots, s_n$ , a sentence containing the word; and,  $r_1, r_2, \dots, r_m$ , a list of candidate simplifications for  $w$ . The goal of the task is to rank the candidate simplifications according to their simplicity in the context of the sentence. Figure 4 shows an example from the data set. The data set contains a development set of 300 examples and a test set of 1710 examples.<sup>3</sup> For our experiments, we evaluated the models on the test set.

Given a language model  $p(\cdot)$  and a lexical simplification example, we ranked the list of candidates based on the probability the language model assigns to the sentence with the candidate simplification inserted in context. Specifically, we scored each candidate simplification  $r_j$  by

$$p(s_1 \dots s_{i-1} r_j s_{i+1} \dots s_n)$$

and then ranked them based on this score. For example, to calculate the ranking for the example in Figure 4 we calculate the probability of each of:

- With the physical market as *constricted* as it has been ...
- With the physical market as *pressurised* as it has been ...
- With the physical market as *low* as it has been ...
- With the physical market as *high-strung* as it has been ...
- With the physical market as *tight* as it has been ...

with the language model and then rank them by their probability. *We do not suggest this as a com-*

<sup>3</sup><http://www.cs.york.ac.uk/semeval-2012/task1/>

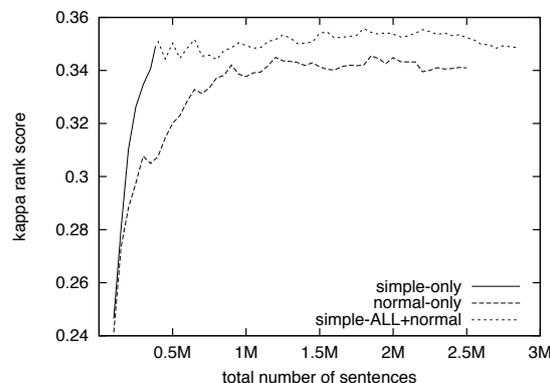

Figure 5: Kappa rank scores for the models trained on increasing amounts of data.

plete lexical substitution system, but it was a common feature for many of the submitted systems, it performs well relative to the other systems, and it allows for a concrete comparison between the language models on a simplification task.

To evaluate the rankings, we use the metric from the SemEval 2012 task, the Cohen’s kappa coefficient (Landis and Koch, 1977) between the system ranking and the human ranking, which we denote the “kappa rank score”. See Specia et al. (2012) for the full details of how the evaluation metric is calculated.

We use the same setup for training the language models as in the perplexity experiments except the models are open vocabulary instead of closed. Open vocabulary models allow for the language models to better utilize the varying amounts of data and since the lexical simplification problem only requires a comparison of probabilities within a given model to produce the final ranking, we do not need the closed vocabulary requirement.

## 5.2 Lexical Simplification Results

Figure 5 shows the kappa rank scores for the simple-only, normal-only and combined models. As with the perplexity results, for similar amounts of data the simple-only model performs better than the normal-only model. We also again see that the performance difference between the two models grows as the amount of data increases. However,

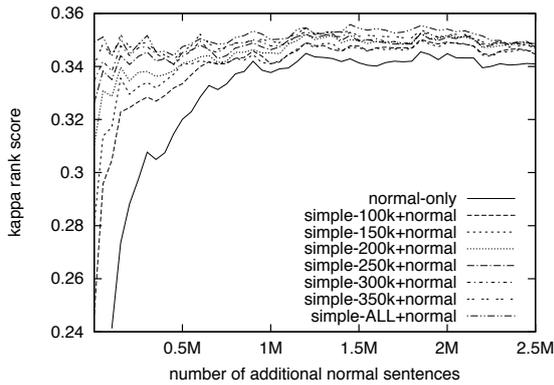

Figure 6: Kappa rank scores for models trained with varying amounts of simple data combined with increasing amounts of normal data.

unlike the perplexity results, simply appending additional normal data to the entire simple data set does not improve the performance of the lexical simplifier.

To determine if additional normal data improves the performance for models trained on smaller amounts of simple data, Figure 6 shows the kappa rank scores for models trained on different amounts of simple data as additional normal data is added. For smaller amounts of simple data adding normal data does improve the kappa rank score. For example, a language model trained with 100K simple sentences achieves a score of 0.246 and is improved by almost 40% to 0.344 by adding all of the additional normal data. Even the performance of a model trained with 300K simple sentences is increased by 3% (0.01 improvement in kappa rank score) by adding normal data.

### 5.3 Language Model Adaptation

The results in the previous section show that adding normal data to a simple data set can improve the lexical simplifier if the amount of simple data is limited. To investigate this benefit further, we again generated linearly interpolated language models between the simple-only model and the normal-only model. Figure 7 shows results for the same experimental design as Figure 6 with varying amounts of simple and normal data, however, rather than appending the normal data we trained the models separately and created a linearly interpolated model as described in Section 4.3. The best lambda was chosen based on a linear search optimized on the SemEval 2012 development set.

For all starting amounts of simple data, interpo-

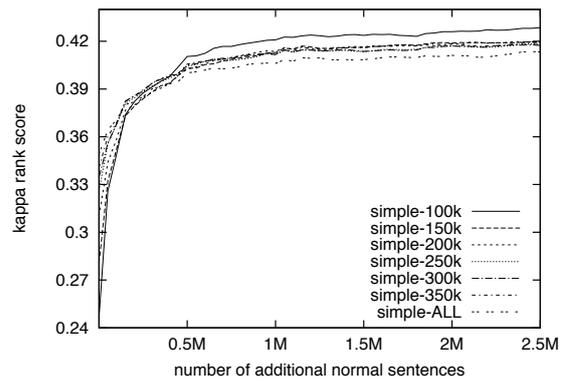

Figure 7: Kappa rank scores for linearly interpolated models between simple-only and normal-only models trained with varying amounts of simple and normal data.

lating the simple model with the normal model results in a large increase in the kappa rank score. *Combining the model trained on all the simple data with the model trained on all the normal data achieves a score of 0.419, an improvement of 23% over the model trained on only simple data.* Although our goal was not to create the best lexical simplification system, this approach would have ranked 6th out of 11 submitted systems in the SemEval 2012 competition (Specia et al., 2012).

Interestingly, although the performance of the simple-only models varied based on the amount of simple data, when these models are interpolated with a model trained on normal data, the performance tended to converge. This behavior is also seen in Figure 6, though to a lesser extent. This may indicate that for some tasks like lexical simplification, only a modest amount of simple data is required when combining with additional normal data to achieve reasonable performance.

## 6 Why Does Unsimplified Data Help?

For both the perplexity experiments and the lexical simplification experiments, utilizing additional normal data resulted in large performance improvements; using **all** of the simple data available, performance is still significantly improved when combined with normal data. In this section, we investigate why the additional normal data is beneficial for simple language modeling.

### 6.1 More $n$ -grams

Intuitively, adding normal data provides additional English data to train on. Most language models are

	Perplexity test data			Lexical simplification		
	simple	normal	% inc.	simple	normal	% inc.
1-grams	0.85	0.93	9.4%	0.74	0.78	6.2%
2-grams	0.66	0.82	24%	0.34	0.54	56%
3-grams	0.39	0.57	46%	0.088	0.19	117%

Table 3: Proportion of  $n$ -grams in the test sets that occur in the simple and normal training data sets.

trained using a smoothed version of the maximum likelihood estimate for an  $n$ -gram. For trigrams, this is:

$$p(a|bc) = \frac{\text{count}(abc)}{\text{count}(bc)}$$

where  $\text{count}(\cdot)$  is the number of times the  $n$ -gram occurs in the training corpus. For interpolated and backoff  $n$ -gram models, these counts are smoothed based on the probabilities of lower order  $n$ -gram models, which are in-turn calculated based on counts from the corpus.

We hypothesize that the key benefit of additional normal data is access to more  $n$ -gram counts and therefore better probability estimation, particularly for  $n$ -grams in the simple corpus that are unseen or have low frequency. For  $n$ -grams that have never been seen before, the normal data provides some estimate from English text. This is particularly important for unigrams (i.e. words) since there is no lower order model to gain information from and most language models assume a uniform prior on unseen words, treating them all equally. For  $n$ -grams that have been seen but are rare, the additional normal data can help provide better probability estimates. Because frequencies tend to follow a Zipfian distribution, these rare  $n$ -grams make up a large portion of  $n$ -grams in real data (Ha et al., 2003).

To partially validate this hypothesis, we examined the  $n$ -gram overlap between the  $n$ -grams in the training data and the  $n$ -grams in the test sets from the two tasks. Table 3 shows the percentage of unigrams, bigrams and trigrams from the two test sets that are found in the simple and normal training data.

For all  $n$ -gram sizes the normal data contained more test set  $n$ -grams than the simple data. Even at the unigram level, the normal data contained significantly more of the test set unigrams than the simple data. On the perplexity data set, the 9.4% increase in word occurrence between the simple and normal data set represents an over 50% reduction in the number of out of vocabulary words. For

	Perplexity test data		Lexical simplification	
	simple + normal	% inc. over normal	simple + normal	% inc. over normal
1-grams	0.93	0.2%	0.78	0.0%
2-grams	0.83	0.8%	0.54	1.1%
3-grams	0.58	2.5%	0.20	2.6%

Table 4: Proportion of  $n$ -grams in the test sets that occur in the *combination* of both the simple and normal data.

larger  $n$ -grams, the difference between the simple and normal data sets are even more pronounced. On the lexical simplification data the normal data contained more than twice as many test trigrams as the simple data. These additional  $n$ -grams allow for better probability estimates on the test data and therefore better performance on the two tasks.

## 6.2 The Role of Normal Data

Estimation of rare events is one component of language model performance, but other factors also impact performance. Table 4 shows the test set  $n$ -gram overlap on the combined data set of simple and normal data. Because the simple and normal data come from the same content areas, the simple data provides little additional coverage if the normal data is already used. For example, adding the simple data to the normal data only increases the number of seen unigrams by 0.2%, representing only about 600 new words. However, the experiments above showed the combined models performed much better than models trained only on normal data.

This discrepancy highlights the key problem with normal data: it is out-of-domain data. While it shares some characteristics with the simple data, it represents a different distribution over the language. To make this discrepancy more explicit, we created a sentence aligned data set by aligning the simple and normal articles using the approach from Coster and Kauchak (2011b). This approach has been previously used for aligning English Wikipedia and Simple English Wikipedia with reasonable accuracy. The resulting data set contains 150K aligned simple-normal sentence pairs.

Figure 8 shows the perplexity scores for language models trained on this data set. Because the data is aligned and therefore similar, we see the perplexity curves run parallel to each other as more data is added. However, even though these

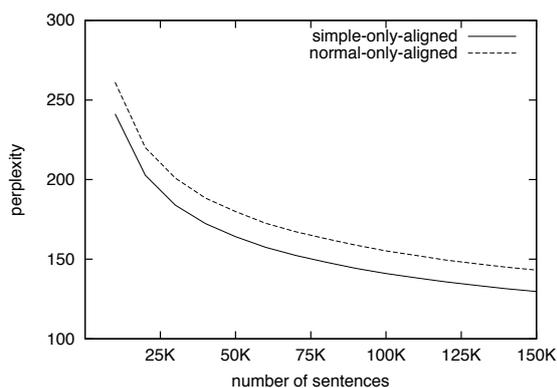

Figure 8: Language model perplexities for models trained on increasing data sizes for a simple-normal sentence aligned data set.

sentences represent the same content, the language use is different between simple and normal and the normal data performs consistently worse.

### 6.3 A Balance Between Simple and Normal

Examining the optimal lambda values for the linearly interpolated models also helps understand the role of the normal data. On the perplexity task, the best perplexity results were obtained with a lambda of 0.5, or an equal weighting between the simple and normal models. Even though the normal data contained six times as many sentences and nine times as many words, the best modeling performance balanced the quality of the simple model with the coverage of the normal model.

For the simplification task, the optimal lambda value determined on the development set was 0.98, with a very strong bias towards the simple model. Only when the simple model did not provide differentiation between lexical choices will the normal model play a role in selecting the candidates. For the lexical simplification task, the role of the normal model is even more clear: to handle rare occurrences not covered by the simple model and to smooth the simple model estimates.

## 7 Conclusions and Future Work

In the experiments above we have shown that on two different tasks utilizing additional normal data improves the performance of simple English language models. On the perplexity task, the combined model achieved a performance improvement of 23% over the simple-only model and on the lexical simplification task, the combined model achieved a 24% improvement. These improve-

ments are achieved over a simple-only model that uses *all* simple English data currently available in this domain.

For both tasks, the best improvements were seen when using language model adaptation techniques, however, the adaptation results also indicated that the role of normal data is partially task dependent. On the perplexity task, the best results were achieved with an equal weighting between the simple-only and normal-only model. However, on the lexical simplification task, the best results were achieved with a very strong bias towards the simple-only model. For other simplification tasks, the optimal parameters will need to be investigated.

For many of the experiments, combining a smaller amount of simple data (50K-100K sentences) with normal data achieved results that were similar to larger simple data set sizes. For example, on the lexical simplification task, when using a linearly interpolated model, the model combining 100K simple sentences with all the normal data achieved comparable results to the model combining all the simple sentences with all the normal data. This is encouraging for other monolingual domains such as text compression or text simplification in non-English languages where less data is available.

There are still a number of open research questions related to simple language modeling. First, further experiments with larger normal data sets are required to understand the limits of adding out-of-domain data. Second, we have only utilized data from Wikipedia for normal text. Many other text sources are available and the impact of not only size, but also of domain should be investigated. Third, it still needs to be determined how language model performance will impact sentence-level and document-level simplification approaches. In machine translation, improved language models have resulted in significant improvements in translation performance (Brants et al., 2007). Finally, in this paper we only investigated linearly interpolated language models. Many other domain adaptations techniques exist and may produce language models with better performance.

# Combining Referring Expression Generation and Surface Realization: A Corpus-Based Investigation of Architectures

Sina Zarriß      Jonas Kuhn

Institut für maschinelle Sprachverarbeitung

University of Stuttgart, Germany

sina.zarriess, jonas.kuhn@ims.uni-stuttgart.de

## Abstract

We suggest a generation task that integrates discourse-level referring expression generation and sentence-level surface realization. We present a data set of German articles annotated with deep syntax and referents, including some types of implicit referents. Our experiments compare several architectures varying the order of a set of trainable modules. The results suggest that a revision-based pipeline, with intermediate linearization, significantly outperforms standard pipelines or a parallel architecture.

## 1 Introduction

Generating well-formed linguistic utterances from an abstract non-linguistic input involves making a multitude of conceptual, discourse-level as well as sentence-level, lexical and syntactic decisions. Work on rule-based natural language generation (NLG) has explored a number of ways to combine these decisions in an architecture, ranging from integrated systems where all decisions happen jointly (Appelt, 1982) to strictly sequential pipelines (Reiter and Dale, 1997). While integrated or interactive systems typically face issues with efficiency and scalability, they can directly account for interactions between discourse-level planning and linguistic realization. For instance, Rubinfoff (1992) mentions Example (1) where the sentence planning component needs to have access to the lexical knowledge that “order” and not “home” can be realized as a verb in English.

- (1)    a.    \*John homed him with an order.  
      b.    John ordered him home.

In recent data-driven generation research, the focus has somewhat shifted from full data-to-text systems to approaches that isolate well-defined

subproblems from the NLG pipeline. In particular, the tasks of surface realization and referring expression generation (REG) have received increasing attention using a number of available annotated data sets (Belz and Kow, 2010; Belz et al., 2011). While these single-task approaches have given rise to many insights about algorithms and corpus-based modelling for specific phenomena, they can hardly deal with aspects of the architecture and interaction between generation levels.

This paper suggests a middle ground between full data-to-text and single-task generation, combining two well-studied NLG problems. We integrate a discourse-level approach to REG with sentence-level surface realization in a data-driven framework. We address this integrated task with a set of components that can be trained on flexible inputs which allows us to systematically explore different ways of arranging the components in a generation architecture. Our main goal is to investigate how different architectural set-ups account for interactions between generation decisions at the level of referring expressions (REs), syntax and word order.

Our basic set-up is inspired from the Generating Referring Expressions in Context (GREC) tasks, where candidate REs have to be assigned to instances of a referent in a Wikipedia article (Belz and Kow, 2010). We have created a dataset of German texts with annotations that extend this standard in three substantial ways: (i) our domain consists of articles about *robbery* events that mainly involve two main referents, a *victim* and a *perpetrator* (*perp*), (ii) annotations include deep and shallow syntactic relations similar to the representations used in (Belz et al., 2011) (iii) annotations include empty referents, as e.g. in passives and nominalizations directing attention to the phenomenon of implicit reference, which is largely understudied in NLG. Figure 1 presents an example for a deep syntax tree with underspecified RE

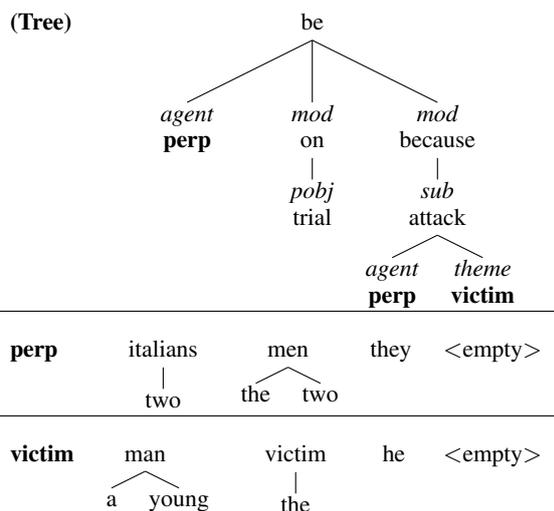

Figure 1: Underspecified tree with RE candidates

slots and lists of candidates REs for each referent.

Applying a strictly sequential pipeline on our data, we observe incoherent system output that is related to an interaction of generation levels, very similar to the interleaving between sentence planning and lexicalization in Example (1). A pipeline that first inserts REs into the underspecified tree in Figure 1, then generates syntax and finally linearizes, produces inappropriate sentences like (2-a).

- (2) a. \*[The two men]<sub>p</sub> are on trial because of an attack by [two italians]<sub>p</sub> on [a young man]<sub>v</sub>.  
 b. [Two italians]<sub>p</sub> are on trial because of an attack on [a young man]<sub>v</sub>.

Sentence (2-a) is incoherent because the syntactic surface obscures the intended meaning that “two italians” and “the two men” refer to the same referent. In order to generate the natural Sentence (2-b), the RE component needs information about linear precedence of the two *perp* instances and the nominalization of “attack”. These types of interactions between referential and syntactic realization have been thoroughly discussed in theoretical accounts of textual coherence, as e.g. Centering Theory (Grosz et al., 1995).

The integrated modelling of REG and surface realization leads to a considerable expansion of the choice space. In a sentence with 3 referents that each have 10 RE candidates and can be freely ordered, the number of surface realizations increases from 6 to  $6 \cdot 10^3$ , assuming that the remaining words can not be syntactically varied. Thus, even when the generation problem is restricted to these tasks, a fully integrated architecture faces scalability issues on realistic corpus data.

In this work, we assume a modular set-up of the generation system that allows for a flexible ordering of the single components. Our experiments vary 3 parameters of the generation architecture: 1) the sequential order of the modules, 2) parallelization of modules, 3) joint vs. separate modelling of implicit referents. Our results suggest that the interactions between RE and syntax can be modelled in sequential generation architecture where the RE component has access to information about syntactic realization and an approximative, intermediate linearization. Such a system is reminiscent of earlier work in rule-based generation that implements an interactive or revision-based feedback between discourse-level planning and linguistic realisation (Hovy, 1988; Robin, 1993).

## 2 Related Work

Despite the common view of NLG as a pipeline process, it is a well-known problem that high-level, conceptual knowledge and low-level linguistic knowledge are tightly interleaved (Danlos, 1984; Mellish et al., 2000). In rule-based, strictly sequential generators these interactions can lead to a so-called *generation gap*, where a downstream module cannot realize a text or sentence plan generated by the preceding modules (Meteer, 1991; Wanner, 1994). For this reason, a number of other architectures has been proposed, see De Smedt et al. (1996) for an overview. For reasons of tractability and scalability, many practical NLG systems still have been designed as sequential pipelines that follow the basic layout of macroplanning-microplanning-linguistic realization (Reiter, 1994; Cahill et al., 1999; Bateman and Zock, 2003).

In recent data-driven research on NLG, many single tasks have been addressed with corpus-based methods. For surface realization, the standard set-up is to regenerate from syntactic representations that have been produced for realistic corpus sentences. The first widely known statistical approach by Langkilde and Knight (1998) used language-model n-gram statistics on a word lattice of candidate realisations to guide a ranker. Subsequent work explored ways of exploiting linguistically annotated data for trainable generation models (Ratnaparkhi, 2000; Belz, 2005). Work on data-driven approaches has led to insights about the importance of linguistic features for sentence

linearization decisions (Ringger et al., 2004; Filipova and Strube, 2007; Cahill and Riester, 2009). (Zarriß et al., 2012) have recently argued that the good performance of these linguistically motivated word order models, which exploit morpho-syntactic features of noun phrases (i.e. referents), is related to the fact that these morpho-syntactic features implicitly encode a lot of knowledge about the underlying discourse or information structure.

A considerable body of REG research has been done in the paradigm established by Dale (1989; 1995). More closely related to our work are approaches in the line of Siddharthan and Copestake (2004) or Belz and Varges (2007) who generate contextually appropriate REs for instances of a referent in a text. Belz and Varges (2007)’s GREC data set includes annotations of implicit subjects in coordinations. Zarriß et al. (2011) deal with implicit subjects in passives, proposing a set of heuristics for adding these agents to the generation input. Roth and Frank (2012) acquire automatic annotations of implicit roles for the purpose of studying coherence patterns in texts. Implicit referents have also received attention for the analysis of semantic roles (Gerber and Chai, 2010; Ruppenhofer et al., 2010).

Statistical methods for data-to-text generation have been explored only recently. Belz (2008) trains a probabilistic CFG to generate weather forecasts, Chen et al. (2010) induce a synchronous grammar to generate sportcaster text. Both address a restricted domain where a direct alignment between units in the non-linguistic representation and the linguistic utterance can be learned. Marciniak and Strube (2005) propose an ILP model for global optimization in a generation task that is decomposed into a set of classifiers. Bohnet et al. (2011) deal with multi-level generation in a statistical framework and in a less restricted domain. They adopt a standard sequential pipeline approach.

Recent corpus-based generation approaches faced the problem that existing standard treebank representations for parsing or other analysis tasks do not necessarily fit the needs of generation (Bohnet et al., 2010; Wanner et al., 2012). Zarriß et al. (2011) discuss the problem of an input representation that is appropriately underspecified for the realistic generation of voice alternations.

### 3 The Data Set

The data set for our generation experiments consists of 200 newspaper articles about robbery events. The articles were extracted from a large German newspaper corpus. A complete example text with RE annotations is given in Figure 2, Table 1 summarizes some data set statistics.

#### 3.1 RE annotation

The RE annotations mark explicit and implicit mentions of referents involved in the robbery event described in an article. Explicit mentions are marked as spans on the surface sentence, labeled with the referent’s role and an ID. We annotate the following referential roles: (i) *perpetrator* (*perp*), (ii) *victim*, (iii) *source*, according to the core roles of the *Robbery* frame in English FrameNet. We include *source* since some texts do not mention a particular *victim*, but rather the location of the robbery (e.g. a bank, a service station). The ID distinguishes referents that have the same role, e.g. “the husband” and the “young family” in Sentences (3-a) and (3-d) in Figure 2. Each RE is linked to its syntactic head. This complies with the GREC data sets, and is also useful for further annotation of the deep syntax level (see Section 3.2).

The RE implicit mentions of *victim*, *perp*, and *source* are annotated as attributes of their syntactic heads in the surface sentence. We consider the following types of implicit referents: (i) agents in passives (e.g. “robbed” in (3-a)), (ii) arguments of nominalizations (e.g. “resistance” in (3-e)), (iii) possessives (e.g. “watch” in (3-f)), (iv) missing subjects in coordinations. (e.g. “flee” in (3-f))

The brat tool (Stenetorp et al., 2012) was used for annotation. We had 2 annotators with a computational linguistic background, provided with annotation guidelines. They were trained on a set of 20 texts. We measure a good agreement on another set of 15 texts: the simple pairwise agreement for explicit mentions is 95.14%-96.53% and 78.94%-76.92% for implicit mentions.<sup>1</sup>

#### 3.2 Syntax annotation

The syntactic annotation of our data includes two layers: shallow and deep, labeled dependencies, similar to the representation used in surface realization shared tasks (Belz et al., 2011). We use

<sup>1</sup>Standard measures for the “above chance annotator agreement” are only defined for task where the set of annotated items is pre-defined.

- (3) a. Junge Familie<sub>v:0</sub> auf dem Heimweg<sub>poss:v</sub> ausgeraubt<sub>ag:p</sub>  
Young family on the way home<sub>poss:v</sub> robbed<sub>ag:p</sub>
- b. Die Polizei sucht nach zwei ungepflegt wirkenden jungen Männern im Alter von etwa 25 Jahren<sub>p:0</sub>.  
The police looks for two shabby-looking young men of about 25 years.
- c. Sie<sub>p:0</sub> sollen am Montag gegen 20 Uhr eine junge Familie mit ihrem sieben Monate alten Baby<sub>v:0</sub> auf  
They are said to on Monday around 20 o'clock a young family with their seven month old baby on  
dem Heimweg<sub>poss:v</sub> von einem Einkaufsbummel überfallen und ausgeraubt haben.  
the way home<sub>poss:v</sub> from a shopping tour attacked and robbed have.
- d. Wie die Polizei berichtet, drohten die zwei Männer<sub>p:0</sub> dem Ehemann<sub>v:1</sub>, ihn<sub>v:1</sub> zusammenschlagen.  
As the police reports, threatened the two men the husband him beat up.
- e. Er<sub>v:1</sub> gab deshalb seine<sub>v:1</sub> Brieftasche ohne Gegenwehr<sub>ag:v,the:p</sub> heraus.  
He gave therefore his wallet without resistance<sub>ag:v,the:p</sub> out.
- f. Anschließend nahmen ihm<sub>v:1</sub> die Räuber<sub>p:0</sub> noch die Armbanduhr<sub>poss:v</sub> ab und flüchteten<sub>ag:p</sub>.  
Afterwards took him the robbers also the watch<sub>poss:v</sub> off and fleed<sub>ag:p</sub>.

Figure 2: Example text with RE annotations, oval boxes mark *victim* mentions, square boxes mark *perp* mentions, heads of implicit arguments are underlined

the Bohnet (2010) dependency parser to obtain an automatic annotation of shallow or surface dependencies for the corpus sentences.

The deep syntactic dependencies are derived from the shallow layer by a set of hand-written transformation rules. The goal is to link referents to their main predicate in a uniform way, independently of the surface-syntactic realization of the verb. We address passives, nominalizations and possessives corresponding to the contexts where we annotated implicit referents (see above). The transformations are defined as follows:

1. remove auxiliary nodes, verb morphology and finiteness, a tense feature distinguishes past and present, e.g. “haben:AUX überfallen:VVINF” (*have attacked*) maps to “überfallen:VV:PAST” (*attack:PAST*)
2. map subjects in actives and oblique agents in passives to “agents”; objects in actives and subjects in passive to “themes”, e.g. *victim/subj was attacked by perp/obl-ag* maps to *perp/agent attack victim/theme*
3. attach particles to verb lemma, e.g. “gab” ... “heraus” in (3-e) is mapped to “herausgeben” (*give to*)
4. map nominalized to verbal lemmas, their prepositional and genitive arguments to semantic subjects and objects, e.g. *attack on victim* is mapped to *attack victim/theme*
5. normalize prenominal and genitive postnominal possessives, e.g. “seine Brieftasche” (*his wallet*) and “die Brieftasche des Opfers” (*the wallet of the victim*) map to “die Brieftasche POSS victim” (*the wallet of victim*), only applies if possessive is an annotated RE

Nominalizations are mapped to their verbal base forms on the basis of lexicalized rules for the nominalized lemmas observed in the corpus. The other transformations are defined on the shallow dependency annotation.

# sentences	2030
# explicit REs	3208
# implicit REs	1778
# passives	383
# nominalizations	393
# possessives	1150

Table 1: Basic annotation statistics

### 3.3 Multi-level Representation

In the final representation of our data set, we integrate the RE and deep syntax annotation by replacing subtrees corresponding to an RE span. The RE slot in the tree of the sentence is labeled with its referential role and its ID. All RE subtrees for a referent in a text are collected in a candidate list which is initialized with three default REs: (i) a pronoun, (ii) a default nominal (e.g. “the victim”), (iii) the empty RE. In contrast to the GREC data sets, our RE candidates are not represented as the original surface strings, but as non-linearized subtrees. The resulting multi-layer representation for each text is structured as follows:

1. unordered deep trees with RE slots (*deepSyn<sub>-re</sub>*)
2. unordered shallow trees with RE slots (*shallowSyn<sub>-re</sub>*)
3. unordered RE subtrees
4. linearized, fully specified surface trees (*linSyn<sub>+re</sub>*)
5. alignments between nodes in 1., 2., 4.

The generation components in Section 4 also use intermediate layers where REs are inserted into the deep trees (*deepSyn<sub>+re</sub>*) or shallow trees (*shallowSyn<sub>+re</sub>*).

Nodes in unordered trees are deterministically sorted by their : 1. distance to the root, 2. label,

3. PoS tag, 4. lemma. The generation components traverse the nodes in this the order.

## 4 Generation Systems

Our main goal is to investigate different architectures for combined surface realization and referring expression generation. We assume that this task is split into three main modules: a syntax generator, an REG component, and a linearizer. The components are implemented in a way that they can be trained and applied on varying inputs, depending on the pipeline. Section 4.1 describes the basic set-up of our components. Section 4.2 defines the architectures that we will compare in our experiments (Section 5). Section 4.3 presents the implementation of the underlying feature models.

### 4.1 Components

#### 4.1.1 SYN: Deep to Shallow Syntax

For mapping deep to shallow dependency trees, the syntax generator induces a probabilistic tree transformation. The transformations are restricted to verb nodes in the deep tree (possessives are handled in the RE module) and extracted from the alignments between the deep and shallow layer in the training input. As an example, the deep node “attack:VV” aligns to “have:AUX attacked:VVINF”, “attacks:VVFİN”, “the:ART attack:NN on:PRP”. The learner is implemented as a ranking component, trained with SVMrank (Joachims, 2006). During training, each instance of a verb node has one optimal shallow dependency alignment and a set of distractor candidates. During testing, the module has to pick the best shallow candidate according to its feature model.

In our crossvalidation set-up (see Section 5), we extract, on average, 374 transformations from the training sets. This set subdivides into non-lexicalized and lexicalized transformations. The mapping rule in (4-a) that simply rewrites the verb underspecified PoS tag to the finite verb tag in the shallow tree illustrates the non-lexicalized case. Most transformation rules (335 out of 374 on average) are lexicalized for a specific verb lemma and mostly transform nominalizations as in rule (4-b) and particles (see Section 3.2).

- (4) a.  $(x, lemma, VV, y) \rightarrow (x, lemma, VVFİN, y)$   
b.  $(x, überfallen/attack, VV, y) \rightarrow (x, bei/at, PREP, y), (z, Überfall/attack, NN, x), (q, der/the, ART, z)$

The baseline for the verb transformation component is a two-step procedure: 1) pick a lexical-

ized rule if available for that verb lemma, 2) pick the most frequent transformation.

#### 4.1.2 REG: Realizing Referring Expressions

Similar to the syntax component, the REG module is implemented as a ranker that selects surface RE subtrees for a given referential slot in a deep or shallow dependency tree. The candidates for the ranking correspond to the entire set of REs used for that referential role in the original text (see Section 3.1). The basic RE module is a joint model of all RE types, i.e. nominal, pronominal and empty realizations of the referent. For the experiment in Section 5.4, we use an additional separate classifier for implicit referents, also trained with SVMrank. It uses the same feature model as the full ranking component, but learns a binary distinction for implicit or explicit mentions of a referent. The explicit mentions will be passed to the RE ranking component.

The baseline for the REG component is defined as follows: if the preceding and the current RE slot are instances of the same referent, realize a pronoun, else realize the longest nominal RE candidate that has not been used in the preceding text.

#### 4.1.3 LIN: Linearization

For linearization, we use the state-of-the-art dependency linearizer described in Bohnet et al. (2012). We train the linearizer on an automatically parsed version of the German TIGER treebank (Brants et al., 2002). This version was produced with the dependency parser by Bohnet (2010), trained on the dependency conversion of TIGER by Seeker and Kuhn (2012).

### 4.2 Architectures

Depending on the way the generation components are combined in an architecture, they will have access to different layers of the input representation. The following definitions of architectures recur to the layers introduced in Section 3.3.

#### 4.2.1 First Pipeline

The first pipeline corresponds most closely to a standard generation pipeline in the sense of (Reiter and Dale, 1997). REG is carried out prior to surface realization such that the RE component does not have access to surface syntax or word order whereas the SYN component has access to fully specified RE slots.

- training

1. train REG: ( $deepSyn_{-re}, deepSyn_{+re}$ )
2. train SYN: ( $deepSyn_{+re}, shallowSyn_{+re}$ )

- prediction
  1. apply REG:  $deepSyn_{-re} \rightarrow deepSyn_{+re}$
  2. apply SYN:  $deepSyn_{+re} \rightarrow shallowSyn_{+re}$
  3. linearize:  $shallowSyn_{+re} \rightarrow linSyn_{+re}$

#### 4.2.2 Second Pipeline

In the second pipeline, the order of the RE and SYN component is switched. In this case, REG has access to surface syntax without word order but the surface realization is trained and applied on trees with underspecified RE slots.

- training
  1. train SYN: ( $deepSyn_{-re}, shallowSyn_{-re}$ )
  2. train REG: ( $shallowSyn_{-re}, shallowSyn_{+re}$ )
- prediction
  1. apply SYN:  $deepSyn_{-re} \rightarrow shallowSyn_{-re}$
  2. apply REG:  $shallowSyn_{-re} \rightarrow shallowSyn_{+re}$
  3. linearize:  $shallowSyn_{+re} \rightarrow linSyn_{+re}$

#### 4.2.3 Parallel System

A well-known problem with pipeline architectures is the effect of error propagation. In our parallel system, the components are trained independently of each other and applied in parallel on the deep syntactic input with underspecified REs.

- training
  1. train SYN: ( $deepSyn_{-re}, shallowSyn_{-re}$ )
  2. train REG: ( $deepSyn_{-re}, deepSyn_{+re}$ )
- prediction
  1. apply REG and SYN:  $deepSyn_{-re} \rightarrow shallowSyn_{+re}$
  2. linearize:  $shallowSyn_{+re} \rightarrow linSyn_{+re}$

#### 4.2.4 Revision-based System

In the revision-based system, the RE component has access to surface syntax and a preliminary linearization, called *prelinSyn*. In this set-up, we apply the linearizer first on trees with underspecified RE slots. For this step, we insert the default REs for the referent into the respective slots. After REG, the tree is linearized once again.

- training
  1. train SYN on gold pairs of ( $deepSyn_{-re}, shallowSyn_{-re}$ )
  2. train REG on gold pairs of ( $prelinSyn_{-re}, prelinSyn_{+re}$ )
- prediction
  1. apply SYN:  $deepSyn_{-re} \rightarrow shallowSyn_{-re}$
  2. linearize:  $shallowSyn_{-re} \rightarrow prelinSyn_{-re}$
  3. apply REG:  $prelinSyn_{-re} \rightarrow prelinSyn_{+re}$
  4. linearize:  $prelinSyn_{+re} \rightarrow linSyn_{+re}$

### 4.3 Feature Models

The implementation of the feature models is based on a general set of templates for the SYN and REG component. The exact form of the models depends on the input layer of a component in a given architecture. For instance, when SYN is trained on  $deepSyn_{-re}$ , the properties of the children nodes are less specific for verbs that have RE slots as their dependents. When the SYN component is trained on  $deepSyn_{+re}$ , lemma and POS of the children nodes are always specified.

The feature templates for SYN combine properties of the shallow candidate nodes (label, PoS and lemma for top node and its children) with the properties of the instance in the tree: (i) lemma, tense, (ii) sentence is a header, (iii) label, PoS, lemma of mother node, children and grandchildren nodes (iv) number, lemmas of other verbs in the sentence.

The feature templates for REG combine properties of the candidate RE (PoS and lemma for top node and its children, length) with properties of the RE slot in the tree: lemma, PoS and labels for the (i) mother node, (ii) grandmother node, (iii) uncle and sibling nodes. Additionally, we implement a small set of global properties of a referent in a text: (i) identity is known, (ii) plural or singular referent, (iii) age is known, and a number of contextual properties capturing the previous referents and their predicted REs: (i) role and realization of the preceding referent, (ii) last mention of the current referent, (iii) realization of the referent in the header.

## 5 Experiments

In this experimental section, we provide a corpus-based evaluation of the generation components and architectures introduced in Section 4. In the following, Section 5.1 presents the details of our evaluation methodology. In Section 5.2, we discuss the first experiment that evaluates the pipeline architectures and the single components on oracle inputs. Section 5.3 describes an experiment which compares the parallel and the revision-based architecture against the pipeline. In Section 5.4, we compare two methods for dealing with the implicit referents in our data. Section 5.5 provides some general discussion of the results.

Input	System	Sentence overlap			SYN Accuracy		RE Accuracy		
		BLEU	NIST	BLEU <sub>r</sub>	String	Type	String	Type	Impl
<i>deepSyn<sub>-re</sub></i>	Baseline	42.38	9.9	47.94	35.66	44.81	33.3	36.03	50.43
<i>deepSyn<sub>-re</sub></i>	1st pipeline	54.65	11.30	59.95	57.09	68.15	54.61	71.51	84.72
<i>deepSyn<sub>-re</sub></i>	2nd pipeline	54.28	11.25	59.62	59.14	68.58	52.24	68.2	82
gold <i>deepSyn<sub>+re</sub></i>	SYN→LIN	63.9	12.7	62.86	60.83	69.74	100	100	100
gold <i>shallowSyn<sub>-re</sub></i>	REG→LIN	60.57	11.87	68.06	100	100	60.53	75.86	88.86
gold <i>shallowSyn<sub>+re</sub></i>	LIN	79.17	13.91	72.7	100	100	100	100	100

Table 2: Evaluating pipeline architectures against the baseline and upper bounds

## 5.1 Evaluation Measures

We split our data set into 10 splits of 20 articles. We use one split as the development set, and cross-validate on the remaining splits. In each case, the downstream modules of the pipeline will be trained on the jackknifed training set.

**Text normalization:** We carry out automatic evaluation calculated on lemmatized text without punctuation, excluding additional effects that would be introduced from a morphology generation component.

**Measures:** First, we use a number of evaluation measures familiar from previous generation shared tasks:

1. BLEU, sentence-level geometric mean of 1- to 4-gram precision, as in (Belz et al., 2011)
2. NIST, sentence-level n-gram overlap weighted in favour of less frequent n-grams, as in (Belz et al., 2011)
3. RE Accuracy on String, proportion of REs selected by the system with a string identical to the RE string in the original corpus, as in (Belz and Kow, 2010)
4. RE Accuracy on Type, proportion of REs selected by the system with an RE type identical to the RE type in the original corpus, as in (Belz and Kow, 2010)

Second, we define a number of measures motivated by our specific set-up of the task:

1. BLEU<sub>r</sub>, sentence-level BLEU computed on post-processed output where predicted referring expressions for *victim* and *perp* are replaced in the sentences (both gold and predicted) by their original role label, this score does not penalize lexical mismatches between corpus and system REs
2. RE Accuracy on Impl, proportion of REs predicted correctly as implicit/non-implicit
3. SYN Accuracy on String, proportion of shallow verb candidates selected by the system with a string identical to the verb string in the original corpus
4. SYN Accuracy on Type, proportion of shallow verb candidates selected by the system with a syntactic category identical to the category in the original corpus

## 5.2 Pipelines and Upper Bounds

The first experiment addresses the first and second pipeline introduced in Section 4.2.1 and 4.2.2. The baseline combines the baseline version of the SYN component (Section 4.1.1) and the REG component (Section 4.1.2) respectively. As we report in Table 2, both pipelines largely outperform the baseline. Otherwise, they obtain very similar scores in all measures with a small, weakly significant tendency for the first pipeline. The only remarkable difference is that the accuracy of the individual components is, in each case, lower when they are applied as the second step in the pipeline. Thus, the RE accuracy suffers from mistakes from the predicted syntax in the same way that the quality of syntax suffers from predicted REs.

The three bottom rows in Table 2 report the performance of the individual components and linearization when they are applied to inputs with an REG and SYN oracle, providing upper bounds for the pipelines applied on *deepSyn<sub>-re</sub>*. When REG and linearization are applied on *shallowSyn<sub>-re</sub>* with gold shallow trees, the BLEU score is lower (60.57) as compared to the system that applies syntax and linearization on *deepSyn<sub>+re</sub>*, deep trees with gold REs (BLEU score of 63.9). However, the BLEU<sub>r</sub> score, which generalizes over lexical RE mismatches, is higher for the REG→LIN components than for SYN→LIN. Moreover, the BLEU<sub>r</sub> score for the REG→LIN system comes close to the upper bound that applies linearization on *lin.Syn<sub>+re</sub>*, gold shallow trees with gold REs (BLEU<sub>r</sub> of 72.4), whereas the difference in standard BLEU and NIST is high. This effect indicates that the RE prediction mostly decreases BLEU due to lexical mismatches, whereas the syntax prediction is more likely to have a negative impact on final linearization.

The error propagation effects that we find in the first and second pipeline architecture clearly show that decisions at the levels of syntax, reference and word order interact, otherwise their predic-

Input	System	BLEU	NIST	BLEU <sub>r</sub>
<i>deepSyn-re</i>	1st pipeline	54.65	11.30	59.95
<i>deepSyn-re</i>	Parallel	54.78	11.30	60.05
<i>deepSyn-re</i>	Revision	56.31	11.42	61.30

Table 3: Architecture evaluation

tion would not affect each other. In particular, the REG module seems to be affected more seriously, the String Accuracy decreases from 60.53 on gold shallow trees to 52.24 on predicted shallow trees whereas the Verb String Accuracy decreases from 60.83 on gold REs to 57.04 on predicted REs.

### 5.3 Revision or parallelism?

The second experiment compares the first pipeline against the parallel and the revision-based architecture introduced in Section 4.2.3 and 4.2.4. The evaluation in Table 3 shows that the parallel architecture improves only marginally over the pipeline. By contrast, we obtain a clearly significant improvement for the revision-based architecture on all measures. The fact that this architecture significantly improves the BLEU, NIST and the BLEU<sub>r</sub> score of the parallel system indicates that the REG benefits from the predicted syntax when it is approximatively linearized. The fact that also the BLEU<sub>r</sub> score improves shows that a higher lexical quality of the REs leads to better final linearizations.

Table 4 shows the performance of the REG module on varying input layers, providing a more detailed analysis of the interaction between RE, syntax and word order. In order to produce the *deeplinSyn-re* layer, deep syntax trees with approximative linearizations, we preprocessed the deep trees by inserting a default surface transformation for the verb nodes. We compare this input for REG against the *prelinSyn-re* layer used in the revision-based architecture, and the *deepSyn-re* layer used in the pipeline and the parallel architecture. The REG module benefits from the linearization in the case of *deeplinSyn-re* and *prelinSyn-re*, outperforming the component trained applied on the non-linearized deep syntax trees. However, the REG module applied on *prelinSyn-re*, predicted shallow and linearized trees, clearly outperforms the module applied on *deeplinSyn-re*. This shows that the RE prediction can actually benefit from the predicted shallow syntax, but only when the predicted trees are approximatively linearized. As an upper bound, we report the performance obtained on

Input	System	RE Accuracy		
		String	Type	Impl
<i>deepSyn-re</i>	RE	54.61	71.51	84.72
<i>deeplinSyn-re</i>	RE	56.78	72.23	84.71
<i>prelinSyn-re</i>	RE	58.81	74.34	86.37
gold <i>linSyn-re</i>	RE	68.63	83.63	94.74

Table 4: RE generation from different input layers

*linSyn-re*, gold shallow trees with gold linearizations. This set-up corresponds to the GREC tasks. The gold syntax leads to a huge increase in performance.

These results strengthen the evidence from the previous experiment that decisions at the level of syntax, reference and word order are interleaved. A parallel architecture that simply “circumvents” error propagation effects by making decisions independent of each other is not optimal. Instead, the automatic prediction of shallow syntax can positively impact on RE generation if these shallow trees are additionally processed with an approximative linearization step.

### 5.4 A joint treatment of implicit referents?

The previous experiments have pursued a joint approach for modeling implicit referents. The hypothesis for this experiment is that the SYN component and the intermediate linearization in a revision-based architecture could benefit from a separate treatment of implicit referents since verb alternations like passive or nominalization often involve referent deletions.

The evaluation in Table 5 provides contradictory results depending on the evaluation measure. For the first pipeline, the system with a separate treatment of implicit referents significantly outperforms the joint system in terms of BLEU. However, the BLEU<sub>r</sub> score does not improve. In the revision-based architecture, we do not find a clear result for or against a joint modelling approach. The revision-based system with disjoint modelling of implicits shows a slight, non-significant increase in BLEU score. By contrast, the BLEU<sub>r</sub> score is significantly better for the joint approach. We experimented with parallelization of syntax generation and prediction of implicit referents in a revision-based system. This has a small positive effect on the BLEU<sub>r</sub> score and a small negative effect on the plain BLEU and NIST score. These contradictory scores might indicate that the automatic evaluation measures cannot capture all aspects of text quality, an issue that we discuss in the following.

- (5) Generated by sequential system:
- a. Deshalb gab dem Täter seine Brieftasche ohne daß das Opfer Widerstand leistet heraus.  
 Therefore gave to the robber his wallet without that the victim resistance shows out.
- b. Er nahm anschließend dem Opfer die Armbanduhr ab und der Täter flüchtete.  
 He takes afterwards the victim the watch off and the robber fled.
- (6) Generated by revision-based system:
- a. Das Opfer gibt deshalb seine Brieftasche ohne Widerstand zu leisten heraus.  
 The victim gave therefore his wallet without resistance to show out.
- b. Anschließend nahm der Täter dem Opfer die Armbanduhr ab und flüchtete.  
 Afterwards took the robber the victim the watch off and fled.

Figure 3: Two automatically generated outputs for the Sentences (3e-f) in Figure 2.

Joint	System	BLEU	NIST	BLEU <sub>r</sub>
+	1st pipeline	54.65	11.30	59.95
-	1st pipeline	55.38	11.48	59.52
+	Revision	56.31	11.42	61.30
-	Revision	56.42	11.54	60.52
-	Parallel+Revision	56.29	11.51	60.63

Table 5: Implicit reference and architectures

## 5.5 Discussion

The results presented in the preceding evaluations consistently show the tight connections between decisions at the level of reference, syntax and word order. These interactions entail highly interdependent modelling steps: Although there is a direct error propagation effect from predicted verb transformation on RE accuracy, predicted syntax still leads to informative intermediate linearizations that improve the RE prediction. Our optimal generation architecture thus has a sequential set-up, where the first linearization step can be seen as an intermediate feedback that is revised in the final linearization. This connects to work in, e.g. (Hovy, 1988; Robin, 1993).

In Figure 3, we compare two system outputs for the last two sentences of the text in Figure 2. The output of the sequential system is severely incoherent and would probably be rejected by a human reader: In sentence (5a) the *victim* subject of an active verb is deleted, and the relation between the possessive and the embedded *victim* RE is not clear. In sentence (5b) the first conjunct realizes a pronominal *perp* RE and the second conjunct a nominal *perp* RE. The output of the revision-based system reads much more natural. This example shows that the extension of the REG problem to texts with more than one main referent (as in the GREC data set) yields interesting inter-sentential interactions that affect textual coherence.

We are aware of the fact that our automatic eval-

uation might only partially render certain effects, especially with respect to textual coherence. It is likely that the BLEU scores do not capture the magnitude of the differences in text quality illustrated by the Examples (5-6). Ultimately, a human evaluation for this task is highly desirable. We leave this for future work since our integrated set-up rises a number of questions with respect to evaluation design. In a preliminary analysis, we noticed the problem that human readers find it difficult to judge discourse-level properties of a text like coherence or naturalness when the generation output is not perfectly grammatical or fluent at the sentence level.

## 6 Conclusion

We have presented a data-driven approach for investigating generation architectures that address discourse-level reference and sentence-level syntax and word order. The data set we created for our experiments basically integrates standards from previous research on REG and surface realization and extends the annotations to further types of implicit referents. Our results show that interactions between the different generation levels are best captured in a sequential, revision-based pipeline where the REG component has access to predictions from the syntax and the linearization module. These empirical findings obtained from experiments with generation architectures have clear connections to theoretical accounts of textual coherence.

# Named Entity Recognition using Cross-lingual Resources: Arabic as an Example

Kareem Darwish

Qatar Computing Research Institute

Doha, Qatar

kdarwish@qf.org.qa

## Abstract

Some languages lack large knowledge bases and good discriminative features for Name Entity Recognition (NER) that can generalize to previously unseen named entities. One such language is Arabic, which: a) lacks a capitalization feature; and b) has relatively small knowledge bases, such as Wikipedia. In this work we address both problems by incorporating cross-lingual features and knowledge bases from English using cross-lingual links. We show that such features have a dramatic positive effect on recall. We show the effectiveness of cross-lingual features and resources on a standard dataset as well as on two new test sets that cover both news and microblogs. On the standard dataset, we achieved a 4.1% relative improvement in F-measure over the best reported result in the literature. The features led to improvements of 17.1% and 20.5% on the new news and microblogs test sets respectively.

## 1 Introduction

Named Entity Recognition (NER) is essential for a variety of Natural Language Processing (NLP) applications such as information extraction. There has been a fair amount of work on NER for a variety of languages including Arabic. To train an NER system, some of the following feature types are typically used (Benajiba and Rosso, 2008; Nadeau and Sekine, 2009):

- Orthographic features: These features include capitalization, punctuation, existence of digits, etc. One of the most effective orthographic features is capitalization in English, which helps NER to generalize to new text of different genres. However, capitalization is not very useful in some languages such as German, and nonexistent in other languages such

as Arabic. Further, even in English social media, capitalization may be inconsistent.

- Contextual features: Certain words are indicative of the existence of named entities. For example, the word “said” is often preceded by a named entity of type “person” or “organization”. Sequence labeling algorithms (ex. Conditional Random Fields (CRF)) can often identify such indicative words.

- Character-level features: These features typically include the leading and trailing letters of words. In some languages, these letters could be prefixes and suffixes. Such features can be indicative or counter-indicative of the existence of named entities. For example, a word ending with “ing” is typically not a named entity, while a word ending in “berg” is often a named entity.

- Part-of-speech (POS) tags and morphological features: POS tags indicate (or counter-indicate) the possible presence of a named entity at word level or at word sequence level. Morphological features can mostly indicate the absence of named entities. For example, Arabic allows the attachment of pronouns to nouns and verbs. However, pronouns are rarely ever attached to named entities.

- Gazetteers: This feature checks the presence of a word or a sequence of words in large lists of named entities. If gazetteers are small, then they would have low coverage, and if they are very large then their entries may be ambiguous. For example, “syntax” may refer to sentence construction or the music band “Syntax”.

Typically, a subset of these features are available for different languages. For example, morphological, contextual, and character-level features have been shown to be effective for Arabic NER (Benajiba and Rosso, 2008). However, Arabic lacks indicative orthographic features that generalize to previously unseen named entities. Also, although some

of the Arabic gazetteers that were used for NER were small (Benajiba and Rosso, 2008), there has been efforts to build larger Arabic gazetteers (Attia et al., 2010). Since training and test parts of standard datasets for Arabic NER are drawn from the same genre in relatively close temporal proximity, a named entity recognizer that simply memorizes named entities in the training set generally performs well on such test sets. Thus, the results that are reported in the literature are generally high (Abdul-Hamid and Darwish, 2010; Benajiba et al., 2008). We illustrate the limited capacity of existing recognizers to generalize to previously unseen named entities using two new test sets that include microblogs as well as news texts that cover local and international politics, economics, health, sports, entertainment, and science. As we will show later, recall is well below 50% for all named entity types on the new test sets.

To address this problem, we introduce the use of cross-lingual links between a disadvantaged language, Arabic, and a language with good discriminative features and large resources, English, to improve Arabic NER. We exploit English’s orthographic features, particularly capitalization, as well as Arabic and English Wikipedias, including existing annotations from large knowledge sources such as DBpedia. We also show how to use transliteration mining to improve NER, even when neither language has a capitalization (or similar) feature. The intuition is that if the translation of a word is in fact a transliteration, then the word is likely a named entity. Cross-lingual links are obtained using Wikipedia cross-language links and a large Machine Translation (MT) phrase table that is true cased, where word casing is preserved during training. We show the effectiveness of these new features on a standard dataset as well as two new test sets. The contributions of this paper are as follows:

- Using cross-lingual links to exploit orthographic features in other languages.
- Employing transliteration mining to improve NER.
- Using cross-lingual links to exploit a large knowledge base, namely English DBpedia, to benefit NER.
- Introducing two new NER test sets for Arabic that include recent news as well as microblogs. We plan to release these test sets.

- Improving over the best reported results in the literature by 4.1% (Abdul-Hamid and Darwish, 2010) by strictly adding cross-lingual features. We also show improvements of 17.1% and 20.5% on the new test sets.

The remainder of the paper is organized as follows: Section 2 provides related work; Section 3 describes the baseline system; Section 4 introduces the cross-lingual features and reports on their effectiveness; and Section 5 concludes the paper.

## 2 Related Work

### 2.1 Using cross-lingual Features

For many NLP tasks, some languages may have significantly more training data, better knowledge resources, or more discriminating features than other languages. If cross-lingual resources are available, such as parallel data, increased training data, better resources, or superior features can be used to improve the processing (ex. tagging) for other languages (Ganchev et al., 2009; Shi et al., 2010; Yarowsky and Ngai, 2001). Some work has attempted to use bilingual features in NER. Burkett et al. (2010) used bilingual text to improve monolingual models including NER models for German, which lacks a good capitalization feature. They did so by training a bilingual model and then generating more training data from unlabeled parallel data. They showed significant improvement in German NER effectiveness, particularly for recall. In our work, there is no need for tagged text that has a parallel equivalent in another language. Benajiba et al. (2008) used an Arabic English dictionary from MADA, an Arabic analyzer, to indicate if a word is capitalized in English or not. They reported that it was the second most discriminating feature that they used. However, there seems to be room for improvement because: (1) MADA’s dictionary is relatively small and would have low coverage; and (2) the use of such a binary feature is problematic, because Arabic names are often common Arabic words and hence a word may be translated as a named entity and as a common word. To overcome these two problems, we use cross-lingual features to improve NER using large bilingual resources, and we incorporate confidences to avoid having a binary feature. Richman and Schone (2008) used English linguis-

tic tools and cross language links in Wikipedia to automatically annotate text in different languages. Transliteration Mining (TM) has been used to enrich MT phrase tables or to improve cross language search (Udupa et al., 2009). Conversely, people have used NER to determine if a word is to be transliterated or not (Hermjakob et al., 2008). However, we are not aware of any prior work on using TM to determine if a sequence is a NE. Further, we are not aware of prior work on using TM (or transliteration in general) as a cross lingual feature in any annotation task. In our work, we use state-of-the-art TM as described by El-Kahki et al. (2011)

## 2.2 Arabic NER

Much work has been done on NER with multiple public evaluation forums. Nadeau and Sekine (Nadeau and Sekine, 2009) surveyed lots of work on NER for a variety of languages. Significant work has been conducted by Benajiba and colleagues on Arabic NER (Benajiba and Rosso, 2008; Benajiba et al., 2008; Benajiba and Rosso, 2007; Benajiba et al., 2007). Benajiba et al. (2007) used a maximum entropy classifier trained on a feature set that includes the use of gazetteers and a stop-word list, appearance of a NE in the training set, leading and trailing word bigrams, and the tag of the previous word. They reported 80%, 37%, and 47% F-measure for locations, organizations, and persons respectively on the ANERCORP dataset that they created and publicly released. Benajiba and Rosso (2007) improved their system by incorporating POS tags to improve NE boundary detection. They reported 87%, 46%, and 52% F-measure for locations, organizations, and persons respectively. Benajiba and Rosso (2008) used CRF sequence labeling and incorporated many language specific features, namely POS tagging, base-phrase chunking, Arabic tokenization, and adjectives indicating nationality. They reported that tokenization generally improved recall. Using POS tagging generally improved recall at the expense of precision, leading to overall improvements in F-measure. Using all their suggested features, they reported 90%, 66%, and 73% F-measure for location, organization, and persons respectively. In Benajiba et al. (2008), they examined the same feature set on the Automatic Content Extraction (ACE) datasets using CRF

sequence labeling and a Support Vector Machine (SVM) classifier. They did not report per category F-measure, but they reported overall 81%, 75%, and 78% macro-average F-measure for broadcast news and newswire on the ACE 2003, 2004, and 2005 datasets respectively. Huang (2005) used an HMM-based NE recognizer for Arabic and reported 77% F-measure on the ACE 2003 dataset. Farber et al. (2008) used POS tags obtained from an Arabic tagger to enhance NER. They reported 70% F-measure on the ACE 2005 dataset. Shaalan and Raza (2007) reported on a rule-based system that uses hand crafted grammars and regular expressions in conjunction with gazetteers. They reported upwards of 93% F-measure, but they conducted their experiments on non-standard datasets, making comparison difficult. Abdul-Hamid and Darwish (2010) used a simplified feature set that relied primarily on character level features, namely leading and trailing letters in a word. They also experimented with a variety of phrase level features with little success. They reported an F-measure of 76% and 81% for the ACE2005 and the ANERCORP datasets respectively. We used their simplified features in our baseline system. The different experiments reported in the literature may not have been done on the same training/test splits. Thus, the results may not be completely comparable. Mohit et al. (2012) performed NER on a different genre from news, namely Arabic Wikipedia articles, and reported recall values as low as 35.6%. They used self training and recall oriented classification to improve recall, typically at the expense of precision. McNamee and Mayfield (2002) and Mayfield et al. (2003) used thousands of language independent features such as character n-grams, capitalization, word length, and position in a sentence, along with language dependent features such as POS tags and BP chunking. The use of CRF sequence labeling for NER has shown success (McCallum and Li, 2003; Nadeau and Sekine, 2009; Benajiba and Rosso, 2008).

## 3 Baseline Arabic NER System

For the baseline system, we used the CRF++<sup>1</sup> implementation of CRF sequence labeling with default parameters. We opted to reimplement the most suc-

<sup>1</sup><http://code.google.com/p/crfpp/>

cessful features that were reported by Benajiba et al. (2008) and Abdul-Hamid and Darwish (2010), namely the leading and trailing 1, 2, 3, and 4 letters in a word; whether a word appears in the gazetteer that was created by Benajiba et al. (2008), which is publicly available, but is rather small (less than 5,000 entries); and the stemmed form of words (after removing coordinating conjunctions, prepositions, and determiners using a rule-based stemmer akin to (Larkey et al., 2002)). As mentioned earlier, the leading and trailing letters in a word may indicate or counter-indicate the presence of named entities. Stemming is important due to the morphological complexity of Arabic. We used the previous and the next words in their raw and stemmed forms as features. For training and testing, we used the ANERCORP dataset (Benajiba and Rosso, 2007). The dataset has approximately 150k tokens and we used the 80/20 training/test splits of Abdul-Hamid and Darwish (2010), who graciously provided us with their splits of the collection and they achieved the best reported results on the dataset. We will refer to their results, which are provided in Table 1, as “baseline-lit”. Table 2 (a) shows our results on the ANERCORP dataset. Our results were slightly lower than their results (Abdul-Hamid and Darwish, 2010). It is noteworthy that 69% of the named entities in the test part were seen during training.

We also created two new test sets. The first test set is composed of news snippets from the RSS feed of the Arabic (Egypt) version of news.google.com from Oct. 6, 2012. The RSS feed contains the headline and the first 50-100 words in the news articles. The set has news from over a dozen different news sources and covers international and local news, politics, financial news, health, sports, entertainment, and technology. This set contains roughly 15k tokens. The second set contains a set of 1,423 tweets that were randomly selected from tweets authored between November 23, 2011 and November 27, 2011. We scraped tweets from Twitter using the query “lang:ar” (language=Arabic). This set contains approximately 26k tokens. The test sets will be henceforth be referred to as the NEWS and TWEETS sets respectively. They were annotated by one person, a native Arabic speaker, using the Linguistics Data Consortium tagging guidelines. Table 2 (b) and (c) report on the results for the baseline

system on both test sets. The results on the NEWS test are substantially lower than those for ANERCORP. It is worth noting that only 27% of the named entities in the NEWS test set were observed in the training set (compared to 69% for ANERCORP). As Table 3 shows for the ANERCORP dataset, using only the tokens as features, where the labeler mainly memorizes previously seen named entities, yields higher results than the baseline results for the NEWS dataset (Table 2 (b)). The results on the TWEETS test are very poor, with 24% of the named entities in the test set appearing in the training set.

## 4 Cross-lingual Features

We experimented with three different cross-lingual features that used Arabic and English Wikipedia cross-language links and a true-cased phrase table that was generated using Moses (Koehn et al., 2007). True-casing preserves case information during training. We used the Arabic Wikipedia snapshot from September 28, 2012. The snapshot has 348,873 titles including redirects, which are alternative names to articles. Of these articles, 254,145 have cross-lingual links to English Wikipedia. We used DBpedia 3.8 which includes 6,157,591 entries of Wikipedia titles and their “types”, such as “person”, “plant”, or “device”, where a title can have multiple types. The phrase table was trained on a set of 3.69 million parallel sentences containing 123.4 million English tokens. The sentences were drawn from the UN parallel data along with a variety of parallel news data from LDC and the GALE project. The Arabic side was stemmed (by removing just prefixes) using the Stanford word segmenter (Green and DeNero, 2012).

### 4.1 Cross-lingual Capitalization

As we mentioned earlier, Arabic lacks capitalization and Arabic names are often common Arabic words. For example, the Arabic name “Hasan” means good. To capture cross-lingual capitalization, we used the aforementioned true-cased phrase table at word and phrase levels as follows:

**Input:** True-cased phrase table  $PT$ , sentence  $S$  containing  $n$  words  $w_{0..n}$ , max sequence length  $l$ , translations  $T_{1..k..m}$  of  $w_{i..j}$

```

for  $i = 0 \rightarrow n$  do
   $j = \min(i + l - 1, n)$ 
  if  $PT$  contains  $w_{i..j}$  &  $\exists T_k$   $isCaps$  then
     $weight(w_{i..j}) = \frac{\sum_{T_k.isCaps} P(T_k)}{\sum_{T_k.isCaps} P(T_k) + \sum_{T_k.notCaps} P(T_k)}$ 
    round  $weight(w_{i..j})$  to first significant figure
    set tag of  $w_i = B-CAPS-weight$ 
    set tag for words  $w_{i+1..j} = I-CAPS-weight$ 
  else
    if  $j > i$  then
       $j--$ 
    else
      tag of  $w_i = null$ 
    end if
  end if
end for

```

Where:  $PT$  was the aforementioned phrase table;  $l = 4$ ;  $P(T_k)$  equaled to the product of  $p(source|target)$  and  $p(target|source)$  for a word sequence;  $isCaps$  and  $notCaps$  were whether the

translation was capitalized or not respectively; and the weights were binned because CRF++ only takes nominal features. In essence we tried every subsequence of  $S$  of length  $l$  or less to see if the translation was capitalized. A subsequence can be 1 word long. We tried longer sequences first. To determine if the corresponding phrase was capitalized ( $isCaps$ ), all non-function words on the English side needed to be capitalized. As an example, the phrase المحيط الهادي (meaning “Pacific Ocean”) was translated to a capitalized phrase 36.7% of the time. Thus, the word المحيط was assigned B-CAPS-0.4 and الهادي was assigned I-CAPS-0.4. Using weights avoids using capitalization as a binary feature.

Table 4 reports on the results of the baseline system with the capitalization feature on the three datasets. In comparing baseline results in Table 2 and cross-lingual capitalization results in Table 4, recall consistently increased for all datasets, particularly for “persons” and “locations”. For the different test sets, recall increased by 3.1 to 6.1 points (absolute) or by 8.4% to 13.6% (relative). This led to an overall improvement in F-measure of 1.8 to 3.4 points (absolute) or 4.2% to 5.7% (relative). Precision dropped overall on the ANERCORP dataset and dropped substantially for the NEWS and TWEETS test sets.

Table 4: Results with cross-lingual capitalization with /absolute/relative differences compared to baseline

## 4.2 Transliteration Mining

An alternative to capitalization can be transliteration mining. The intuition is that named entities are often transliterated, particularly the names of locations and persons. This feature is helpful if cross-lingual resources do not have capitalization information, or if the “helper” language to be consulted does not have a useful capitalization feature. We performed transliteration mining (aka cognate matching) at word level for each Arabic word against all its possible translations in the phrase table. We used a transliteration miner akin to that of El-Kahki et al. (2011) that was trained using 3,452 parallel Arabic-English transliteration pairs. We aligned the word-pairs at character level using GIZA++ and the phrase extractor and scorer from the Moses machine translation package (Koehn et al., 2007). The alignment produced mappings between English letters sequences and Arabic letter sequences with associated mapping probabilities. Given an Arabic word, we produced all its possible segmentations along with their associated mappings into English letters. We retained valid target sequences that produced translations in the phrase table.

Again we used a weight similar to the one for cross-lingual capitalization and we rounded the values of the ratio the significant figure. The weights were computed as:

$$\frac{\sum_{T_k \text{ is Transliteration}} P(T_k)}{\sum_{T_k \text{ is Transliteration}} P(T_k) + \sum_{T_k \text{ not Transliteration}} P(T_k)} \quad (1)$$

where  $P(T_k)$  is probability of the  $k^{\text{th}}$  translation of a word in the phrase table.

If a word was not found in the phrase table, the feature value was assigned null. For example, if the translations of the word حسن are “Hasan”, “Hassan”, and “good”, where the first two are transliterations and the last not, then the weight of the word would be:

$$\frac{P(\text{Hasan}|\text{حسن}) + P(\text{Hassan}|\text{حسن})}{P(\text{Hasan}|\text{حسن}) + P(\text{Hassan}|\text{حسن}) + P(\text{good}|\text{حسن})} \quad (2)$$

In our experiments, the weight of حسن was equal to 0.5 (after rounding). Table 5 reports on the results using the baseline system with the transliteration mining feature. Like the capitalization fea-

ture, transliteration mining slightly lowered precision – except for the TWEETS test set where the drop in precision was significant – and positively increased recall, leading to an overall improvement in F-measure for all test sets. Overall, F-measure improved by 1.9%, 3.7%, and 3.9% (relative) compared to the baseline for the ANERCORP, NEWS, and TWEETS test sets respectively. The similarity of results between using transliteration mining and word-level cross-lingual capitalization suggests that perhaps they can serve as surrogates.

## 4.3 Using DBpedia

DBpedia<sup>2</sup> is a large collaboratively-built knowledge base in which structured information is extracted from Wikipedia (Bizer et al., 2009). DBpedia 3.8, the release we used in this paper, contains 6,157,591 Wikipedia titles belonging to 296 types. Types vary in granularity with each Wikipedia title having one or more type. For example, NASA is assigned the following types: Agent, Organization, and GovernmentAgency. In all, DBpedia includes the names of 764k persons, 573k locations, and 192k organizations. Of the Arabic Wikipedia titles, 254,145 have Wikipedia cross-lingual links to English Wikipedia, and of those English Wikipedia titles, 185,531 have entries in DBpedia. Since Wikipedia titles may have multiple DBpedia types, we opted to keep the most popular type (by count of how many Wikipedia titles are assigned a particular type) for each title, and we disregarded the rest. We also chose not to use the “Agent” and “Work” types because they were highly ambiguous. We found word sequences in the manner described in the pseudocode for cross-lingual capitalization. For translation, we generated two features using two translation resources, namely the aforementioned phrase table and Arabic-English Wikipedia cross-lingual links. When using the phrase table, we used the most likely translation into English that matches an entry in DBpedia provided that the product of  $p(\text{source}|\text{target})$  and  $p(\text{target}|\text{source})$  of translation was above  $10^{-5}$ . We chose the threshold qualitatively using offline experiments. When using Arabic-English Wikipedia cross-lingual links, if an entry was found in the Arabic Wikipedia, we performed a look up in DB-

<sup>2</sup><http://dbpedia.org>

pedia using the English Wikipedia title that corresponds to the Arabic Wikipedia title. We used Arabic Wikipedia page-redirects to improve coverage. For both features (using the two translation methods), for an Arabic word sequence corresponding to the DBpedia entry, the first word in the sequence was assigned the feature “B-” plus the DBpedia type and subsequent words were assigned the feature “I-” plus the DBpedia type. For example, for حزب الله (meaning “Hezbollah”), the words حزب and الله were assigned “B-Organization” and “I-Organization” respectively. For all other words, the feature was assigned “null”. Using the phrase table for translation likely yielded improved coverage over using Wikipedia cross-lingual links. However, Wikipedia cross-lingual links likely led to higher quality translations, because they were manually curated. Table 6 reports on the results of using the baseline system with the two DBpedia features. Using DBpedia consistently improved precision and recall for named entity types on all test sets, except for a small drop in precision for locations on the ANERCORP dataset and for locations and persons on the TWEETS test set. For the different test sets, improvements in recall ranged between 4.4 and 7.5 points (absolute) or 6.5% and 19.1% (relative). Precision improved by 0.9 and 5.5 points (absolute) or 1.0% and 7.1% (relative) for the ANERCORP and NEWS test sets respectively. Overall improvement in F-measure ranged between 3.2 and 7.6 points (absolute) or 4.1% and 13.9% (relative).

#### 4.4 Putting it All Together

Table 7 reports on the results of using all aforementioned cross-lingual features together. Figures 1, 2, and 3 compare the results of the different setups. As the results show, the impact of cross-lingual features on recall were much more pronounced on the NEWS and TWEETS test sets – compared to the ANERCORP dataset. Further, the recall values for the ANERCORP dataset in the baseline experiments were much higher than those for the two other test sets. This confirms our suspicion that the reported values in the literature on the standard datasets are unrealistically high due to the similarity between the training and test sets. Hence, these high effectiveness results may not generalize to other test sets. Of all the cross-

Table 6: Results using DBpedia with /absolute/relative differences compared to baseline

lingual features that we experimented with, the use of DBpedia led to improvements in both precision and recall (except for precision on the TWEETS test set). Other cross-lingual features yielded overall improvements in F-measure, mostly due to gains in recall, typically at the expense of precision. Overall, F-measure improved by 5.5%, 17.1%, and 20.5% (relative) compared to the baseline for the ANERCORP, NEWS, and TWEETS test sets respectively. For the ANERCORP test set, our results improved over the baseline-lit results (Abdul-Hamid and Darwish, 2010) by 4.1% (relative).

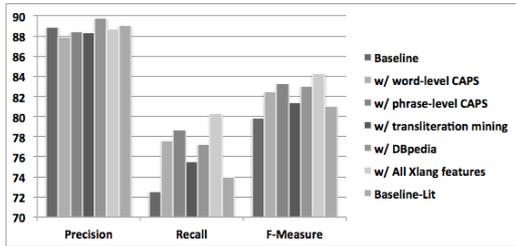

Figure 1: ANERCORP Dataset Results

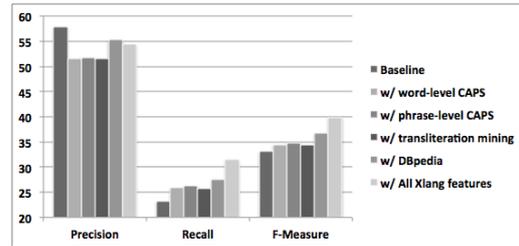

Figure 3: TWEETS Test Set Results

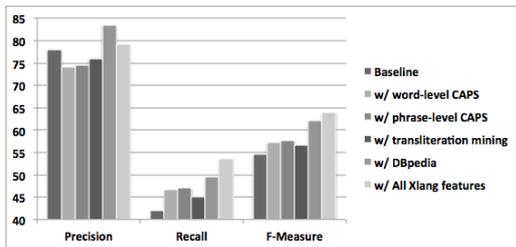

Figure 2: NEWS Test Set Results

When using all the features together, one notable result is that precision dropped significantly for the TWEETS test sets. We examined the output for the TWEETS test set and here are some of the factors that affected precision:

- the presence of words that would typically be named entities in news but would generally be regular words in tweets. For example, the Arabic word “Mubarak” is most likely the name of the former Egyptian president in the context of news, but it would most likely mean “blessed”, which is common in expressions of congratulations, in tweets.
- the use of dialectic words that may have transliterations or a named entity as the most likely translation into English. For example, the word شي is typically the dialectic version of the Arabic word شيء, meaning something. However, since the MT system that we used was trained on modern standard Arabic, the dialectic word would not appear in training and would typically be translated/transliterated to the name “Che” (as in Che Guevara).
- Since tweets are restricted in length, authors frequently use shortened versions of named entities. For example, tweets would mostly have “Morsi” instead of “Mohamed Morsi” and without trigger words such as “Dr.” or “president”. The full version of a name and trigger words are more com-

Table 7: Results using all the cross-lingual features with /absolute/relative differences compared to baseline

mon in news. This same problem was present in the NEWS test set, because it was constructed from an RSS feed, and headlines, which are typically compact, had a higher representation in the test collection. We observed the same phenomenon for organization names. For example, “the Real” refers to “Real Madrid”. Nicknames are also prevalent. For example, “the Land of the two Sanctuaries” refers to “Saudi Arabia”.

We believe that this problem can be overcome by introducing new training data that include tweets (or other social text) and performing domain adaptation. New training data would help: identify words and expressions that are common in conversations, account for common dialectic words, and learn a better word transition model. Further, gazetteers that cover shortened versions of names could be helpful as well.

## 5 Conclusion

In this paper, we presented different cross-lingual features that can make use of linguistic properties and knowledge bases of other languages for NER. For translation, we used an MT phrase table and Wikipedia cross-lingual links. We used English as the “helper” language and we exploited the English capitalization feature and an English knowledge base, DBpedia. If the helper language did not have capitalization, then transliteration mining could provide some of the benefit of capitalization. Transliteration mining requires limited amounts of training examples. We believe that the proposed cross-lingual features can be used to help NER for other languages, particularly languages that lack good features that generalize well. For Arabic NER, the new features yielded an improvement of 5.5% over a strong baseline system on a standard dataset, with 10.7% gain in recall and negligible change in precision. We tested on a new news test set, NEWS, which has recent news articles (the same genre as the standard dataset), and indeed NER effectiveness was much lower. For the new NEWS test set, cross-lingual features led to a small increase in precision (1.6%) and a very large improvement in recall (27.7%). This led to a 17.1% improvement in overall F-measure. We also tested NER on the TWEETS test set, where we observed substantial improvements in recall (35.9%). However, precision dropped by 6.2% for the reasons we mentioned earlier. For future work, it would be interesting to apply cross-lingual features to other language pairs and to make use of joint cross-lingual models. Further, we also plan to investigate Arabic NER on social media, particularly microblogs.

## Abstract

In this paper we address the problem of solving substitution ciphers using a beam search approach. We present a conceptually consistent and easy to implement method that improves the current state of the art for decipherment of substitution ciphers and is able to use high order  $n$ -gram language models. We show experiments with 1:1 substitution ciphers in which the guaranteed optimal solution for 3-gram language models has 38.6% decipherment error, while our approach achieves 4.13% decipherment error in a fraction of time by using a 6-gram language model. We also apply our approach to the famous Zodiac-408 cipher and obtain slightly better (and near to optimal) results than previously published. Unlike the previous state-of-the-art approach that uses additional word lists to evaluate possible decipherments, our approach only uses a letter-based 6-gram language model. Furthermore we use our algorithm to solve large vocabulary substitution ciphers and improve the best published decipherment error rate based on the Gigaword corpus of 7.8% to 6.0% error rate.

## 1 Introduction

State-of-the-art statistical machine translation (SMT) systems use large amounts of parallel data to estimate translation models. However, parallel corpora are expensive and not available for every domain.

Recently different works have been published that train translation models using only non-parallel data. Although first practical applications of these approaches have been shown, the overall

decipherment accuracy of the proposed algorithms is still low. Improving the core decipherment algorithms is an important step for making decipherment techniques useful for practical applications.

In this paper we present an effective beam search algorithm which provides high decipherment accuracies while having low computational requirements. The proposed approach allows using high order  $n$ -gram language models, is scalable to large vocabulary sizes and can be adjusted to account for a given amount of computational resources. We show significant improvements in decipherment accuracy in a variety of experiments while being computationally more effective than previous published works.

## 2 Related Work

The experiments proposed in this paper touch many of previously published works in the decipherment field.

Regarding the decipherment of 1:1 substitution ciphers various works have been published: Most older papers do not use a statistical approach and instead define some heuristic measures for scoring candidate decipherments. Approaches like (Hart, 1994) and (Olson, 2007) use a dictionary to check if a decipherment is useful. (Clark, 1998) defines other suitability measures based on  $n$ -gram counts and presents a variety of optimization techniques like simulated annealing, genetic algorithms and tabu search.

On the other hand, statistical approaches for 1:1 substitution ciphers were published in the natural language processing community: (Ravi and Knight, 2008) solve 1:1 substitution ciphers optimally by formulating the decipherment problem as an integer linear program (ILP) while (Corlett and Penn, 2010) solve the problem using  $A^*$  search. We use our own implementation of these methods to report optimal solutions to 1:1 substitution ci-

phers for language model orders  $n = 2$  and  $n = 3$ .

(Ravi and Knight, 2011a) report the first automatic decipherment of the Zodiac-408 cipher. They use a combination of a 3-gram language model and a word dictionary. We run our beam search approach on the same cipher and report better results without using an additional word dictionary—just by using a high order  $n$ -gram language model.

(Ravi and Knight, 2011b) report experiments on large vocabulary substitution ciphers based on the Transtac corpus. (Dou and Knight, 2012) improve upon these results and provide state-of-the-art results on a large vocabulary word substitution cipher based on the Gigaword corpus. We run our method on the same corpus and report improvements over the state of the art.

(Ravi and Knight, 2011b) and (Nuhn et al., 2012) have shown that—even for larger vocabulary sizes—it is possible to learn a full translation model from non-parallel data. Even though this work is currently only able to deal with substitution ciphers, phenomena like reordering, insertions and deletions can in principle be included in our approach.

### 3 Definitions

In the following we will use the machine translation notation and denote the **ciphertext** with  $f_1^N = f_1 \dots f_j \dots f_N$  which consists of cipher tokens  $f_j \in V_f$ . We denote the **plaintext** with  $e_1^N = e_1 \dots e_i \dots e_N$  (and its vocabulary  $V_e$  respectively). We define

$$e_0 = f_0 = e_{N+1} = f_{N+1} = \$ \quad (1)$$

with “\$” being a special sentence boundary token. We use the abbreviations  $\bar{V}_e = V_e \cup \{\$\}$  and  $\bar{V}_f$  respectively.

A **general substitution cipher** uses a table  $s(e|f)$  which contains for each cipher token  $f$  a probability that the token  $f$  is substituted with the plaintext token  $e$ . Such a table for substituting cipher tokens  $\{A, B, C, D\}$  with plaintext tokens  $\{a, b, c, d\}$  could for example look like

	a	b	c	d
A	0.1	0.2	0.3	0.4
B	0.4	0.2	0.1	0.3
C	0.4	0.1	0.2	0.3
D	0.3	0.4	0.2	0.1

The **1:1 substitution cipher** encrypts a given plaintext into a ciphertext by replacing each plaintext token with a unique substitute: This means that the table  $s(e|f)$  contains all zeroes, except for one “1.0” per  $f \in V_f$  and one “1.0” per  $e \in V_e$ . For example the text

abadcab

would be enciphered to

BCBADBC

when using the substitution

	a	b	c	d
A	0	0	0	1
B	1	0	0	0
C	0	1	0	0
D	0	0	1	0

In contrast to the 1:1 substitution cipher, the **homophonic substitution cipher** allows multiple cipher tokens per plaintext token, which means that the table  $s(e|f)$  is all zero, except for one “1.0” per  $f \in V_f$ . For example the above plaintext could be enciphered to

ABCDECF

when using the homophonic substitution

	a	b	c	d
A	1	0	0	0
B	0	1	0	0
C	1	0	0	0
D	0	0	0	1
E	0	0	1	0
F	0	1	0	0

We will use the definition

$$n_{max} = \max_e \sum_f s(e|f) \quad (2)$$

to characterize the maximum number of different cipher symbols allowed per plaintext symbol.

We formalize the 1:1 substitutions with a *bijective* function  $\phi : V_f \rightarrow V_e$  and homophonic substitutions with a *general* function  $\phi : V_f \rightarrow V_e$ .

Following (Corlett and Penn, 2010), we call cipher functions  $\phi$ , for which not all  $\phi(f)$ ’s are fixed, **partial cipher functions**. Further,  $\phi'$  is **said to extend**  $\phi$ , if for all  $f$  that are fixed in  $\phi$ , it holds that  $f$  is also fixed in  $\phi'$  with  $\phi'(f) = \phi(f)$ .

The **cardinality** of  $\phi$  counts the number of fixed  $f$ 's in  $\phi$ .

When talking about partial cipher functions we use the **notation for relations**, in which  $\phi \subseteq V_f \times V_e$ . For example with

$$\phi = \{(A, a)\} \quad \phi' = \{(A, a), (B, b)\}$$

it follows that  $\phi \subseteq^1 \phi'$  and

$$\begin{array}{ll} |\phi| = 1 & |\phi'| = 2 \\ \phi(A) = a & \phi'(A) = a \\ \phi(B) = \text{undefined} & \phi'(B) = b \end{array}$$

The general **decipherment goal** is to obtain a mapping  $\phi$  such that the probability of the deciphered text is maximal:

$$\hat{\phi} = \arg \max_{\phi} p(\phi(f_1)\phi(f_2)\phi(f_3)\dots\phi(f_N)) \quad (3)$$

Here  $p(\dots)$  denotes the **language model**. Depending on the structure of the language model Equation 3 can be further simplified.

## 4 Beam Search

In this Section we present our beam search approach to solving Equation 3. We first present the general algorithm, containing many higher level functions. We then discuss possible instances of these higher level functions.

### 4.1 General Algorithm

Figure 1 shows the general structure of the beam search algorithm for the decipherment of substitution ciphers. The general idea is to keep track of all partial hypotheses in two arrays  $H_s$  and  $H_t$ . During search all possible extensions of the partial hypotheses in  $H_s$  are generated and scored. Here, the function `EXT_ORDER` chooses which cipher symbol is used next for extension, `EXT_LIMITS` decides which extensions are allowed, and `SCORE` scores the new partial hypotheses. `PRUNE` then selects a subset of these hypotheses which are stored to  $H_t$ . Afterwards the array  $H_s$  is copied to  $H_t$  and the search process continues with the updated array  $H_s$ .

Due to the structure of the algorithm the cardinality of all hypotheses in  $H_s$  increases in each step. Thus only hypotheses of the same cardinality

<sup>1</sup>shorthand notation for  $\phi'$  extends  $\phi$

---

```

1: function      BEAM_SEARCH(EXT_ORDER,
   EXT_LIMITS, PRUNE)
2:   init sets  $H_s, H_t$ 
3:   CARDINALITY = 0
4:    $H_s$ .ADD( $(\emptyset, 0)$ )
5:   while CARDINALITY <  $|V_f|$  do
6:      $f = \text{EXT\_ORDER}[\text{CARDINALITY}]$ 
7:     for all  $\phi \in H_s$  do
8:       for all  $e \in V_e$  do
9:          $\phi' := \phi \cup \{(e, f)\}$ 
10:        if EXT_LIMITS( $\phi'$ ) then
11:           $H_t$ .ADD( $\phi'$ , SCORE( $\phi'$ ))
12:        end if
13:      end for
14:    end for
15:    PRUNE( $H_t$ )
16:    CARDINALITY = CARDINALITY + 1
17:     $H_s = H_t$ 
18:     $H_t$ .CLEAR()
19:  end while
20:  return best scoring cipher function in  $H_s$ 
21: end function

```

---

Figure 1: The general structure of the beam search algorithm for decipherment of substitution ciphers. The high level functions `SCORE`, `EXT_ORDER`, `EXT_LIMITS` and `PRUNE` are described in Section 4.

are compared in the pruning step. When  $H_s$  contains full cipher relations, the cipher relation with the maximal score is returned.<sup>2</sup>

Figure 2 illustrates how the algorithm explores the search space for a homophonic substitution cipher. In the following we show several instances of `EXT_ORDER`, `EXT_LIMITS`, `SCORE`, and `PRUNE`.

### 4.2 Extension Limits (EXT\_LIMITS)

In addition to the implicit constraint of  $\phi$  being a function  $V_f \rightarrow V_e$ , one might be interested in functions of a specific form:

For 1:1 substitution ciphers (`EXT_LIMITS_SIMPLE`)  $\phi$  must fulfill that the number of cipher letters  $f \in V_f$  that map to any  $e \in V_e$  is at most one. Since partial hypotheses violating this condition can never “recover” when being extended, it becomes clear that these partial hypotheses can be left out from search.

<sup>2</sup> $n$ -best output can be implemented by returning the  $n$  best scoring hypotheses in the final array  $H_s$ .

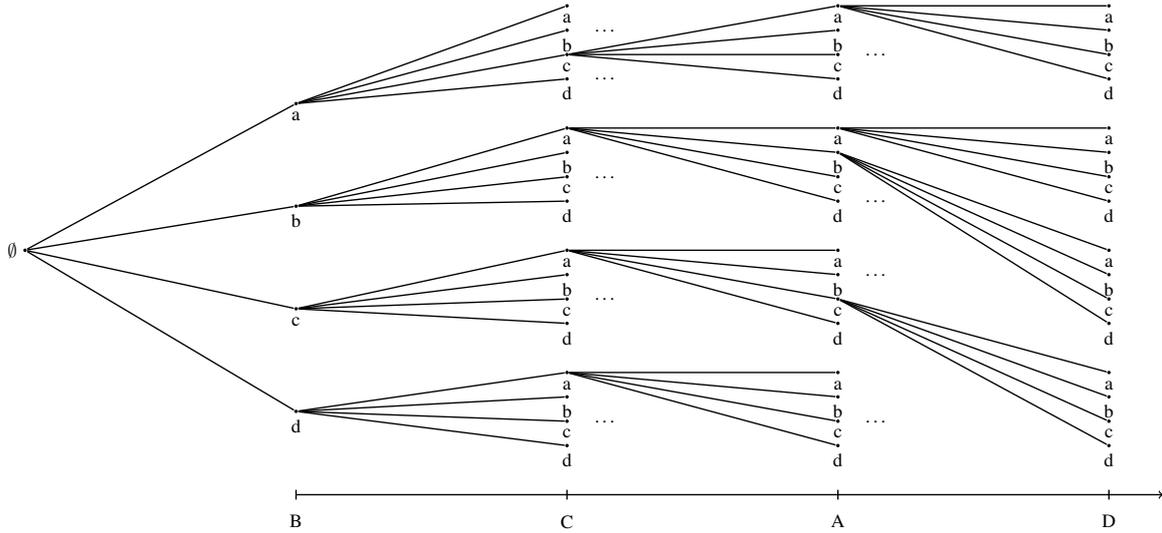

Figure 2: Illustration of the search space explored by the beam search algorithm with cipher vocabulary  $V_f = \{A, B, C, D\}$ , plaintext vocabulary  $V_e = \{a, b, c, d\}$ ,  $\text{EXT\_ORDER} = (B, C, A, D)$ , homophonic extension limits ( $\text{EXT\_LIMITS\_HOMOPHONIC}$ ) with  $n_{max} = 4$ , and histogram pruning with  $n_{keep} = 4$ . Hypotheses are visualized as nodes in the tree. The  $x$ -axis represents the extension order. At each level only those 4 hypotheses that survived the histogram pruning process are extended.

Homophonic substitution ciphers can be handled by the beam search algorithm, too. Here the condition that  $\phi$  must fulfill is that the number of cipher letters  $f \in V_f$  that map to any  $e \in V_e$  is at most  $n_{max}$  (which we will call  $\text{EXT\_LIMITS\_HOMOPHONIC}$ ). As soon as this condition is violated, all further extensions will also violate the condition. Thus, these partial hypotheses can be left out.

### 4.3 Score Estimation (SCORE)

The score estimation function needs to predict how good or bad a *partial* hypothesis (cipher function) might become. We propose simple heuristics that use the  $n$ -gram counts rather than the original ciphertext. The following formulas consider the 2-gram case. Equations for higher  $n$ -gram orders can be obtained analogously.

With Equation 3 in mind, we want to estimate the best possible score

$$\prod_{j=1}^{N+1} p(\phi'(f_j) | \phi'(f_{j-1})) \quad (4)$$

which can be obtained by extensions  $\phi' \supseteq \phi$ . By defining counts<sup>3</sup>

$$N_{ff'} = \sum_{i=1}^{N+1} \delta(f, f_{i-1}) \delta(f', f_i) \quad (5)$$

<sup>3</sup> $\delta$  denotes the Kronecker delta.

we can equivalently use the scores

$$\sum_{f, f' \in \bar{V}_f} N_{ff'} \log p(\phi'(f') | \phi'(f)) \quad (6)$$

Using this formulation it is easy to propose a whole class of heuristics: We only present the simplest heuristic, which we call  $\text{TRIVIAL\_HEURISTIC}$ . Its name stems from the fact that it only evaluates those parts of a given  $\phi'$  that are already fixed, and thus does not estimate any future costs. Its score is calculated as

$$\sum_{f, f' \in \phi'} N_{ff'} \log p(\phi'(f') | \phi'(f)). \quad (7)$$

Here  $f, f' \in \phi'$  denotes that  $f$  and  $f'$  need to be covered in  $\phi'$ . This heuristic is *optimistic* since we implicitly use “0” as estimate for the non fixed parts of the sum, for which  $N_{ff'} \log p(\cdot | \cdot) \leq 0$  holds.

It should be noted that this heuristic can be implemented very efficiently. Given a partial hypothesis  $\phi$  with given  $\text{SCORE}(\phi)$  the score of an extension  $\phi'$  can be calculated as

$$\text{SCORE}(\phi') = \text{SCORE}(\phi) + \text{NEWLY\_FIXED}(\phi, \phi') \quad (8)$$

where  $\text{NEWLY\_FIXED}$  only includes scores for  $n$ -grams that have been newly fixed in  $\phi'$  during the extension step from  $\phi$  to  $\phi'$ .

#### 4.4 Extension Order (EXT\_ORDER)

For the choice which ciphertext symbol should be fixed next during search, several possibilities exist: The overall goal is to choose an extension order that leads to an overall low error rate. Intuitively it seems a good idea to first try to decipher higher frequent words rather than the lowest frequent ones. It is also clear that the choice of a good extension order is dependent on the score estimation function SCORE: The extension order should lead to informative scores early on so that misleading hypotheses can be pruned out early.

In most of our experiments we will make use of a very simple extension order: HIGHEST\_UNIGRAM\_FREQUENCY simply fixes the most frequent symbols first.

In case of the Zodiac-408, we use another strategy that we call HIGHEST\_NGRAM\_COUNT extension order. In each step it greedily chooses the symbol that will maximize the number of fixed ciphertext  $n$ -grams. This strategy is useful because the SCORE function we use is TRIVIAL\_HEURISTIC, which is not able to provide informative scores if only few full  $n$ -grams are fixed.

#### 4.5 Pruning (PRUNE)

We propose two pruning methods: HISTOGRAM\_PRUNING sorts all hypotheses according to their score and then keeps only the best  $n_{keep}$  hypotheses.

THRESHOLD\_PRUNING keeps only those hypotheses  $\phi_{keep}$  for which

$$\text{SCORE}(\phi_{keep}) \geq \text{SCORE}(\phi_{best}) - \beta \quad (9)$$

holds for a given parameter  $\beta \geq 0$ . Even though THRESHOLD\_PRUNING has the advantage of not needing to sort all hypotheses, it has proven difficult to choose proper values for  $\beta$ . Due to this, all experiments presented in this paper only use HISTOGRAM\_PRUNING.

### 5 Iterative Beam Search

(Ravi and Knight, 2011b) propose a so called “iterative EM algorithm”. The basic idea is to run a decipherment algorithm—in their case an EM algorithm based approach—on a subset of the vocabulary. After having obtained the results from the restricted vocabulary run, these results are used to initialize a decipherment run with a larger vocabulary. The results from this run will then be used for a further decipherment run with an even

larger vocabulary and so on. In our large vocabulary word substitution cipher experiments we iteratively increase the vocabulary from the 1000 most frequent words, until we finally reach the 50000 most frequent words.

## 6 Experimental Evaluation

We conduct experiments on letter based 1:1 substitution ciphers, the homophonic substitution cipher Zodiac-408, and word based 1:1 substitution ciphers.

For a given reference mapping  $\phi_{ref}$ , we evaluate candidate mappings  $\phi$  using two error measures: **Mapping Error Rate**  $\text{MER}(\phi, \phi_{ref})$  and **Symbol Error Rate**  $\text{SER}(\phi, \phi_{ref})$ . Roughly speaking, SER reports the fraction of symbols in the deciphered text that are not correct, while MER reports the fraction of incorrect mappings in  $\phi$ .

Given a set of symbols  $V_{eval}$  with unigram counts  $N(v)$  for  $v \in V_{eval}$ , and the total amount of running symbols  $N_{eval} = \sum_{v \in V_{eval}} N(v)$  we define

$$\text{MER} = 1 - \sum_{v \in V_{eval}} \frac{1}{|V_{eval}|} \cdot \delta(\phi(v), \phi_{ref}(v)) \quad (10)$$

$$\text{SER} = 1 - \sum_{v \in V_{eval}} \frac{N(v)}{N_{eval}} \cdot \delta(\phi(v), \phi_{ref}(v)) \quad (11)$$

Thus the SER can be seen as a weighted form of the MER, emphasizing errors for frequent words. In decipherment experiments, SER will often be lower than MER, since it is often easier to decipher frequent words.

### 6.1 Letter Substitution Ciphers

As **ciphertext** we use the text of the English Wikipedia article about *History*<sup>4</sup>, remove all pictures, tables, and captions, convert all letters to lowercase, and then remove all non-letter and non-space symbols. This corpus forms the basis for shorter cryptograms of size 2, 4, 8, 16, 32, 64, 128, and 256—of which we generate 50 each. We make sure that these shorter cryptograms do not end or start in the middle of a word. We create the ciphertext using a **1:1 substitution cipher** in which we fix the mapping of the space symbol ' '. This

Table 1: Symbol error rates (SER), Mapping error rates (MER) and runtimes (RT) in dependence of language model order (ORDER) and histogram pruning size (BEAM) for decipherment of letter substitution ciphers of length 128. Runtimes are reported on a single core machine. Results for beam size “ $\infty$ ” were obtained using  $A^*$  search.

makes our experiments comparable to those conducted in (Ravi and Knight, 2008). Note that fixing the ‘\_’ symbol makes the problem much easier: The exact methods show much higher computational demands for lengths beyond 256 letters when not fixing the space symbol.

The **plaintext language model** we use a letter based ( $V_e = \{a, \dots, z, _\}$ ) language model trained on a subset of the Gigaword corpus (Graff et al., 2007).

We use **extension limits** fitting the 1:1 substitution cipher  $n_{max} = 1$  and **histogram pruning** with different beam sizes.

For comparison we reimplemented the ILP approach from (Ravi and Knight, 2008) as well as the  $A^*$  approach from (Corlett and Penn, 2010).

Figure 3 shows the **results** of our algorithm for different cipher length. We use a beam size of 100k for the 4, 5 and 6-gram case. Most remarkably our 6-gram beam search results are significantly better than all methods presented in the literature. For the cipher length of 32 we obtain a symbol error rate of just 4.1% where the optimal solution (i.e. without search errors) for a 3-gram

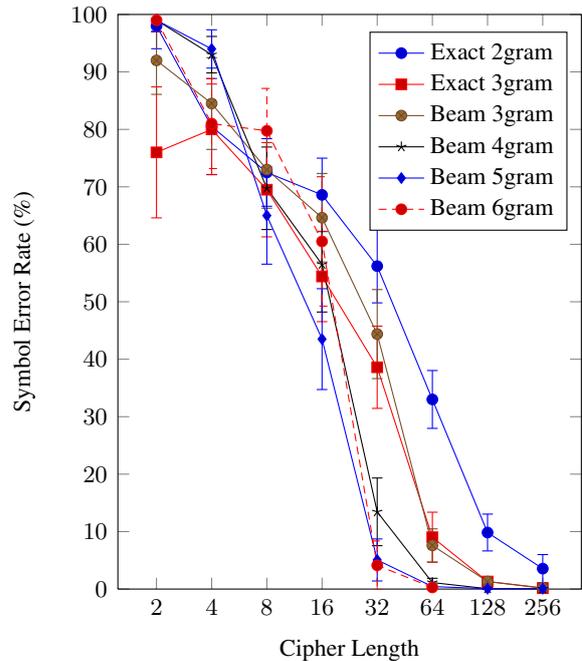

Figure 3: Symbol error rates for decipherment of letter substitution ciphers of different lengths. Error bars show the 95% confidence interval based on decipherment on 50 different ciphers. Beam search was performed with a beam size of “100k”.

language model has a symbol error rate as high as 38.3%.

Table 1 shows error rates and runtimes of our algorithm for different beam sizes and language model orders given a fixed ciphertext length of 128 letters. It can be seen that achieving close to optimal results is possible in a fraction of the CPU time needed for the optimal solution: In the 3-gram case the optimal solution is found in  $\frac{1}{400}$ th of the time needed using  $A^*$  search. It can also be seen that increasing the language model order does not increase the runtime much while providing better results if the beam size is large enough: If the beam size is not large enough, the decipherment accuracy decreases when increasing the language model order: This is because the higher order heuristics do not give reliable scores if only few  $n$ -grams are fixed.

To summarize: The beam search method is significantly faster and obtains significantly better results than previously published methods. Furthermore it offers a good trade-off between CPU time and decipherment accuracy.

Figure 4: First 136 letters of the Zodiac-408 cipher and its decipherment.

## 6.2 Zodiac-408 Cipher

As **ciphertext** we use a transcription of the Zodiac-408 cipher. It consists of 54 different symbols and has a length of 408 symbols.<sup>5</sup> The cipher has been deciphered by hand before. It contains some mistakes and ambiguities: For example, it contains misspelled words like *forrest* (vs. *forest*), *experence* (vs. *experience*), or *paradice* (vs. *paradise*). Furthermore, the last 17 letters of the cipher do not form understandable English when applying the same homophonic substitution that decipheres the rest of the cipher. This makes the Zodiac-408 a good candidate for testing the robustness of a decipherment algorithm.

We assume a **homophonic substitution cipher**, even though the cipher is not strictly homophonic: It contains three cipher symbols that correspond to two or more plaintext symbols. We ignore this fact for our experiments, and count—in case of the MER *only*—the decipherment for these symbols as correct when the obtained mapping is contained in the set of reference symbols. We use **extension limits** with  $n_{max} = 8$  and **histogram pruning** with beam sizes of  $10k$  up to  $10M$ .

The **plaintext language model** is based on the same subset of Gigaword (Graff et al., 2007) data as the experiments for the letter substitution ciphers. However, we first removed all space sym-

Table 2: Symbol error rates (SER), Mapping error rates (MER) and runtimes (RT) in dependence of language model order (ORDER) and histogram pruning size (BEAM) for the decipherment of the Zodiac-408 cipher. Runtimes are reported on a 128-core machine.

bols from the training corpus before training the actual letter based 4-gram, 5-gram, and 6-gram language model on it. Other than (Ravi and Knight, 2011a) we do not use any word lists and by that avoid any degrees of freedom in how to integrate it into the search process: Only an  $n$ -gram language model is used.

Figure 4 shows the first parts of the cipher and our best decipherment. Table 2 shows the **results** of our algorithm on the Zodiac-408 cipher for different language model orders and pruning settings.

To summarize: Our final decipherment—for which we only use a 6-gram language model—has a symbol error rate of only 2.0%, which is slightly better than the best decipherment reported in (Ravi and Knight, 2011a). They used an  $n$ -gram language model together with a word dictionary and obtained a symbol error rate of 2.2%. We thus obtain better results with less modeling.

## 6.3 Word Substitution Ciphers

As **ciphertext**, we use parts of the JRC corpus (Steinberger et al., 2006) and the Gigaword corpus (Graff et al., 2007). While the full JRC corpus contains roughly 180k word types and consists of approximately 70M running words, the full Gigaword corpus contains around 2M word types and roughly 1.5G running words.

We run experiments for three different setups: The “JRC” and “Gigaword” setups use the first half of the respective corpus as ciphertext, while the **plaintext language model** of order  $n = 3$  was

Setup	Top	MER [%]	SER [%]	RT [hh:mm]
Gigaword	1k	81.91	27.38	03h 10m
	10k	30.29	8.55	09h 21m
	20k	21.78	6.51	16h 25m
	50k	19.40	5.96	49h 02m
JRC	1k	73.28	15.42	00h 32m
	10k	15.82	2.61	13h 03m
JRC-Shuf	1k	76.83	19.04	00h 31m
	10k	15.08	2.58	13h 03m

Table 3: Word error rates (WER), Mapping error rates (MER) and runtimes (RT) for iterative decipherment run on the (TOP) most frequent words. Error rates are evaluated on the full vocabulary. Runtimes are reported on a 128-core machine.

trained on the second half. The “JRC-Shuf” setup is created by randomly selecting half of the sentences of the JRC corpus as ciphertext, while the language model was trained on the complementary half of the corpus.

We encrypt the ciphertext using a **1:1 substitution cipher** on word level, imposing a much larger vocabulary size. We use **histogram pruning** with a beam size of 128 and use **extension limits** of  $n_{max} = 1$ . Different to the previous experiments, we use **iterative beam search** with iterations as shown in Table 3.

The results for the Gigaword task are directly comparable to the word substitution experiments presented in (Dou and Knight, 2012). Their final decipherment has a symbol error rate of 7.8%. Our algorithm obtains 6.0% symbol error rate. It should be noted that the improvements of 1.8% symbol error rate correspond to a larger improvement in terms of mapping error rate. This can also be seen when looking at Table 3: An improvement of the symbol error rate from 6.51% to 5.96% corresponds to an improvement of mapping error rate from 21.78% to 19.40%.

To summarize: Using our beam search algorithm in an iterative fashion, we are able to improve the state-of-the-art decipherment accuracy for word substitution ciphers.

## 7 Conclusion

We have presented a simple and effective beam search approach to the decipherment problem. We have shown in a variety of experiments—letter substitution ciphers, the Zodiac-408, and word substitution ciphers—that our approach outperforms the current state of the art while being con-

ceptually simpler and keeping computational demands low.

We want to note that the presented algorithm is not restricted to 1:1 and homophonic substitution ciphers: It is possible to extend the algorithm to solve  $n:m$  mappings. Along with more sophisticated pruning strategies, score estimation functions, and extension orders, this will be left for future research.

## Abstract

We introduce a social media text normalization system that can be deployed as a preprocessing step for Machine Translation and various NLP applications to handle social media text. The proposed system is based on unsupervised learning of the normalization equivalences from unlabeled text. The proposed approach uses Random Walks on a contextual similarity bipartite graph constructed from n-gram sequences on large unlabeled text corpus. We show that the proposed approach has a very high precision of (92.43) and a reasonable recall of (56.4). When used as a preprocessing step for a state-of-the-art machine translation system, the translation quality on social media text improved by 6%. The proposed approach is domain and language independent and can be deployed as a preprocessing step for any NLP application to handle social media text.

## 1 Introduction

Social Media text is usually very noisy and contains a lot of typos, ad-hoc abbreviations, phonetic substitutions, customized abbreviations and slang language. The social media text is evolving with new entities, words and expressions. Natural language processing and understanding systems such as Machine Translation, Information Extraction and Text-to-Speech are usually trained and optimized for clean data; therefore such systems would face a challenging problem with social media text.

Various social media genres developed distinct characteristics. For example, SMS developed a nature of shortening messages to avoid multiple keystrokes. On the other hand, Facebook and instant messaging developed another genre where

more emotional expressions and different abbreviations are very common. Somewhere in between, Twitter's statuses come with some brevity similar to SMS along with the social aspect of Facebook. On the same time, various social media genres share many characteristics and typologies. For example, repeating letters or punctuation for emphasizing and emotional expression such as "*gooooood morniiiiing*". Using phonetic spelling in a generalized way or to reflect a local accent; such as "*wuz up bro*" (*what is up brother*). Eliminating vowels such as "*cm to c my luv*". Substituting numbers for letters such as "*4get*" (*forget*), "*2morrow*" (*tomorrow*), and "*b4*" (*before*). Substituting phonetically similar letters such as "*phone*" (*fon*). Slang abbreviations which usually abbreviates multi-word expression such as "*LMS*" (*like my status*), "*idk*" (*i do not know*), "*rofl*" (*rolling on floor laughing*).

While social media genres share many characteristics, they have significant differences as well. It is crucial to have a solution for text normalization that can adapt to such variations automatically. We propose a text normalization approach using an unsupervised method to induce normalization equivalences from noisy data which can adapt to any genre of social media.

In this paper, we focus on providing a solution for social media text normalization as a preprocessing step for NLP applications. However, this is a challenging problem for several reasons. First, it is not straightforward to define the Out-of-Vocabulary (OOV) words. Traditionally, an OOV word is defined as a word that does not exist in the vocabulary of a given system. However, this definition is not adequate for the social media text which has a very dynamic nature. Many words and named entities that do not exist in a given vocabulary should not be considered for normalization. Second, same OOV word may have many

appropriate normalization depending on the context and on the domain. Third, text normalization as a preprocessing step should have very high precision; in other words, it should provide conservative and confident normalization and not overcorrect. Moreover, the text normalization should have high recall, as well, to have a good impact on the NLP applications.

In this paper, we introduce a social media text normalization system which addresses the challenges mentioned above. The proposed system is based on constructing a lattice from possible normalization candidates and finding the best normalization sequence according to an n-gram language model using a Viterbi decoder. We propose an unsupervised approach to learn the normalization candidates from unlabeled text data. The proposed approach uses Random Walks on a contextual similarity graph constructed from n-gram sequences on large unlabeled text corpus. The proposed approach is very scalable, accurate and adaptive to any domain and language. We evaluate the approach on the normalization task as well as machine translation task.

The rest of this paper is organized as follows: Section(2) discusses the related work, Section(3) introduces the text normalization system and the baseline candidate generators, Section(4) introduces the proposed graph-based lexicon induction approach, Section(5) discusses the experiments and output analysis, and finally Section(6) concludes and discusses future work.

## 2 Related Work

Early work handled the text normalization problem as a noisy channel model where the normalized words go through a noisy channel to produce the noisy text. (Brill and Moore, 2000) introduced an approach for modeling the spelling errors as a noisy channel model based on string to string edits. Using this model gives significant performance improvements compared to previously proposed models. (Toutanova and Moore, 2002) improved the string to string edits model by modeling pronunciation similarities between words. (Choudhury et al., 2007) introduced a supervised HMM channel model for text normalization which has been expanded by (Cook and Stevenson, 2009) to introduce unsupervised noisy channel model using probabilistic models for common abbreviation and various spelling errors types. Some

researchers used Statistical Machine Translation approach for text normalization; formalizing the problem as a translation from the noisy forms to the normalized forms. (Aw et al., 2006) proposed an approach for normalizing Short Messaging Service (SMS) texts by translating it into normalized forms using Phrase-based SMT techniques on character level. The main drawback of these approaches is that the noisy channel model cannot accurately represent the errors types without contextual information.

More recent approaches tried to handle the text normalization problem using normalization lexicons which map the noisy form of the word to a normalized form. For example, (Han et al., 2011) proposed an approach using a classifier to identify the noisy words candidate for normalization; then using some rules to generate lexical variants and a small normalization lexicon. (Gouws et al., 2011) proposed an approach using an impoverished normalization lexicon based on string and distributional similarity along with a dictionary lookup approach to detect noisy words. More recently, (Han et al., 2012) introduced a similar approach by generating a normalization lexicon based on distributional similarity and string similarity. This approach uses pairwise similarity where any two words that share the same context are considered as normalization equivalences. The pairwise approach has a number of limitations. First, it does not take into account the relative frequencies of the normalization equivalences that might share different contexts. Therefore, the selection of the normalization equivalences is performed on pairwise basis only and is not optimized over the whole data. Secondly, the normalization equivalences must appear in the exact same context to be considered as a normalization candidate. These limitations affect the accuracy and the coverage of the produced lexicon.

Our approach also adopts a lexicon based approach for text normalization, we construct a lattice from possible normalization candidates and find the best normalization sequence according to an n-gram language model using a Viterbi decoder. The normalization lexicon is acquired from unlabeled data using random walks on a contextual similarity graph constructed from n-gram sequences on large unlabeled text corpus. Our approach has some similarities with (Han et al., 2012) since both approaches utilize a normaliza-

tion lexicon acquired from unlabeled data using distributional and string similarities. However, our approach is significantly different since we acquire the lexicon using random walks on a contextual similarity graph which has a number of advantages over the pairwise similarity approach used in (Han et al., 2012). Namely, the acquired normalization equivalences are optimized globally over the whole data, the rare equivalences are not considered as good candidates unless there is a strong statistical evidence across the data, and finally the normalization equivalences may not share the same context. Those are clear advantages over the pairwise similarity approach and result in a lexicon with higher accuracy as well as wider coverage. Those advantages will be clearer when we describe the proposed approach in details and during evaluation and comparison to the pairwise approach.

### 3 Text Normalization System

In this paper, we handle text normalization as a lattice scoring approach, where the translation is performed from noisy text as the source side to the normalized text as the target side. Unlike conventional MT systems, the translation table is not learned from parallel aligned data; instead it is modeled by the graph-based approach of lexicon generation as we will describe later. We construct a lattice from possible normalization candidates and find the best normalization sequence according to an n-gram language model using a Viterbi decoder.

In this paper, we restrict the normalization lexicon to one-to-one word mappings, we do not consider multi words mapping for the lexicon induction. To identify OOV candidates for normalization; we restrict proposing normalization candidates to the words that we have in our induced normalization lexicon only. This way, the system would provide more confident and conservative normalization. We move the problem of identifying OOV words to training time; at training time we use soft criteria to identify OOV words.

#### 3.1 Baseline Normalization Candidates Generation

We experimented with two normalization candidate generators as baseline systems. The first is a dictionary based spelling correction similar to Aspell<sup>1</sup>. In this experiment we used the spell checker

<sup>1</sup><http://aspell.net/>

to generate all possible candidates for OOV words and then applied the Viterbi decoder on the constructed lattice to score the best correction candidates using a language model.

Our second candidates generator is based on a trie approximate string matching with  $K$  errors similar to the approach proposed in (Chang et al., 2010), where  $K$  errors can be caused by substitution, insertion, or deletion operations. In our implementation, we customized the errors operations to accommodate the nature of the social media text. Such as lengthening, letter substitution, letter-number substitution and phonetic substitution. This approach overcomes the main problem of the dictionary-based approach which is providing inappropriate normalization candidates to the errors styles in the social media text.

As we will show in the experiments in Section(5), dictionary-based normalization methods proved to be inadequate for social media domain normalization for many reasons. First, they provide generic corrections which are inappropriate for social media text. Second, they usually provide corrections with the minimal edit distance for any word or named entity regardless of the nature of the words. Finally, the previous approaches do not take into account the dynamics of the social media text where new terms can be introduced on a daily basis.

### 4 Normalization Lexicons using Graph-based Random Walks

#### 4.1 Bipartite Graph Representation

The main motivation of this approach is that normalization equivalences share similar context; which we call contextual similarity. For instance, assume 5-gram sequences of words, two words may be normalization equivalences if their n-gram context shares the same two words on the left and the same two words on the right. In other words, they are sharing a wild card pattern such as ( $word_1 word_2 * word_4 word_5$ ).

This contextual similarity can be represented as a bipartite graph with the first partite representing the words and the second partite representing the n-gram contexts that may be shared by words. A word node can be either normalized word or noisy word. Identifying if a word is normalized or noisy (candidate for normalization) is crucial since this decision limits the candidate noisy words to be normalized. We adopted a soft criteria for iden-

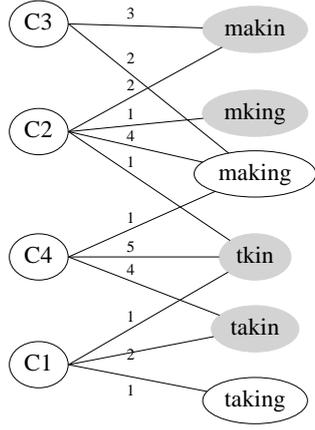

Figure 1: Bipartite Graph Representation, left nodes represent contexts, gray right nodes represent the noisy words and white right nodes represent the normalized words. Edge weight is the co-occurrence count of a word and its context.

tifying noisy words. A vocabulary is constructed from a large clean corpus. Any word that does not appear in this vocabulary more than a predefined threshold (i.e. 10 times) is considered as a candidate for normalization (noisy word). Figure(1) shows a sample of the bipartite graph  $G(W, C, E)$ , where noisy words are shown as gray nodes.

---

**Algorithm 4.1:** CONSTRUCTBIPARTITE(*text*)

---

**comment:** Construct Bipartite Graph  
**output** ( $G(W, C, E)$ )  
**comment:** Extract all  $n$ -gram sequences  
 $Ngrams \leftarrow \text{EXTRACTNGRAMS}(TextCorpus)$   
**for each**  $n \in Ngrams$   
  **do**  
    **comment:** Check for center word  
    **if** ISNOISY(*CenterWord*)  
       $W \leftarrow \text{ADDSOURCENODE}(\text{CenterWord})$   
    **else**  
       $W \leftarrow \text{ADDABSORBINGNODE}(\text{CenterWord})$   
    **comment:** add the context pattern  
     $C \leftarrow \text{ADD}(\text{Context})$   
    **comment:** edge weight  
     $E \leftarrow \text{ADD}(\text{Context}, \text{Word}, \text{count})$

---

The bipartite graph,  $G(W, C, E)$ , is composed of  $W$  which includes all nodes representing normalized words and noisy words,  $C$  which includes all nodes representing shared context, and finally  $E$  which represents the edges of the graph connecting word nodes and context nodes. The weight on the edge is simply the number of occurrences of a given word in a context. While constructing the graph, we identify if a node represents a

noisy word ( $N$ ) (called source node) or a normalized word ( $M$ ) (called absorbing node). The bipartite graph is constructed using the procedure in Algorithm(4.1).

## 4.2 Lexicon generation using Random Walks

Our proposed approach uses Markov Random Walks on the bipartite graph in Figure(1) as defined in (Norris, 1997). The main objective is to identify pairs of noisy and normalized words that can be considered as normalization equivalences. In principal, this is similar to using random walks for semi-supervised label propagation which has been introduced in (Szummer and Jaakkola, 2002) and then used in many other applications. For example, (Hughes and Ramage, 2007) used random walks on Wordnet graph to measure lexical semantic relatedness between words. (Das and Petrov, 2011) used graph-based label propagation for cross-lingual knowledge transfers to induce POS tags between two languages. (Minkov and Cohen, 2012) introduced a path constrained graph walk algorithm given a small number of labeled examples to assess nodes relatedness in the graph. In this paper, we apply the label propagation approach to the text normalization problem.

Consider a random walk on the bipartite graph  $G(W, C, E)$  starting at a noisy word (source node) and ending at a normalized word (absorbing node). The walker starts from any source node  $N_i$  belonging to the noisy words then move to any other connected node  $M_j$  with probability  $P_{ij}$ . The transition between each pair of nodes is defined by a transition probability  $P_{ij}$  which represents the normalized probability of the co-occurrence counts of the word and the corresponding context. Though the counts are symmetric, the probability is not symmetric. This is due to the probability normalization which is done according to the nodes connectivity. Therefore, the transition probability between any two nodes  $i, j$  is defined as:

$$P_{ij} = W_{ij} / \sum_{\forall k} W_{ik} \quad (1)$$

For any non-connected pair of nodes,  $P_{ij} = 0$ . It is worth noting that due to the bipartite graph representation; any word node, either noisy (source) or normalized (absorbing), is only connected to context nodes and not directly connected to any other word node.

The algorithm repeats independent random walks for  $K$  times where the walks traverse the graph randomly according to the transition probability distribution in Eqn(1); each walk starts from the source noisy node and ends at an absorbing normalized node, or consumes the maximum number of steps without hitting an absorbing node.

For any random walk the number of steps taken to traverse between any two nodes is called the hitting time (Norris, 1997). Therefore, the hitting time between a noisy and a normalized pair of nodes  $(n, m)$  with a walk  $r$  is  $h_r(n, m)$ . We define the cost between the two nodes as the average hitting time  $H(n, m)$  of all walks that connect those two nodes:

$$H(n, m) = \sum_{\forall r} h_r(n, m) / R \quad (2)$$

Consider the bipartite graph in Figure(1), assume a random walk starting at the source node representing the noisy word "tkin" then moves to the context node  $C1$  then to the absorbing node representing the normalized word "taking". This random walk will associate "tkin" with "taking" with a walk of two steps (hits). Another random walk that can connect the two words is ["tkin"  $\rightarrow$   $C4$   $\rightarrow$  "takin"  $\rightarrow$   $C1$   $\rightarrow$  "taking"], which has 4 steps (hits). In this case, the cost of this pair of nodes is the average number of hits connecting them which is 3.

It is worth noting that the random walks are selected according to the transition probability in Eqn(1); therefore, the more probable paths will be picked more frequently. The same pair of nodes can be connected with many walks of various steps (hits), and the same noisy word can be connected to many other normalized words.

We define the contextual similarity probability of a normalization equivalence pair  $n, m$  as  $L(n, m)$ . Which is the relative frequency of the average hitting of those two nodes,  $H(n, m)$ , and all other normalized nodes linked to that noisy word. Thus  $L(n, m)$ , is calculated as:

$$L(n, m) = H(n, m) / \sum_i H(n, m_i) \quad (3)$$

Furthermore, we add another similarity cost between a noisy word and a normalized word based on the lexical similarity cost,  $SimCost(n, m)$ , which we will describe in the next section. The final cost associated with a pair is:

$$Cost(n, m) = \lambda_1 L(n, m) + \lambda_2 SimCost(n, m) \quad (4)$$

---

**Algorithm 4.2:** INDUCELEXICON( $G$ )

---

```

output ( $Lexicon$ )
INIT( $Lexicon$ )

     $Ln \leftarrow$  SIMCOST( $Ln$ )
     $Ln \leftarrow$  PRUNE( $Ln$ )
   $Lexicon \leftarrow$  ADD( $Ln$ )

```

---

We used uniform interpolation, both  $\lambda_1$  and  $\lambda_2$  equals 1. The final Lexicon is constructed using those entries and if needed we prune the list to take top N according to the cost above. The algorithm is outlined in 4.2.

### 4.3 Lexical Similarity Cost

We use a similarity function proposed in (Contractor et al., 2010) which is based on Longest Common Subsequence Ratio (LCSR) (Melamed, 1999). This cost function is defined as the ratio of LCSR and Edit distance between two strings as follows:

$$SimCost(n, m) = LCSR(n, m) / ED(n, m) \quad (5)$$

$$LCSR(n, m) = LCS(n, m) / MaxLenght(n, m) \quad (6)$$

We have modified the Edit Distance calculation  $ED(n, m)$  to be more adequate for social media text. The edit distance is calculated between the consonant skeleton of the two words; by removing all vowels, we used Editex edit distance as proposed in (Zobel and Philip, 1996), repetition is reduced to a single letter before calculating the edit distance, and numbers in the middle of words are substituted by their equivalent letters.

## 5 Experiments

### 5.1 Training and Evaluation Data

We collected large amount of social media data to generate the normalization lexicon using the ran-

dom walk approach. The data consists of 73 million Twitter statuses. All tweets were collected from March/April 2012 using the Twitter Streaming APIs<sup>2</sup>. We augmented this data with 50 million sentences of clean data from English LDC Gigaword corpus<sup>3</sup>. We combined both data, noisy and clean, together to induce the normalization dictionary from them. While the Gigaword clean data was used to train the language model to score the normalized lattice.

We constructed a test set of 1000 sentences of social media which had been corrected by a native human annotator, the main guidelines were to normalize noisy words to its corresponding clean words in a consistent way according to the evidences in the context. We will refer to this test set as SM-Test. Furthermore, we developed a test set for evaluating the effect of the normalization system when used as a preprocessing step for Machine translation. The machine translation test set is composed of 500 sentences of social media English text translated to normalized Spanish text by a bi-lingual translator.

## 5.2 Evaluating Normalization Lexicon Generation

We extracted 5-gram sequences from the combined noisy and clean data; then we limited the space of noisy 5-gram sequences to those which contain only one noisy word as the center word and all other words, representing the context, are not noisy. As we mentioned before, we identify whether the word is noisy or not by looking up a vocabulary list constructed from clean data. In these experiments, the vocabulary is constructed from the Language Model data (50M sentences of the English Gigaword corpus). Any word that appears less than 10 times in this vocabulary is considered noisy and candidate for normalization during the lexicon induction process. It is worth noting that our notion of noisy word does not mean it is an OOV that has to be corrected; instead it indicates that it is candidate for correction but may be opted not to be normalized if there is no confident normalization for it. This helps to maintain the approach as a high precision text normalization system which is highly preferable as an NLP preprocessing step.

We constructed a lattice using normalization

candidates and score the best Viterbi path with 5-gram language model. We experimented with two candidate generators as baseline systems, namely the dictionary-based spelling correction and the trie approximate match with  $K$  errors; where  $K=3$ . For both candidate generators the cost function for a given candidate is calculated using the lexical similarity cost in Eqn(5). We compared those approaches with our newly proposed unsupervised normalization lexicon induction; for this case the cost for a candidate is the combined cost of the contextual similarity probability and the lexical similarity cost as defined in Eqn(4). We examine the effect of data size and the steps of the random walks on the accuracy and the coverage of the induced dictionary.

We constructed the bipartite graph with the n-gram sequences as described in Algorithm 4.1. Then the Random Walks Algorithm in 4.2 is applied with 100 walks. The total number of word nodes is about 7M nodes and the total number of context nodes is about 480M nodes. We used MapReduce framework to implement the proposed technique to handle such large graph. We experimented with the maximum number of random walk steps of 2, 4 and 6; and with different portions of the data as well. Finally, we pruned the lexicon to keep the top 5 candidates per noisy word.

Table(1) shows the resulting lexicons from different experiments.

Lexicon	Lexicon	Data	Steps
Lex1	123K	20M	4
Lex2	281K	73 M	2
Lex3	327K	73M	4
Lex4	363K	73M	6

Table 1: Generated Lexicons, steps are the Random Walks maximum steps.

As shown in Table(1), we experimented with different data sizes and steps of the random walks. The more data we have the larger the lexicon we get. Also larger steps increase the induced lexicon size. A random walk step size of 2 means that the noisy/normalized pair shares the same context; while a step size of 4 or more means that they may not share the same context. Next, we will examine the effect of lexicon size on the normalization task.

<sup>2</sup><https://dev.twitter.com/docs/streaming-apis>

<sup>3</sup><http://www ldc.upenn.edu/Catalog/LDC2011T07>

### 5.3 Text Normalization Evaluation

We experimented different candidate generators and compared it to the unsupervised lexicon approach. Table(2) shows the precision and recall on a the SM-Test set.

System	Candidates	Precision	Recall	F-Measure
Base1	Dict	33.9	15.1	20.98
Base2	Trie	26.64	27.65	27.13
RW1	Lex1	88.76	59.23	71.06
RW2	Lex2	90.66	54.06	67.73
<b>RW3</b>	<b>Lex3</b>	<b>92.43</b>	<b>56.4</b>	<b>70.05</b>
RW4	Lex4	90.87	60.73	72.8

Table 2: Text Normalization with different lexicons

In Table(2), the first baseline is using a dictionary based spell checker; which gets low precision and very low recall. Similarly the trie approximate string match is doing a similar job with better recall though the precision is worst. Both of the baseline approaches are inadequate for social media text since both will try to correct any word that is similar to a word in the dictionary. The Trie approximate match is doing better job on the recall since the approximate match is based on phonetic and lexical similarities.

On the other hand, the induced normalization lexicon approach is doing much better even with a small amount of data as we can see with system RW1 which uses Lex1 generated from 20M sentences and has 123K lexicon entry. Increasing the amount of training data does impact the performance positively especially the recall. On the other hand, increasing the number of steps has a good impact on the recall as well; but with a considerable impact on the precision. It is clear that increasing the amount of data and keeping the steps limit at "4" gives better precision and coverage as well. This is a preferred setting since the main objective of this approach is to have better precision to serve as a reliable preprocessing step for Machine Translation and other NLP applications.

### 5.4 Comparison with Pairwise Similarity

We present experimental results to compare our proposed approach with (Han et al., 2012) which used pairwise contextual similarity to induce a normalization lexicon of 40K entries, we will refer to this lexicon as HB-Dict. We compare the performance of HB-Dict and our induced dictionary (system RW3). We evaluate both system on SM-

Test test set and on (Han et al., 2012) test set of 548 sentences which we call here HB-Test.

System	Precision	Recall	F-Measure
SM-Test			
HB-Dict	71.90	26.30	38.51
RW3	92.43	56.4	70.05
HB-Test			
HB-Dict	70.0	17.9	26.3
RW3	85.37	56.4	69.93

Table 3: Text Normalization Results

As shown in Table(3), RW3 system significantly outperforms HB-Dict system with the lexicon from (Han et al., 2012) on both test sets for both precision and recall. The contextual graph random walks approach helps in providing high precision lexicon since the sampling nature of the approach helps in filtering out unreliable normalization equivalences. The random walks will traverse more frequent paths; which would lead to more probable normalization equivalence. On the other hand, the proposed approach provides high recall as well which is hard to achieve with higher precision. Since the proposed approach deploys random walks to sample paths that can traverse many steps, this relaxes the constraints that the normalization equivalences have to share the same context. Instead a noisy word may share a context with another noisy word which in turn shares a context with a clean equivalent normalization word. Therefore, we end up with a lexicon that have much higher recall than the pairwise similarity approach since it explores equivalences beyond the pairwise relation. Moreover, the random walk sampling emphasis the more frequent paths and hence provides high precision lexicon.

### 5.5 Output Analysis

Table(4) shows some examples of the induced normalization equivalences, the first part shows good examples where vowels are restored and phonetic similar words are matched. Remarkably the correction "viewability" to "visibility" is interesting since the system picked the more frequent form. Moreover, the lexicon contains some entries with foreign language words normalized to its English translation. On the other hand, the lexicon has some bad normalization such as "unrecycled" which should be normalized to "non recycled" but since the system is limited to one word correction it did not get it. Another interesting bad normalization is "tutting" which is new type of

dancing and should not be corrected to "tweeting".

Noisy	Clean	Remarks
tnght	tonight	Vowels restored
darlin	darling	g restored
urung	orange	phonetic similarity
viewability	visibility	good correction
unrecycled	recycled	negation ignored
tutting	tweeting	tutting is dancing type

Table 4: Lexicon Samples

Table 5 lists a number of examples and their normalization using both **Baseline1** and **RW3**. At the first example, **RW3** got the correct normalization as "interesting" which apparently is not the one with the shortest edit distance, though it is the most frequent candidate at the generated lexicon. The baseline system did not get it right; it got a wrong normalization with shorter edit distance. Example(2) shows the same effect by getting "cuz" normalized to "because". At Example(3), both the baseline and RW3 did not get the correct normalization of "yur" to "you are" which is currently a limitation in our system since we only allow one-to-one word mapping in the generated lexicons not one-to-many or many-to-many. At Example(4), RW3 did not normalize "dure" to "sure"; however the baseline normalized it by mistake to "dare". This shows a characteristic of the proposed approach; it is very conservative in proposing normalization which is desirable as a preprocessing step for NLP applications. This limitation can be marginalized by providing more data for generating the lexicon. Finally, Example 4 shows also that the system normalize "gr8" which is mainly due to having a flexible similarity cost during the normalization lexicon construction.

<b>1. Source:</b> <i>Mad abt dt so mch intesting</i> <b>Baseline1:</b> <i>Mad at do so much ingesting</i> <b>RW3:</b> <i>Mad about that so much interesting</i>
<b>2. Source:</b> <i>i'l do cuz ma parnts r ma lyf</i> <b>Baseline1:</b> <i>I'll do cut ma parents r ma life</i> <b>RW3:</b> <i>I'll do because my parents are my life</i>
<b>3. Source:</b> <i>yur cuuuuute</i> <b>Baseline1:</b> <i>your cuuuuute</i> <b>RW3:</b> <i>your cute</i>
<b>4. Source:</b> <i>I'm dure u will get a gr8 score</i> <b>Baseline1:</b> <i>I'm dare you will get a gr8 score</i> <b>RW3:</b> <i>I'm dure you will get a great score</i>

Table 5: Normalization Examples

## 5.6 Machine Translation Task Evaluation

The final evaluation of the text normalization system is an extrinsic evaluation where we evaluate the effect of the text normalization task on a social media text translating from English to Spanish using a large scale translation system trained on general domain data. The system is trained on English-Spanish parallel data from WMT 2012 evaluation<sup>4</sup>. The data consists of about 5M parallel sentences on news, europal and UN data. The system is a state of the art phrase based system similar to Moses (Hoang et al., 2007). We used The BLEU score (Papineni et al., 2002) to evaluate the translation accuracy with and without the normalization. Table(6) shows the translation evaluation with different systems. The translation with normalization was improved by about 6% from 29.02 to 30.87 using RW3 as a preprocessing step.

System	BLEU	Impreovemnet
No Normalization	29.02	0%
Baseline1	29.13	0.37%
HB-Dict	29.76	3.69%
RW3	30.87	6.37%

Table 6: Translation Results

## 6 Conclusion and Future Work

We introduced a social media text normalization system that can be deployed as a preprocessor for MT and various NLP applications to handle social media text. The proposed approach is very scalable, adaptive to any domain and language. We show that the proposed unsupervised approach provides a normalization system with very high precision and a reasonable recall. We compared the system with conventional correction approaches and with recent previous work; and we showed that it highly outperforms other systems. Finally, we have used the system as a preprocessing step for a machine translation system which improved the translation quality by 6%.

As an extension to this work, we will extend the approach to handle many-to-many normalization pairs; also we plan to apply the approach to more languages. Furthermore, the approach can be easily extended to handle similar problems such as accent restoration and generic entity normalization.

## Abstract

Hiero translation models have two limitations compared to phrase-based models: 1) Limited hypothesis space; 2) No lexicalized reordering model. We propose an extension of Hiero called Phrasal-Hiero to address Hiero's second problem. Phrasal-Hiero still has the same hypothesis space as the original Hiero but incorporates a phrase-based distance cost feature and lexicalized reordering features into the chart decoder. The work consists of two parts: 1) for each Hiero translation derivation, find its corresponding discontinuous phrase-based path. 2) Extend the chart decoder to incorporate features from the phrase-based path. We achieve significant improvement over both Hiero and phrase-based baselines for Arabic-English, Chinese-English and German-English translation.

## 1 Introduction

Phrase-based and tree-based translation model are the two main streams in state-of-the-art machine translation. The tree-based translation model, by using a synchronous context-free grammar formalism, can capture longer reordering between source and target language. Yet, tree-based translation often underperforms phrase-based translation in language pairs with short range reordering such as Arabic-English translation (Zollmann et al., 2008; Birch et al., 2009).

We follow Koehn et al. (2003) for our phrase-based system and Chiang (2005) for our Hiero system. In both systems, the translation of a source sentence  $\mathbf{f}$  is the target sentence  $\mathbf{e}^*$  that maximizes a linear combination of features and weights:

$$\langle \mathbf{e}^*, \mathbf{a}^* \rangle = \operatorname{argmax}_{(\mathbf{e}, \mathbf{a}) \in \mathcal{H}(\mathbf{f})} \sum_{m \in M} \lambda_m h_m(\mathbf{e}, \mathbf{f}, \mathbf{a}). \quad (1)$$

where

- $\mathbf{a}$  is a translation path of  $\mathbf{f}$ . In the phrase-based system,  $\mathbf{a}_{\text{ph}}$  represents a segmentation of  $\mathbf{e}$  and  $\mathbf{f}$  and a correspondance of phrases. In the Hiero system,  $\mathbf{a}_{\text{tr}}$  is a derivation of a parallel parse tree of  $\mathbf{f}$  and  $\mathbf{e}$ , each nonterminal representing a rule in the derivation.
- $\mathcal{H}(\mathbf{f})$  is the hypothesis space of the sentence  $\mathbf{f}$ . We denote  $\mathcal{H}_{\text{ph}}(\mathbf{f})$  as the phrase-based hypothesis space of  $\mathbf{f}$  and  $\mathcal{H}_{\text{tr}}(\mathbf{f})$  as its tree-based hypothesis space. Galley and Manning (2010) point out that due to the hard constraints of rule combination, the tree-based system does not have the same excessive hypothesis space as the phrase-based system.
- $M$  is the set of feature indexes used in the decoder. Many features are shared between phrase-based and tree-based systems including language model, word count, and translation model features. Phrase-based systems often use a lexical reordering model in addition to the distance cost feature.

The biggest difference in a Hiero system and a phrase-based system is in how the reordering is modeled. In the Hiero system, the reordering decision is encoded in weighted translation rules, determined by nonterminal mappings. For example, the rule  $X \rightarrow ne X_1 pas ; not X_1 : w$  indicates the translation of the phrase between *ne* and *pas* to be after the English word *not* with score  $w$ . During decoding, the system parses the source sentence and synchronously generates the target output.

To achieve reordering, the phrase-based system translates source phrases out of order. A reordering distance limit is imposed to avoid search space explosion. Most phrase-based systems are equipped with a distance reordering cost feature to tune the system towards the right amount of reordering, but then also a lexicalized reordering

model to model the direction of adjacent source phrases reordering as either *monotone*, *swap* or *discontinuous*.

There are two reasons to explain the shortcomings of the current Hiero system:

1. A limited hypothesis space because the synchronous context-free grammar is not applicable to non-projective dependencies.
2. It does not have the expressive lexicalized reordering model and distance cost features of the phrase-based system.

When comparing phrase-based and Hiero translation models, most of previous work on tree-based translation addresses its limited hypothesis space problem. Huck et al. (2012) add new rules into the Hiero system, Carreras and Collins (2009) apply the tree adjoining grammar formalism to allow highly flexible reordering. On the other hand, the Hiero model has the advantage of capturing long distance and structure reordering. Galley and Manning (2010) extend phrase-based translation by allowing gaps within phrases such as  $\langle ne \dots pas, not \rangle$ , so the decoder still has the discriminative reordering features of phrase-based, but also uses on average longer phrases. However, these phrase pairs with gaps do not capture structure reordering as do Hiero rules with non-terminal mappings. For example, the rule  $X \rightarrow ne X_1 pas ; not X_1$  explicitly places the translation of the phrase between *ne* and *pas* behind the English word *not* through nonterminal  $X_1$ . This is important for language pairs with strict reordering. In our Chinese-English experiment, the Hiero system still outperforms the discontinuous phrase-based system.

We address the second problem of the original Hiero decoder by mapping Hiero translation derivations to corresponding phrase-based paths, which not only have the same output but also preserve structure distortion of the Hiero translation. We then include phrase-based features into the Hiero decoder.

A phrase-based translation path is the sequence of phrase-pairs, whose source sides cover the source sentence and whose target sides generate the target sentence from left to right. If we look at the leaves of a Hiero derivation tree, the lexicals also form a segmentation of the source and target sentence, thus also form a discontinuous phrase-based translation path. As an example, let us look

at the translation of the French sentence *je ne parle pas le française* into English *i don't speak french* in Figure 1. The Hiero decoder translates the sentence using a derivation of three rules:

- $r_1 = X \rightarrow parle ; speak.$
- $r_2 = X \rightarrow ne X_1 pas ; don't X_1.$
- $r_3 = X \rightarrow Je X_1 le Français ; I X_1 french.$

From this Hiero derivation, we have a segmentation of the sentence pairs into phrase pairs according to the word alignments, as shown on the left side of Figure 1. Ordering these phrase pairs according the word sequence on the target side, shown on the right side of Figure 1, we have a phrase-based translation path consisting of four phrase pairs:  $(je, i)$ ,  $(ne \dots pas, not)$ ,  $(parle, speak)$ ,  $(le française, french)$  that has the same output as the Hiero system. Note that even though the Hiero decoder uses a composition of three rules, the corresponding phrase-based path consists of four phrase pairs. We name this new variant of the Hiero decoder, which uses phrase-based features, Phrasal-Hiero.

Our Phrasal-Hiero addresses the shortcoming of the original Hiero system by incorporating phrase-based features. Let us revisit machine translation's loglinear model combination of features in equation 1. We denote  $ph(\mathbf{a})$  as the corresponding phrase-based path of a Hiero derivation  $\mathbf{a}$ , and  $M_{Ph \setminus H}$  as the indexes of phrase-based features currently not applicable to the Hiero decoder. Our Phrasal-Hiero decoder seeks to find the translation, which optimizes:

$$\langle \mathbf{e}^*, \mathbf{a}^* \rangle = \operatorname{argmax}_{(\mathbf{e}, \mathbf{a}) \in \mathcal{H}_{tr}(\mathbf{f})} \left( \sum_{m \in M_H} \lambda_m h_m(\mathbf{e}, \mathbf{f}, \mathbf{a}) + \sum_{m' \in M_{Ph \setminus H}} \lambda_{m'} h_{m'}(\mathbf{e}, \mathbf{f}, ph(\mathbf{a})) \right).$$

We focus on improving the modelling of reordering within Hiero and include discriminative reordering features (Tillmann, 2004) and a distance cost feature, both of which are not modeled in the original Hiero system. Chiang et al. (2008) added structure distortion features into their decoder and showed improvements in their Chinese-English experiment. To our knowledge, Phrasal-Hiero is the first system, which directly integrates phrase-based and Hiero features into one model.

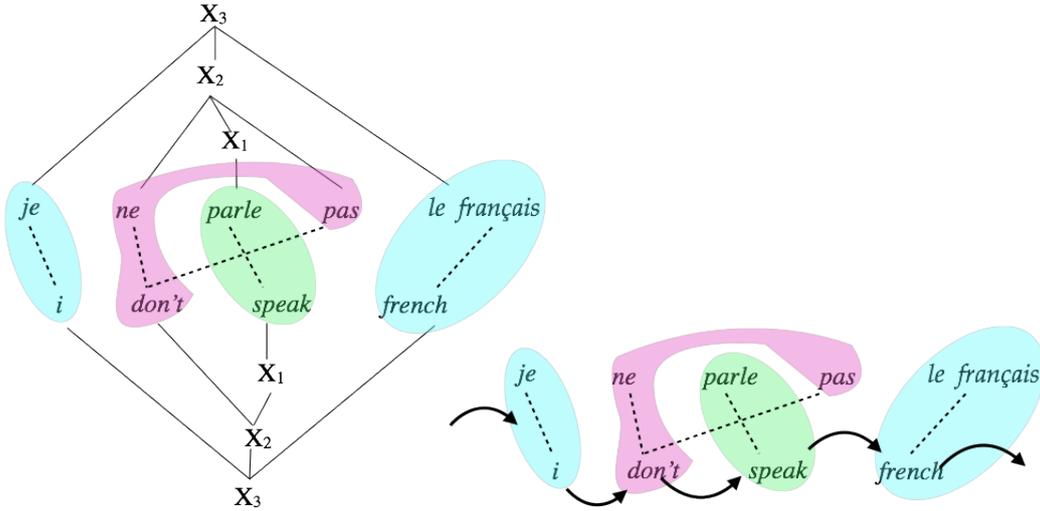

Figure 1: Example of French-English Hiero Translation on the left and its corresponding discontinuous phrase-based translation on the right.

Rules	Alignments	Phrase pairs & nonterminals
$r_1 = X \rightarrow \text{parle} ; \text{ speak}.$	0-0	$(\text{parle} ; \text{ speak})$
$r_2 = X \rightarrow \text{ne } X_1 \text{ pas} ; \text{ don't } X_1.$	0-0 1-1 2-0	$(\text{ne} \dots \text{pas} ; \text{ don't}) ; X_1$
$r_3 = X \rightarrow \text{Je } X_1 \text{ le Francais} ; \text{ I } X_1 \text{ French}$	0-0 1-1 3-2	$(\text{Je} ; \text{ I}) ; X_1 ; (\text{le Francais} ; \text{ french})$
$r_4 = X \rightarrow \text{je } X_1 \text{ le } X_2 ; \text{ i } X_1 X_2$	0-0 1-1 3-2	Not Applicable

Table 1: Rules and their sequences of phrase pairs and nonterminals

Previous work has attempted to weaken the context free assumption of the synchronous context free grammar formalism, for example using syntactic non-terminals (Zollmann and Venugopal, 2006). Our approach can be viewed as applying soft context constraint to make the probability of substituting a nonterminal by a subtree depending on the corresponding phrase-based reordering features.

In the next section, we explain the model in detail.

## 2 Phrasal-Hiero Model

Phrasal-Hiero maps a Hiero derivation into a discontinuous phrase-based translation path by the following two steps:

1. Training: Represent each rule as a sequence of phrase pairs and nonterminals.
2. Decoding: Use the rules' sequences of phrase pairs and nonterminals to find the corresponding phrase-based path of a Hiero derivation and calculate its feature scores.

### 2.1 Map Rule to A Sequence of Phrase Pairs and Nonterminals

We segment the rules' lexical items into phrase pairs. These phrase pairs will be part of the phrase-based translation path in the decoding step. The rules' nonterminals are also preserved in the sequence, during the decoding they will be substituted by other rules' phrase pairs. We now explain how to map a rule to a sequence of phrase pairs and nonterminals.

Let  $r = X \rightarrow s_0 X_1 s_1 \dots X_k s_k ; t_0 X_{\alpha(1)} t_1 \dots X_{\alpha(k)} t_k$  be a rule of  $k$  nonterminals,  $\alpha(\cdot)$  defines the sequence of nonterminals on the target.  $s_i$  or  $t_i$ ,  $i = 0 \dots k$  are phrases between nonterminals, they can be empty because nonterminals can be at the border of the rule or two nonterminals are adjacent. For example the rule  $X \rightarrow \text{ne } X_1 \text{ pas} ; \text{ not } X_1$  has  $k = 1$ ,  $s_0 = \text{ne}$ ,  $s_1 = \text{pas}$ ,  $t_0 = \text{not}$ ,  $t_1$  is an empty phrase because the target  $X_1$  is at the rightmost position.

Phrasal-Hiero retains both nonterminals and lexical alignments of Hiero rules instead of only nonterminal mappings as in (Chiang, 2005). A

erates  $(je, i)$  once for the sentence. Phrase pairs are generated together with phrase-based reordering orientations to build lexicalized reordering table.

### 3 Decoding

Chiang (2007) applied bottom up chart parsing to parse the source sentence and project on the target side for the best translation. Each chart cell  $[X, i, j, r]$  indicates a subtree with rule  $r$  at the root covers the translation of the  $i$ -th word upto the  $j$ -th word of the source sentence. We extend the chart parsing, mapping the subtree to the equivalent discontinuous phrase-based path and includes phrase-based features to the log-linear model.

In Phrasal-Hiero, each chart cell  $[X, i, j, r]$  also stores the first phrase pair and the last phrase pair of the phrase-based translation path covered the  $i$ -th to the  $j$ -th word of the source sentence. These two phrase pairs are the back pointers to calculate reordering features of later larger spans. Because the distance cost feature and phrase-based discriminative reordering feature calculation are both only required the source coverage of two adjacent phrase pairs, we explain here the distance cost calculation.

We will again use three rules  $r_1, r_2, r_3$  in Table 1 and the translation *je ne parle pas le français* into *I don't speak French* to present the technique. Table 3 shows the distance cost calculation.

First, when the rule  $r$  has only terminals, the rule's sequence of phrase pairs and nonterminals consists of only a phrase pair. No calculation is needed, the first phrase pair and the last phrase pair are the same. The chart cell  $X_1 : 2 \dots 2$  in Table 3 shows the translation with the rule  $r_1 = X \rightarrow \textit{parle} ; \textit{speak}$ . The first phrase pair and the last phrase pair point to the phrase  $(\textit{parle}, \textit{speak})$  spanning  $2 \dots 2$  of the source sentence.

When the translation rule's right hand side has nonterminals, the nonterminals in the sequence belong to smaller chart cells that we already found phrase-based paths and calculated their features before. The decoder then substitute these paths into the rule's sequence of phrase pairs and nonterminals to form the complete path for the current span.

We now demonstrate finding the phrase based path and calculate distance cost of the chart cell  $X_2$  spanning  $1 \dots 3$ . The next phrase pair of  $(\textit{ne} \dots \textit{pas}, \textit{don't})$  is the first phrase pair

of the chart cell  $X_1$  which is  $(\textit{parle}, \textit{speak})$ . The distance cost of these two phrase pairs according to discontinuous phrase-based model is  $|2 - 3 - 1| = 2$ . The distance cost of the whole chart cell  $X_2$  also includes the cost of the translation path covered by chart cell  $X_1$  which is 0, therefore the distance cost for  $X_2$  is  $2 + \text{dist}(X_1) = 2$ . We then update the first phrase pair and the last phrase pair of cell  $X_2$ . The first phrase pair of  $X_2$  is  $(\textit{ne} \dots \textit{pas}, \textit{don't})$ , the last phrase pair is also the last phrase pair of cell  $X_1$  which is  $(\textit{parle}, \textit{speak})$ .

Similarly, finding the phrase-based path and calculate its distortion features in the chart cell  $X_3$  include calculate the feature values for moving from the phrase pair  $(\textit{je}, I)$  to the first phrase pair of chart cell  $X_2$  and also from last phrase pair of chart cell  $X_2$  to the phrase pair  $(\textit{le fran}\c{c}aise, \textit{french})$ .

## 4 Experiment Results

In all experiments we use phrase-orientation lexicalized reordering (Galley and Manning, 2008)<sup>2</sup> which models monotone, swap, discontinuous orientations from both reordering with previous phrase pair and with the next phrase pair. There are total six features in lexicalized reordering model.

We will report the impact of integrating phrase-based features into Hiero systems for three language pairs: Arabic-English, Chinese-English and German-English.

### 4.1 System Setup

We are using the following three baselines:

- Phrase-based without lexicalized reordering features. (PB+nolex)
- Phrase-based with lexicalized reordering features.(PB+lex)
- Hiero system with all rules extracted from training data. (Hiero)

We use Moses phrase-based and chart decoder (Koehn et al., 2007) for the baselines. The score difference between PB+nolex and PB+lex results indicates the impact of lexicalized reordering features on phrase-based system. In Phrasal-Hiero we

<sup>2</sup>Galley and Manning (2008) introduce three orientation models for lexicalized reordering: word-based, phrase-based and hierarchical orientation model. We apply phrase-based orientation in all experiment using lexicalized reordering.

Chart Cell	Rule’s phrase pairs & NTs	Distance	First Phrase Pair	Last Phrase Pair
$X_1 : 2 \dots 2$	$(parle, speak)$	$\emptyset$	$2 \dots 2 (parle, speak)$	
$X_2 : 1 \dots 3$	$(ne \dots pas, don't) ; X_1$	$2 + \text{dist}(X_1) = 2$	$1 \dots 3 (ne \dots pas, don't)$	$2 \dots 2 (parle, speak)$
$X_3 : 0 \dots 5$	$(Je ; I) ; X_2 ; (le Franais; french)$	$0 + \text{dist}(X_2) + 1 = 3$	$0 \dots 0 (je, I)$	$4 \dots 5 (le Franais; french)$

Table 3: Phrasal-Hiero Decoding Example: Calculate distance cost feature for the translation in Figure 1.

will compare if these improvements still carry on into Hiero systems.

The original Hiero system with all rules extracted from training data (Hiero) is the most relevant baseline. We will evaluate the difference between this Hiero baseline and our Phrasal-Hiero.

To implement Phrasal-Hiero, we extended Moses chart decoder (Koehn et al., 2007) to include distance-based reordering as well as the lexicalized phrase orientation reordering model. We will report the following results for Phrasal-Hiero:

- Hiero translation results on the subset of rules without unaligned phrases. (we denote this in the table scores as P.H.)
- Phrasal-Hiero with phrase-based distance cost feature (P.H.+dist).
- Phrasal-Hiero with phrase-based lexicalized reordering features(P.H.+lex).
- Phrasal-Hiero with distance cost and lexicalized reordering features(P.H.+dist+lex).

## 4.2 Arabic-English Results

The Arabic-English system was trained from 264K sentence pairs with true case English. The Arabic is in ATB morphology format. The language model is the interpolation of 5-gram language models built from news corpora of the NIST 2012 evaluation. We tuned the parameters on the MT06 NIST test set (1664 sentences) and report the BLEU scores on three unseen test sets: MT04 (1353 sentences), MT05 (1056 sentences) and MT09 (1313 sentences). All test sets have four references per each sentence.

The results are in Table 4. The three rows in the first block are the baseline scores. Phrase-based with lexicalized reordering features(PB+lex) shows significant improvement on all test sets over the simple phrase-based system without lexicalized reordering (PB+nolex). On average the improvement is 1.07 BLEU score (45.66

	MT04	MT05	MT09	Avg.
PB+nolex	47.40	46.83	42.75	45.66
PB+lex	48.62	48.07	43.51	46.73
Hiero	48.17	47.85	42.37	46.13
P.H. (48.54% rules)	48.52	47.78	42.80	46.37
P.H.+dist	48.46	47.92	42.62	46.33
P.H. +lex	48.70	48.59	<b>43.84</b>	47.04
P.H +lex+dist	<b>49.35</b>	<b>49.07</b>	43.40	<b>47.27</b>
Improv. over PB+lex	0.73	1.00	0.34	0.54
Improv. over P.H.	0.83	1.29	1.04	0.90
Improv. over Hiero	1.18	1.22	1.47	1.14

Table 4: Arabic-English true case translation scores in BLEU metric. The three rows in the first block are the baseline scores. The next four rows in the second block are Phrasal-Hiero scores, the best scores are in boldface. The three rows in the last block are the Phrasal-Hiero improvements.

versus 46.73). We make the same observation as Zollmann et al. (2008), i.e., that the Hiero baseline system underperforms compared to the phrase-based system with lexicalized phrase-based reordering for Arabic-English in all test sets, on average by about 0.60 BLEU points (46.13 versus 46.73). This is because Arabic language has relative free reordering, but mostly short distance, which is better captured by discriminative reordering features.

The next four rows in the second block of Table 4 show Phrasal-Hiero results. The P.H. line is the result of Hiero experiment on only a subset of rules without nonaligned phrases. As mentioned in section 2.1, Phrasal-Hiero only uses 48.54% of the rules but achieves as good or even better performance (on average 0.24 BLEU points better) compared to the original Hiero system using the full set of rules.

We do not benefit from adding only the

distance-based reordering feature (P.H+dist) to the Arabic-English experiment but get significant improvements when adding the six features of the lexicalized reordering (P.H+lex). Table 4 shows that the P.H.+lex system gains on average 0.67 BLEU points (47.04 versus 46.37). Even though the baseline Hiero underperforms phrase-based system with lexicalized reordering(P.B+lex), the P.H.+lex system already outperforms P.B+lex in all test sets (on average 47.04 versus 46.73).

Adding both distance cost and lexicalized reordering features (P.H.+dist+lex) performs the best. On average P.H.+dist+lex improves 0.90 BLEU points over P.H. without new phrase-based features and 1.14 BLEU score over the baseline Hiero system. Note that Hiero rules already have lexical context in the reordering, but adding phrase-based lexicalized reordering features to the system still gives us about as much improvement as the phrase-based system gets from lexicalized reordering features, here 1.07 BLEU points. And our best Phrasal-Hiero significantly improves over the best phrase-based baseline by 0.54 BLEU points. This shows that the underperformance of the Hiero system is due to its lack of lexicalized reordering features rather than a limited hypothesis space.

### 4.3 Chinese-English Results

The Chinese-English system was trained on FBIS corpora of 384K sentence pairs, the English corpus is lower case. The language model is the trigram SRI language model built from Xinhua corpus of 180 millions words. We tuned the parameters on MT06 NIST test set of 1664 sentences and report the results of MT04, MT05 and MT08 unseen test sets. The results are in Table 5.

We also make the same observation as Zollmann et al. (2008) on the baselines for Chinese-English translation. Even though the phrase-based system benefits from lexicalized reordering, PB+lex on average outperforms PB+nolex by 1.16 BLEU points (25.87 versus 27.03), it is the Hiero system that has the best baseline scores across all test sets, with an average of 27.70 BLEU points.

Phrasal Hiero scores are given in the second block of Table 5. It uses 84.19% of the total training rules, but unlike the Arabic-English system, using a subset of the rules costs Phrasal-Hiero on all test sets and on average it loses 0.49 BLEU points (27.21 versus 27.70). Similar to Chiang

	MT04	MT05	MT08	Avg.
PB+nolex	29.99	26.4	21.23	25.87
PB+lex	31.03	27.57	22.41	27.03
Hiero	32.49	28.06	22.57	27.70
P.H. (84.19% rules)	31.83	27.66	22.16	27.21
P.H.+dist	32.18	28.25	22.46	27.63
P.H.+lex	32.55	28.51	23.08	28.05
P.H.+lex+dist	<b>33.06</b>	<b>28.78</b>	<b>23.23</b>	<b>28.35</b>
Improv. over PB+lex	2.03	1.21	0.82	1.32
Improv. over P.H.	1.23	1.12	1.07	1.14
Improv. over Hiero	0.57	0.72	0.66	0.65

Table 5: Chinese-English lower case translation scores in BLEU metric.

et al. (2008) in their Chinese-English experiment, we benefit by adding the distance cost feature. PH.+dist outperforms P.H. on all test sets. We have better improvements when adding the six features of the lexicalized reordering model: P.H.+lex on average has 28.05 BLEU points, i.e. gains 0.84 over P.H.. The P.H.+lex system is even better than the best Hiero baseline using the whole set of rules.

We again get the best translation when adding both the distance cost feature and the lexicalized reordering features. The P.H.+dist+lex has the best score across all the test sets and on average gains 1.14 BLEU points over P.H. So adding phrase-based features to the Hiero system yields nearly the same improvement as adding lexicalized reordering features to the phrase-based system. This shows that a strong Chinese-English Hiero system still benefits from phrase-based features. Furthermore, the P.H.+dist+lex also outperforms the Hiero baseline using all rules from training data.

### 4.4 German-English Results

We next consider German-English translation. The systems were trained on 1.8 million sentence pairs using the Europarl corpora. The language model is three-gram SRILM trained from the target side of the training corpora. We use WMT 2010 (2489 sentences) as development set and report scores on WMT 2008 (2051 sentences), WMT 2009 (2525 sentences), WMT 2011 (3003 sentences). All test sets have one reference per test sentence. The results are in Table 6.

WMT test	08	09	11	Avg.
PB+nolex	17.46	17.38	16.76	17.20
PB+lex	18.16	17.85	17.18	17.73
Hiero	18.20	18.23	17.46	17.96
P.H. (80.54% rules)	18.24	18.15	17.39	17.92
P.H. +dist	18.19	17.97	17.41	17.85
P.H. +lex	18.59	18.46	17.69	18.24
P.H.+lex+dist	<b>18.70</b>	<b>18.53</b>	<b>17.81</b>	<b>18.34</b>
Improv. over PB+lex	0.54	0.68	0.63	0.61
Improv. over P.H.	0.46	0.38	0.42	0.42
Improv. over Hiero	0.50	0.30	0.35	0.38

Table 6: German-English lower case translation scores in BLEU metric.

The Hiero baseline performs on average 0.26 BLEU points better than the phrase-based system with lexicalized reordering features (PB+lex). The Phrasal-Hiero system used 80.54% of the total training rules, but on average the P.H. system has the same performance as the Hiero system using all the rules extracted from training data. Similar to the Arabic-English experiment, Phrasal-Hiero does not benefit from adding the distance cost feature. We do, however, see improvements on all test sets when adding lexicalized reordering features. On average the P.H.+lex results are 0.32 BLEU points higher than the P.H. results. The best scores are achieved with P.H.+lex+dist. The German-English translations on average gain 0.38 BLEU score by adding both distance cost and discriminative reordering features.

#### 4.5 Impact of segment rules into phrase pairs

Phrasal Hiero is the first system using rules' lexical alignments. If lexical alignments are not available, we can not divide the rules' lexicals into phrase pairs without losing their dependancies. An alternative approach would be combining all lexicals of a rule into one phrase pair. We run an addition experiment for this approach on Arabic-English dataset. Table 7 shows the examples rules and its new sequence of nonterminals and phrase pairs. The rules  $r_1$  and  $r_2$  have the same sequences as in Table 1. Without segment rules into phrase pairs, the rule  $r_3$  has only one phrase pair:  $ph = (Je...le Francaise ; I...french)$  and

$ph$  is repeated twice in  $r_3$ 's sequence of phrase pairs and nonterminals. The new experiment uses the complete set of rules so the rule  $r_4$  is included.

According to the new sequence of phrase pairs and nonterminals, during decoding the rule  $r_3$  has *discontinuous* translation directions on both from phrase pair  $ph$  to the nonterminal  $X_1$  and from  $X_1$  to  $ph$ . But using lexical alignment and divide the rule into phrase pairs as in section 2.1, the sequence preserves the translation order of  $r_3$  as two *monotone* translations from  $(je; I)$  to  $X_1$  and from  $X_1$  to  $(le Francaise ; french)$ .

	Avg
Hiero	46.13
Hiero+lex (no lex. alignments)	46.45 (+0.32)
P.H.	46.37
P.H.+lex (with lex. alignments)	47.04 (+0.67)

Table 8: Average of Arabic-English translation scores in BLEU metric. Compare the improvement of using rules' lexical alignments (2nd block) and not using rules' lexical alignments (1st block).

Table 8 compares the two experiments results. The additional experiment is denoted as Hiero+lex in the table. The first block shows an improvement of 0.32 BLEU score when adding discriminated reordering features on Hiero (using the whole set of rules and no rule segmentation). The second block is the impact of adding discriminated reordering features on Phrasal Hiero (using a subset of rules and segment rules into phrase pairs). Here the improvement of P.H.+lex over P.H. is 0.67 BLEU score. It shows the benefit of segment rules into phrase pairs.

#### 4.6 Rules without unaligned phrases

	A-E	C-E	G-E
Hiero	46.13	27.70	17.96
P.H.	46.36	27.21	17.92
%Rules used	48.54%	84.19%	80.54%
P.H.+lex+dist	47.27	28.35	18.34

Table 9: The impact of using only rules without nonaligned phrases on Phrasal-Hiero results.

Table 9 summarizes the impact of using only rules without nonaligned phrases on Phrasal-

Rules	Phrase pairs & nonterminals
$r_1 = X \rightarrow \text{parle} ; \text{ speak}.$	$(\text{parle} ; \text{ speak})$
$r_2 = X \rightarrow \text{ne } X_1 \text{ pas} ; \text{ don't } X_1.$	$(\text{ne} \dots \text{pas} ; \text{ don't}) ; X_1$
$r_3 = X \rightarrow \text{Je } X_1 \text{ le Francais} ; \text{ I } X_1 \text{ French}$	$(\text{Je} \dots \text{le Francais} ; \text{ I} \dots \text{ french}) ; X_1 ;$ $(\text{Je} \dots \text{le Francais} ; \text{ I} \dots \text{ french})$
$r_4 = X \rightarrow \text{je } X_1 \text{ le } X_2 ; \text{ i } X_1 X_2$	$(\text{je} \dots \text{le} ; \text{ i}) ; X_1 ; X_2$

Table 7: Example of translation rules and their sequences of phrase pairs and nonterminals when lexical alignments are not available.

Hiero. Using only rules without nonaligned phrases can get the same performance with translation with full set of rules for Arabic-English and German-English experiments but underperforms for the Chinese-English system. We suggest the difference might come from the linguistic divergences of source and target languages.

Phrasal Hiero includes all lexical rules (rules without nonterminal) therefore it still has the same lexical coverage as the original Hiero system. In the Arabic-English system, the Arabic is in ATB format, therefore most English words should have alignments in the ATB source, rules with nonaligned phrases could be the results of bad alignments or non-informative rules, therefore we could have better performance by using a subset of rules in Phrasal-Hiero.

As Chinese and English are highly divergent, we expect many phrases in one language correctly unaligned in the other language. So leaving out the rules with nonaligned phrases could degrade the system. Even though the current Phrasal-Hiero with extra phrase-based features outperforms the Hiero baseline, future work for Phrasal-Hiero will focus on including all rules extracted from training corpora.

#### 4.7 Discontinuous Phrase-Based

	C-E	G-E
PB+lex	27.03	17.73
PB+lex+gap	27.11	17.55
Hiero	27.70	17.96
P.H.+lex+dist	28.35	18.34

Table 10: Comparing Phrasal-Hiero with translation with gap for Chinese-English and German-English. The numbers are average BLEU scores of all test sets.

We compare Phrasal-Hiero with a discontinuous phrase-based system introduced by Galley and

Manning (2010) for Chinese-English and German-English system. Table 10 shows the average results. We used Phrasal decoder (Cer et al., 2010) for phrase-based with gaps (PB+lex+gap) results. While we do not focus on the differences in the toolkits, our Phrasal-Hiero still outperforms the phrase-based with gaps experiments.

## Conclusion

We have presented a technique to combine phrase-based features and tree-based features into one model. Adding a distance cost feature, we only get better translation for Chinese-English translation. Phrasal-Hiero benefits from adding discriminative reordering features in all experiment. We achieved the best result when adding both distance cost and lexicalized reordering features. Phrasal-Hiero currently uses only a subset of rules from training data. A future work on the model can include complete rule sets together with word insertion/deletion features for nonaligned phrases.

## Abstract

We propose a method for automatically detecting low-quality Web-text translated by statistical machine translation (SMT) systems. We focus on the *phrase salad* phenomenon that is observed in existing SMT results and propose a set of computationally inexpensive features to effectively detect such machine-translated sentences from a large-scale Web-mined text. Unlike previous approaches that require bilingual data, our method uses only *monolingual* text as input; therefore it is applicable for refining data produced by a variety of Web-mining activities. Evaluation results show that the proposed method achieves an accuracy of 95.8% for sentences and 80.6% for text in noisy Web pages.

## 1 Introduction

The Web provides an extremely large volume of textual content on diverse topics and areas. Such data is beneficial for constructing a large scale monolingual (Microsoft Web N-gram Services, 2010; Google N-gram Corpus, 2006) and bilingual (Nie et al., 1999; Shi et al., 2006; Ishisaka et al., 2009; Jiang et al., 2009) corpus that can be used for training statistical models for NLP tools, as well as for building a large-scale knowledge-base (Suchanek et al., 2007; Zhu et al., 2009; Fader et al., 2011; Nakashole et al., 2012). With recent advances in statistical machine translation (SMT) systems and their wide adoption in Web services through APIs (Microsoft Translator, 2009; Google Translate, 2006), a large amount of text in Web pages is translated by SMT systems. According to Rarrick et al. (2011), their Web crawler finds that more than 15% of English-Japanese parallel documents are machine translation. Machine-translated sentences are useful if

they are of sufficient quality and indistinguishable from human-generated sentences; however, the quality of these machine-translated sentences is generally much lower than sentences generated by native speakers and professional translators. Therefore, a method to detect and filter such SMT results is desired to best make use of Web-mined data.

To solve this problem, we propose a method for automatically detecting Web-text translated by SMT systems<sup>1</sup>. We especially target machine-translated text produced through the Web APIs that is rapidly increasing. We focus on the *phrase salad* phenomenon (Lopez, 2008), which characterizes translations by existing SMT systems, *i.e.*, each phrase in a sentence is semantically and syntactically correct but becomes incorrect when combined with other phrases in the sentence. Based on this trait, we propose features for evaluating the likelihood of machine-translated sentences and use a classifier to determine whether the sentence is generated by the SMT systems.

The primary contributions of the proposed method are threefold. First, unlike previous studies that use parallel text and bilingual features, such as (Rarrick et al., 2011), our method only requires monolingual text as input. Therefore, our method can be used in monolingual Web data mining where bilingual information is unavailable. Second, the proposed features are designed to be computationally light so that the method is suitable for handling a large-scale Web-mined data. Our method determines if an input sentence contains phrase salads using a simple yet effective features, *i.e.*, language models (LMs) and automatically obtained non-contiguous phrases that are frequently used by people but difficult for SMT systems to generate. Third, our method computes features using both human-generated text and SMT

<sup>1</sup>In this paper, the term *machine-translated* is used for indicating translation by SMT systems.

results to capture a phrase salad by contrasting these features, which significantly improves detection accuracy.

We evaluate our method using Japanese and English datasets, including a human evaluation to assess its performance. The results show that our method achieves an accuracy of 95.8% for sentences and 80.6% for noisy Web-text.

## 2 Related Work

Previous methods for detecting machine-translated text are mostly designed for bilingual corpus construction. Antonova and Misyurev (2011) design a phrase-based decoder for detecting machine-translated documents in Russian-English Web data. By evaluating the BLEU score (Papineni et al., 2002) of translated documents (by their decoder) against the target-side documents, machine translation (MT) results are detected. Rarrick et al. (2011) extract a variety of features, such as the number of tokens and character types, from sentences in both the source and target languages to capture words that are mis-translated by MT systems. With these features, the likelihood of a bilingual sentence pair being machine-translated can be determined.

Confidence estimation of MT results is also a related area. These studies aim to precisely replicate human judgment in terms of the quality of machine-translated sentences based on features extracted using a syntactic parser (Corston-Oliver et al., 2001; Gamon et al., 2005; Avramidis et al., 2011) or essay scoring system (Parton et al., 2011), assuming that their input is always machine-translated. In contrast, our method aims at making a binary judgment to distinguish machine-translated sentences from a mixture of machine-translated and human-generated sentences. In addition, although methods for confidence estimation can assume sentences of a known source language and reference translations as inputs, these are unavailable in our problem setting.

Another related area is automatic grammatical error detection for English as a second language (ESL) learners (Leacock et al., 2010). We use common features that are also used in this area. They target specific error types commonly made by ESL learners, such as errors in prepositions and subject-verb agreement. In contrast, our method does not specify error types and aims to de-

tect machine-translated sentences focusing on the phrase salad phenomenon produced by SMT systems. In addition, errors generated by ESL learners and SMT systems are different. ESL learners make spelling and grammar mistakes at the word level but their sentence are generally structured while SMT results are unstructured due to phrase salads. Works on *translationese* detection (Baroni and Bernardini, 2005; Kurokawa et al., 2009; Ilisei et al., 2010) aim to automatically identify *human-translated* text by professionals using text generated by native speakers. These are related, but our work focuses on machine-translated text.

The closest to our approach is the method proposed by Moore and Lewis (2010). It automatically selects data for creating a domain-specific LM. Specifically, the method constructs LMs using corpora of target and non-target domains and computes a cross-entropy score of an input sentence for estimating the likelihood that the input sentence belongs to the target or non-target domains. While the context is different, our work uses a similar idea of data selection for the purpose of detecting low-quality sentences translated by SMT systems.

## 3 Proposed Method

When APIs of SMT services are used for machine-translating an Web page, they typically insert specific tags into the HTML source. Utilizing such tags makes MT detection trivial. However, the actual situation is more complicated in real Web data. When people manually copy and paste machine-translated sentences, such tags are lost. In addition, human-generated and machine-translated sentences are often mixed together even in a single paragraph. To observe the distribution of machine-translated sentences in such difficult cases, we examine 3K sentences collected by our in-house Web crawler. Among them, excluding the pages with the tags of MT APIs, 6.7% of them are found to be clearly machine translation. Our goal is to automatically identify these sentences that cannot be simply detected by the tags, except when the sentences are of sufficient quality to be indistinguishable from human-generated sentences.

### 3.1 Phrase Salad Phenomenon

Fig. 1 illustrates the phrase salad phenomenon that characterizes a sentence translated by an existing

| Of surprise | was up | foreigners flocked | overseas | as well, | they publicized not only | Japan, | saw an article from the news. |  
 Natural English: The news was broadcasted not only in Japan but also overseas, and it surprised foreigners who read the article.

Figure 1: The phrase salad phenomenon in a sentence translated by an SMT system; each (segmented) phrase is correct and fluent, but dotted arcs show unnatural sequences of phrases and the boxed phrase shows an incomplete non-contiguous phrase.

SMT system. Each phrase, a sequence of consecutive words, is fluent and grammatically correct; however, the fluency and grammar correctness are both poor in inter-phrases. In addition, a phrase salad becomes obvious by observing distant phrases. For example, the boxed phrase in Fig. 1 is a part of the non-contiguous phrase “not only  $\star$  but also<sup>2</sup>,” however, it lacks the latter part of the phrase (“but also”) that is also necessary for composing a meaning. Such non-contiguous phrases are difficult for most SMT systems to generate, since these phrases require insertion of sub-phrases in distant parts of the sentence.

Based on the observation of these characteristics, we define features to capture a phrase salad by examining local and distant phrases. These features evaluate (1) fluency (Sec. 3.2), (2) grammaticality (Sec. 3.3), and (3) completeness of non-contiguous phrases in a sentence (Sec. 3.4). Furthermore, humans can distinguish machine-translated text because they have prior knowledge of how a human-generated sentence would look like, which has been accumulated by observing a lot of examples through their life. This knowledge makes phrase-salads, e.g., missing objects and influent sequence of words, obvious for humans since they rarely appear on human-generated sentences. Based on this assumption, we extract these features using both human-generated and machine-translated text. Features extracted from human-generated text represent the similarity to human-generated text. Likewise, features extracted from machine-translated text depict the similarity to machine-translated text. By contrasting these feature weights, we can effectively capture phrase salads in the sentence.

### 3.2 Fluency Feature

In a machine-translated sentence, fluency becomes poor among phrases where a phrase salad occurs. We capture this infuency using two independent LM scores;  $f_{w,H}$  and  $f_{w,MT}$ . The former LM is

<sup>2</sup>We use the symbol  $\star$  to represent a gap in which any word or phrase can be placed.

trained with human-generated sentences and the latter one is trained with machine-translated sentences. We input a sentence into both of the LMs and use the scores as the fluency features.

### 3.3 Grammaticality Feature

In a sentence with phrase salads, its grammaticality is poor because tense and voice become inconsistent among phrases. We capture this using LMs trained with part-of-speech (POS) sequences of human-generated and machine-translated sentences, and the features of  $f_{pos,H}$  and  $f_{pos,MT}$  are respectively computed. In a similar manner with a word-based LM, such grammatical inconsistency among phrases is detectable when computing a POS LM score, since the score becomes worse when an  $N$ -gram covers inter-phrases where a phrase salad occurs. This approach achieves computational efficiency since it only requires a POS tagger.

Since a phrase salad may occur among distant phrases of a sentence, it is also effective to evaluate combinations of phrases that cannot be covered by the span of  $N$ -gram. For this purpose, we make use of function words that sparsely appear in a sentence where their combinations are syntactically constrained. For example, the same preposition rarely appears many times in a human-generated sentence, while it does in a machine-translated sentence due to the phrase salad. Similar to the POS LM, we first analyze sentences generated by human or SMT by a POS tagger, extract sequences of function words, and finally train LMs with the sequences. We use these LMs to obtain scores that are used as features  $f_{fw,H}$  and  $f_{fw,MT}$ .

### 3.4 Gappy-Phrase Feature

There are a lot of common non-contiguous phrases that consist of sub-phrases (contiguous word string) and gaps, which we refer to as *gappy-phrases* (Bansal et al., 2011). We specifically use gappy-phrases of 2-tuple, *i.e.*, phrases consisting of two sub-phrases and one gap in the middle. Let us take an English example “not only  $\star$  but

Sequences
World population not only grows , but grows old .
A press release not only informs but also teases .
Hazelnuts are not only for food , but also fuel .
The coalition must not only listen but also act .

Table 1: Example of a sequence database

also.” When a sentence contains the phrase “not only,” the phrase “but also” is likely to appear in human-generated sentences. Such a gappy-phrase is difficult for SMT systems to correctly generate and causes a phrase salad. Therefore, we define a feature to evaluate how likely a sentence contains gappy-phrases in a complete form without missing sub-phrases. This feature is effective to complement LMs that capture characteristics in  $N$ -grams.

**Sequential Pattern Mining** It is costly to manually collect a lot of such gappy-phrases. Therefore, we regard the task as sequential pattern mining and apply PrefixSpan proposed by Pei et al. (2001), which is a widely used sequential pattern mining method<sup>3</sup>.

Given a set of sequences and a user-specified  $min\_support \in \mathbb{N}$  threshold, the sequential pattern mining finds all frequent subsequences whose occurrence frequency is no less than  $min\_support$ . For example, given a sequence database like Table 1, the sequential pattern mining finds all frequent subsequences, e.g., “not only,” “not only  $\star$  but also,” “not  $\star$  but  $\star$ ,” and *etc.*

To capture a phrase salad by contrasting appearance of gappy-phrases in human-generated and machine-translated text, we independently extract gappy-phrases from each of them using PrefixSpan. We then compute features  $f_{g,H}$  and  $f_{g,MT}$  using the obtained phrases.

### Observation of Extracted Gappy-Phrases

Based on a preliminary experiment, we set the parameter  $min\_support$  of PrefixSpan to 100 for computational efficiency. We extract gappy-phrases (of 2-tuple) from our development dataset described in Sec. 4.1 that includes 254K human-generated and 134K machine-translated sentences in Japanese, and 210K human-generated and 159K machine-translated sentences in English.

Regarding the Japanese dataset, we obtain about 104K and 64K gappy-phrases from human-

generated and machine-translated sentences, respectively. According to our observation of the extracted phrases, 21K phrases commonly appear in human-generated and machine-translated sentences. Many of these common phrases are incomplete forms of gappy-phrases that lack semantic meaning to humans, such as “not only  $\star$  the” and “not only  $\star$  and.” On the other hand, complete forms of gappy-phrases that preserve semantic meaning exclusively appear in phrases extracted from human-generated sentences. We also obtain about 74K and 42K phrases from human-generated and machine-translated sentences in the English dataset (21K of them are common).

**Phrase Selection** As a result of sequential pattern mining, we can gather a huge number of gappy-phrases from human-generated and machine-translated text, but as we described above, many of them are common. In addition, it is computationally expensive to use all of them. Therefore, our method selects useful phrases for detecting machine-translated sentences.

Although there are several approaches for feature selection, e.g., (Sebastiani, 2002), we use a method that is suitable for handling a large number of feature candidates. Specifically, we evaluate gappy-phrases based on the information gain that measures the amount of information in bits obtained for class prediction when knowing the presence or absence of a phrase and the corresponding class distribution. This corresponds to measuring an expected reduction in entropy, i.e., uncertainty associated with a random factor. The information gain  $G \in \mathbb{R}$  for a gappy-phrase  $g$  is defined as

$$G(g) \doteq H(C) - P(X_g^1)H(C|X_g^1) - P(X_g^0)H(C|X_g^0),$$

where  $H(C)$  represents the entropy of the classification,  $C$  is a stochastic variable taking a class,  $X_g$  is a stochastic variable representing the presence ( $X_g^1$ ) or absence ( $X_g^0$ ) of the phrase  $g$ ,  $P(X_g)$  represents the probability of presence or absence of the phrase  $g$ , and  $H(C|X_g)$  is the conditional entropy due to the phrase  $g$ . We use top- $k$  phrases based on the information gain  $G$ . Specifically, we use the top 40% of phrases to compute the feature values. Table 2 shows examples of gappy-phrases extracted from human-generated and machine-translated text in our development dataset and remain after feature selection.

<sup>3</sup>Due to the severe space limitation, readers are referred to that paper.

Human	in the early * period	MT	after * after the
	known as * to		and also * and
	more * than		and * but the
	not only * but also		no * not
	with * as well as		not * not

Table 2: Example of gappy-phrases extracted from human-generated and machine-translated text; phrases preserving semantic meaning are extracted only from human-generated text.

The gappy-phrases depend on each other, and the more phrases extracted from human-generated (machine-translated) text are found in a sentence, the more likely the sentence is human-generated (machine-translated). Therefore, we compute the feature as

$$f_c(s) = \sum_{i \in k} w_i \delta(i, s),$$

where  $w_i$  is a weight of the  $i$ -th phrase, and  $\delta(i, s)$  is a Kronecker’s delta function that takes 1 if the sentence  $s$  includes the  $i$ -th phrase and takes 0 otherwise. We may set the weight  $w_i$  according to the importance of the phrase, such as the information gain. In this work, we set  $w_i$  to 1 for simplicity.

### 3.5 Classification

Table 3 summarizes the features employed in our method. In addition to the discussed features, we use the length of a sentence as a feature  $f_{len}$  to avoid the bias of LM-based features that favor shorter sentences. The proposed method takes a monolingual sentence from Web data as input and computes a feature vector of  $f = (f_{w,H}, \dots, f_{len}) \in \mathbb{R}^9$ . Each feature is finally normalized to have a zero-mean and unit variance distribution. In the feature space, a support vector machine (SVM) classifier (Vapnik, 1995) is used to determine the likelihoods of machine-translated and human-generated sentences.

## 4 Experiments

We evaluate our method using both Japanese and English datasets from various aspects and investigate its characteristics. In this section, we describe our experiment settings.

### 4.1 Data Preparation

For the purpose of evaluation, we use human-generated and machine-translated sentences for

Feature	Notation
Fluency	$f_{w,H}, f_{w,MT}$
Grammaticality	$f_{pos,H}, f_{pos,MT}$ $f_{fw,H}, f_{fw,MT}$
Gappy-phrase	$f_{g,H}, f_{g,MT}$
Length	$f_{len}$

Table 3: List of proposed features and their notations

constructing LMs, extracting gappy-phrases, and training a classifier. These sentences should be ensured to be human-generated or machine-translated, and the human-generated and machine-translated sentences express the same content for fairness of evaluation to avoid effects due to vocabulary difference.

As a dataset that meets these requirements, we use parallel text in public websites (this is for fair evaluation and our method can be trained using *nonparallel* text on an actual deployment). Eight popular sites having Japanese and English parallel pages are crawled, whose text is manually verified to be human-generated. The main textual content of these 131K parallel pages are extracted, and the sentences are aligned using (Ma, 2006). As illustrated in Fig. 2, the text in one language is fed to the Bing translator, Google Translate, and an in-house SMT system<sup>4</sup> implemented based on (Chiang, 2005) by ourselves for obtaining sentences translated by SMT systems. Due to a severe limitation on the number of requests to the APIs, we randomly subsample sentences before sending them to these SMT systems. We use text in the other language as human-generated sentences<sup>5</sup>.

In this manner, we prepare 508K human-generated and 268K machine-translated sentences as a Japanese dataset, and 420K human-generated and 318K machine-translated sentences as an English dataset. We split each of them into two even datasets and use one for development and the other for evaluation.

### 4.2 Experiment Setting

For the fluency and grammaticality features, we train 4-gram LMs using the development dataset with the SRI toolkit (Stolcke, 2002). To obtain the POS information, we use Mecab (Kudo et al., 2004) for Japanese and a POS tagger developed by Toutanova et al. (2003) for English. We evaluate

<sup>4</sup>A preliminary evaluation of the in-house SMT system shows that it has comparable quality with Bing translator.

<sup>5</sup>These are a mixture of sentences generated by native speakers and professional translators/editors.

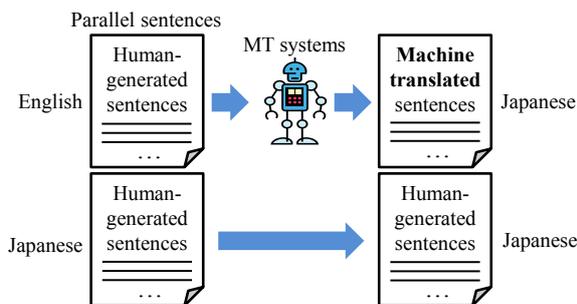

Figure 2: Experimental data preparation; text in one language is fed to SMT systems and the other is used as human-generated sentences.

the effect of the sizes of  $N$ -grams and development dataset in the experiments.

Using the proposed features, we train an SVM classifier for detecting machine-translated sentences. We use an implementation of LIBSVM (Chang and Lin, 2011) with a radial basis function kernel due to the relatively small number of features in the proposed method. We set appropriate parameters by grid search in a preliminary experiment.

We evaluate the performance of MT detection based on accuracy<sup>6</sup> that is a broadly used evaluation metric for classification problems:

$$\text{accuracy} = \frac{n_{TP} + n_{TN}}{n},$$

where  $n_{TP}$  and  $n_{TN}$  are the numbers of true-positives and true-negatives, respectively, and  $n$  is the total number of exemplars. The accuracy scores that we report in Sec. 5 are all based on 10-fold cross validation.

### 4.3 Comparison Method

We compare our method with the method of (Moore and Lewis, 2010) (*Cross-Entropy*). Although the Cross-Entropy method is designed for the task of domain adaptation of an LM, our problem is a variant of their original problem and thus their method is directly relevant. In our context, the method computes the cross-entropy scores  $I_{MT}(s)$  and  $I_H(s)$  of an input sentence  $s$  against LMs trained on machine-translated and human-generated sentences. Cross-entropy and perplexity are monotonically related, as perplexity of  $s$  according to an LM  $M$  is simply ob-

<sup>6</sup>Although we also examine precision and recall of classification results, they are similar to accuracy reported in this paper.

Method		Accuracy
Cross-Entropy		90.7
Lexical Feature		87.8
Proposed feature	<b>Word LMs</b>	<b>94.1</b>
	POS LMs	91.3
	FW LMs	82.7
	GPs	85.7

Table 4: Accuracy (%) of individual features and comparison methods

tained by  $b^{I_M(s)}$  where  $I_M(s)$  is cross-entropy score and  $b$  is a base with regard to which the cross-entropy is measured. The method scores the sentence according to the cross-entropy difference, *i.e.*,  $I_{MT}(s) - I_H(s)$ , and decides that the sentence is machine-translated when the score is lower than a predefined threshold. The classification is performed by 10-fold cross validation. We find the best performing threshold on a training set and evaluate the accuracy with a test set using the determined threshold.

Additionally, we compare our method to a method that uses a feature indicating presence or absence of unigrams, which we call *Lexical Feature*. This feature is commonly used for translationese detection and shows the best performance as a single feature in (Baroni and Bernardini, 2005). It is also used by Rarrick et al. (2011) and shows the best performance by itself in detecting machine-translated sentences in English-Japanese translation in the setting of bilingual input. We implement the feature and use it against a monolingual input to fit our problem setting.

## 5 Results and Discussions

In this section, we analyze and discuss the experiment results in detail.

### 5.1 Accuracy on Japanese Dataset

We evaluate the sentence-level and document-level accuracy of our method using the Japanese dataset. Specifically, we evaluate effects of individual features and their combinations, compare with human annotations, and assess performance variations across different sentence lengths and various settings on LM training.

**Effect of Individual Feature** Table 4 shows the accuracy scores of individual features and comparison methods. We refer to features for fluency ( $f_{w,H}$ ,  $f_{w,MT}$ ) as *Word LMs*, grammaticality using POS LMs ( $f_{pos,H}$ ,  $f_{pos,MT}$ ) as *POS LMs*

Method	Accuracy
Word LMs + GPs	94.7
Word LMs + POS LMs	95.1
Word LMs + POS LMs + GPs	95.4
Word LMs + POS LMs + FW LMs	95.5
<b>All</b>	<b>95.8</b>

Table 5: Accuracy (%) of feature combinations; there are significant differences ( $p \ll .01$ ) against the accuracy score of Word LMs.

and function word LMs ( $f_{fw,H}$ ,  $f_{fw,MT}$ ) as *FW LMs*, respectively, and for completeness of gappy-phrases ( $f_{g,H}$ ,  $f_{g,MT}$ ) as *GPs*. The Word LMs show the best accuracy that outperforms Cross-Entropy by 3.4% and Lexical Feature by 6.3%. This high accuracy is achieved by contrasting fluency in human-generated and machine-translated text to capture the phrase salad phenomenon. The accuracy of Word LM trained only on human-generated sentences is limited to 65.5%. On the other hand, the accuracy of Word LM trained on machine-translated sentences shows a better performance (84.4%). By combining these into a single feature vector  $f = (f_{w,H}, f_{w,MT}, f_{len})$ , the accuracy is largely improved.

It is interesting that Lexical Feature achieves a high accuracy of 87.8% despite its simplicity. Since Lexical Feature is a bag-of-words model, it can consider distant words in a sentence. This is effective for capturing a phrase salad that occurs among distant phrases, which  $N$ -gram cannot cover. As for Cross-Entropy, a simple subtraction of cross-entropy scores cannot well contrast the fluency in human-generated and machine-translated text and results in poorer accuracy than Word LMs.

The accuracy of POS LMs (91.3%) is slightly lower than that of Word LMs due to the limited vocabulary, *i.e.*, the number of POSs. The accuracy of FW LMs and GPs are even lower. This is convincing since these features cannot have reasonable values when a sentence does not include a function word and gappy-phrase. However, these features are complementary to Word LMs as we will see in the next paragraph.

**Effect of Feature Combination** Table 5 shows the accuracy when combining features. Sign tests show that the accuracy scores of these feature combinations are significantly different ( $p \ll .01$ ) against the accuracy of Word LMs. The results show that the features complement each other. The

Error	Ratio (%)	Accuracy	
		Word LMs	All
Has wrong content words	37.8	93.1	95.0
Misses content words	12.2	91.8	96.5
Has wrong function words	19.7	92.7	97.1
Misses function words	13.0	93.3	95.6
Has wrong inflections	10.8	97.3	98.7

Table 6: Distribution (%) of machine translation errors and accuracy (%) of proposed method on the different errors

combination of all features reaches an accuracy of 95.8%, which improves the accuracy of Word LMs by 1.7%. This result supports that FW LMs and GPs are effective to capture a phrase salad occurring in distant phrases and complement the evidence in  $N$ -grams that is captured by LMs. This effect becomes more obvious in the human evaluation.

We also evaluate the accuracy of the proposed method at a document level. Due to the high accuracy at the sentence-level, we use a voting method to judge a document, *i.e.*, deciding if the document is machine-translated when  $\gamma\%$  of its sentences are judged as machine-translated. We use all features and find that our method achieves 99% precision and recall with  $\gamma = 50$ .

**Human Evaluation** To further investigate the characteristics of our method, we conduct a human evaluation. We sample Japanese sentences and ask three native speakers to 1) judge whether a sentence is human-generated or machine-translated and 2) list errors that the sentence contains. Regarding the task 1), we allow the annotators to assign “hard to determine” for difficult cases. We allocate about 230 sentences for each annotator (in total 700 sentences) without overlapping annotation sets.

The accuracy of annotations is found to be 88.2%, which shows that our method is even superior to native speakers. Agreement between the annotators and our method (with all features) is 85.1%. As we interview the annotators, we find that human annotations are strongly affected by the annotators’ domain knowledge. For example, technical sentences are more often misclassified by the annotators.

Table 6 shows the distribution of errors on machine-translated sentences found by the annotators (on sentences that they correctly classified) with the accuracy of Word LMs and all features on

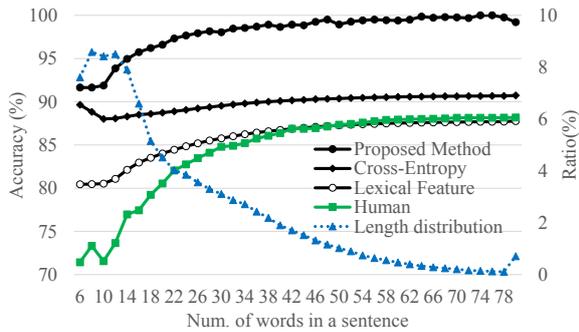

Figure 3: Accuracy (%) across different sentence lengths (the primary axis) and distribution (%) of sentence lengths in the evaluation dataset (the secondly axis)

these sentences (a sentence may contain multiple errors). It indicates that the accuracy of Word LMs is improved by feature combination; from 1.4% on sentences of “Has wrong inflections” to 4.7% on sentences of “Misses content words”.

**Effect of Sentence Length** The accuracy of the proposed method is significantly affected by sentence length (the number of words in a sentence). Fig. 3 shows the accuracy of the proposed method (with all features) and comparison methods w.r.t. sentence lengths (with the primary axis), as well as the distribution of sentence lengths in the evaluation dataset (with the secondly axis). We aggregate the classification results on each cross-validation (test results). It also shows the accuracy of human annotations w.r.t. sentence lengths, which we obtain for the 700 sentences in the human evaluation. The accuracy drops on all methods when sentences are short; the accuracy of our method is 91.6% when a sentence contains less than or equal to 10 words. The proposed method shows the similar trend with the human annotations, and even the accuracy of human annotations significantly drops on such short sentences. This result indicates that SMT results on short sentences tend to be of sufficient quality and indistinguishable from human-generated sentences. Since such high-quality machine-translations do not harm the quality of Web-mined data, we do not need to detect them.

**Effect of Setting on LM Training** We evaluate the performance variation w.r.t. the sizes of  $N$ -grams and development dataset. Fig. 4 shows the accuracy of the LM based features and feature combination when changing sizes of  $N$ -grams. The performance of Word LMs is stabilized after

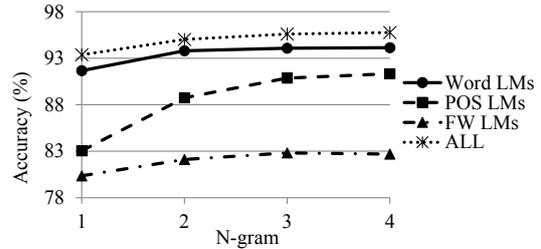

Figure 4: Effect of the sizes of  $N$ -grams on MT detection accuracy (%)

3-gram while that of POS LMs is still improved at 4-gram. This is because POS LMs need more evidence to compensate for their limited vocabulary. FW LMs become stable at 3-gram because the possible number of function words in a sentence should be small.

When we change the size of the development dataset with 10% increments, the accuracy curve is stabilized when the size is 40% of all set. Considering the fact that the overall development dataset is small, it shows that our method is deployable with a small dataset.

## 5.2 Accuracy on English Dataset

To investigate the applicability of our method to other languages, we apply the same method to the English dataset. Because English is a configurational language, function words are less flexible than case markers in Japanese. Therefore, SMT systems may better handle English function words, which potentially decreases the effect of FW LMs in our method. In addition, because English is a morphologically poor language, the effect of POS LMs may be reduced.

Nevertheless, in our experiment, all features are shown to be effective even with the English dataset. The combination of all features achieves the best performance, with an accuracy of 93.1%, which outperforms Cross-Entropy by 1.9%, and Lexical Feature by 8.5%. Even though improvements by POS LMs and FW LMs are smaller than Japanese case, their effects are still positive. We also find that GPs stably contribute to the accuracy. These results show the applicability of our method to other languages.

## 5.3 Accuracy on Raw Web Pages

To avoid unmodeled factors affecting the evaluation, we have carefully removed noise from our experiment datasets. However, real Web pages are

more complex; there are often instances of sentence fragments, such as captions and navigational link text. To evaluate the accuracy of our method on real Web pages, we conduct experiments using the dataset generated by Rarrick et al. (2011) that contains randomly crawled Web pages annotated by two annotators to judge if a page is human-generated or machine-translated. We use Japanese sentences extracted from 69 pages (43 human-generated and 26 machine-translated pages) where the annotators' judgments agree; 3,312 sentences consisting of 1,399 machine-translated and 1,913 human-generated sentences. To replicate the situation in real Web pages, we conduct a minimal preprocessing, *i.e.*, simply removing HTML tags, and then feed all the remaining text to our method.

An SVM classifier is trained with features obtained by the LMs and gappy-phrases computed from the data described in Sec. 4.1. Our method shows 80.6% accuracy at a sentence level and 82.4% accuracy at a document level using the voting method. One factor for this performance difference is again sentence lengths, as SMT results of short phrases in Web pages can be of high-quality. Another factor is the noise in Web pages. We find that experimental pages contain lots of non-sentences, such as fragments of scripts and product codes. The results show that we need a preprocessing to remove typical noise in Web text before SMT detection to handle noisy Web pages.

#### 5.4 Quality of Cleaned Data

Finally, we briefly demonstrate the effect of machine-translation filtering in an end-to-end scenario, taking LM construction as an example. We construct LMs reusing the Japanese evaluation dataset described in Sec. 4.1 where machine-translated sentences are removed by the proposed method (LM-Proposed), Lexical Feature (LM-LF), and Cross-Entropy (LM-CE), as well as an LM with all sentences, *i.e.*, with machine-translated sentences (LM-All). As a result of 5-fold cross-validation, LM-Proposed has 17.8%, 17.1%, and 16.3% lower perplexities on average compared to LM-All, LM-LF, and LM-CE, respectively. These results show that our method is useful for improving the quality of Web-mined data.

## 6 Conclusion

We propose a method for detecting machine-translated sentences from monolingual Web-text focusing on the phrase salad phenomenon produced by existing SMT systems. The experimental results show that our method achieves an accuracy of 95.8% for sentences and 80.6% for noisy Web text.

We plan to extend our method to detect machine-translated sentences produced by different MT systems, *e.g.*, a rule-based system, and develop a unified framework for cleaning various types of noise in Web-mined data. In addition, we will investigate the effect of source and target languages on translation in terms of MT detection. As Lopez (2008) describes, a phrase-salad is a common phenomenon that characterizes current SMT results. Therefore, we expect that our method is basically effective on different language pairs. We will conduct experiments to evaluate performance difference using various language pairs.

## Acknowledgments

We sincerely appreciate Spencer Rarrick and Will Lewis for active discussion and sharing the experimental data with us. We thank Junichi Tsujii for his valuable feedback to improve our work.

## Abstract

We study question answering as a machine learning problem, and induce a function that maps open-domain questions to queries over a database of web extractions. Given a large, community-authored, question-paraphrase corpus, we demonstrate that it is possible to learn a semantic lexicon and linear ranking function without manually annotating questions. Our approach automatically generalizes a seed lexicon and includes a scalable, parallelized perceptron parameter estimation scheme. Experiments show that our approach more than quadruples the recall of the seed lexicon, with only an 8% loss in precision.

## 1 Introduction

Open-domain question answering (QA) is a long-standing, unsolved problem. The central challenge is to automate every step of QA system construction, including gathering large databases and answering questions against these databases. While there has been significant work on large-scale information extraction (IE) from unstructured text (Banko et al., 2007; Hoffmann et al., 2010; Riedel et al., 2010), the problem of answering questions with the noisy knowledge bases that IE systems produce has received less attention. In this paper, we present an approach for learning to map questions to formal queries over a large, open-domain database of extracted facts (Fader et al., 2011).

Our system learns from a large, noisy, question-paraphrase corpus, where question clusters have a common but unknown query, and can span a diverse set of topics. Table 1 shows example paraphrase clusters for a set of factual questions. Such data provides strong signal for learning about lexical variation, but there are a number

Who wrote the Winnie the Pooh books? Who is the author of winnie the pooh? What was the name of the authur of winnie the pooh? Who wrote the series of books for Winnie the poo? Who wrote the children’s storybook ‘Winnie the Pooh’? Who is poohs creator?
What relieves a hangover? What is the best cure for a hangover? The best way to recover from a hangover? Best remedy for a hangover? What takes away a hangover? How do you lose a hangover? What helps hangover symptoms?
What are social networking sites used for? Why do people use social networking sites worldwide? Advantages of using social network sites? Why do people use social networks a lot? Why do people communicate on social networking sites? What are the pros and cons of social networking sites?
How do you say Santa Claus in Sweden? Say santa clause in sweden? How do you say santa clause in swedish? How do they say santa in Sweden? In Sweden what is santa called? Who is sweden santa?

Table 1: Examples of paraphrase clusters from the WikiAnswers corpus. Within each cluster, there is a wide range of syntactic and lexical variations.

of challenges. Given that the data is community-authored, it will inevitably be incomplete, contain incorrectly tagged paraphrases, non-factual questions, and other sources of noise.

Our core contribution is a new learning approach that scalably sifts through this paraphrase noise, learning to answer a broad class of factual questions. We focus on answering open-domain questions that can be answered with single-relation queries, *e.g.* all of the paraphrases of “Who wrote Winnie the Pooh?” and “What cures a hangover?” in Table 1. The algorithm answers such questions by mapping them to executable queries over a tuple store containing relations such as `authored(milne, winnie-the-pooh)` and `treat(bloody-mary, hangover-symptoms)`.

The approach automatically induces lexical structures, which are combined to build queries for unseen questions. It learns lexical equivalences for relations (e.g., *wrote*, *authored*, and *creator*), entities (e.g., *Winnie the Pooh* or *Pooh Bear*), and question templates (e.g., *Who  $\tau$  the  $e$  books?* and *Who is the  $\tau$  of  $e$ ?*). Crucially, the approach does not require any explicit labeling of the questions in our paraphrase corpus. Instead, we use 16 seed question templates and string-matching to find high-quality queries for a small subset of the questions. The algorithm uses learned word alignments to aggressively generalize the seeds, producing a large set of possible lexical equivalences. We then learn a linear ranking model to filter the learned lexical equivalences, keeping only those that are likely to answer questions well in practice.

Experimental results on 18 million paraphrase pairs gathered from WikiAnswers<sup>1</sup> demonstrate the effectiveness of the overall approach. We performed an end-to-end evaluation against a database of 15 million facts automatically extracted from general web text (Fader et al., 2011). On known-answerable questions, the approach achieved 42% recall, with 77% precision, more than quadrupling the recall over a baseline system.

In sum, we make the following contributions:

- We introduce PARALEX, an end-to-end open-domain question answering system.
- We describe scalable learning algorithms that induce general question templates and lexical variants of entities and relations. These algorithms require no manual annotation and can be applied to large, noisy databases of relational triples.
- We evaluate PARALEX on the end-task of answering questions from WikiAnswers using a database of web extractions, and show that it outperforms baseline systems.
- We release our learned lexicon and question-paraphrase dataset to the research community, available at <http://openie.cs.washington.edu>.

## 2 Related Work

Our work builds upon two major threads of research in natural language processing: information extraction (IE), and natural language interfaces to databases (NLIDB).

<sup>1</sup><http://wiki.answers.com/>

Research in IE has been moving towards the goal of extracting facts from large text corpora, across many domains, with minimal supervision (Mintz et al., 2009; Hoffmann et al., 2010; Riedel et al., 2010; Hoffmann et al., 2011; Banko et al., 2007; Yao et al., 2012). While much progress has been made in converting text into structured knowledge, there has been little work on answering natural language questions over these databases. There has been some work on QA over web text (Kwok et al., 2001; Brill et al., 2002), but these systems do not operate over extracted relational data.

The NLIDB problem has been studied for decades (Grosz et al., 1987; Katz, 1997). More recently, researchers have created systems that use machine learning techniques to automatically construct question answering systems from data (Zelle and Mooney, 1996; Popescu et al., 2004; Zettlemoyer and Collins, 2005; Clarke et al., 2010; Liang et al., 2011). These systems have the ability to handle questions with complex semantics on small domain-specific databases like GeoQuery (Tang and Mooney, 2001) or subsets of Freebase (Cai and Yates, 2013), but have yet to scale to the task of general, open-domain question answering. In contrast, our system answers questions with more limited semantics, but does so at a very large scale in an open-domain manner. Some work has been made towards more general databases like DBpedia (Yahya et al., 2012; Unger et al., 2012), but these systems rely on hand-written templates for question interpretation.

The learning algorithms presented in this paper are similar to algorithms used for paraphrase extraction from sentence-aligned corpora (Barzilay and McKeown, 2001; Barzilay and Lee, 2003; Quirk et al., 2004; Bannard and Callison-Burch, 2005; Callison-Burch, 2008; Marton et al., 2009). However, we use a paraphrase corpus for extracting lexical items relating natural language patterns to database concepts, as opposed to relationships between pairs of natural language utterances.

## 3 Overview of the Approach

In this section, we give a high-level overview of the rest of the paper.

**Problem** Our goal is to learn a function that will map a natural language question  $x$  to a query  $z$  over a database  $D$ . The database  $D$  is a collection of assertions in the form  $r(e_1, e_2)$  where  $r$  is a bi-

nary relation from a vocabulary  $R$ , and  $e_1$  and  $e_2$  are entities from a vocabulary  $E$ . We assume that the elements of  $R$  and  $E$  are human-interpretable strings like `population` or `new-york`. In our experiments,  $R$  and  $E$  contain millions of entries representing ambiguous and overlapping concepts. The database is equipped with a simple interface that accepts queries in the form  $r(?, e_2)$  or  $r(e_1, ?)$ . When executed, these queries return all entities  $e$  that satisfy the given relationship. Thus, our task is to find the query  $z$  that best captures the semantics of the question  $x$ .

**Model** The question answering model includes a lexicon and a linear ranking function. The lexicon  $L$  associates natural language patterns to database concepts, thereby defining the space of queries that can be derived from the input question (see Table 2). Lexical entries can pair strings with database entities (`nyc` and `new-york`), strings with database relations (`big` and `population`), or question patterns with templated database queries (`how r is e?` and `r(?, e)`). We describe this model in more detail in Section 4.

**Learning** The learning algorithm induces a lexicon  $L$  and estimates the parameters  $\theta$  of the linear ranking function. We learn  $L$  by bootstrapping from an initial seed lexicon  $L_0$  over a corpus of question paraphrases  $\mathcal{C} = \{(x, x') : x' \text{ is a paraphrase of } x\}$ , like the examples in Table 1. We estimate  $\theta$  by using the initial lexicon to automatically label queries in the paraphrase corpus, as described in Section 5.2. The final result is a scalable learning algorithm that requires no manual annotation of questions.

**Evaluation** In Section 8, we evaluate our system against various baselines on the end-task of question answering against a large database of facts extracted from the web. We use held-out known-answerable questions from WikiAnswers as a test set.

## 4 Question Answering Model

To answer questions, we must find the best query for a given natural language question.

### 4.1 Lexicon and Derivations

To define the space of possible queries, PARALEX uses a lexicon  $L$  that encodes mappings from natural language to database concepts (entities, relations, and queries). Each entry in  $L$  is a pair  $(p, d)$

Entry Type	NL Pattern	DB Concept
Entity	<code>nyc</code>	<code>new-york</code>
Relation	<code>big</code>	<code>population</code>
Question (1-Arg.)	<code>how big is e</code>	<code>population(?, e)</code>
Question (2-Arg.)	<code>how r is e</code>	<code>r(?, e)</code>

Table 2: Example lexical entries.

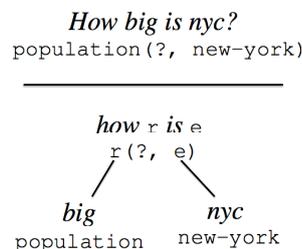

where  $p$  is a pattern and  $d$  is an associated database concept. Table 2 gives examples of the entry types in  $L$ : entity, relation, and question patterns.

**Entity patterns** match a contiguous string of words and are associated with some database entity  $e \in E$ .

**Relation patterns** match a contiguous string of words and are associated with a relation  $r \in R$  and an argument ordering (e.g. the string `child` could be modeled as either `parent-of` or `child-of` with opposite argument ordering).

**Question patterns** match an entire question string, with gaps that recursively match an entity or relation patterns. Question patterns are associated with a templated database query, where the values of the variables are determined by the matched entity and relation patterns. A question pattern may be **1-Argument**, with a variable for an entity pattern, or **2-Argument**, with variables for an entity pattern and a relation pattern. A 2-argument question pattern may also invert the argument order of the matched relation pattern, e.g. `who r e?` may have the opposite argument order of `who did e r?`

The lexicon is used to generate a derivation  $y$  from an input question  $x$  to a database query  $z$ . For example, the entries in Table 2 can be used to make the following derivation from the question `How big is nyc?` to the query `population(?, new-york)`:

This derivation proceeds in two steps: first matching a question form like `How r is e?` and then mapping `big` to `population` and `nyc` to `new-york`. Factoring the derivation this way allows the lexical entries for `big` and `nyc` to be reused in semanti-

cally equivalent variants like *nyc how big is it?* or *approximately how big is nyc?* This factorization helps the system generalize to novel questions that do not appear in the training set.

We model a derivation as a set of  $(p_i, d_i)$  pairs, where each  $p_i$  matches a substring of  $x$ , the substrings cover all words in  $x$ , and the database concepts  $d_i$  compose to form  $z$ . Derivations are rooted at either a 1-argument or 2-argument question entry and have entity or relation entries as leaves.

## 4.2 Linear Ranking Function

In general, multiple queries may be derived from a single input question  $x$  using a lexicon  $L$ . Many of these derivations may be incorrect due to noise in  $L$ . Given a question  $x$ , we consider all derivations  $y$  and score them with  $\theta \cdot \phi(x, y)$ , where  $\phi(x, y)$  is a  $n$ -dimensional feature representation and  $\theta$  is a  $n$ -dimensional parameter vector. Let  $\text{GEN}(x; L)$  be the set of all derivations  $y$  that can be generated from  $x$  using  $L$ . The best derivation  $y^*(x)$  according to the model  $(\theta, L)$  is given by:

$$y^*(x) = \arg \max_{y \in \text{GEN}(x; L)} \theta \cdot \phi(x, y)$$

The best query  $z^*(x)$  can be computed directly from the derivation  $y^*(x)$ .

Computing the set  $\text{GEN}(x; L)$  involves finding all 1-Argument and 2-Argument question patterns that match  $x$ , and then enumerating all possible database concepts that match entity and relation strings. When the database and lexicon are large, this becomes intractable. We prune  $\text{GEN}(x; L)$  using the model parameters  $\theta$  by only considering the  $N$ -best question patterns that match  $x$ , before additionally enumerating any relations or entities.

For the end-to-end QA task, we return a ranked list of answers from the  $k$  highest scoring queries. We score an answer  $a$  with the highest score of all derivations that generate a query with answer  $a$ .

## 5 Learning

PARALEX uses a two-part learning algorithm; it first induces an overly general lexicon (Section 5.1) and then learns to score derivations to increase accuracy (Section 5.2). Both algorithms rely on an initial seed lexicon, which we describe in Section 7.4.

### 5.1 Lexical Learning

The lexical learning algorithm constructs a lexicon  $L$  from a corpus of question paraphrases  $\mathcal{C} =$

$\{(x, x') : x' \text{ is a paraphrase of } x\}$ , where we assume that all paraphrased questions  $(x, x')$  can be answered with a single, initially unknown, query (Table 1 shows example paraphrases). This assumption allows the algorithm to generalize from the initial seed lexicon  $L_0$ , greatly increasing the lexical coverage.

As an example, consider the paraphrase pair  $x = \textit{What is the population of New York?}$  and  $x' = \textit{How big is NYC?}$  Suppose  $x$  can be mapped to a query under  $L_0$  using the following derivation  $y$ :

*what is the*  $r$  *of*  $e$  =  $r(? , e)$   
*population* =  $\text{population}$   
*new york* =  $\text{new-york}$

We can induce new lexical items by aligning the patterns used in  $y$  to substrings in  $x'$ . For example, suppose we know that the words in  $(x, x')$  align in the following way:

What is the population of New York?  
 \ / | / \ / \ /  
 How big is NYC?

Using this information, we can hypothesize that *how*  $r$  *is*  $e$ , *big*, and *nyc* should have the same interpretations as *what is the*  $r$  *of*  $e$ , *population*, and *new york*, respectively, and create the new entries:

*how*  $r$  *is*  $e$  =  $r(? , e)$   
*big* =  $\text{population}$   
*nyc* =  $\text{new-york}$

We call this procedure  $\text{InduceLex}(x, x', y, A)$ , which takes a paraphrase pair  $(x, x')$ , a derivation  $y$  of  $x$ , and a word alignment  $A$ , and returns a new set of lexical entries. Before formally describing  $\text{InduceLex}$  we need to introduce some definitions.

Let  $n$  and  $n'$  be the number of words in  $x$  and  $x'$ . Let  $[k]$  denote the set of integers  $\{1, \dots, k\}$ . A word alignment  $A$  between  $x$  and  $x'$  is a subset of  $[n] \times [n']$ . A phrase alignment is a pair of index sets  $(I, I')$  where  $I \subseteq [n]$  and  $I' \subseteq [n']$ . A phrase alignment  $(I, I')$  is consistent with a word alignment  $A$  if for all  $(i, i') \in A$ ,  $i \in I$  if and only if  $i' \in I'$ . In other words, a phrase alignment is consistent with a word alignment if the words in the phrases are aligned only with each other, and not with any outside words.

We will now define  $\text{InduceLex}(x, x', y, A)$  for the case where the derivation  $y$  consists of a 2-argument question entry  $(p_q, d_q)$ , a relation entry

**function** LEARNLEXICON**Inputs:**

- A corpus  $\mathcal{C}$  of paraphrases  $(x, x')$ . (Table 1)
- An initial lexicon  $L_0$  of (pattern, concept) pairs.
- A word alignment function  $\text{WordAlign}(x, x')$ . (Section 6)
- Initial parameters  $\theta_0$ .
- A function  $\text{GEN}(x; L)$  that derives queries from a question  $x$  using lexicon  $L$ . (Section 4)
- A function  $\text{InduceLex}(x, x', y, A)$  that induces new lexical items from the paraphrases  $(x, x')$  using their word alignment  $A$  and a derivation  $y$  of  $x$ . (Section 5.1)

**Output:** A learned lexicon  $L$ .

```

 $L = \{\}$ 
for all  $x, x' \in \mathcal{C}$  do
  if  $\text{GEN}(x; L_0)$  is not empty then
     $A \leftarrow \text{WordAlign}(x, x')$ 
     $y^* \leftarrow \arg \max_{y \in \text{GEN}(x; L_0)} \theta_0 \cdot \phi(x, y)$ 
     $L \leftarrow L \cup \text{InduceLex}(x, x', y^*, A)$ 
return  $L$ 

```

Figure 1: Our lexicon learning algorithm.

$(p_r, d_r)$ , and an entity entry  $(p_e, d_e)$ , as shown in the example above.<sup>2</sup>  $\text{InduceLex}$  returns the set of all triples  $(p'_q, d_q), (p'_r, d_r), (p'_e, d_e)$  such that for all  $p'_q, p'_r, p'_e$  such that

1.  $p'_q, p'_r, p'_e$  are a partition of the words in  $x'$ .
2. The phrase pairs  $(p_q, p'_q), (p_r, p'_r), (p_e, p'_e)$  are consistent with the word alignment  $A$ .
3. The  $p'_r$  and  $p'_e$  are contiguous spans of words in  $x'$ .

Figure 1 shows the complete lexical learning algorithm. In practice, for a given paraphrase pair  $(x, x')$  and alignment  $A$ ,  $\text{InduceLex}$  will generate multiple sets of new lexical entries, resulting in a lexicon with millions of entries. We use an existing statistical word alignment algorithm for  $\text{WordAlign}$  (see Section 6). In the next section, we will introduce a scalable approach for learning to score derivations to filter out lexical items that generalize poorly.

## 5.2 Parameter Learning

Parameter learning is necessary for filtering out derivations that use incorrect lexical entries like  $\text{new mexico} = \text{mexico}$ , which arise from noise in the paraphrases and noise in the word alignment.

<sup>2</sup> $\text{InduceLex}$  has similar behavior for the other type of derivation, which consists of a 1-argument question entry  $(p_q, d_q)$  and an entity  $(p_e, d_e)$ .

We use the hidden variable structured perceptron algorithm to learn  $\theta$  from a list of (question  $x$ , query  $z$ ) training examples. We adopt the iterative parameter mixing variation of the perceptron (McDonald et al., 2010) to scale to a large number of training examples.

Figure 2 shows the parameter learning algorithm. The parameter learning algorithm operates in two stages. First, we use the initial lexicon  $L_0$  to automatically generate (question  $x$ , query  $z$ ) training examples from the paraphrase corpus  $\mathcal{C}$ . Then we feed the training examples into the learning algorithm, which estimates parameters for the learned lexicon  $L$ .

Because the number of training examples is large, we adopt a parallel perceptron approach. We first randomly partition the training data  $\mathcal{T}$  into  $K$  equally-sized subsets  $\mathcal{T}_1, \dots, \mathcal{T}_K$ . We then perform perceptron learning on each partition in parallel. Finally, the learned weights from each parallel run are aggregated by taking a uniformly weighted average of each partition’s parameter vector. This procedure is repeated for  $T$  iterations.

The training data consists of (question  $x$ , query  $z$ ) pairs, but our scoring model is over (question  $x$ , derivation  $y$ ) pairs, which are unobserved in the training data. We use a hidden variable version of the perceptron algorithm (Collins, 2002), where the model parameters are updated using the highest scoring derivation  $y^*$  that will generate the correct query  $z$  using the learned lexicon  $L$ .

## 6 Data

For our database  $D$ , we use the publicly available set of 15 million REVERB extractions (Fader et al., 2011).<sup>3</sup> The database consists of a set of triples  $r(e_1, e_2)$  over a vocabulary of approximately 600K relations and 2M entities, extracted from the ClueWeb09 corpus.<sup>4</sup> The REVERB database contains a large cross-section of general world-knowledge, and thus is a good testbed for developing an open-domain QA system. However, the extractions are noisy, unnormalized (e.g., the strings `obama`, `barack-obama`, and `president-obama` all appear as distinct entities), and ambiguous (e.g., the relation `born-in` contains facts about both dates and locations).

<sup>3</sup>We used version 1.1, downloaded from <http://reverb.cs.washington.edu/>.

<sup>4</sup>The full set of REVERB extractions from ClueWeb09 contains over six billion triples. We used the smaller subset of triples to simplify our experiments.

```

function LEARNPARAMETERS
  Inputs:
  - A corpus  $\mathcal{C}$  of paraphrases  $(x, x')$ . (Table 1)
  - An initial lexicon  $L_0$  of (pattern, db concept) pairs.
  - A learned lexicon  $L$  of (pattern, db concept) pairs.
  - Initial parameters  $\theta_0$ .
  - Number of perceptron epochs  $T$ .
  - Number of training-data shards  $K$ .
  - A function  $\text{GEN}(x; L)$  that derives queries from a question  $x$  using lexicon  $L$ . (Section 4)
  - A function  $\text{PerceptronEpoch}(\mathcal{T}, \theta, L)$  that runs a single epoch of the hidden-variable structured perceptron algorithm on training set  $\mathcal{T}$  with initial parameters  $\theta$ , returning a new parameter vector  $\theta'$ . (Section 5.2)

  Output: A learned parameter vector  $\theta$ .

  // Step 1: Generate Training Examples  $\mathcal{T}$ 
   $\mathcal{T} = \{\}$ 
  for all  $x, x' \in \mathcal{C}$  do
    if  $\text{GEN}(x; L_0)$  is not empty then
       $y^* \leftarrow \arg \max_{y \in \text{GEN}(x; L_0)} \theta_0 \cdot \phi(x, y)$ 
       $z^* \leftarrow \text{query of } y^*$ 
      Add  $(x', z^*)$  to  $\mathcal{T}$ 

  // Step 2: Learn Parameters from  $\mathcal{T}$ 
  Randomly partition  $\mathcal{T}$  into shards  $\mathcal{T}_1, \dots, \mathcal{T}_K$ 
  for  $t = 1 \dots T$  do
    // Executed on  $k$  processors
     $\theta_{k,t} = \text{PerceptronEpoch}(\mathcal{T}_k, \theta_{t-1}, L)$ 
    // Average the weights
     $\theta_t = \frac{1}{K} \sum_k \theta_{k,t}$ 

  return  $\theta_T$ 

```

Figure 2: Our parameter learning algorithm.

Our paraphrase corpus  $\mathcal{C}$  was constructed from the collaboratively edited QA site WikiAnswers. WikiAnswers users can tag pairs of questions as alternate wordings of each other. We harvested a set of 18M of these question-paraphrase pairs, with 2.4M distinct questions in the corpus.

To estimate the precision of the paraphrase corpus, we randomly sampled a set of 100 pairs and manually tagged them as ‘paraphrase’ or ‘not-paraphrase.’ We found that 55% of the sampled pairs are valid paraphrased. Most of the incorrect paraphrases were questions that were related, but not paraphrased *e.g.* *How big is the biggest mall?* and *Most expensive mall in the world?*

We word-aligned each paraphrase pair using the MGIZA++ implementation of IBM Model 4 (Och and Ney, 2000; Gao and Vogel, 2008). The word-alignment algorithm was run in each direction  $(x, x')$  and  $(x', x)$  and then combined using the grow-diag-final-and heuristic (Koehn et al., 2003).

## 7 Experimental Setup

We compare the following systems:

- **PARALEX:** the full system, using the lexical learning and parameter learning algorithms from Section 5.
- **NoParam:** PARALEX without the learned parameters.
- **InitOnly:** PARALEX using only the initial seed lexicon.

We evaluate the systems’ performance on the end-task of QA on WikiAnswers questions.

### 7.1 Test Set

A major challenge for evaluation is that the REVERB database is incomplete. A system may correctly map a test question to a valid query, only to return 0 results when executed against the incomplete database. We factor out this source of error by semi-automatically constructing a sample of questions that are known to be answerable using the REVERB database, and thus allows for a meaningful comparison on the task of question understanding.

To create the evaluation set, we identified questions  $x$  in a held out portion of the WikiAnswers corpus such that (1)  $x$  can be mapped to some query  $z$  using an initial lexicon (described in Section 7.4), and (2) when  $z$  is executed against the database, it returns at least one answer. We then add  $x$  and all of its paraphrases as our evaluation set. For example, the question *What is the language of Hong-Kong* satisfies these requirements, so we added these questions to the evaluation set:

*What is the language of Hong-Kong?*  
*What language do people in hong kong use?*  
*How many languages are spoken in hong kong?*  
*How many languages hong kong people use?*  
*In Hong Kong what language is spoken?*  
*Language of Hong-kong?*

This methodology allows us to evaluate the systems’ ability to handle syntactic and lexical variations of questions that should have the same answers. We created 37 question clusters, resulting in a total of 698 questions. We removed all of these questions and their paraphrases from the training set. We also manually filtered out any incorrect paraphrases that appeared in the test clusters.

We then created a gold-standard set of  $(x, a, l)$  triples, where  $x$  is a question,  $a$  is an answer, and  $l$

Question Pattern	Database Query
<i>who</i> <sub>r</sub> <i>e</i>	$r(? , e)$
<i>what</i> <sub>r</sub> <i>e</i>	$r(? , e)$
<i>who</i> <i>does</i> <sub>e</sub> <i>r</i>	$r(e , ?)$
<i>what</i> <i>does</i> <sub>e</sub> <i>r</i>	$r(e , ?)$
<i>what is the</i> <sub>r</sub> <i>of</i> <i>e</i>	$r(? , e)$
<i>who is the</i> <sub>r</sub> <i>of</i> <i>e</i>	$r(? , e)$
<i>what is</i> <sub>r</sub> <i>by</i> <i>e</i>	$r(e , ?)$
<i>who is</i> <sub>e</sub> 's <sub>r</sub>	$r(? , e)$
<i>what is</i> <sub>e</sub> 's <sub>r</sub>	$r(? , e)$
<i>who is</i> <sub>r</sub> <i>by</i> <i>e</i>	$r(e , ?)$
<i>when did</i> <sub>e</sub> <i>r</i>	$r\text{-in}(e , ?)$
<i>when did</i> <sub>e</sub> <i>r</i>	$r\text{-on}(e , ?)$
<i>when was</i> <sub>e</sub> <i>r</i>	$r\text{-in}(e , ?)$
<i>when was</i> <sub>e</sub> <i>r</i>	$r\text{-on}(e , ?)$
<i>where was</i> <sub>e</sub> <i>r</i>	$r\text{-in}(e , ?)$
<i>where did</i> <sub>e</sub> <i>r</i>	$r\text{-in}(e , ?)$

Table 3: The question patterns used in the initial lexicon  $L_0$ .

is a label (correct or incorrect). To create the gold-standard, we first ran each system on the evaluation questions to generate  $(x, a)$  pairs. Then we manually tagged each pair with a label  $l$ . This resulted in a set of approximately 2,000 human judgments. If  $(x, a)$  was tagged with label  $l$  and  $x'$  is a paraphrase of  $x$ , we automatically added the labeling  $(x', a, l)$ , since questions in the same cluster should have the same answer sets. This process resulted in a gold standard set of approximately 48,000  $(x, a, l)$  triples.

## 7.2 Metrics

We use two types of metrics to score the systems. The first metric measures the precision and recall of each system’s highest ranked answer. Precision is the fraction of predicted answers that are correct and recall is the fraction of questions where a correct answer was predicted. The second metric measures the accuracy of the entire ranked answer set returned for a question. We compute the mean average precision (MAP) of each systems’ output, which measures the average precision over all levels of recall.

## 7.3 Features and Settings

The feature representation  $\phi(x, y)$  consists of indicator functions for each lexical entry  $(p, d) \in L$  used in the derivation  $y$ . For parameter learning, we use an initial weight vector  $\theta_0 = 0$ , use  $T = 20$

	F1	Precision	Recall	MAP
PARALEX	<b>0.54</b>	0.77	<b>0.42</b>	<b>0.22</b>
NoParam	0.30	0.53	0.20	0.08
InitOnly	0.18	<b>0.84</b>	0.10	0.04

Table 4: Performance on WikiAnswers questions known to be answerable using REVERB.

	F1	Precision	Recall	MAP
PARALEX	<b>0.54</b>	0.77	<b>0.42</b>	<b>0.22</b>
No 2-Arg.	0.40	<b>0.86</b>	0.26	0.12
No 1-Arg	0.35	0.81	0.22	0.11
No Relations	0.18	0.84	0.10	0.03
No Entity	0.36	0.55	0.27	0.15

Table 5: Ablation of the learned lexical items.

iterations and shard the training data into  $K = 10$  pieces. We limit each system to return the top 100 database queries for each test sentence. All input words are lowercased and lemmatized.

## 7.4 Initial Lexicon

Both the lexical learning and parameter learning algorithms rely on an initial seed lexicon  $L_0$ . The initial lexicon allows the learning algorithms to bootstrap from the paraphrase corpus.

We construct  $L_0$  from a set of 16 hand-written 2-argument question patterns and the output of the identity transformation on the entity and relation strings in the database. Table 3 shows the question patterns that were used in  $L_0$ .

## 8 Results

Table 4 shows the performance of PARALEX on the test questions. PARALEX outperforms the baseline systems in terms of both F1 and MAP. The lexicon-learning algorithm boosts the recall by a factor of 4 over the initial lexicon, showing the utility of the InduceLex algorithm. The

String	Learned Database Relations for String
<i>get rid of</i>	treatment-for, cause, get-rid-of, cure-for, easiest-way-to-get-rid-of
<i>word</i>	word-for, slang-term-for, definition-of, meaning-of, synonym-of
<i>speak</i>	speak-language-in, language-speak-in, principal-language-of, dialect-of
<i>useful</i>	main-use-of, purpose-of, importance-of, property-of, usefulness-of

String	Learned Database Entities for String
<i>smoking</i>	smoking, tobacco-smoking, cigarette, smoking-cigar, smoke, quit-smoking
<i>radiation</i>	radiation, electromagnetic-radiation, nuclear-radiation
<i>vancouver</i>	vancouver, vancouver-city, vancouver-island, vancouver-british-columbia
<i>protein</i>	protein, protein-synthesis, plasma-protein, monomer, dna

Table 6: Examples of relation and entity synonyms learned from the WikiAnswers paraphrase corpus.

parameter-learning algorithm also results in a large gain in both precision and recall: InduceLex generates a noisy set of patterns, so selecting the best query for a question is more challenging.

Table 5 shows an ablation of the different types of lexical items learned by PARALEX. For each row, we removed the learned lexical items from each of the types described in Section 4, keeping only the initial seed lexical items. The learned 2-argument question templates significantly increase the recall of the system. This increased recall came at a cost, lowering precision from 0.86 to 0.77. Thresholding the query score allows us to trade precision for recall, as shown in Figure 3. Table 6 shows some examples of the learned entity and relation synonyms.

The 2-argument question templates help PARALEX generalize over different variations of the same question, like the test questions shown in Table 7. For each question, PARALEX combines a 2-argument question template (shown below the questions) with the rules *celebrate* = holiday-of and *christians* = christians to derive a full query. Factoring the problem this way allows PARALEX to reuse the same rules in different syntactic configurations. Note that the imperfect training data can lead to overly-specific templates like *what are the religious r of e*, which can lower accuracy.

## 9 Error Analysis

To understand how close we are to the goal of open-domain QA, we ran PARALEX on an unrestricted sample of questions from WikiAnswers. We used the same methodology as described in the previous section, where PARALEX returns the top answer for each question using REVERB.

We found that PARALEX performs significantly worse on this dataset, with recall maxing out at ap-

Celebrations for Christians? <i>r for e?</i>
Celebrations of Christians? <i>r of e?</i>
What are some celebrations for Christians? <i>what are some r for e?</i>
What are some celebrations of the Christians? <i>what are some r of e?</i>
What are some of Christians celebrations? <i>what are some of e r?</i>
What celebrations do Christians do? <i>what r do e do?</i>
What did Christians celebrate? <i>what did e r?</i>
What are the religious celebrations of Christians? <i>what are the religious r of e?</i>
What celebration do Christians celebrate? <i>what r do e celebrate?</i>

Table 7: Questions from the test set with 2-argument question patterns that PARALEX used to derive a correct query.

proximately 6% of the questions answered at precision 0.4. This is not surprising, since the test questions are not restricted to topics covered by the REVERB database, and may be too complex to be answered by any database of relational triples.

We performed an error analysis on a sample of 100 questions that were either incorrectly answered or unanswered. We examined the candidate queries that PARALEX generated for each question and tagged each query as correct (would return a valid answer given a correct and complete database) or incorrect. Because the input questions are unrestricted, we also judged whether the questions could be faithfully represented as a  $r(?, e)$  or  $r(e, ?)$  query over the database vocabulary. Table 8 shows the distribution of errors.

The largest source of error (36%) were on com-

plex questions that could not be represented as a query for various reasons. We categorized these questions into groups. The largest group (14%) were questions that need n-ary or higher-order database relations, for example *How long does it take to drive from Sacramento to Cancun?* or *What do cats and dogs have in common?* Approximately 13% of the questions were how-to questions like *How do you make axes in minecraft?* whose answers are a sequence of steps, instead of a database entity. Lastly, 9% of the questions require database operators like joins, for example *When were Bobby Orr’s children born?*

The second largest source of error (32%) were questions that could be represented as a query, but where PARALEX was unable to derive any correct queries. For example, the question *Things grown on Nigerian farms?* was not mapped to any queries, even though the REVERB database contains the relation `grown-in` and the entity `nigeria`. We found that 13% of the incorrect questions were cases where the entity was not recognized, 12% were cases where the relation was not recognized, and 6% were cases where both the entity and relation were not recognized.

We found that 28% of the errors were cases where PARALEX derived a query that we judged to be correct, but returned no answers when executed against the database. For example, given the question *How much can a dietician earn?* PARALEX derived the query `salary-of(?, dietician)` but this returned no answers in the REVERB database.

Finally, approximately 4% of the questions included typos or were judged to be inscrutable, for example *Barovier hiriacy of evidence based for pressure sore?*

**Discussion** Our experiments show that the learning algorithms described in Section 5 allow PARALEX to generalize beyond an initial lexicon and answer questions with significantly higher accuracy. Our error analysis on an unrestricted set of WikiAnswers questions shows that PARALEX is still far from the goal of truly high-recall, open-domain QA. We found that many questions asked on WikiAnswers are either too complex to be mapped to a simple relational query, or are not covered by the REVERB database. Further, approximately one third of the missing recall is due to entity and relation recognition errors.

Incorrectly Answered/Unanswered Questions	
36%	Complex Questions <i>Need n-ary or higher-order relations (14%)</i> <i>Answer is a set of instructions (13%)</i> <i>Need database operators e.g. joins (9%)</i>
32%	Entity or Relation Recognition Errors <i>Entity recognition errors (13%)</i> <i>Relation recognition errors (12%)</i> <i>Entity &amp; relation recognition errors (7%)</i>
28%	Incomplete Database <i>Derived a correct query, but no answers</i>
4%	Typos/Inscrutable Questions

## 10 Conclusion

We introduced a new learning approach that induces a complete question-answering system from a large corpus of noisy question-paraphrases. Using only a seed lexicon, the approach automatically learns a lexicon and linear ranking function that demonstrated high accuracy on a held-out evaluation set.

A number of open challenges remain. First, precision could likely be improved by adding new features to the ranking function. Second, we would like to generalize the question understanding framework to produce more complex queries, constructed within a compositional semantic framework, but without sacrificing scalability. Third, we would also like to extend the system with other large databases like Freebase or DBpedia. Lastly, we believe that it would be possible to leverage the user-provided answers from WikiAnswers as a source of supervision.

## Abstract

The 2011 Great East Japan Earthquake caused a wide range of problems, and as countermeasures, many aid activities were carried out. Many of these problems and aid activities were reported via Twitter. However, most problem reports and corresponding aid messages were not successfully exchanged between victims and local governments or humanitarian organizations, overwhelmed by the vast amount of information. As a result, victims could not receive necessary aid and humanitarian organizations wasted resources on redundant efforts. In this paper, we propose a method for discovering matches between problem reports and aid messages. Our system contributes to problem-solving in a large scale disaster situation by facilitating communication between victims and humanitarian organizations.

## 1 Introduction

The 2011 Great East Japan Earthquake in March 11, 2011 killed 15,883 people and destroyed over 260,000 households (National Police Agency of Japan, 2013). Accustomed way of living suddenly became unmanageable and people found themselves in extreme conditions for months.

Just after the disaster, many people used Twitter for posting problem reports and aid messages as it functioned while most communication channels suffered disruptions (Winn, 2011; Acar and Muraki, 2011; Sano et al., 2012). Examples of such problem reports and aid messages, translated from Japanese tweets, are given below (P1, A1).

**P1** *My friend said infant formula is sold out. If somebody knows shops in Sendai-city where they still have it in stock, please let us know.*

**A1** *At Jusco supermarket in Sendai, you can still buy water and infant formula.*

If A1 would have been forwarded to the sender of P1, it could have helped since it would help the “friend” to obtain infant formula. But in reality, the majority of such reports/messages, especially unforeseen ones went unnoticed amongst the mass of information (Ohtake et al., 2013). In addition, there were cases where many humanitarian organizations responded to the same problems and wasted precious resources. For instance, many volunteers responded to problems which were heavily reported by public media, leading to oversupply (Saijo, 2012). Such waste of resources could have been avoided if the organizations would have successfully shared the aid messages for the same problems.

Such observations motivated this work. We developed methods for recognizing problem reports and aid messages in tweets and finding proper matches between them. By browsing the discovered matches, victims can be assisted to overcome their problems, and humanitarian organizations can avoid redundant relief efforts. We define problem reports, aid messages and their successful matches as follows.

**Problem report:** A tweet that informs about the possibility or emergence of a problem that requires a treatment or countermeasure.

**Aid message:** A tweet that (1) informs about situations or actions that can be a remedy or solution for a problem, or (2) informs that the problem is solved or is about to be solved.

**Problem-aid tweet match:** A tweet pair is a problem-aid tweet match (1) if the aid message informs how to overcome the problem, (2) if the aid message informs about the set-

tlement of the problem, or (3) if the aid message provides information which contributes to the settlement of the problem.

In this work we excluded *direct requests*, such as “Send us food!”, from problem reports. This is because it is relatively easy to recognize such direct requests by checking mood types (i.e., imperative) and their behavior is quite different from problem reports like “People in Sendai are starving”. Problem reports in this work do not directly state which actions are required, only implying the necessity of a countermeasure through claiming the existence of problems.

An underlying assumption of our method is that we can find a noun-predicate dependency relation that works as an *indicator* of problems and aids in problem reports and aid messages, which we refer to as *problem nucleus* and *aid nucleus*.<sup>1</sup> An example of problem nucleus is “infant formula is sold out” in P1, and that of aid nucleus is “(can) buy infant formula” in A1. Many problem-aid tweet matches can be recognized through problem and aid nuclei pairs.

We also assume that if the problem and aid nuclei match, they share the same noun. Then, the semantics of predicates in the nuclei is the main factor that decides whether the nuclei constitute a match. We introduce a semantic classification of predicates according to the framework of excitation polarities proposed in Hashimoto et al. (2012). Our hypothesis is that excitation polarities along with trouble expressions can characterize problem reports, aid messages and their matches. We developed a supervised method encoding such information into its features.

An evident alternative to this approach is to use sentiment analysis (Mandel et al., 2012; Tsagkaldou et al., 2011) assuming that problem reports should include something ‘bad’ while aid messages describe something ‘good’. However, we will show that this does not work well in our experiments. We think this is due to mismatch between the concepts of problem/aid and sentiment polarity. Note that previous work on ‘demand’ recognition also found similar tendencies (Kanayama and Nasukawa, 2008).

Another issue in this task is, of course, the context surrounding problem/aid nuclei. The fol-

<sup>1</sup>We found that out of 500 random tweets only 4.5% of problem reports and 9.1% of aid messages did not contain any problem report/aid message nuclei.

lowing (imaginary) tweets exemplify the problems caused by contexts.

**FP1** *I do not believe infant formula is sold out in Sendai.*

**FA1** *At Jusco supermarket in Iwaki, you can still buy infant formula.*

The problem nuclei of FP1 and P1 are the same but FP1 is not a problem report because of the expression “I do not believe”. The aid nuclei of FA1 and A1 are the same but FA1 does not constitute a proper match with P1 because FA1 and P1 refer to different cities, “Iwaki” and “Sendai”. In this work, the problems concerning the modality and other semantic modifications to problem/aid nuclei by context are dealt with by the introduction of features representing the text surrounding the nuclei in machine learning. As for the location problem, we apply a location recognizer to all tweets and restrict the matching candidates to the tweet pairs referring to the same location.

## 2 Approach

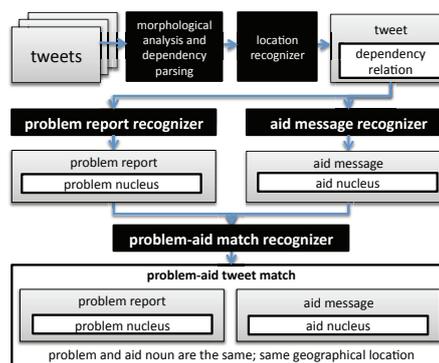

Figure 1: Problem-aid matching system overview.

We developed machine learning based systems to recognize problem reports, aid messages and problem-aid tweet matches. Figure 1 illustrates the whole system. First, location names in tweets are identified by matching tweets against our location dictionary, described in Section 3. Then, each tweet is paired with *each* dependency relation in the tweet, which is a candidate of problem/aid nuclei and given to the problem report and aid message recognizers. A tweet-nucleus-candidate pair judged as problem report is combined with another tweet-nucleus-candidate pair recognized as an aid message if the two nuclei share the same noun and the tweets share the same location name, and given to the problem-aid match recognizer.

In the following, problem and aid nuclei are denoted by a noun-template pair. A *template* is composed of a predicate and its argument position. For instance, “water supply stopped” in P2 is a problem nucleus, “water supply recovered” in A2 is an aid nucleus and they are denoted by the noun-template pairs ⟨water supply, X stopped⟩ and ⟨water supply, X recovered⟩.

**P2** *In Sendai city, water supply stopped.*

**A2** *In Sendai city, water supply recovered.*

Roughly speaking, we regard the tasks of problem report recognition and aid message recognition as the tasks of finding proper problem/aid nuclei in tweets and our method performs these tasks based on the semantic properties of nouns and templates in problem/aid nucleus candidates and their surrounding contexts.

The basic intuition behind this approach can be explained using excitation polarity proposed in Hashimoto et al. (2012). Excitation polarity differentiates *templates* into ‘excitatory’ or ‘inhibitory’ with regard to the main function or effect of entities referred to by their argument noun. While excitatory templates (e.g., cause X, buy X, suffer from X) entail that the main function or effect is activated or enhanced, inhibitory templates (e.g., ruin X, prevent X, X runs out) entail that the main function or effect is deactivated or suppressed. The templates that do not fit into the above categorization are classified as ‘neutral’.

We observed that problem reports in general included either of (A) a dependency relation between a noun referring to some trouble and an excitatory template or (B) a dependency relation between a noun not referring to any trouble and an inhibitory template. Examples of (A) include ⟨carbon monoxide poisoning, suffer from X⟩, ⟨false rumor, spread X⟩. They refer to events that activate troubles. On the other hand, (B) is exemplified by ⟨school, X is collapsed⟩, ⟨battery, X runs out⟩, which imply that some non-trouble objects such as resources, appliances and facilities are dysfunctional. We assume that if we can find such dependency relations in tweets, the tweets are likely to be problem reports.

Contrary, a tweet is more likely to be an aid message when it includes either (C) a dependency relation between a noun referring to some trouble and an inhibitory template or (D) a dependency relation between a noun not referring to any trou-

	trouble	non-trouble
<b>excitatory</b>	(A) problem nucleus	(D) aid nucleus
<b>inhibitory</b>	(C) aid nucleus	(B) problem nucleus

Table 1: Problem/aid-excitation matrix.

ble and an excitatory template. Examples of (C) are ⟨flu, X was eradicated (in some shelter)⟩ and ⟨debris, remove X⟩. They represent the *dysfunction* of troubles and can mean the solution or the settlement of troubles. On the other hand, examples of (D) include ⟨school, X re-build⟩ and ⟨baby formula, buy X⟩. They entail that some resources function properly or become available. These formulations are summarized in Table 1.

As an interesting consequence of such a view on problem/aid nucleus, we can say the following regarding problem-aid tweet matchings: when a problem nucleus and an aid nucleus are an adequate match, the excitation polarities of their templates are opposite. Consider the following tweets.

**P3** *Some people were going back to Iwaki, but the water system has not come back yet. It’s terrible that **bath is unusable**.*

**A3** *We **open the bath** for the public, located on the 2F of Iwaki Kuhon temple. If you’re staying at a relief shelter and would like to take a bath, you can use it.*

“Bath is unusable” in P3 is a problem nucleus while “open the bath” in A3 is an aid nucleus. Since the problem reported in P3 can be solved with A3, they are a successful match. The inhibitory template “X is unusable” indicates that the function of “bath”, a non-trouble expression, is suppressed. The excitatory template “open X” indicates that the function of “bath” is activated.

The same holds when we consider the noun referring to troubles like “flu”. The polarity of the template in a problem nucleus should be excitatory like “flu is raging” while that of an aid nucleus should be inhibitory like ⟨flu, X was eradicated⟩. These examples keep the constraint that the problem and aid nucleus should have opposite polarities when they constitute a match.

Note that the formulations of problem report, aid message and their matches or the excitation matrix (Table 1) were not presented to our annotators and our test/training data may contain data that contradict with the formulations. These formulations constitute the hypothesis to be validated in this work.

An important point to be stressed here is that there are problem-aid tweet matches that do not fit into our formulations. For instance, we assume that the problem nucleus and aid nucleus in a proper match share the same noun. However, tweet pairs such as “There are many injured people in Sendai city” and “We are sending ambulances to Sendai” can constitute a proper match, but there is no proper problem-aid nuclei pair that share the same noun in these tweets. (We can find the dependency relations sharing “Sendai” but they do not express anything about the contents of problem and aid.) The point is that the tweet pairs can be judged because people know ambulances can be a *countermeasure* to injured people as world knowledge. Introducing such world knowledge is beyond the scope of this current study.

Also, we exclude direct requests from problem reports. As mentioned in the introduction, identifying direct requests is relatively easy, hence we excluded them from our target.

### 3 Problem Report and Aid Message Recognizers

We recognize problem reports and aid messages in given tweets using a supervised classifier, SVMs with linear kernel, which worked best in our preliminary experiments. The feature set given to the SVMs are summarized in the top part of Table 2. Note that we used a common feature set for both the problem report recognizer and aid message recognizer and that it is categorized into several types: features concerning trouble expressions (TR), excitation polarity (EX), their combination (TRES1) and word sentiment polarity (WSP), features expressing morphological and syntactic structures of nuclei and their context surrounding problem/aid nuclei (MSA), features concerning semantic word classes (SWC) appearing in nuclei and their context, request phrases, such as “Please help us”, appearing in tweets (REQ), and geographical locations in tweets recognized by our location recognizer (GL). MSA is used to express the modality of nuclei and other contextual information surrounding nuclei. REQ was introduced based on our observation that if there are some requests in tweets, problem nuclei tend to appear as justification for the requests.

We also attempted to represent nucleus template IDs, noun IDs and their combinations directly in our feature set to capture typical templates fre-

TR	Whether the nucleus noun is a trouble/non-trouble expression.
EX1	The excitation polarity and the value of the excitation score of the nucleus template.
TRES1	All possible combinations of trouble/non-trouble of TR and excitation polarities of EX1.
WSP1	Whether the nucleus noun is positive/negative/not in the Word Sentiment Polarity (WSP) dictionary.
WSP2	Whether the nucleus template is positive/negative/not in the WSP dictionary.
WSP3	Whether the nucleus template is followed by a positive/negative word within the tweet.
MSA1	Morpheme $n$ -grams, syntactic dependency $n$ -grams in the tweet and morpheme $n$ -grams before and after the nucleus template. ( $1 \leq n \leq 3$ )
MSA2	Character $n$ -grams of the nucleus template to capture conjugation and modality variations. ( $1 \leq n \leq 3$ )
MSA3	Morpheme and part-of-speech $n$ -grams within the <i>bunsetsu</i> containing the nucleus template to capture conjugation and modality variations. ( $1 \leq n \leq 3$ ) (A <i>bunsetsu</i> is a syntactic constituent composed of a content word and several function words, the smallest unit of syntactic analysis in Japanese.)
MSA4	The part-of-speech of the nucleus template’s head to capture modality variations outside the nucleus template’s <i>bunsetsu</i> .
MSA5	The number of <i>bunsetsu</i> between the nucleus noun and the nucleus template. We found that a long distance between the noun and the template suggests parsing errors.
MSA6	Re-occurrence of the nucleus noun’s postpositional particle between the nucleus noun and the nucleus template. We found that the re-occurrence of the same postpositional particle within a clause suggests parsing errors.
SWC1	The semantic class $n$ -grams in the tweet.
SWC2	The semantic class(es) of the nucleus noun.
REQ	Presence of a request phrase in the tweet, identified from within 426 manually collected request phrases.
GL	Geographical locations in the tweet identified using our location recognizer. Existence/non-existence of locations in tweets are also encoded.
EX2	Whether the problem and aid nucleus templates have the same or opposite excitation polarities.
EX3	Product of the values of the excitation scores for the problem and the aid nucleus template.
TRES2	All possible combinations of trouble/non-trouble of TR, excitation polarity EX1 of the problem nucleus template and excitation polarity EX1 of the aid nucleus template.
SIM1	Common semantic word classes of the problem report and aid message.
SIM2	Whether there are common nouns modifying the common nucleus noun or not in the problem report and aid message.
SIM3	Whether the words in the same word class modify the common nucleus noun or not in the problem report and aid message.
SIM4	The semantic similarity score between the problem nucleus template and the aid nucleus template.
CTP	Whether the problem nucleus template and the aid nucleus template are in contradiction relation dictionary or not.
SSR1	Problem report recognizer’s SVM score of problem nucleus template.
SSR2	Problem report recognizer’s SVM score of aid nucleus template.
SSR3	Aid message recognizer’s SVM score of the problem nucleus template.
SSR4	Aid message recognizer’s SVM score of the aid nucleus template.

Table 2: Features used with the problem report recognizer and the aid message recognizer (*above*); additional features used in training the problem-aid match recognizer (*below*).

quently appearing in problem and aid nuclei, but since there was no improvement we omit them.

The other feature types need some non-trivial dictionaries. In the following, we explain how we created the dictionaries for each feature type along with the motivation behind their introduction.

**Trouble Expressions (TR)** As mentioned previously, trouble expressions work as good evidence for recognizing problem reports and aid messages. The TR feature indicates whether the noun in the problem/aid nucleus candidate is a trouble ex-

pression or not. For this purpose, we created a list of trouble expressions following the semi-supervised procedure presented in De Saeger et al. (2008). After manual validation of the list, we obtained 20,249 expressions referring to some troubles, such as “tsunami” and “flu”. The value of the TR feature is determined by checking whether the nucleus noun is contained in the list.

**Excitation Polarities (EX)** The excitation polarities are also important in recognizing problem reports and aid messages as mentioned before. For constructing the dictionary for excitation polarities of templates, we applied the bootstrapping procedure in Hashimoto et al. (2012) to 600 million Web pages. Hashimoto’s method provides the value of the *excitation score* in  $[-1, 1]$  for each template indicating the polarities and their *strength*. Positive value indicates excitatory, negative value inhibitory and small absolute value neutral. After manual checking of the results by the majority vote of three human annotators (other than the authors), we limited the templates to the ones that have score values consistent with the majority vote of the annotators, obtaining a dictionary consisting of 7,848 excitatory, 836 inhibitory and 7,230 neutral templates. The Fleiss’ (1971) kappa-score was 0.48 (moderate agreement). We used the excitation score values as feature values. Excitation has already been used in many works, such as causality and contradiction extraction (Hashimoto et al., 2012) or Why-QA (Oh et al., 2013).

**Word Sentiment Polarity (WSP)** As we suggested before, full-fledged sentiment analysis to recognize the expressions, including clauses and phrases, that refer to something good or bad was not effective in our task. However, the sentiment polarity, assigned to single words turned out to be effective. To identify the sentiment polarity of words, we employed the word sentiment polarity dictionary used with a sentiment analysis tool for Japanese, the Opinion Extraction Tool software<sup>2</sup>, which is an implementation of Nakagawa et al. (2010). The dictionary includes 9,030 positive and 27,951 negative words. Note that we used the Opinion Extraction Tool in the experiments to check the effectiveness of the full-fledged sentiment analysis in this task.

**Semantic Word Class (SWC)** We assume that nouns in the same semantic class behave simi-

<sup>2</sup>Provided at the ALAGIN Forum (<http://www.alagin.jp/>).

larly in crisis situations. For example, if “infection” appears in a problem report, the tweets including “pulmonary embolism” are also likely to be problem reports. Semantic word class features are used to capture such tendencies. We applied an EM-style word clustering algorithm in Kazama and Torisawa (2008) to 600 million Web pages and clustered 1 million nouns into 500 classes. This algorithm has been used in many works, such as relation extraction (De Saeger et al., 2011) and Why-QA (Oh et al., 2012), and can generate various kinds of semantically clean word classes, such as *foods*, *disease names*, and *natural disasters*. We used the word classes in tweets as features.<sup>3</sup>

**Geographical Locations (GL)** Our location recognizer matches tweets against our location dictionary. Location names and their existence/non-existence in tweets constitute evidence, thus we encoded such information into our features. The location dictionary was created from the Japan Post code data<sup>4</sup> and Wikipedia, containing 2.7 million location names including cities, schools and other facilities (Kazama et al., 2013).

## 4 Problem-Aid Match Recognizer

After problem report and aid message recognition, the positive outputs of the respective classifiers are used as input in this step. The problem-aid match recognizer classifies an aid message-nucleus pair together with the problem report-nucleus pair employing SVMs with linear kernel, which performed best in this task again. The problem-aid match recognizer uses all the features used in the problem report recognizer and the aid message recognizer along with additional features regarding: excitation polarity (EX) and trouble expressions (TR), distributional similarity (SIM), contradiction (CTP) and SVM-scores of the problem report and aid message recognizers (SSR). Here also we attempted to capture typical or frequent matches of nuclei using template and noun IDs and their combinations, but we did not observe any improvement so we omit them from the feature set. The bottom part of Table 2 summarizes the additional feature set, some of which are described below in more detail.

<sup>3</sup>There is a slight complication here. For each noun  $n$ , EM clustering estimates a probability distribution  $P(n|c^*)$  for  $n$  and semantic class  $c^*$ . From this distribution we obtained discrete semantic word classes by assigning each noun  $n$  to semantic class  $c = \operatorname{argmax}_{c^*} p(c^*|n)$ .

<sup>4</sup><http://www.post.japanpost.jp/zipcode/download.html>

As for TR and EX, our intuition is that if a problem nucleus and an aid nucleus are an adequate match, their excitation polarities are opposite, as described in Section 2. We encode whether the excitation polarities of nuclei templates are the same or not in our features. Also, the excitation polarities of problem and aid nuclei and TR are combined (TRES1, TRES2) so that the classifier can know whether the nuclei follow the constraint for adequate matches described in Section 2.

As for SIM, if an aid message matches a problem report, besides the common nucleus noun, it is reasonable to assume that certain contexts are semantically similar. We capture this characteristic in three ways. SIM1 looks for common semantic word classes in the problem report and aid message. SIM2 and SIM3 target the modifiers of the common nucleus noun if they exist.

We also observed that if an aid message matches a problem report, the problem nucleus template and aid nucleus template are often distributionally similar. A typical example is “X is sold out” and “buy X”. SIM4 captures this tendency. As the distributional similarity between templates, we used a Bayesian distributional similarity measure proposed by Kazama et al. (2010).<sup>5</sup>

CTP indicates whether the problem and aid nuclei are in contradiction relation or not. This feature was implemented based on the observation that when problem and aid nuclei are in contradiction relation, they are often proper matches (e.g., ⟨blackout, “X starts”⟩ and ⟨blackout, “X ends”⟩). CTP indicates whether nucleus pairs are in the one million contradiction phrase pairs<sup>6</sup> automatically obtained by applying a method proposed by Hashimoto et al. (2012) to 600 million Web pages.

## 5 Experiments

We evaluated our problem report recognizer and problem-aid match recognizer. For the sake of space, we give only the performance figures of the aid message recognizer at the end of Section 5.1.

We collected tweets posted during and after the 2011 Great East Japan Earthquake, between March 10 and April 4, 2011. After applying keyword-based filtering with a list of over 300

<sup>5</sup>The original similarity was defined over noun pairs and it was estimated from dependency relations. Obtaining similarity between template pairs, not noun pairs, is straightforward given the same dependency relations. We used 600 million Web pages for this similarity estimation.

<sup>6</sup>The precision of the pairs was reported as around 70%.

disaster related keywords, we obtained 55 million tweets. After dependency parsing<sup>7</sup>, we used them in our evaluation.

### 5.1 Problem Report Recognition

Firstly, we evaluated our problem report recognizer. Particularly, we assessed the effect of excitation polarities and trouble expressions in two settings. The first is against a naturally distributed gold standard data. The second targets problem reports with problem nuclei unseen in the training data.

In both experiments we observed that the performance drops when excitation polarities and trouble expressions are removed from the feature set. The performance drop was larger in the second experiment which suggests that the excitation polarities and trouble expressions are more effective against unseen problem reports.

Training and test data for problem report recognition consist of tweet-nucleus candidate pairs randomly sampled from our 55 million tweet data. The training data ( $R$ ) and test data ( $T$ ) consist of 13,000 and 1,000 pairs, respectively, manually labeled by three annotators (other than the authors) as problem or other. Final judgment was made by majority vote. The Fleiss’ kappa score for training and test data for annotation judgement is 0.74 (substantial agreement).

Our problem report recognizer and its variants are listed in Table 3. Table 4 shows the evaluation results. The proposed method achieved about 44% recall and nearly 80% precision, outperforming all other systems in terms of precision, F-score and average precision<sup>8</sup>. The improvement in precision when using TR&EX is statistically significant ( $p < 0.05$ ).<sup>9</sup> Note that F-measure dropped

PROPOSED-REQ	42.64	76.16	55.50	54.67
PROPOSED-GL	44.14	78.34	55.50	56.46
PROPOSED+OET	44.24	<b>79.41</b>	56.82	71.81
RULE-BASED	30.32	67.96	41.93	n/a

Table 4: Recall (R), precision (P), F-score (F) and average precision (aP) of the problem report recognizers.

whenever each type of feature was removed, implying that each type of feature is effective in this task. Especially note the performance drop if we remove excitation polarities (EX), trouble expression (TR) and both excitation and trouble expression features (TR&EX), confirming that they are crucial in recognizing problem reports with high accuracy. Also note that the performance of PROPOSED+OET was actually slightly worse than that of the proposed method. This suggests that full-fledged sentiment analysis is not effective at least in this setting. The rule-based method achieved relatively high precision despite of the low recall, demonstrating the importance of problem and aid nuclei formulations described in Section 1.

The second experiment assessed the efficiency of our problem report recognizer against unseen problem nuclei under the condition that every template in nuclei has excitation polarity. We sampled the training and test data so that the problem nucleus nouns and templates in the training and test data are disjoint. First we created a subset of the test data by selecting the samples which had nuclei with excitation templates. We call this subset  $T'$ . Next, we removed samples from training data  $R$  if either of their problem nouns or templates appeared in the nuclei of  $T'$ . The resulting new training data (called  $R'$ ) and test data ( $T'$ ) consist of 6,484 and 407 tweet-nucleus candidate pairs, respectively. We trained our problem report recognizer using  $R'$  and tested its performance using  $T'$ . Figure 2 shows the precision-recall curves obtained by changing the threshold on the SVM scores. The effectiveness of excitation polarities and trouble expressions was more evident in this setting. The PROPOSED’s performance was actually better in this setting (almost 50% recall at

population proportion (Ott and Longnecker, 2010) using SVM-threshold=0.

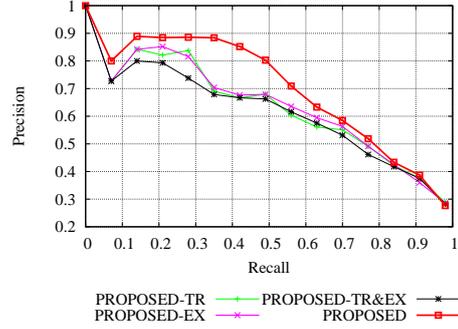

Figure 2: Precision-recall curves of problem report recognizers against unseen problem nuclei.

more than 80% precision), than the previous setting, showing that excitation templates and trouble expressions are crucial in achieving high performance especially for unseen problem nuclei. The same was confirmed when we removed excitation polarity and trouble expression related features, with performance dropping by 7.43 points in terms of average precision. The improvement in precision when using TR&EX is statistically significant ( $p < 0.01$ ). This implies, assuming that we have a wide-coverage dictionary of templates with excitation polarities, that excitation polarities are important in dealing with unexpected problems in disaster situations.

We also evaluated the aid-message recognizer, using tweet-nucleus pairs in  $R$  and  $T$  as training and test data and the annotation scheme was also the same. The average Fleiss’ kappa score was 0.55 (moderate agreement). Our recognizer achieved 53.82% recall and 65.67% precision and showed similar tendencies with the problem report recognizer, with the excitation polarities and trouble expressions contributing to higher accuracy.

We can conclude that excitation polarities and trouble expressions are important in identifying problem reports and aid messages during disaster situations.

## 5.2 Problem-Aid Matching

Next, we evaluated the performance of the problem-aid match recognizer. We applied our problem report recognizer and aid message recognizer to all 55 million tweets and combined the tweet-nucleus pairs judged as problem reports and aid messages, respectively, to create the training and test data.

The training data consists of two parts ( $M1$  and  $M2$ ).  $M1$  includes many variations of the aid messages for each problem report, while  $M2$  en-

sure diversity in nouns and templates in problem nuclei. For  $M1$ , we randomly picked up problem reports from the output of the problem report recognizer and to each we attached up to 30 randomly picked, distinct aid messages that have the same nucleus noun. Building  $M2$  follows the construction method of  $M1$ , except that: (1) we used up to 30 distinct problem nuclei for each noun; (2) for each problem report we attached only *one* randomly picked aid message.

In creating the test data  $T2$ , we followed the construction method used for  $M2$  to assess the performance of our proposal with a large variety of problems.  $M1$ ,  $M2$  and  $T2$  consist of 3,000, 6,000 and 1,000 samples, respectively. The annotation was done by majority vote of three human annotators (other than the authors), the average Fleiss’ kappa-score for training and test data was 0.63 (substantial agreement).

We trained the problem-aid match recognizers of Table 5 with  $M1$  and  $M2$ . The evaluation results performed on  $T2$  are shown in Table 6. We can observe that, among the nuclei related features, the trouble expression (TR) and excitation polarity (EX) features and their combination (TR&EX) contribute most to the performance, although the contribution of nuclei related features is less in comparison to the problem report and aid message recognition. The improvement in precision when using TR&EX is marginally significant ( $p = 0.056$ ). Instead, morphological and syntactic analysis (MSA) and semantic word class (SWC) features greatly improved performance.

As the final experiments, we evaluated top-ranking matches of our problem-aid match recognizer, where the recognizer classified all the possible combinations of tweet-nuclei pairs taken from 55 million tweets. In addition, we assessed the effectiveness of excitation polarities and trouble expressions by comparing all positive matches produced by our full problem-aid match recognizer (PROPOSED) and those produced by the problem-aid match recognizer (PROPOSED-TR&EX) that

<b>PROPOSED:</b> Our proposed method with all features used.
<b>PROPOSED-*</b> : The proposed method without the feature set denoted by “*”. Here also EX and TR denote all excitation polarity and trouble expression related features, respectively, including their combinations (TRES1 and TRES2).
<b>RULE-BASED:</b> The method that judges only problem-aid nuclei combinations with opposite excitation polarities as proper matches.

Table 5: Evaluated problem-aid match recognizers.

Matching system	R (%)	P (%)	F (%)	aP (%)
PROPOSED	30.67	<b>70.42</b>	<b>42.92</b>	<b>55.16</b>
PROPOSED-TR&EX	28.83	67.14	40.33	53.99
PROPOSED-EX	<b>31.29</b>	67.11	42.68	54.19

PROPOSED-SWC	26.99	67.69	38.59	52.23
PROPOSED-WSP	30.61	69.51	42.50	54.81
PROPOSED-CTP	30.06	70.00	42.05	54.94
PROPOSED-SIM	29.95	70.11	41.97	54.98
PROPOSED-REQ	30.58	70.25	42.61	54.67
PROPOSED-GL	30.61	70.31	42.65	55.02
PROPOSED-SSR	30.67	69.44	42.72	54.91
RULE-BASED	15.33	17.36	16.28	n/a

Table 6: Recall (R), precision (P), F-score (F) and average precision (aP) of the problem-aid match recognizers.

did not use excitation polarities and trouble expressions in its feature set. Note that PROPOSED-TR&EX was fed by the problem report and aid message recognizers that didn’t use excitation polarities and trouble expressions. For both systems’ training data we used  $R$  for the problem report and aid message recognizers;  $M1$  and  $M2$  for the problem-aid matching recognizers.

PROPOSED and PROPOSED-TR&EX output 15.2 million and 13.4 million positive matches, covering 1,691 and 1,442 nucleus nouns, respectively. Table 7 shows match samples identified with PROPOSED. We observed that the output of each system was dominated by just a handful of frequent nucleus nouns, such as “water” or “gasoline”. We preferred to assess the performance of our system against a large variation of problem-aid nuclei, thus we restricted the number of matches to 10 for each noun<sup>10</sup>. After this restriction the number of matches found by PROPOSED and PROPOSED-

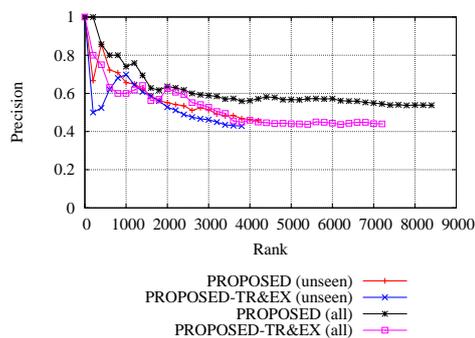

Figure 3: Problem-aid match recognition performance for ‘all’ and ‘unseen’ problem reports.

<sup>10</sup>Note that this setting is a pessimistic estimation of our system’s overall performance, since according to our observations problem reports with very frequent nucleus nouns had proper matches with a higher accuracy than problem reports with less frequent nucleus nouns.

<p><b>Problem report:</b> いわきの常磐病院、いわき泌尿器科病院、竹林貞吉記念クリニック、泉中央クリニックは、17日から透析を中止します。患者の方は至急連絡してください。(Starting from the 17th, the Iwaki Joban Hospital, the Iwaki Urology Clinic, the Takebayashi Sadakichi Memorial Clinic and the Izumi Central Clinic have all <b>suspended dialysis sessions</b>. Patients are advised to urgently make contact.)</p>
<p><b>Aid message:</b> いわき泌尿器科病院で短時間透析が可能です。受付時間は9時から16時までです。(透析の再開) (Restart of dialysis sessions: short <b>dialysis sessions are available</b> at the Iwaki Urology Clinic between 9 AM and 4 PM.)</p>
<p><b>Problem report:</b> ごめんなさい拡散をお願いしてもいいですか。仙台の父親の話ですと携帯の充電がもうない人が続出しているそうです。携帯充電器の支援が必要かと思われます。 (Please spread this message. According to my father in Sendai, there are more and more people whose phones <b>ran out of battery</b>. We need phone chargers!)</p>
<p><b>Aid message:</b> 【拡散希望】仙台若林区役所で携帯電話の充電ができるそうです。 ([Please spread] At the City Hall of Wakabayashi-ku, Sendai, you <b>can recharge</b> your phone battery.)</p>

Table 7: Examples from the output of the proposed method in the ‘all’ setting. Problem report and aid message nuclei are boldfaced in the English translations.

TR&EX was 8,484 and 7,363, respectively.

The performance of PROPOSED and PROPOSED-TR&EX were assessed in two settings: ‘all’ and ‘unseen’. For ‘all’, we selected 400 problem-aid matches from the outputs of the respective systems after applying the 10-match restriction. For ‘unseen’, first we removed the samples from the systems’ outputs if either the nucleus noun or template pair appear in the nuclei of the problem-aid match recognizers’ training data. Next we applied the same sampling process as with ‘all’. Three annotators (other than the authors) manually labeled the sample sets, final judgment being made by majority vote. The Fleiss’ kappa score for all test data was 0.73 (substantial agreement).

Figure 3 shows the systems’ precision curves, drawn from the samples whose X-axis positions represent the ranks according to SVM scores. In both scenarios we can confirm that excitation polarity and trouble expression related features contribute to this task. In the ‘all’ setting in terms of average precision calculated over the top 7,200 matches, PROPOSED’s 62.36% is 10.48 points higher than that of PROPOSED-TR&EX. For unseen problem/aid nuclei PROPOSED method’s average precision of 58.57% calculated at the top 3,800 matches is 5.47 points higher than that of PROPOSED-TR&EX at the same data point. The improvement in precision when using TR&EX is

statistically significant in both settings ( $p < 0.01$ ).

## 6 Related Work

Twitter has been observed as a platform for situational awareness during various crisis situations (Starbird et al., 2010; Vieweg et al., 2010), as sensors for an earthquake reporting system (Sakaki et al., 2010; Okazaki and Matsuo, 2010) or to detect epidemics (Aramaki et al., 2011). Besides Twitter, blogs or forums have also been the target of community response analysis (Qu et al., 2009; Torrey et al., 2007). Similar to our work are the ones of Neubig et al. (2011) and Ishino et al. (2012), who tackle specific problems that occur during disasters (i.e., *safety information* and *transportation information*, respectively); and Munro (2011), who extracted “actionable messages” (requests and aids, indiscriminately), matching being performed manually. Our work differs from (Neubig et al., 2011) and (Ishino et al., 2012) in that we do not restrict the range of problem reports, and as opposed to (Munro, 2011), matching is automatic.

Systems such as that of Seki (2011)<sup>11</sup> or Munro (2013)<sup>12</sup> are successful examples of crisis crowdsourcing, but these require extensive human intervention to coordinate useful information.

Another category of related work relevant to our task is troubleshooting. Baldwin et al. (2007) and Raghavan et al. (2010) use discussion forums to solve technical problems using supervised learning methods, but these approaches presume that the solution of a specific problem is within the same thread. In our work we do not employ structural characteristics of tweets as restrictions (e.g., a problem report and its aid message need to be in the same tweet chain).

## 7 Conclusions

In this paper, we proposed a method to discover matches between problem reports and aid messages from tweets in large-scale disasters. Through a series of experiments, we demonstrated that the performance of the problem-aid matching can be improved with the usage of semantic orientation of excitation polarities, proposed in (Hashimoto et al., 2012), and trouble expressions.

We are planning to deploy our system and release model files of the classifiers to assist relief efforts in future crisis scenarios.

## Abstract

We propose a joint model for unsupervised induction of sentiment, aspect and discourse information and show that by incorporating a notion of latent discourse relations in the model, we improve the prediction accuracy for aspect and sentiment polarity on the sub-sentential level. We deviate from the traditional view of discourse, as we induce types of discourse relations and associated discourse cues relevant to the considered opinion analysis task; consequently, the induced discourse relations play the role of opinion and aspect shifters. The quantitative analysis that we conducted indicated that the integration of a discourse model increased the prediction accuracy results with respect to the discourse-agnostic approach and the qualitative analysis suggests that the induced representations encode a meaningful discourse structure.

## 1 Introduction

With the rapid growth of the Web, it is becoming increasingly difficult to discern useful from irrelevant information, particularly in user-generated content, such as product reviews. To make it easier for the reader to separate the wheat from the chaff, it is necessary to structure the available information. In the review domain, this is done in *aspect-based sentiment analysis* which aims at identifying text fragments in which *opinions* are expressed about ratable *aspects of products*, such as ‘room quality’ or ‘service quality’. Such fine-grained analysis can serve as the first step in *aspect-based sentiment summarization* (Hu and Liu, 2004), a task with many practical applications.

Aspect-based summarization is an active research area for which various techniques have been developed, both statistical (Mei et al., 2007; Titov and McDonald, 2008b) and not (Hu and Liu, 2004), and relying on different types of supervision sources, such as sentiment-annotated texts or polarity lexica (Turney and Littman, 2002). Most methods rely on local information (bag-of-words, short ngrams or elementary syntactic fragments) and do not attempt to account for more complex interactions. However, these local lexical representations by themselves are often not sufficient to infer a sentiment or aspect for a fragment of text. For instance, in the following example taken from a TripAdvisor<sup>1</sup> review:

**Example 1.** *The room was nice but let’s not talk about the view.*

it is difficult to deduce on the basis of local lexical features alone that the opinion about the view is negative. The clause *let’s not talk about the view* could by itself be neutral or even positive given the right context (e.g., *I’ve never seen such a fancy hotel room, my living room doesn’t look that cool... and let’s not talk about the view*). However, the contrast relation signaled by the connective *but* makes it clear that the second clause has a negative polarity. The same observations can be made about transitions between aspects: changes in aspect are often clearly marked by discourse connectives. Importantly, some of these cues are not discourse connectives in the strict linguistic sense and are specific to the review domain (e.g., the phrase *I would also* in a review indicates that the topic is likely to be changed). In order to accurately predict sentiment and topic,<sup>2</sup> a model needs to ac-

<sup>1</sup><http://www.tripadvisor.com/>

<sup>2</sup>In what follows, we use the terms *aspect* and *topic*, inter-

count for these discourse phenomena and cannot rely solely on local lexical information.

These issues have not gone unnoticed to the research community. Consequently, there has recently been an increased interest in models that leverage content and discourse structure in sentiment analysis tasks. However, discourse-level information is typically incorporated in a pipeline architecture, either in the form of sentiment polarity shifters (Polanyi and Zaenen, 2006; Nakagawa et al., 2010) that operate on the lexical level or by using discourse relations (Taboada et al., 2008; Zhou et al., 2011) that comply with discourse theories like Rhetorical Structure Theory (RST) (Mann and Thompson, 1988). Such approaches have a number of disadvantages. First, they require additional resources, such as lists of polarity shifters or discourse connectives which signal specific relations. These resources are available only for a handful of languages. Second, relying on a generic discourse analysis step that is carried out before sentiment analysis may introduce additional noise and lead to error propagation. Furthermore, these techniques will not necessarily be able to induce discourse relations informative for the sentiment analysis domain (Voll and Taboada, 2007).

An alternative approach is to define a task-specific scheme of discourse relations (Somasundaran et al., 2009). This previous work showed that task-specific discourse relations are helpful in predicting sentiment, however, in doing so they relied on gold-standard discourse annotation at test time rather than predicting it automatically or inducing it jointly with sentiment polarity.

We take a different approach and induce discourse and sentiment information jointly in an unsupervised (or weakly supervised) manner. This has the advantage of not having to pre-specify a mapping from discourse cues to discourse relations; our model induces this automatically, which makes it portable to new domains and languages. Joint induction of discourse and sentiment structure also has the added benefit that the model is able to learn exactly those aspects of discourse structure that are relevant for sentiment analysis.

We start with a relatively standard joint model of sentiment and topic, which can be regarded as a cross-breed between the JST model (Lin and He, 2009) and the ASUM model (Jo and Oh, 2011),

changeably as well as *sentiment levels* and *opinion polarity*.

both state-of-the-art techniques. This model is weakly supervised, as it relies solely on document-level (i.e. not aspect-specific) opinion polarity labels to induce topics and sentiment on the sub-sentential level. In order to test our hypothesis that discourse information is beneficial, we add a discourse modeling component. Note that in modeling discourse we do not exploit any kind of supervision. We demonstrate that the resulting model outperforms the baseline on a product review dataset (see Section 5).

To the best of our knowledge, unsupervised joint induction of discourse structure, sentiment and topic information has not been considered before, particularly not in the context of the aspect-based sentiment analysis task. Importantly, our method for discourse modeling is a general method which can be integrated in virtually any LDA-style model of aspect and sentiment.

## 2 Modeling Discourse Structure

Discourse cues typically do not directly indicate sentiment polarity (or aspect). However, they can indicate how polarity (or aspect) changes as the text unfolds. As we have seen in the examples above, changes in polarity can happen on a sub-sentential level, i.e., between adjacent clauses or, from a discourse-theoretic point of view, between adjacent *elementary discourse units (EDUs)*. To model these changes we need a strong linguistic signal, for example, in the form of discourse connectives or other discourse cues. We hypothesize that these are more likely to occur at the beginning of an EDU than in the middle or at the end. This is certainly true for most of the traditional discourse relation cues (particularly connectives).

Changes in polarity or aspect are often correlated with specific discourse relations, such as ‘contrast’. However, not all relations are relevant and there is no one-to-one correspondence between relations and sentiment changes.<sup>3</sup> Furthermore, if a discourse relation signals a change, it is typically ambiguous whether this change occurs with the polarity (example 1) or the aspect (*the room was nice but the breakfast was even better*) or both (*the room was nice but the breakfast was awful*). Therefore, we do not explicitly model

<sup>3</sup>The ‘explanation’ relation, for example, can occur with a polarity change (*We were upgraded to a really nice room because the hotel made a terrible blunder with our booking*) but does not have to (*The room was really nice because the hotel was newly renovated*).

Name	Description
AltSame	<b>different</b> polarity, <b>same</b> aspect
SameAlt	<b>same</b> polarity, <b>different</b> aspect
AltAlt	<b>different</b> polarity and aspect

Table 1: Discourse relations

generic discourse relations; instead, inspired by the work of Somasundaran et al. (2008), we define three very general relations which encode how polarity and aspect change (Table 1). Note that we do not have a discourse relation *SameSame* since we do not expect to have strong linguistic evidence which states that an EDU contains the same sentiment information as the previous one.<sup>4</sup> However, we assume that the sentiment and topic flow is fairly smooth in general. In other words, for two adjacent EDUs not connected by any of the above three relations, the prior probability of staying at the same topic and sentiment level is higher than picking a new topic and sentiment level (i.e. we use “sticky states” (Fox et al., 2008)).

### 3 Model

In this section we describe our Bayesian model, first the discourse-agnostic model and then an extension needed to encode discourse information. The formal generative story is presented in Figure 1: the red fragments correspond to the discourse modeling component. In order to obtain the generative story for the discourse-agnostic model, they simply need to be ignored.

#### 3.1 Discourse-agnostic model

In our approach we make an assumption that all the words in an EDU correspond to the same topic and sentiment level. We also assume that an overall sentiment of the document is defined, this is the only supervision we use in inducing the model. Unlike some of the previous work (e.g., (Titov and McDonald, 2008a)), we do not constrain aspect-specific sentiment to be the same across the document. We describe our discourse-agnostic model by first describing the set of corpus-level and document-level parameters, and then explain how the content of each document is generated.

**Drawing model parameters** On the corpus level, for every topic  $z \in \{1, \dots, K\}$  and every sentiment polarity level  $y \in \{-1, 0, +1\}$ , we start by drawing a unigram language model

<sup>4</sup>The typical connective in this situation would be *and* which is highly ambiguous and can signal several traditional discourse relations.

from a Dirichlet prior. For example, the language model of the aspect *service* may indicate that the word *friendly* is used to express a positive opinion, whereas the word *rude* expresses a negative one.

Similarly, for every topic  $z$  and every overall sentiment polarity  $\hat{y}$ , we draw a distribution  $\psi_{\hat{y},z}$  over opinion polarity in this topic  $z$ . Intuitively, one would expect the sentiment of an aspect to more often agree with the overall sentiment  $\hat{y}$  than not. This intuition is encoded in an asymmetric Dirichlet prior  $Dir(\gamma_{\hat{y}})$  for  $\psi_{\hat{y},z} : \gamma_{\hat{y}} = (\gamma_{\hat{y},1}, \dots, \gamma_{\hat{y},M})$ ,  $\gamma_{\hat{y},y} = \beta + \tau\delta_{y,\hat{y}}$ , where  $\delta_{y,\hat{y}}$  is the Kronecker symbol,  $\beta$  and  $\tau$  are nonnegative scalar parameters. Using these “heavy-diagonal” priors is crucial, as this is the way to ensure that the overall sentiment level is tied to the aspect-specific sentiment level. Otherwise, sentiment levels will be specific to individual aspects (e.g., the “+1” sentiment for one topic may correspond to a “-1” sentiment for another one). Without this property we would not be able to encode soft constraints imposed by the discourse relations.

**Drawing documents** On the document level, as in the standard LDA model, we choose the distribution over topics for the document from a symmetric Dirichlet prior parametrized by  $\alpha$ , which is used to control sparsity of topic assignments. Furthermore, we draw the global sentiment  $\hat{y}_d$  from a uniform distribution.

The generation of a document is done on the EDU-by-EDU basis. In this work, we assume that EDU segmentation is provided by the preprocessing step. First, we generate the aspect  $z_{d,s}$  for EDU  $s$  according to the distribution of topics  $\theta_d$ . Then, we choose a sentiment level  $y_{d,s}$  for the considered EDU from the categorical distribution  $\psi_{\hat{y}_d, z_{d,s}}$ , conditioned on the aspect  $z_{d,s}$ , as well as on the global sentiment of the document  $\hat{y}_d$ . Finally, we generate the bag of words for the EDU by drawing the words from the aspect- and sentiment-specific language model.

This model can be seen as a variant of a state-of-the-art model for jointly inducing sentiment and aspect at the sentence level (Jo and Oh, 2011), or, more precisely, as its combination with the JST model (Lin and He, 2009), adapted to the specifics of our setting. Both these models have been shown to perform well on sentiment and topic prediction tasks, outperforming earlier models, such as the TSM model (Mei et al., 2007). Consequently, it can be considered as a strong baseline.

### 3.2 Discourse-informed model

In order to integrate discourse information into the discourse-agnostic model, we need to define a set of extra parameters and random variables.

**Drawing model parameters** First, at the corpus level, we draw a distribution  $\tilde{\varphi}$  over four discourse relations: three relations as defined in Table 1 and an additional dummy relation 4 to indicate that there is no relation between two adjacent EDUs (*NoRelation*). This distribution is drawn from an asymmetric Dirichlet prior parametrized by a vector of hyperparameters  $\nu$ . These parameters encode the intuition that most pairs of EDUs do not exhibit a discourse relation relevant for the task (i.e. favor *NoRelation*), that is  $\nu_4$  has a distinct and larger value than other parameters  $\nu_{\bar{4}}$ .

Every discourse relation  $c$  (including *NoRelation* which is treated here as *Same-Same*) is associated with two groups of transition distributions, one governing transitions of sentiment ( $\tilde{\psi}_c$ ) and another one controlling topic transitions ( $\tilde{\theta}_c$ ). The parameter  $\tilde{\psi}_{c,y_s}$ , defines a distribution over sentiment polarity for the EDU  $s + 1$  given the sentiment for the  $s$ th EDU  $y_s$  and the discourse relation  $c$ . This distribution encodes our beliefs about sentiment transitions between EDUs  $s$  and  $s + 1$  related through  $c$ . For example, the distribution  $\tilde{\psi}_{SameAlt,+1}$  would assign higher probability mass to the positive sentiment polarity (+1) than to the other 2 sentiment levels (0, -1). Similarly, the parameter  $\tilde{\theta}_{c,z_s}$ , defines a distribution over  $K$  aspects.

These two families of transition distributions are each defined in the following way. For the distribution  $\tilde{\theta}$ , for relations that favor changing the aspect (*SameAlt* and *AltAlt*), the probability of the preferred ( $K-1$ ) transitions is proportional to  $\omega_\theta$  and for the remaining transitions it is proportional to 1. On the other hand, for the relations that favor keeping the same aspect (*NoRelation* and *AltSame*), the probability of the preferred transition is proportional to  $\omega'_\theta$ , whereas the probability of the ( $K-1$ ) remaining transitions is again proportional to 1. For the sentiment transitions, the distribution  $\tilde{\psi}_{c,y_s}$  is defined in the analogous way (but depends on  $\omega_\psi$  and  $\omega'_\psi$ ). These scalars are hand-coded and define soft constraints that discourse relations impose on the local flow of sentiment and aspects.

The parameter  $\tilde{\phi}_c$  is a language model over discourse cues  $\tilde{w}$ , which are not restricted to unigrams but can generate phrases of arbitrary (and

variable) size. For this reason, we draw them from a Dirichlet process (DP) (i.e. one for each discourse relation, except for *NoRelation*). The base measure  $G_0$  provides the probability of an  $n$ -word sequence calculated with the bigram probability model estimated from the corpus.<sup>5</sup> This model component bears strong similarities to the Bayesian model of word segmentation (Goldwater et al., 2009), though we use the DP process to generate only the prefix of the EDU, whereas the rest of the EDU is generated from the bag-of-words model.

**Drawing documents** As pointed out above, the content generation is broken into two steps, where first we draw the discourse cue  $\tilde{w}_{d,s}$  from  $\tilde{\phi}_c$  and then we generate the remaining words.

The second difference at the data generation step (Figure 1) is in the way the aspect and sentiment labels are drawn. As the discourse relation between the EDUs has already been chosen, we have some expectations about the values of the sentiment and aspect of the following EDU, which are encoded by the distributions  $\tilde{\psi}$  and  $\tilde{\theta}$ . These are only soft constraints that have to be taken into consideration along with the information provided by the aspect-sentiment model. This coupling of information naturally translates into the *product-of-experts* (PoE) (Hinton, 1999) approach, where two sources of information jointly contribute to the final result. The PoE model seems to be more appropriate here than a mixture model, as we do not want the discourse transition to overpower the sentiment-topic model. In the PoE model, in order for an outcome to be chosen, it needs to have a non-negligible probability under both models.

## 4 Inference

Since exact inference of our model is intractable, we use collapsed Gibbs sampling. The variables that need to be inferred are the topic assignments  $\mathbf{z}$ , the sentiment assignments  $\mathbf{y}$ , the discourse relations  $\mathbf{c}$  and the discourse cue  $\tilde{w}$  (or, more precisely, its length) and are all sampled jointly (for each EDU) since we expect them to be highly dependent. All other variables (i.e. unknown distributions) could be marginalized out to obtain a collapsed Gibbs sampler (Griffiths and Steyvers, 2004).

<sup>5</sup>This measure is improper but it serves the purpose of favoring long cues, the behavior arguably desirable for our application.

Global parameters:	
$\tilde{\varphi} \sim Dir(\nu)$	[distrib of disc rel]
for each discourse relation $c = 1, \dots, 4$ :	
$\tilde{\phi}_c \sim DP(\eta, G_o)$	[distrib of disc rel specific disc cues]
$\tilde{\theta}_{c,k}$ - fixed	[distrib of rel specific aspect transitions]
$\tilde{\phi}_{c,y}$ - fixed	[distrib of rel specific sent transitions]
for each aspect $k = 1, 2 \dots K$ :	
for each sentiment $y = -1, 0, +1$ :	
$\phi_{k,y} \sim Dir(\lambda_k)$	[unigram language models]
for each global sentiment $\hat{y} = -1, 0, +1$ :	
$\psi_{\hat{y},k} \sim Dir(\gamma)$	[sent distrib given overall sentiment]
Data Generation:	
for each document $d$ :	
$\hat{y}_d \sim Unif(-1, 0, +1)$	[global sentiment]
$\theta_d \sim Dir(\alpha)$	[distr over aspects]
for every EDU $s$ :	
$c_{d,s} \sim \tilde{\varphi}$	[draw disc relation]
if $c_{d,s} \neq NoRelation$	
$\tilde{w}_{d,s} \sim \tilde{\phi}_{c_{d,s}}$	[draw disc cue]
$z_{d,s} \sim \theta_d * \tilde{\theta}_{c_{d,s}, z_{d,s}-1}$	[draw aspect]
$y_{d,s} \sim \psi_{\hat{y}_d, z_{d,s}} * \tilde{\psi}_{c_{d,s}, y_{d,s}-1}$	[draw sentiment level]
for each word after disc cue:	
$w_{d,s} \sim \phi_{z_{d,s}, y_{d,s}}$	[draw words]

Figure 1: The generative story for the joint model. The components responsible for modeling discourse information are emphasized in red: when dropped, one is left with the discourse-agnostic model.

Unfortunately, the use of the PoE model prevents us from marginalizing the parameters exactly. Instead, as in Naseem et al. (2009), we resort to an approximation. We assume that  $z_{d,s}$  and  $y_{d,s}$  are drawn twice; once from the document specific distribution and once from the discourse transition distributions. Under this simplification, we can easily derive the conditional probabilities for the collapsed Gibbs sampling.

## 5 Experiments

To the best of our knowledge, this is the first work that aims at evaluating directly the joint information of the sentiment and aspect assignment at the sub-sentential level of full reviews; most existing studies either focus on indirect evaluation of the produced models (e.g., classifying the overall sentiment of sentences (Titov and McDonald, 2008a; Brody and Elhadad, 2010) or even reviews (Nakagawa et al., 2010; Jo and Oh, 2011)) or evaluated solely at the sentential or even document level. Consequently, in order to evaluate our methods, we created a new dataset which will be publicly released.

Aspects	Frequency
service	246
value	55
location	121
rooms	316
sleep quality	56
cleanliness	59
amenities	180
food	81
recommendation	121
rest	306
<b>Total</b>	<b>1541</b>

Table 2: Distribution of aspects in the data.

**Dataset and Annotation** The dataset we created consists of 13559 hotel reviews from TripAdvisor.com.<sup>6</sup> Since our modeling is performed on the EDU level, all sentences were segmented using the SLSEG software package.<sup>7</sup> As a result, our dataset consists of 322,935 EDUs.

For creating the gold standard, 9 annotators annotated a random subset of our dataset (65 reviews, 1541 EDUs). The annotators were presented with the whole review partitioned in EDUs and were asked to annotate every EDU with the aspect and sentiment (i.e. +1, 0 or -1) it expresses. Table 2 presents the distribution of aspects in the dataset. The distribution of the sentiments is uniform. The label *rest* captures cases where EDUs do not refer to any aspect or to a very rare aspect. The inter-annotator agreement (IAA), as measured in terms of Cohen’s kappa score, was 66% for the aspect labeling, 70% for the sentiment annotation and 61% for the joint task of sentiment and aspect annotation. Though these scores may not seem very high, they are similar to the ones reported in related sentiment annotation efforts (see e.g., Ganu et al. (2009)).

**Experimental setup** In order to quantitatively evaluate the model predictions, we run two sets of experiments. In the first, we treat the task as an unsupervised classification problem and evaluate the output of the models directly against the gold standard annotation. This is a very challenging set-up, as the model has no prior information about the aspects defined (Table 2). In the second set of experiments, we show that aspects and sentiments induced by our model can be used to construct informative features for supervised classification. In

Model	Unmarked	Marked
<i>SentAsp</i>	9.2	5.4
<i>Discourse</i>	<b>9.3</b>	<b>11.5</b>

Table 4: Separate evaluation (F1) of the “marked” and the “unmarked” EDUs.

all the cases, we compare the discourse-agnostic and the discourse-informed models.

In order to induce the model, we let the sampler run for 2000 iterations. We use the last sample to define the labeling. The number of topics  $K$  was set to 10 in order to match the number of aspects defined in our annotation scheme (see Table 2). The hyperpriors were chosen in a qualitative experiment over a subset of our dataset by manually inspecting the produced languages models. The resulting values are:  $\alpha = 10^{-3}$ ,  $\beta = 5 * 10^{-4}$ ,  $\tau = 5 * 10^{-4}$ ,  $\eta = 10^{-3}$ ,  $\nu_4 = 10^3$ ,  $\nu_{\bar{4}} = 10^{-4}$ ,  $\omega_\theta = 85$  and  $\omega'_\theta = \omega_\psi = \omega'_\psi = 5$ .

### 5.1 Direct clustering evaluation

Our labels encoding aspect and sentiment level can be regarded as clusters. Consequently we can apply techniques developed in the context of clustering evaluation. We use a version of the standard metrics considered for the word sense induction task (Agirre and Soroa, 2007) where a clustering is converted to a classification problem. This is achieved by splitting the gold standard into two subsets; the training portion is used to choose one-to-one correspondence from the gold classes to the induced clusters and then the chosen mapping is applied to the testing portion. We perform 10-fold cross validation and report precision, recall and F1 score. Our dataset is very skewed and the majority class (*rest*) is arguably the least important, so we use macro-averaging over labels and then average those across folds to arrive to the reported numbers. We compare the discourse-informed model (*Discourse*) against two baselines; the discourse-agnostic *SentAsp* model and *Random* which assigns a random label to an EDU while respecting the distribution of labels in the training set.

Table 3 presents the first analysis conducted on the full set of EDUs. We observe that by incorporating latent discourse relation we improve per-

	Content	Aspect	Polarity
1	<i>but</i> certainly off <b>its</b> greatness	value	neg
2	<i>and</i> while small <b>they</b> are nice	rooms	pos
3	<i>but</i> <b>it</b> is not free for all guests	amenities	neg
4	<i>and</i> the water was brown	clean	neg
5	<i>and</i> no tea making facilities	rooms	neg

Table 5: Examples of EDUs where local information is not sufficiently informative.

formance over the discourse-agnostic model *SentAsp* (statistically significant according to paired t-test with  $p < 0.01$ ). Note that fairly low scores in this evaluation setting are expected for any unsupervised model of sentiment and topics, as models are unsupervised both in the aspect-specific sentiment and in topic labels and the total number of labels is 28 (all aspects can be associated with the 3 sentiment levels except for *rest* which can only be used with neutral (0) sentiment). Consequently, induced topics, though informative (as we confirm in Section 5.3), may not correspond to the topics defined in the gold standard. For example, one well-known property of LDA-style topic models is their tendency to induce topics which account for similar fraction of words in the dataset (Jagaramudi et al., 2012), thus, over-splitting ‘heavy’ topics (e.g. *rooms* in our case). The same, though to lesser degree, is true for sentiment levels where the border between neutral and positive (or negative) is also vaguely defined.

To gain insight into our model, we conducted an experiment similar to the one presented in Somasundaran et al. (2009). We divide the dataset in two subsets; one containing all EDUs starting with a discourse cue (“marked”) and one containing the remaining EDUs (“unmarked”). We hypothesize that the effect of the discourse-aware model should be stronger on the first subset, since the presence of the connective indicates the possibility of a discourse relation with the previous EDU. The set of discourse connectives is taken from the Penn Discourse Treebank (Prasad et al., 2008), thus creating a list of 240 potential connectives.

Table 5 presents a subset of “marked” EDUs for which trying to assign the sentiment and aspect out of context (i.e. without the previous EDU) is a difficult task. In examples 1-3 there is no explicit mention of the aspect. However, there is an anaphoric expression (marked in bold) which

refers to a mention of the aspect in some previous EDU. On the other hand, in examples 4 and 5 there is an ambiguity in the choice of aspect; in example 5, *tea making facilities* can refer to a breakfast at the hotel (label *food*) or to facilities in the room (label *rooms*). Finally, examples 6-8 are too short and not informative at all which indicates that the segmentation tool does not always predict a desirable segmentation. Consequently, automatic induction of segmentation may be a better option.

Table 4 presents quantitative results of this analysis. Although the performance over the “unmarked” example is the same for the two models, this is not the case for the “marked” instances where the discourse-informed model leverages the discourse signal and achieves better performance. This behavior agrees with our initial hypothesis, and suggests that our discourse representation, though application-specific, relies in part on the information encoded in linguistically-defined discourse cues. We will confirm this intuition in the qualitative evaluation section. The increase for the “marked” EDUs does not translate into greater differences for the overall scores (Table 3) as marked relations are considerably less frequent than unmarked ones in our gold standard (i.e. 35% of the EDUs are “marked”). Nevertheless, this clearly suggests that the discourse-informed model is in fact capable of exploiting discourse signal.

## 5.2 Qualitative analysis

To investigate the quality of the induced discourse structure, we present the most frequent discourse cues extracted for every discourse relation. Table 6 presents a selection of cues that best explain the discourse relation they have been associated with. A general observation is that among the cues there are not only “traditional” discourse connectives like *even though*, *although*, *and*, but also cues that are discriminative for the specific application.

In relation *SameAlt* we can mostly observe phrases that tend to introduce a new aspect, since an explicit mention of it is provided (e.g. *the location is*, *the room was*) and more specific phrases like *in addition* are used to introduce a new aspect with the same sentiment. However, these cues reveal important information about the aspect of the EDU, and since they are associated with the language model  $\tilde{\phi}$ , they are not visible anymore to the language model of aspects  $\phi$ .

Cues for the relation *AltSame* also include

Discourse relation	Discourse Cues
SameAlt	<b>the location is</b> , <b>the room was</b> , the hotel has, <b>and the room</b> , and the bed, breakfast was, the staff were, <b>in addition</b> , good luck
AltSame	<b>but</b> , and, it was, and it was, and they, although, and it, but it, <b>but it was</b> , however, which was, this is, <b>this was</b> , they were, the only thing, even though, <b>unfortunately</b> , needless to say, fortunately
AltAlt	<b>the room was</b> , the staff were, <b>the only</b> , the hotel is, but the, however, also, or, <b>overall i</b> , unfortunately, <b>we will definitely</b> , on the plus, the only downside , even though, and even though, <b>i would definately</b>

Table 6: Induced cues from the discourse relations

phrases that contain some anaphoric expressions, which might refer to previous mentions of an aspect in the discourse (i.e. previous EDU). We expect that since there is an anaphoric expression, explicit lexical features for the aspect will be missing, making thus the decision concerning aspect assignment ambiguous for any discourse-agnostic model. Interestingly, we found the expressions *unfortunately*, *fortunately*, *the only thing* in the same relation, since all indicate a change in sentiment. Finally, *AltAlt* can be viewed as a mixture of the other two relations. Furthermore, for this relation we can find expressions that tend to be used at the end of a review, since at this point we normally change the aspect and often even sentiment. Some examples of these cases are *overall*, *we will definitely* and even the misspelled version of the latter *i would definately*.

## 5.3 Features in supervised learning

As an additional experiment to demonstrate informative of the output of the two models, we design a supervised learning task of predicting sentiment and topic of EDUs. In this setting, the feature vector of every EDU consists of its bag-of-word-representation to which we add two extra features; the models’ predictions of topic and sentiment. We train a support vector machine with a polynomial kernel using the default parameters of Weka<sup>8</sup> and perform 10-fold cross-validation.

Table 7 presents results of this analysis in terms of accuracy for four classification tasks, i.e. predicting both sentiment and topic, only sentiment and only topic for all EDUs, as well as predicting sentiment and topic for the “marked” dataset. First, we observe that incorporation of the topic-

<sup>8</sup><http://www.cs.waikato.ac.nz/ml/weka/>

Features	aspect+sentiment (28 classes)	aspect (10 classes)	sentiment (3 classes)	Marked only sentiment+aspect (28 classes)
<i>only unigrams</i>	36.3	49.8	57.1	26.2
<i>unigrams + SentAsp</i>	38.0	50.4	59.3	27.8
<i>unigrams + Discourse</i>	<b>39.1</b>	<b>52.4</b>	<b>59.4</b>	<b>29.1</b>

Table 7: Supervised learning at the EDU level (accuracy)

model features on a *unigram-only* model results in an improvement in classification performance across all tasks (predicting sentiment, predicting aspects, or both); as a matter of fact, our accuracy results for predicting sentiment are comparable to the sentence-level results presented by Täckström and McDonald (2011). We have to stress that accuracies for the joint task (i.e. predicting both sentiment and topic) are expected to be lower since it can also be seen as the product of the two other tasks (i.e. predicting only sentiment and only topic). We also observe that the features induced from the *Discourse* model result in higher accuracy than the ones from the discourse-agnostic model *SentAsp* both in the complete set of EDUs and the “marked” subset, results that are in line with the ones presented in Table 4. Finally, the fact that the results for the complete set of EDUs are higher than the ones for the “marked” dataset clearly suggests that the latter constitute a hard case for sentiment analysis, in which exploiting discourse signal proves to be beneficial.

## 6 Related Work

Recently, there has been significant interest in leveraging content structure for a number of NLP tasks (Webber et al., 2011). Sentiment analysis has not been an exception to this and discourse has been used in order to enforce constraints on the assignment of polarity labels at several granularity levels, ranging from the lexical level (Polanyi and Zaenen, 2006) to the review level (Taboada et al., 2011). One way to deal with this problem is to model the interactions by using a pre-compiled set of polarity shifters (Nakagawa et al., 2010; Polanyi and Zaenen, 2006; Sadamitsu et al., 2008). Socher et al. (2011) defined a recurrent neural network model, which, in essence, learns those polarity shifters relying on sentence-level sentiment labels. Though successful, this model is unlikely to capture intra-sentence non-local phenomena such as effect of discourse connectives, unless it is provided with syntactic information as an input. This may be problematic for the noisy sentiment-analysis domain and especially

for poor-resource languages. Similar to our work, others have focused on modeling interactions between phrases and sentences. However, this has been achieved by either using a subset of relations that can be found in discourse theories (Zhou et al., 2011; Asher et al., 2008; Snyder and Barzilay, 2007) or by using directly (Taboada et al., 2008) the output of discourse parsers (Soricut and Marcu, 2003). Discourse cues as predictive features of topic boundaries have also been considered in Eisenstein and Barzilay (2008). This work was extended by Trivedi and Eisenstein (2013), where discourse connectors are used as features for modeling subjectivity transitions.

Another related line of research was presented in Somasundaran et al. (2009) where a domain-specific discourse scheme is considered. Similarly to our set-up, discourse relations enforce constraints on sentiment polarity of associated sentiment expressions. Somasundaran et al. (2009) show that gold-standard discourse information encoded in this way provides a useful signal for prediction of sentiment, but they leave automatic discourse relation prediction for future work. They use an integer linear programming framework to enforce agreement between classifiers and soft constraints provided by discourse annotations. This contrasts with our work; we do not rely on expert discourse annotation, but rather induce both discourse relations and cues jointly with aspect and sentiment.

## 7 Conclusions and Future Work

In this work, we showed that by jointly inducing discourse information in the form of discourse cues, we can achieve better predictions for aspect-specific sentiment polarity. Our contribution consists in proposing a general way of how discourse information can be integrated in any LDA-style discourse-agnostic model of aspect and sentiment. In the future, we aim at modeling more flexible sets of discourse relations and automatically inducing discourse segmentation relevant to the task.

cardie@cs.cornell.edu

## Abstract

This paper addresses the task of fine-grained opinion extraction – the identification of opinion-related entities: the opinion expressions, the opinion holders, and the targets of the opinions, and the relations between opinion expressions and their targets and holders. Most existing approaches tackle the extraction of opinion entities and opinion relations in a pipelined manner, where the interdependencies among different extraction stages are not captured. We propose a joint inference model that leverages knowledge from predictors that optimize subtasks of opinion extraction, and seeks a globally optimal solution. Experimental results demonstrate that our joint inference approach significantly outperforms traditional pipeline methods and baselines that tackle subtasks in isolation for the problem of opinion extraction.

## 1 Introduction

Fine-grained opinion analysis is concerned with identifying opinions in text at the expression level; this includes identifying the subjective (i.e., opinion) expression itself, the opinion holder and the target of the opinion (Wiebe et al., 2005). The task has received increasing attention as many natural language processing applications would benefit from the ability to identify text spans that correspond to these key components of opinions. In question-answering systems, for example, users may submit questions in the form “What does entity A think about target B?”; opinion-oriented summarization systems also need to recognize opinions and their targets and holders.

In this paper, we address the task of identifying opinion-related entities and opinion relations. We

consider three types of opinion entities: *opinion expressions* or direct subjective expressions as defined in Wiebe et al. (2005) — expressions that explicitly indicate emotions, sentiment, opinions or other private states (Quirk et al., 1985) or speech events expressing private states; *opinion targets* — expressions that indicate what the opinion is about; and *opinion holders* — mentions of whom or what the opinion is from. Consider the following examples in which opinion expressions (O) are underlined and targets (T) and holders (H) of the opinion are bracketed.

S1: [The workers]<sub>[H<sub>1,2</sub>]</sub> were irked<sub>[O<sub>1</sub>]</sub> by [the government report]<sub>[T<sub>1</sub>]</sub> and were worried<sub>[O<sub>2</sub>]</sub> as they went about their daily chores.

S2: From the very start it could be predicted<sub>[O<sub>1</sub>]</sub> that on the subject of economic globalization, [the developed states]<sub>[T<sub>1,2</sub>]</sub> were going to come across fierce opposition<sub>[O<sub>2</sub>]</sub>.

The numeric subscripts denote *linking relations*, one of IS-ABOUT or IS-FROM. In S1, for instance, opinion expression “were irked” ( $O_1$ ) IS-ABOUT “the government report” ( $T_1$ ). Note that the IS-ABOUT relation can contain an empty target (e.g. “were worried” in S1); similarly for IS-FROM w.r.t. the opinion holder (e.g. “predicted” in S2). We also allow an opinion entity to be involved in multiple relations (e.g. “the developed states” in S2).

Not surprisingly, fine-grained opinion extraction is a challenging task due to the complexity and variety of the language used to express opinions and their components (Pang and Lee, 2008). Nevertheless, much progress has been made in extracting opinion information from text. Sequence labeling models have been successfully employed to identify opinion expressions (e.g. (Breck et al.,

2007; Yang and Cardie, 2012)) and relation extraction techniques have been proposed to extract opinion holders and targets based on their linking relations to the opinion expressions (e.g. Kim and Hovy (2006), Kobayashi et al. (2007)). However, most existing work treats the extraction of different opinion entities and opinion relations in a pipelined manner: the interaction between different extraction tasks is not modeled jointly and error propagation is not considered. One exception is Choi et al. (2006), which proposed an ILP approach to jointly identify opinion holders, opinion expressions and their IS-FROM linking relations, and demonstrated the effectiveness of joint inference. Their ILP formulation, however, does not handle *implicit linking relations*, i.e. opinion expressions with no explicit opinion holder; nor does it consider IS-ABOUT relations.

In this paper, we present a model that jointly identifies opinion-related entities, including *opinion expressions*, *opinion targets* and *opinion holders* as well as the associated opinion linking relations, IS-ABOUT and IS-FROM. For each type of opinion relation, we allow implicit (i.e. empty) arguments for cases when the opinion holder or target is not explicitly expressed in text. We model entity identification as a sequence tagging problem and relation extraction as binary classification. A joint inference framework is proposed to jointly optimize the predictors for different sub-problems with constraints that enforce global consistency. We hypothesize that the ambiguity in the extraction results will be reduced and thus, performance increased. For example, uncertainty w.r.t. the spans of opinion entities can adversely affect the prediction of opinion relations; and evidence of opinion relations might provide clues to guide the accurate extraction of opinion entities.

We evaluate our approach using a standard corpus for fine-grained opinion analysis (the MPQA corpus (Wiebe et al., 2005)) and demonstrate that our model outperforms by a significant margin traditional baselines that do not employ joint inference for extracting opinion entities and different types of opinion relations.

## 2 Related Work

Significant research effort has been invested into fine-grained opinion extraction for open-domain text such as news articles (Wiebe et al., 2005; Wilson et al., 2009). Many techniques were proposed

to identify the text spans for opinion expressions (e.g. (Breck et al., 2007; Johansson and Moschitti, 2010b; Yang and Cardie, 2012)), opinion holders (e.g. (Choi et al., 2005)) and topics of opinions (Stoyanov and Cardie, 2008). Some consider extracting opinion targets/holders along with their relation to the opinion expressions. Kim and Hovy (2006) identifies opinion holders and targets by using their semantic roles related to opinion words. Ruppenhofer et al. (2008) argued that semantic role labeling is not sufficient for identifying opinion holders and targets. Johansson and Moschitti (2010a) extract opinion expressions and holders by applying reranking on top of sequence labeling methods. Kobayashi et al. (2007) considered extracting “aspect-evaluation” relations (relations between opinion expressions and targets) by identifying opinion expressions first and then searching for the most likely target for each opinion expression via a binary relation classifier. All these methods extract opinion arguments and opinion relations in separate stages instead of extracting them jointly.

Most similar to our method is Choi et al. (2006), which jointly extracts opinion expressions, holders and their IS-FROM relations using an ILP approach. In contrast, our approach (1) also considers the IS-ABOUT relation which is arguably more complex due to the larger variety in the syntactic structure exhibited by opinion expressions and their targets, (2) handles implicit opinion relations (opinion expressions without any associated argument), and (3) uses a simpler ILP formulation.

There has also been substantial interest in opinion extraction from product reviews (Liu, 2012). Most existing approaches focus on the extraction of opinion targets and their associated opinion expressions and usually employ a pipeline architecture: generate candidates of opinion expressions and opinion targets first, and then use rule-based or machine-learning-based approaches to identify potential relations between opinions and targets (Hu and Liu, 2004; Wu et al., 2009; Liu et al., 2012). In addition to pipeline approaches, bootstrapping-based approaches were proposed (Qiu et al., 2009; Qiu et al., 2011; Zhang et al., 2010) to identify opinion expressions and targets iteratively; however, they suffer from the problem of error propagation.

There is much work demonstrating the benefit of performing global inference. Roth and Yih

(2004) proposed a global inference approach in the formulation of a linear program (LP) and applied it to the task of extracting named entities and relations simultaneously. Their problem is similar to ours — the difference is that Roth and Yih Roth and Yih (2004) assume that named entity spans are known a priori and only their labels need to be assigned. Joint inference has also been applied to semantic role labeling (Punyakanok et al., 2008; Srikumar and Roth, 2011; Das et al., 2012), where the goal is to jointly identify semantic arguments for given lexical predicates. The problem is conceptually similar to identifying opinion arguments for opinion expressions, however, we do not assume prior knowledge of opinion expressions (unlike in SRL, where predicates are given).

### 3 Model

As proposed in Section 1, we consider the task of jointly identifying opinion entities and opinion relations. Specifically, given a sentence, our goal is to identify spans of opinion expressions, opinion arguments (targets and holders) and their associated linking relations. Training data consists of text with manually annotated opinion expression and argument spans, each with a list of relation ids specifying the linking relation between opinion expressions and their arguments.

In this section, we will describe how we model opinion entity identification and opinion relation extraction, and how we combine them in a joint inference model.

#### 3.1 Opinion Entity Identification

We formulate the task of opinion entity identification as a sequence labeling problem and employ conditional random fields (CRFs) (Lafferty et al., 2001) to learn the probability of a sequence assignment  $\mathbf{y}$  for a given sentence  $\mathbf{x}$ . Through inference we can find the best sequence assignment for sentence  $x$  and recover the opinion entities according to the standard “IOB” encoding scheme. We consider four entity labels:  $D, T, H, N$ , where  $D$  denotes opinion expressions,  $T$  denotes opinion targets,  $H$  denotes opinion holders and  $N$  denotes “NONE” entities.

We define potential function  $f_{iz}$  that gives the probability of assigning a span  $i$  with entity label  $z$ , and the probability is estimated based on the learned parameters from CRFs. Formally, given a within-sentence span  $i = (a, b)$ , where  $a$  is the

starting position and  $b$  is the end position, and label  $z \in \{D, T, H\}$ , we have

$$f_{iz} = p(\mathbf{y}_a = B_z, \mathbf{y}_{a+1} = I_z, \dots, \mathbf{y}_b = I_z, \mathbf{y}_{b+1} \neq I_z | \mathbf{x})$$

$$f_{iN} = p(\mathbf{y}_a = O, \dots, \mathbf{y}_b = O | \mathbf{x})$$

These probabilities can be efficiently computed using the forward-backward algorithm.

#### 3.2 Opinion Relation Extraction

We consider extracting the IS-ABOUT and IS-FROM opinion relations. In the following we will not distinguish these two relations, since they can both be characterized as relations between opinion expressions and opinion arguments, and the methods for relation extraction are the same.

We treat the relation extraction problem as a combination of two binary classification problems: *opinion-arg classification*, which decides whether a pair consisting of an opinion candidate  $o$  and an argument candidate  $a$  forms a relation; and *opinion-implicit-arg classification*, which decides whether an opinion candidate  $o$  is linked to an implicit argument, i.e. no argument is mentioned. We define a potential function  $r$  to capture the strength of association between an opinion candidate  $o$  and an argument candidate  $a$ ,

$$r_{oa} = p(y = 1 | x) - p(y = 0 | x)$$

where  $p(y = 1 | x)$  and  $p(y = 0 | x)$  are the logistic regression estimates of the positive and negative relations. Similarly, we define potential  $r_{o\emptyset}$  to denote the confidence of predicting opinion span  $o$  associated with an implicit argument.

##### 3.2.1 Opinion-Arg Relations

For *opinion-arg* classification, we construct candidates of opinion expressions and opinion arguments and consider each pair of an opinion candidate and an argument candidate as a potential opinion relation. Conceptually, all possible subsequences in the sentence are candidates. To filter out candidates that are less reasonable, we consider the opinion expressions and arguments obtained from the  $n$ -best predictions by CRFs<sup>1</sup>. We also employ syntactic patterns from dependency

<sup>1</sup>We randomly split the training data into 10 parts and obtained the 50-best CRF predictions on each part for the generation of candidates. We also experimented with candidates generated from more CRF predictions, but did not find any performance improvement for the task.

trees to generate candidates. Specifically, we selected the most common patterns of the shortest dependency paths<sup>2</sup> between an opinion candidate  $o$  and an argument candidate  $a$  in our dataset, and include all pairs of candidates that satisfy at least one dependency pattern. For the IS-ABOUT relation, the top three patterns are (1)  $o \uparrow_{dobj} a$ , (2)  $o \uparrow_{ccomp} x \uparrow_{nsubj} a$  ( $x$  is a word in the path that is not covered by either  $o$  nor  $a$ ), (3)  $o \uparrow_{ccomp} a$ ; for the IS-FROM relation, the top three patterns are (1)  $o \uparrow_{nsubj} a$ , (2)  $o \uparrow_{poss} a$ , (3)  $o \downarrow_{ccomp} x \uparrow_{nsubj} a$ .

Note that generating candidates this way will give us a large number of negative examples. Similar to the preprocessing approach in (Choi et al., 2006), we filter pairs of opinion and argument candidates that do not overlap with any gold standard relation in our training data.

Many features we use are common features in the SRL tasks (Punyakanok et al., 2008) due to the similarity of opinion relations to the predicate-argument relations in SRL (Ruppenhofer et al., 2008; Choi et al., 2006). In general, the features aim to capture (a) local properties of the candidate opinion expressions and arguments and (b) syntactic and semantic attributes of their relation.

**Words and POS tags:** the words contained in the candidate and their POS tags.

**Lexicon:** For each word in the candidate, we include its WordNet hypernyms and its strength of subjectivity in the Subjectivity Lexicon<sup>3</sup> (e.g. weaksubj, strongsubj).

**Phrase type:** the syntactic category of the deepest constituent that covers the candidate in the parse tree, e.g. NP, VP.

**Semantic frames:** For each verb in the opinion candidate, we include its frame types according to FrameNet<sup>4</sup>.

**Distance:** the relative distance (number of words) between the opinion and argument candidates.

**Dependency Path:** the shortest path in the dependency tree between the opinion candidate and the target candidate, e.g.  $ccomp \uparrow nsubj \uparrow$ . We also include word types and POS types in the paths, e.g.  $opinion \uparrow_{ccomp} suffering \uparrow_{nsubj} patient$ ,

<sup>2</sup>We use the Stanford Parser to generate parse trees and dependency graphs.

<sup>4</sup><https://framenet.icsi.berkeley.edu/fndrupal/>

$NN \uparrow_{ccomp} VBG \uparrow_{nsubj} NN$ . The dependency path has been shown to be very useful in extracting opinion expressions and opinion holders (Johansson and Moschitti, 2010a).

### 3.2.2 Opinion-Implicit-Arg Relations

When the *opinion-arg* relation classifier predicts that there is no suitable argument for the opinion expression candidate, it does not capture the possibility that an opinion candidate may associate with an implicit argument. To incorporate knowledge of implicit relations, we build an *opinion-implicit-arg* classifier to identify an opinion candidate with an implicit argument based on its own properties and context information.

For training, we consider all gold-standard opinion expressions as training examples — including those with implicit arguments — as positive examples and those associated with explicit arguments as negative examples. For features, we use words, POS tags, phrase types, lexicon and semantic frames (see Section 3.2.1 for details) to capture the properties of the opinion expression, and also features that capture the context of the opinion expression:

**Neighboring constituents:** The words and grammatical roles of neighboring constituents of the opinion expression in the parse tree — the left and right sibling of the deepest constituent containing the opinion expression in the parse tree.

**Parent Constituent:** The grammatical role of the parent constituent of the deepest constituent containing the opinion expression.

**Dependency Argument:** The word types and POS types of the arguments of the dependency patterns in which the opinion expression is involved. We consider the same dependency patterns that are used to generate candidates for *opinion-arg* classification.

### 3.3 Joint Inference

The inference goal is to find the optimal prediction for both opinion entity identification and opinion relation extraction. For a given sentence, we denote  $\mathcal{O}$  as a set of opinion candidates,  $\mathcal{A}_k$  as a set of argument candidates, where  $k$  denotes the type of opinion relation — IS-ABOUT or IS-FROM — and  $\mathcal{S}$  as a set of within-sentence spans that cover all of the opinion candidates and argument can-

didates. We introduce binary variable  $x_{iz}$ , where  $x_{iz} = 1$  means span  $i$  is associated with label  $z$ . We also introduce binary variable  $u_{ij}$  for every pair of opinion candidate  $i$  and argument candidate  $j$ , where  $u_{ij} = 1$  means  $i$  forms an opinion relation with  $j$ , and binary variable  $v_{ik}$  for every opinion candidate  $i$  in relation type  $k$ , where  $v_{ik} = 1$  means  $i$  associates with an implicit argument in relation  $k$ . Given the binary variables  $x_{iz}, u_{ij}, v_{ik}$ , it is easy to recover the entity and relation assignment by checking which spans are labeled as opinion entities, and which opinion span and argument span form an opinion relation.

The objective function is defined as a linear combination of the potentials from different predictors with a parameter  $\lambda$  to balance the contribution of two components: opinion entity identification and opinion relation extraction.

$$\begin{aligned} & \arg \max_{x,u,v} \lambda \sum_{i \in \mathcal{S}} \sum_z f_{iz} x_{iz} \\ & + (1 - \lambda) \sum_k \sum_{i \in \mathcal{O}} \left( \sum_{j \in \mathcal{A}_k} r_{ij} u_{ij} + r_{i\emptyset} v_{ik} \right) \end{aligned} \quad (1)$$

It is subject to the following linear constraints:

Constraint 1: *Uniqueness*. For each span  $i$ , we must assign one and only one label  $z$ , where  $z \in \{H, D, T, N\}$ .

$$\sum_z x_{iz} = 1$$

Constraint 2: *Non-overlapping*. If two spans  $i$  and  $j$  overlap, then at most one of the spans can be assigned to a non-NONE entity label:  $H, D, T$ .

$$\sum_{z \neq N} x_{iz} + \sum_{z \neq N} x_{jz} \leq 1$$

Constraint 3: *Consistency between the opinion-arg and opinion-implicit-arg classifiers*. For an opinion candidate  $i$ , if it is predicted to have an implicit argument in relation  $k$ ,  $v_{ik} = 1$ , then no argument candidate should form a relation with  $i$ . If  $v_{ik} = 0$ , then there exists some argument candidate  $j \in \mathcal{A}_k$  such that  $u_{ij} = 1$ . We introduce two auxiliary binary variables  $a_{ik}$  and  $b_{ik}$  to limit the maximum number of relations associated with each opinion candidate to be less than or equal to

three<sup>5</sup>. When  $v_{ik} = 1$ ,  $a_{ik}$  and  $b_{ik}$  have to be 0.

$$\sum_{j \in \mathcal{A}_k} u_{ij} = 1 - v_{ik} + a_{ik} + b_{ik}$$

$$a_{ik} \leq 1 - v_{ik}, b_{ik} \leq 1 - v_{ik}$$

Constraint 4: *Consistency between opinion-arg classifier and opinion entity extractor*. Suppose an argument candidate  $j$  in relation  $k$  is assigned an argument label by the entity extractor, that is  $x_{jz} = 1$  ( $z = T$  for IS-ABOUT relation and  $z = H$  for IS-FROM relation), then there exists some opinion candidates that associate with  $j$ . Similar to constraint 3, we introduce auxiliary binary variables  $c_j$  and  $d_j$  to enforce that an argument  $j$  links to at most three opinion expressions. If  $x_{jz} = 0$ , then no relations should be extracted for  $j$ .

$$\sum_{i \in \mathcal{O}} u_{ij} = x_{jz} + c_{jk} + d_{jk}$$

$$c_{jk} \leq x_{jz}, d_{jk} \leq x_{jz}$$

Constraint 5: *Consistency between the opinion-implicit-arg classifier and opinion entity extractor*. When an opinion candidate  $i$  is predicted to associate with an implicit argument in relation  $k$ , that is  $v_{ik} = 1$ , then we allow  $x_{iD}$  to be either 1 or 0 depending on the confidence of labeling  $i$  as an opinion expression. When  $v_{ik} = 0$ , there exists some opinion argument associated with the opinion candidate, and we enforce  $x_{iD} = 1$ , which means the entity extractor agrees to label  $i$  as an opinion expression.

$$v_{ik} + x_{iD} \geq 1$$

Note that in our ILP formulation, the label assignment for a candidate span involves one multiple-choice decision among different opinion entity labels and the ‘‘NONE’’ entity label. The scores of different label assignments are comparable for the same span since they come from one entity extraction model. This makes our ILP formulation advantageous over the ILP formulation proposed in Choi et al. (2006), which needs  $m$  binary decisions for a candidate span, where  $m$  is the number of types of opinion entities, and the score for each possible label assignment is obtained by

<sup>5</sup>It is possible to add more auxiliary variables to allow more than three arguments to link to an opinion expression, but this rarely happens in our experiments. For the IS-FROM relation, we set  $a_{ik} = 0, b_{ik} = 0$  since an opinion expression usually has only one holder.

the sum of raw scores from  $m$  independent extraction models. This design choice also allows us to easily deal with multiple types of opinion arguments and opinion relations.

## 4 Experiments

For evaluation, we used version 2.0 of the MPQA corpus (Wiebe et al., 2005; Wilson, 2008), a widely used data set for fine-grained opinion analysis.<sup>6</sup> We considered the subset of 482 documents<sup>7</sup> that contain attitude and target annotations. There are a total of 9,471 sentences with opinion-related labels at the phrase level. We set aside 132 documents as a development set and use 350 documents as the evaluation set. All experiments employ 10-fold cross validation on the evaluation set; the average over the 10 runs is reported.

Our gold standard opinion expressions, opinion targets and opinion holders correspond to the direct subjective annotations, target annotations and agent annotations, respectively. The IS-FROM relation is obtained from the *agent* attribute of each opinion expression. The IS-ABOUT relation is obtained from the attitude annotations: each opinion expression is annotated with attitude frames and each attitude frame is associated with a list of targets. The relations may overlap: for example, in the following sentence, the target of relation 1 contains relation 2.

[John]<sub>H<sub>1</sub></sub> is happy<sub>O<sub>1</sub></sub> because [[he]<sub>H<sub>2</sub></sub>  
loves<sub>O<sub>2</sub></sub> [being at Enderly Park]<sub>T<sub>2</sub></sub>]<sub>T<sub>1</sub></sub>.

We discard relations that contain sub-relations because we believe that identifying the sub-relations usually is sufficient to recover the discarded relations. (Prediction of overlapping relations is considered as future work.) In the example above, we will identify (*loves, being at Enderly Park*) as an IS-ABOUT relation and *happy* as an opinion expression associated with an implicit target. Table 1 shows some statistics of the corpus.

We adopted the evaluation metrics for entity and relation extraction from Choi et al. (2006), which include precision, recall, and F1-measure according to *overlap* and *exact* matching metrics.<sup>8</sup> We

<sup>6</sup>Available at <http://www.cs.pitt.edu/mpqa/>.

<sup>7</sup>349 news articles from the original MPQA corpus, 84 Wall Street Journal articles (Xbank), and 48 articles from the American National Corpus.

<sup>8</sup>Overlap matching considers two spans to match if they overlap, while exact matching requires two spans to be exactly the same.

	Opinion	Target	Holder
TotalNum	5849	4676	4244
	Opinion-arg Relations		Implicit Relations
IS-ABOUT	4823		1302
IS-FROM	4662		1187

Table 1: Data Statistics of the MPQA Corpus.

will focus our discussion on results obtained using overlap matching, since the exact boundaries of opinion entities are hard to define even for human annotators (Wiebe et al., 2005).

We trained CRFs for opinion entity identification using the following features: indicators for words, POS tags, and lexicon features (the subjectivity strength of the word in the Subjectivity Lexicon). All features are computed for the current token and tokens in a  $[-1, +1]$  window. We used L2-regularization; the regularization parameter was tuned using the development set. We trained the classifiers for relation extraction using L1-regularized logistic regression with default parameters using the LIBLINEAR (Fan et al., 2008) package. For joint inference, we used GLPK<sup>9</sup> to provide the optimal ILP solution. The parameter  $\lambda$  was tuned using the development set.

### 4.1 Baseline Methods

We compare our approach to several pipeline baselines. Each extracts opinion entities first using the same CRF employed in our approach, and then predicts opinion relations on the opinion entity candidates obtained from the CRF prediction. Three relation extraction techniques were used in the baselines:

- Adj: Inspired by the adjacency rule used in Hu and Liu (2004), it links each argument candidate to its nearest opinion candidate. Arguments that do not link to any opinion candidate are discarded. This is also used as a strong baseline in Choi et al. (2006).
- Syn: Links pairs of opinion and argument candidates that present prominent syntactic patterns. (We consider the syntactic patterns listed in Section 3.2.1.) Previous work also demonstrates the effectiveness of syntactic information in opinion extraction (Johansson and Moschitti, 2012).

<sup>9</sup><http://www.gnu.org/software/glpk/>

Table 3: Performance on opinion relation extraction using the *overlap* metric.

- RE: Predicts opinion relations by employing the *opinion-arg* classifier and *opinion-implicit-arg* classifier. First, the *opinion-arg* classifier identifies pairs of opinion and argument candidates that form valid opinion relations, and then the *opinion-implicit-arg* classifier is used on the remaining opinion candidates to further identify opinion expressions without explicit arguments.

We report results using opinion entity candidates from the best CRF output and from the merged 10-best CRF output.<sup>10</sup> The motivation of merging the 10-best output is to increase recall for the pipeline methods.

## 5 Results

Table 2 shows the results of opinion entity identification using both *overlap* and *exact* metrics. We compare our approach with the pipeline baselines and CRF (the first step of the pipeline). We can see that our joint inference approach significantly outperforms all the baselines in F1 measure on extracting all types of opinion entities. In general,

<sup>10</sup>It is similar to the *merged 10-best* baseline in Choi et al. (2006). If an entity  $E_i$  extracted by the  $i$ th-best sequence overlaps with an entity  $E_j$  extracted by the  $j$ th-best sequence, where  $i \leq j$ , then we discard  $E_j$ . If  $E_i$  and  $E_j$  do not overlap, then we consider both entities.

by adding the relation extraction step, the pipeline baselines are able to improve precision over the CRF but fail at recall. CRF+Syn and CRF+Adj provide the same performance as CRF, since the relation extraction step only affects the results of opinion arguments. By incorporating syntactic information, CRF+Syn provides better precision than CRF+Adj on extracting arguments at the expense of recall. This indicates that using simple syntactic rules would mistakenly filter many correct relations. By using binary classifiers to predict relations, CRF+RE produces high precision on opinion and target extraction but also results in very low recall. Using the *exact* metric, we observe the same general trend in the results as the *overlap* metric. The scores are lower since the metric is much stricter.

Table 3 shows the results of opinion relation extraction using the *overlap* metric. We compare our approach with pipelined baselines in two settings: one employs relation extraction on 1-best output of CRF (top half of table) and the other employs the merged 10-best output of CRF (bottom half of table). We can see that in general, using merged 10-best CRF outputs boosts the recall while sacrificing precision. This is expected since merging the 10-best CRF outputs favors candidates that are

Table 4: Comparison between our approach and ILP baselines that omit some potentials in our approach.

believed to be more accurate by the CRF predictor. If CRF makes mistakes, the mistakes will propagate to the relation extraction step. The poor performance on precision further confirms the error propagation problem in the pipeline approaches. In contrast, our joint-inference method successfully boosts the recall while maintaining reasonable precision. This demonstrates that joint inference can effectively leverage the advantage of individual predictors and limit error propagation.

To demonstrate the effectiveness of different potentials in our joint inference model, we consider three variants of our ILP formulation that omit some potentials in the joint inference: one is ILP-W/O-ENTITY, which extracts opinion relations without integrating information from opinion entity identification; one is ILP-W-SINGLE-RE, which focuses on extracting a single opinion relation and ignores the information from the other relation; the third one is ILP-W/O-IMPLICIT-RE, which omits the potential for *opinion-implicit-arg* relation and assumes every opinion expression is linked to an explicit argument. The objective function of ILP-W/O-ENTITY can be represented as

$$\arg \max_u \sum_k \sum_{i \in \mathcal{O}} \sum_{j \in \mathcal{A}_k} r_{ij} u_{ij} \quad (2)$$

which is subject to constraints on  $u_{ij}$  to enforce relations to not overlap and limit the maximum number of relations that can be extracted for each opinion expression and each argument. For ILP-W-SINGLE-RE, we simply remove the variables associated with one opinion relation in the objective function (1) and constraints. The formulation of ILP-W/O-IMPLICIT-RE removes the variables associated with potential  $r_i$  in the objective function and corresponding constraints. It can be viewed as an extension to the ILP approach in Choi et al. (2006) that includes opinion targets and uses simpler ILP formulation with only one parameter and fewer binary variables and constraints to represent entity label assignments<sup>11</sup>.

<sup>11</sup>We compared the proposed ILP formulation with the ILP

Table 4 shows the results of these methods on opinion relation extraction. We can see that without the knowledge of the entity extractor, ILP-W/O-ENTITY provides poor performance on both relation extraction tasks. This confirms the effectiveness of leveraging knowledge from entity extractor and relation extractor. The improvement yielded by our approach over ILP-W-SINGLE-RE demonstrates the benefit of jointly optimizing different types of opinion relations. Our approach also outperforms ILP-W/O-IMPLICIT-RE, which does not take into account implicit relations. The results demonstrate that incorporating knowledge of implicit opinion relations is important.

## 6 Discussion

We note that the joint inference model yields a clear improvement on recall but not on precision compared to the CRF-based baselines. Analyzing the errors, we found that the joint model extracts comparable number of opinion entities compared to the gold standard, while the CRF-based baselines extract significantly fewer opinion entities (around 60% of the number of entities in the gold standard). With more extracted opinion entities, the precision is sacrificed but recall is boosted substantially, and overall we see an increase in F-measure. We also found that a good portion of errors were made because the generated candidates failed to cover the correct solutions. Recall that the joint model finds the global optimal solution over a set of opinion entity and relation candidates, which are obtained from the n-best CRF predictions and constituents in the parse tree that satisfy certain syntactic patterns. It is possible that the generated candidates do not contain the gold standard answers. For example, our model failed to identify the IS-ABOUT relation (*offers, general aid*) from the following sentence *Powell had contacted ... and received offers<sub>O1</sub> of [gen-*

formulation in Choi et al. (2006) on extracting opinion holders, opinion expressions and IS-FROM relations, and showed that the proposed ILP formulation performs better on all three extraction tasks.

eral aid] $T_1$ ... because both the CRF predictor and syntactic heuristics fail to capture (*offers, general aid*) as a potential relation candidate. By applying simple heuristics such as treating all verbs or verb phrases as opinion candidates would not help because it would introduce a large number of negative candidates and lower the accuracy of relation extraction (only 52% of the opinion expressions are verbs or verb phrases and 64% of the opinion targets are noun or noun phrases in the corpus we used). Therefore a more effective candidate generation method is needed to allow more candidates while limiting the number of negative candidates. We also observed incorrect parsing to be a cause of error. We hope to study ways to account for such errors in our approach as future work.

For computational time, our ILP formulation can be solved very efficiently using advanced ILP solvers. In our experiment, using GLPK's branch-and-cut solver took 0.2 seconds to produce optimal ILP solutions for 1000 sentences on a machine with Intel Core 2 Duo CPU and 4GB RAM.

## 7 Conclusion

In this paper we propose a joint inference approach for extracting opinion-related entities and opinion relations. We decompose the task into different subproblems, and jointly optimize them using constraints that aim to encourage their consistency and reduce prediction uncertainty. We show that our approach can effectively integrate knowledge from different predictors and achieve significant improvements in overall performance for opinion extraction. For future work, we plan to extend our model to handle more complex opinion relations, e.g. nesting or cross-sentential relations. This can be potentially addressed by incorporating more powerful predictors and more complex linguistic constraints.

## Abstract

Unbiased language is a requirement for reference sources like encyclopedias and scientific texts. Bias is, nonetheless, ubiquitous, making it crucial to understand its nature and linguistic realization and hence detect bias automatically. To this end we analyze real instances of human edits designed to remove bias from Wikipedia articles. The analysis uncovers two classes of bias: *framing bias*, such as praising or perspective-specific words, which we link to the literature on subjectivity; and *epistemological bias*, related to whether propositions that are presupposed or entailed in the text are uncontroversially accepted as true. We identify common linguistic cues for these classes, including factive verbs, implicatives, hedges, and subjective intensifiers. These insights help us develop features for a model to solve a new prediction task of practical importance: given a biased sentence, identify the bias-inducing word. Our linguistically-informed model performs almost as well as humans tested on the same task.

## 1 Introduction

Writers and editors of reference works such as encyclopedias, textbooks, and scientific articles strive to keep their language **unbiased**. For example, Wikipedia advocates a policy called *neutral point of view (NPOV)*, according to which articles should represent “fairly, proportionately, and as far as possible without bias, all significant views that have been published by reliable sources” (Wikipedia, 2013b). Wikipedia’s style guide asks editors to use nonjudgmental language, to indicate the relative prominence of opposing points of view, to avoid presenting uncontroversial

facts as mere opinion, and, conversely, to avoid stating opinions or contested assertions as facts.

Understanding the linguistic realization of bias is important for linguistic theory; automatically detecting these biases is equally significant for computational linguistics. We propose to address both by using a powerful resource: edits in Wikipedia that are specifically designed to remove bias. Since Wikipedia maintains a complete revision history, the edits associated with NPOV tags allow us to compare the text in its biased (before) and unbiased (after) form, helping us better understand the linguistic realization of bias. Our work thus shares the intuition of prior NLP work applying Wikipedia’s revision history (Nelken and Yamangil, 2008; Yatskar et al., 2010; Max and Wisniewski, 2010; Zanzotto and Pennacchiotti, 2010).

The analysis of Wikipedia’s edits provides valuable linguistic insights into the nature of biased language. We find two major classes of bias-driven edits. The first, **framing bias**, is realized by subjective words or phrases linked with a particular point of view. In (1), the term *McMansion*, unlike *homes*, appeals to a negative attitude toward large and pretentious houses. The second class, **epistemological bias**, is related to linguistic features that subtly (often via presupposition) focus on the believability of a proposition. In (2), the assertive *stated* removes the bias introduced by *claimed*, which casts doubt on Kuypers’ statement.

- (1) a. Usually, smaller cottage-style houses have been demolished to make way for these **McMansions**.  
b. Usually, smaller cottage-style houses have been demolished to make way for these **homes**.
- (2) a. Kuypers **claimed** that the mainstream press in America tends to favor liberal viewpoints.  
b. Kuypers **stated** that the mainstream press in America tends to favor liberal viewpoints.

Bias is linked to the lexical and grammatical cues identified by the literature on subjectivity (Wiebe et al., 2004; Lin et al., 2011), sentiment (Liu et al., 2005; Turney, 2002), and especially stance

or “arguing subjectivity” (Lin et al., 2006; Somasundaran and Wiebe, 2010; Yano et al., 2010; Park et al., 2011; Conrad et al., 2012). For example, like stance, framing bias is realized when the writer of a text takes a particular position on a controversial topic and uses its metaphors and vocabulary. But unlike the product reviews or debate articles that overtly use subjective language, editors in Wikipedia are actively trying to avoid bias, and hence biases may appear more subtly, in the form of covert framing language, or presuppositions and entailments that may not play as important a role in other genres. Our linguistic analysis identifies common classes of these subtle bias cues, including factive verbs, implicatives and other entailments, hedges, and subjective intensifiers.

Using these cues could help automatically detect and correct instances of bias, by first finding biased phrases, then identifying the word that introduces the bias, and finally rewording to eliminate the bias. In this paper we propose a solution for the second of these tasks, identifying the bias-inducing word in a biased phrase. Since, as we show below, this task is quite challenging for humans, our system has the potential to be very useful in improving the neutrality of reference works like Wikipedia. Tested on a subset of non-neutral sentences from Wikipedia, our model achieves 34% accuracy—and up to 59% if the top three guesses are considered—on this difficult task, outperforming four baselines and nearing humans tested on the same data.

## 2 Analyzing a Dataset of Biased Language

We begin with an empirical analysis based on Wikipedia’s bias-driven edits. This section describes the data, and summarizes our linguistic analysis.<sup>1</sup>

### 2.1 The NPOV Corpus from Wikipedia

Given Wikipedia’s strict enforcement of an NPOV policy, we decided to build the **NPOV corpus**, containing Wikipedia edits that are specifically designed to remove bias. Editors are encouraged to identify and rewrite biased passages to achieve a more neutral tone, and they can use several NPOV

<sup>1</sup>The data and bias lexicon we developed are available at [http://www.mpi-sws.org/~cristian/Biased\\_language.html](http://www.mpi-sws.org/~cristian/Biased_language.html)

Data	Articles	Revisions	Words	Edits	Sents
Train	5997	2238K	11G	13807	1843
Dev	653	210K	0.9G	1261	163
Test	814	260K	1G	1751	230
Total	7464	2708K	13G	16819	2235

Table 1: Statistics of the NPOV corpus, extracted from Wikipedia. (*Edits* refers to bias-driven edits, i.e., with an NPOV comment. *Sents* refers to sentences with a one-word bias-driven edit.)

tags to mark biased content.<sup>2</sup> Articles tagged this way fall into Wikipedia’s category of *NPOV disputes*.

We constructed the NPOV corpus by retrieving all articles that were or had been in the NPOV-dispute category<sup>3</sup> together with their full revision history. We used Stanford’s CoreNLP tools<sup>4</sup> to tokenize and split the text into sentences. Table 1 shows the statistics of this corpus, which we split into training (train), development (dev), and test. Following Wikipedia’s terminology, we call each version of a Wikipedia article a *revision*, and so an article can be viewed as a set of (chronologically ordered) revisions.

### 2.2 Extracting Edits Meant to Remove Bias

Given all the revisions of a page, we extracted the changes between pairs of revisions with the word-mode *diff* function from the Diff Match and Patch library.<sup>5</sup> We refer to these changes between revisions as *edits*, e.g., *McMansion > large home*. An edit consists of two strings: the old string that is being replaced (i.e., the before form), and the new modified string (i.e., the after form).

Our assumption was that among the edits happening in NPOV disputes, we would have a high density of edits intended to remove bias, which we call *bias-driven edits*, like (1) and (2) from Section 1. But many other edits occur even in NPOV disputes, including edits to fix spelling or grammatical errors, simplify the language, make the meaning more precise, or even vandalism (Max

<sup>2</sup>`{{POV}}`, `{{POV-check}}`, `{{POV-section}}`, etc. Adding these tags displays a template such as “The neutrality of this article is disputed. Relevant discussion may be found on the talk page. Please do not remove this message until the dispute is resolved.”

<sup>3</sup>[http://en.wikipedia.org/wiki/Category:All\\_NPOV\\_disputes](http://en.wikipedia.org/wiki/Category:All_NPOV_disputes)

<sup>4</sup><http://nlp.stanford.edu/software/corenlp.shtml>

<sup>5</sup><http://code.google.com/p/google-diff-match-patch>

and Wisniewski, 2010). Therefore, in order to extract a high-precision set of bias-driven edits, we took advantage of the comments that editors can associate with a revision—typically short and brief sentences describing the reason behind the revision. We considered as bias-driven edits those that appeared in a revision whose comment mentioned (*N*)*POV*, e.g., *Attempts at presenting some claims in more NPOV way*; or *merging in a passage from the researchers article after basic NPOV-ing*. We only kept edits whose before and after forms contained five or fewer words, and discarded those that only added a hyperlink or that involved a minimal change (character-based Levenshtein distance < 4). The final number of bias-driven edits for each of the data sets is shown in the “Edits” column of Table 1.

### 2.3 Linguistic Analysis

Style guides talk about biased language in a prescriptive manner, listing a few words that should be avoided because they are flattering, vague, or endorse a particular point of view (Wikipedia, 2013a). Our focus is on analyzing actual biased text and bias-driven edits extracted from Wikipedia.

As we suggested above, this analysis uncovered two major classes of bias: epistemological bias and framing bias. Table 2 shows the distribution (from a sample of 100 edits) of the different types and subtypes of bias presented in this section.

(A) **Epistemological bias** involves propositions that are either commonly agreed to be true or commonly agreed to be false and that are subtly presupposed, entailed, asserted or hedged in the text.

1. **Factive verbs** (Kiparsky and Kiparsky, 1970) presuppose the truth of their complement clause. In (3-a) and (4-a), *realize* and *reveal* presuppose the truth of “the oppression of black people...” and “the Meditation technique produces...”, whereas (3-b) and (4-b) present the two propositions as somebody’s stand or an experimental result.
  - (3) a. **He realized** that the oppression of black people was more of a result of economic exploitation than anything innately racist.
  - b. **His stand was** that the oppression of black people was more of a result of economic exploitation than anything innately racist.
  - (4) a. The first research **revealed** that the Meditation technique produces a unique state fact.
  - b. The first research **indicated** that the Meditation technique produces a unique state fact.

Bias	Subtype	%
A. Epistemological bias		43
	- Factive verbs	3
	- Entailments	25
	- Assertives	11
	- Hedges	4
B. Framing bias		57
	- Intensifiers	19
	- One-sided terms	38

Table 2: Proportion of the different bias types.

2. **Entailments** are directional relations that hold whenever the truth of one word or phrase follows from another, e.g., *murder* entails *kill* because there cannot be murdering without killing (5). However, *murder* entails killing in an unlawful, premeditated way. This class includes implicative verbs (Karttunen, 1971), which imply the truth or untruth of their complement, depending on the polarity of the main predicate. In (6-a), *coerced into accepting* entails accepting in an unwilling way.

- (5) a. After he **murdered** three policemen, the colony proclaimed Kelly a wanted outlaw.
- b. After he **killed** three policemen, the colony proclaimed Kelly a wanted outlaw.

- (6) a. A computer engineer who **was coerced into accepting** a plea bargain.
- b. A computer engineer who **accepted** a plea bargain.

3. **Assertive verbs** (Hooper, 1975) are those whose complement clauses assert a proposition. The truth of the proposition is not presupposed, but its level of certainty depends on the asserting verb. Whereas verbs of saying like *say* and *state* are usually neutral, *point out* and *claim* cast doubt on the certainty of the proposition.

- (7) a. The “no Boeing” theory is a controversial issue, even among conspiracists, many of whom have **pointed out** that it is disproved by ...
- b. The “no Boeing” theory is a controversial issue, even among conspiracists, many of whom have **said** that it is disproved by...

- (8) a. Cooper says that slavery was worse in South America and the US than Canada, but **clearly states** that it was a horrible and cruel practice.
- b. Cooper says that slavery was worse in South America and the US than Canada, but **points out** that it was a horrible and cruel practice.

4. **Hedges** are used to reduce one’s commitment to the truth of a proposition, thus avoiding any bold predictions (9-b) or statements (10-a).<sup>6</sup>

- (9) a. Eliminating the profit motive **will decrease** the rate of medical innovation.
- b. Eliminating the profit motive **may have a lower** rate of medical innovation.
- (10) a. The lower cost of living in more rural areas means a **possibly** higher standard of living.
- b. The lower cost of living in more rural areas means a higher standard of living.

Epistemological bias is bidirectional, that is, bias can occur because doubt is cast on a proposition commonly assumed to be true, or because a presupposition or implication is made about a proposition commonly assumed to be false. For example, in (7) and (8) above, *point out* is replaced in the former case, but inserted in the second case. If the truth of the proposition is uncontroversially accepted by the community (i.e., reliable sources, etc.), then the use of a factive is unbiased. In contrast, if only a specific viewpoint agrees with its truth, then using a factive is biased.

**(B) Framing bias** is usually more explicit than epistemological bias because it occurs when subjective or one-sided words are used, revealing the author’s stance in a particular debate (Entman, 2007).

1. **Subjective intensifiers** are adjectives or adverbs that add (subjective) force to the meaning of a phrase or proposition.

- (11) a. Schnabel himself did the **fantastic** reproductions of Basquiat’s work.
- b. Schnabel himself did the **accurate** reproductions of Basquiat’s work.
- (12) a. Shwekey’s albums are arranged by many **talented** arrangers.
- b. Shwekey’s albums are arranged by many **different** arrangers.

2. **One-sided terms** reflect only one of the sides of a contentious issue. They often belong to controversial subjects (e.g., religion, terrorism, etc.) where the same event can be seen from two or more opposing perspectives, like the Israeli-Palestinian conflict (Lin et al., 2006).

- (13) a. Israeli forces **liberated** the eastern half of Jerusalem.
- b. Israeli forces **captured** the eastern half of Jerusalem.
- (14) a. Concerned Women for America’s major areas of political activity have consisted of opposition to gay causes, **pro-life** law...
- b. Concerned Women for America’s major areas of political activity have consisted of opposition to gay causes, **anti-abortion** law...
- (15) a. Colombian **terrorist** groups.
- b. Colombian **paramilitary** groups.

Framing bias has been studied within the literature on stance recognition and arguing subjectivity. Because this literature has focused on identifying which side an article takes on a two-sided debate such as the Israeli-Palestinian conflict (Lin et al., 2006), most studies cast the problem as a two-way classification of documents or sentences into *for*/positive vs. *against*/negative (Anand et al., 2011; Conrad et al., 2012; Somasundaran and Wiebe, 2010), or into one of two opposing views (Yano et al., 2010; Park et al., 2011). The features used by these models include subjectivity and sentiment lexicons, counts of unigrams and bigrams, distributional similarity, discourse relationships, and so on.

The datasets used by these studies come from genres that overtly take a specific stance (e.g., debates, editorials, blog posts). In contrast, Wikipedia editors are asked not to advocate a particular point of view, but to provide a balanced account of the different available perspectives. For this reason, overtly biased opinion statements such as “I believe that...” are not common in Wikipedia. The features used by the subjectivity literature help us detect framing bias, but we also need features that capture epistemological bias expressed through presuppositions and entailments.

### 3 Automatically Identifying Biased Language

We now show how the bias cues identified in Section 2.3 can help solve a new task. Given a biased sentence (e.g., a sentence that a Wikipedia editor has tagged as violating the NPOV policy), our goal in this new task is to identify the word that introduces bias. This is part of a potential three-step process for detecting and correcting biased language: (1) finding biased phrases, (2) identifying the word that introduces the bias, (3) rewording to eliminate the bias. As we will see below, it can be

<sup>6</sup>See Choi et al. (2012) for an exploration of the interface between hedging and framing.

hard even for humans to track down the sources of bias, because biases in reference works are often subtle and implicit. An automatic bias detector that can highlight the bias-inducing word(s) and draw the editors’ attention to words that need to be modified could thus be important for improving reference works like Wikipedia or even in news reporting.

We selected the subset of sentences that had a single NPOV edit involving one (original) word. (Although the before form consists of only one word, the after form can be either one or more words or the null string (i.e., deletion edits); we do not use the after string in this identification task). The number of sentences in the train, dev and test sets is shown in the last column of Table 1.

We trained a logistic regression model on a feature vector for every word that appears in the NPOV sentences from the training set, with the bias-inducing words as the positive class, and all the other words as the negative class. The features are described in the next section.

At test time, the model is given a set of sentences and, for each of them, it ranks the words according to their probability to be biased, and outputs the highest ranked word (TOP1 model), the two highest ranked words (TOP2 model), or the three highest ranked words (TOP3 model).

### 3.1 Features

The types of features used in the logistic regression model are listed in Table 3, together with their value space. The total number of features is 36,787. The ones targeting framing bias draw on previous work on sentiment and subjectivity detection (Wiebe et al., 2004; Liu et al., 2005). Features to capture epistemological bias are based on the bias cues identified in Section 2.3.

A major split separates the features that describe the word under analysis (e.g., lemma, POS, whether it is a hedge, etc.) from those that describe its surrounding context (e.g., the POS of the word to the left, whether there is a hedge in the context, etc.). We define *context* as a 5-gram window, i.e., two words to the left of the word under analysis, and two to the right. Taking context into account is important given that biases can be context-dependent, especially epistemological bias since it depends on the truth of a proposition. To define some of the features like POS and grammatical relation, we used the Stanford’s CoreNLP

tagger and dependency parser (de Marneffe et al., 2006).

Features 9–10 use the list of hedges from Hyland (2005), features 11–14 use the factives and assertives from Hooper (1975), features 15–16 use the implicatives from Karttunen (1971), features 19–20 use the entailments from Berant et al. (2012), features 21–25 employ the subjectivity lexicon from Riloff and Wiebe (2003), and features 26–29 use the sentiment lexicon—positive and negative words—from Liu et al. (2005). If the word (or a word in the context) is in the lexicon, then the feature is true, otherwise it is false.

We also included a “bias lexicon” (feature 31) that we built based on our NPOV corpus from Wikipedia. We used the training set to extract the lemmas of words that were the before form of at least two NPOV edits, and that occurred in at least two different articles. Of the 654 words included in this lexicon, 433 were unique to this lexicon (i.e., recorded in neither Riloff and Wiebe’s (2003) subjectivity lexicon nor Liu et al.’s (2005) sentiment lexicon) and represented many one-sided or controversial terms, e.g., *abortion*, *same-sex*, *execute*.

Finally, we also included a “collaborative feature” that, based on the previous revisions of the edit’s article, computes the ratio between the number of times that the word was NPOV-edited and its frequency of occurrence. This feature was designed to capture framing bias specific to an article or topic.

### 3.2 Baselines

Previous work on subjectivity and stance recognition has been evaluated on the task of classifying documents as opinionated vs. factual, *for* vs. *against*, positive vs. negative. Given that the task of identifying the bias-inducing word of a sentence is novel, there were no previous results to compare directly against. We ran the following five baselines.

1. **Random guessing.** Naively returns a random word from every sentence.
2. **Role baseline.** Selects the word with the syntactic role that has the highest probability to be biased, as computed on the training set. This is the parse tree root (probability  $p = .126$  to be biased), followed by verbal arguments ( $p = .085$ ), and the subject ( $p = .084$ ).

ID	Feature	Value	Description
1*	Word	<string>	Word $w$ under analysis.
2	Lemma	<string>	Lemma of $w$ .
3*	POS	{NNP, JJ, ...}	POS of $w$ .
4*	POS - 1	{NNP, JJ, ...}	POS of one word before $w$ .
5	POS - 2	{NNP, JJ, ...}	POS of two words before $w$ .
6*	POS + 1	{NNP, JJ, ...}	POS of one word after $w$ .
7	POS + 2	{NNP, JJ, ...}	POS of two words after $w$ .
8	Position in sentence	{start, mid, end}	Position of $w$ in the sentence (split into three parts).
9	Hedge	{true, false}	$w$ is in Hyland’s (2005) list of hedges (e.g., <i>apparently</i> ).
10*	Hedge in context	{true, false}	One/two words around $w$ is a hedge (Hyland, 2005).
11*	Factive verb	{true, false}	$w$ is in Hooper’s (1975) list of factives (e.g., <i>realize</i> ).
12*	Factive verb in context	{true, false}	One/two word(s) around $w$ is a factive (Hooper, 1975).
13*	Assertive verb	{true, false}	$w$ is in Hooper’s (1975) list of assertives (e.g., <i>claim</i> ).
14*	Assertive verb in context	{true, false}	One/two word(s) around $w$ is an assertive (Hooper, 1975).
15	Implicative verb	{true, false}	$w$ is in Karttunen’s (1971) list of implicatives (e.g., <i>manage</i> ).
16*	Implicative verb in context	{true, false}	One/two word(s) around $w$ is an implicative (Karttunen, 1971).
17*	Report verb	{true, false}	$w$ is a report verb (e.g., <i>add</i> ).
18	Report verb in context	{true, false}	One/two word(s) around $w$ is a report verb.
19*	Entailment	{true, false}	$w$ is in Berant et al.’s (2012) list of entailments (e.g., <i>kill</i> ).
20*	Entailment in context	{true, false}	One/two word(s) around $w$ is an entailment (Berant et al., 2012).
21*	Strong subjective	{true, false}	$w$ is in Riloff and Wiebe’s (2003) list of strong subjectives (e.g., <i>absolute</i> ).
22	Strong subjective in context	{true, false}	One/two word(s) around $w$ is a strong subjective (Riloff and Wiebe, 2003).
23*	Weak subjective	{true, false}	$w$ is in Riloff and Wiebe’s (2003) list of weak subjectives (e.g., <i>noisy</i> ).
24*	Weak subjective in context	{true, false}	One/two word(s) around $w$ is a weak subjective (Riloff and Wiebe, 2003).
25	Polarity	{+, -, both, ...}	The polarity of $w$ according to Riloff and Wiebe (2003), e.g., <i>praising</i> is positive.
26*	Positive word	{true, false}	$w$ is in Liu et al.’s (2005) list of positive words (e.g., <i>excel</i> ).
27*	Positive word in context	{true, false}	One/two word(s) around $w$ is positive (Liu et al., 2005).
28*	Negative word	{true, false}	$w$ is in Liu et al.’s (2005) list of negative words (e.g., <i>terrible</i> ).
29*	Negative word in context	{true, false}	One/two word(s) around $w$ is negative (Liu et al., 2005).
30*	Grammatical relation	{root, subj, ...}	Whether $w$ is the subject, object, root, etc. of its sentence.
31	Bias lexicon	{true, false}	$w$ has been observed in NPOV edits (e.g., <i>nationalist</i> ).
32*	Collaborative feature	<numeric>	Number of times that $w$ was NPOV-edited in the article’s prior history / frequency of $w$ .

Table 3: Features used by the bias detector. The star (\*) shows the most contributing features.

3. **Sentiment baseline.** Logistic regression model that only uses the features based on Liu et al.’s (2005) lexicons of positive and negative words (i.e., features 26–29).

4. **Subjectivity baseline.** Logistic regression model that only uses the features based on Riloff and Wiebe’s (2003) lexicon of subjective words (i.e., features 21–25).

5. **Wikipedia baseline.** Selects as biased the words that appear in Wikipedia’s list of words to avoid (Wikipedia, 2013a).

These baselines assessed the difficulty of the task, as well as the extent to which traditional sentiment-analysis and subjectivity features would suffice to detect biased language.

### 3.3 Results and Discussion

To measure performance, we used accuracy defined as:

$$\frac{\text{\#sentences with the correctly predicted biased word}}{\text{\#sentences}}$$

The results are shown in Table 4. As explained earlier, we evaluated all the models by outputting as biased either the highest ranked word or the two or three highest ranked words. These correspond to the TOP1, TOP2 and TOP3 columns, respectively. The TOP3 score increases to 59%. A tool that highlights up to three words to be revised would simplify the editors’ job and decrease significantly the time required to revise.

Our model outperforms all five baselines by a large margin, showing the importance of considering a wide range of features. Wikipedia’s list of words to avoid falls very short on recall. Fea-

System	TOP1	TOP2	TOP3
Baseline 1: Random	2.18	7.83	9.13
Baseline 2: Role	15.65	20.43	25.65
Baseline 3: Sentiment	14.78	22.61	27.83
Baseline 4: Subjectivity	16.52	25.22	33.91
Baseline 5: Wikipedia	10.00	10.00	10.00
Our system	<b>34.35</b>	<b>46.52</b>	<b>58.70</b>
Humans (AMT)	37.39	50.00	59.13

Table 4: Accuracy (%) of the bias detector on the test set.

tures that contribute the most to the model’s performance (in a feature ablation study on the dev set) are highlighted with a star (\*) in Table 3. In addition to showing the importance of linguistic cues for different classes of bias, the ablation study highlights the role of contextual features. The bias lexicon does not seem to help much, suggesting that it is overfit to the training data.

An error analysis shows that our system makes acceptable errors in that words wrongly predicted as bias-inducing may well introduce bias in a different context. In (16), the system picked *eschew*, whereas *orthodox* would have been the correct choice according to the gold edit. Note that both the sentiment and the subjectivity lexicons list *eschew* as a negative word. The bias type that poses the greatest challenge to the system are terms that are one-sided or loaded in a particular topic, such as *orthodox* in this example.

- (16) a. Some Christians *eschew* **orthodox** theology; such as the Unitarians, Socinian, [...]  
 b. Some Christians *eschew* **mainstream trinitarian** theology; such as the Unitarians, Socinian, [...]

The last row in Table 4 lists the performance of humans on the same task, presented in the next section.

## 4 Human Perception of Biased Language

Is it difficult for humans to find the word in a sentence that induces bias, given the subtle, often implicit biases in Wikipedia. We used Amazon Mechanical Turk<sup>7</sup> (AMT) to elicit annotations from humans for the same 230 sentences from the test set that we used to evaluate the bias detector in Section 3.3. The goal of this annotation was twofold: to compare the performance of our bias detector against a human baseline, and to assess the difficulty of this task for humans. While AMT labelers are not trained Wikipedia editors, under-

<sup>7</sup><http://www.mturk.com>

standing how difficult these cases are for untrained labelers is an important baseline.

### 4.1 Task

Our HIT (Human Intelligence Task) was called “Find the biased word!”. We kept the task description succinct. Turkers were shown Wikipedia’s definition of a “biased statement” and two example sentences that illustrated the two types of bias, framing and epistemological. In each HIT, annotators saw 10 sentences, one after another, and each one followed by a text box entitled “Word introducing bias.” For each sentence, they were asked to type in the text box the word that caused the statement to be biased. They were only allowed to enter a single word.

Before the 10 sentences, turkers were asked to list the languages they spoke as well as their primary language in primary school. This was English in all the cases. In addition, we included a probe question in the form of a paraphrasing task: annotators were given a sentence and two paraphrases (a correct and a bad one) to choose from. The goal of this probe question was to discard annotators who were not paying attention or did not have a sufficient command of English. This simple test was shown to be effective in verifying and eliciting linguistic attentiveness (Munro et al., 2010). This was especially important in our case as we were interested in using the human annotations as an oracle. At the end of the task, participants were given the option to provide additional feedback.

We split the 230 sentences into 23 sets of 10 sentences, and asked for 10 annotations of each set. Each approved HIT was rewarded with \$0.30.

### 4.2 Results and Discussion

On average, it took turkers about four minutes to complete each HIT. The feedback that we got from some of them confirmed our hypothesis that finding the bias source is difficult: “Some of the ‘biases’ seemed very slight if existent at all,” “This was a lot harder than I thought it would be... Interesting though!”.

We postprocessed the answers ignoring case, punctuation signs, and spelling errors. To ensure an answer quality as high as possible, we only kept those turkers who answered attentively by applying two filters: we only accepted answers that matched a valid word from the sentence, and we discarded answers from participants who did not

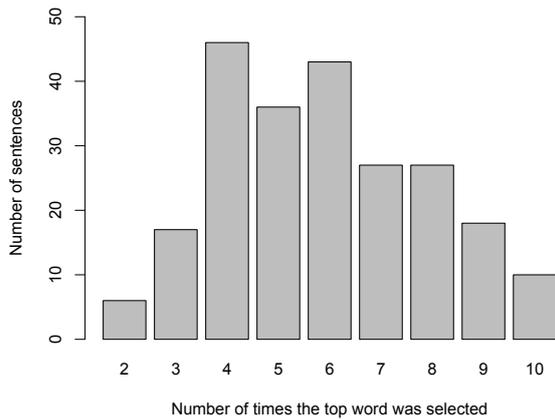

Figure 1: Distribution of the number of turkers who selected the top word (i.e., the word selected by the majority of turkers).

pass the paraphrasing task—there were six such cases. These filters provided us with confidence in the turkers’ answers as a fair standard of comparison.

Overall, humans correctly identified the biased word 30% of the time. For each sentence, we ranked the words according to the number of turkers (out of 10) who selected them and, like we did for the automated system, we assessed performance when considering only the top word (TOP1), the top 2 words (TOP2), and the top 3 words (TOP3). The last row of Table 4 reports the results. Only 37.39% of the majority answers coincided with the gold label, slightly higher than our system’s accuracy. The fact that the human answers are very close to the results of our system reflects the difficulty of the task. Biases in reference works can be very subtle and go unnoticed by humans; automated systems could thus be extremely helpful.

As a measure of inter-rater reliability, we computed pairwise agreement. The turkers agreed 40.73% of the time, compared to the 5.1% chance agreement that would be achieved if raters had randomly selected a word for each sentence. Figure 1 plots the number of times the top word of each sentence was selected. The bulk of the sentences only obtained between four and six answers for the same word.

There is a good amount of overlap (~34%) between the correct answers predicted by our system and those from humans. Much like the automated system, humans also have the hardest time identifying words that are one-sided or controversial to

a specific topic. They also picked *eschew* for (16) instead of *orthodox*. Compared to the system, they do better in detecting bias-inducing intensifiers, and about the same with epistemological bias.

## 5 Related Work

The work in this paper builds upon prior work on subjectivity detection (Wiebe et al., 2004; Lin et al., 2011; Conrad et al., 2012) and stance recognition (Yano et al., 2010; Somasundaran and Wiebe, 2010; Park et al., 2011), but applied to the genre of reference works such as Wikipedia. Unlike the blogs, online debates and opinion pieces which have been the major focus of previous work, bias in reference works is undesirable. As a result, the expression of bias is more implicit, making it harder to detect by both computers and humans. Of the two classes of bias that we uncover, *framing bias* is indeed strongly linked to subjectivity, but *epistemological bias* is not. In this respect, our research is comparable to Greene and Resnik’s (2009) work on identifying *implicit* sentiment or perspective in journalistic texts, based on semantico-syntactic choices.

Given that the data that we use is not supposed to be opinionated, our task consists in detecting (implicit) bias instead of classifying into side A or B documents about a controversial topic like ObamaCare (Conrad et al., 2012) or the Israeli-Palestinian conflict (Lin et al., 2006; Greene and Resnik, 2009). Our model detects whether all the relevant perspectives are fairly represented by identifying statements that are one-sided. To this end, the features based on subjectivity and sentiment lexicons turn out to be helpful, and incorporating more features for stance detection is an important direction for future work.

Other aspects of Wikipedia structure have been used for other NLP applications. The Wikipedia revision history has been used for spelling correction, text summarization (Nelken and Yamangil, 2008), lexical simplification (Yatskar et al., 2010), paraphrasing (Max and Wisniewski, 2010), and textual entailment (Zanzotto and Pennacchiotti, 2010). Ganter and Strube (2009) have used Wikipedia’s weasel-word tags to train a hedge detector. Callahan and Herring (2011) have examined cultural bias based on Wikipedia’s NPOV policy.

## 6 Conclusions

Our study of bias in Wikipedia has implications for linguistic theory and computational linguistics. We show that bias in reference works falls broadly into two classes, framing and epistemological. The cues to framing bias are more explicit and are linked to the literature on subjectivity; cues to epistemological bias are subtle and implicit, linked to presuppositions and entailments in the text. Epistemological bias has not received much attention since it does not play a major role in overtly opinionated texts, the focus of much research on stance recognition. However, our logistic regression model reveals that epistemological and other features can usefully augment the traditional sentiment and subjectivity features for addressing the difficult task of identifying the bias-inducing word in a biased sentence.

Identifying the bias-inducing word is a challenging task even for humans. Our linguistically-informed model performs nearly as well as humans tested on the same task. Given the subtlety of some of these biases, an automated system that highlights one or more potentially biased words would provide a helpful tool for editors of reference works and news reports, not only making them aware of unnoticed biases but also saving them hours of time. Future work could investigate the incorporation of syntactic features or further features from the stance detection literature. Features from the literature on veridicality (de Marneffe et al., 2012) could be informative of the writer’s commitment to the truth of the events described, and document-level features could help assess the extent to which the article provides a balanced account of all the facts and points of view.

Finally, the NPOV data and the bias lexicon that we release as part of this research could prove useful in other bias related tasks.

## Acknowledgments

We greatly appreciate the support of Jean Wu and Christopher Potts in running our task on Amazon Mechanical Turk, and all the Amazon Turkers who participated. We benefited from comments by Valentin Spitkovsky on a previous draft and from the helpful suggestions of the anonymous reviewers. ## Abstract

We present a city navigation and tourist information mobile dialogue app with integrated question-answering (QA) and geographic information system (GIS) modules that helps pedestrian users to navigate in and learn about urban environments. In contrast to existing mobile apps which treat these problems independently, our Android app addresses the problem of navigation and touristic question-answering in an integrated fashion using a shared dialogue context. We evaluated our system in comparison with Samsung S-Voice (which interfaces to Google navigation and Google search) with 17 users and found that users judged our system to be significantly more interesting to interact with and learn from. They also rated our system above Google search (with the Samsung S-Voice interface) for tourist information tasks.

## 1 Introduction

We present a mobile dialogue system (an Android app) called **Spacebook** that addresses the problem of pedestrian navigation and tourist information in urban environments. There has been little prior work that addresses these two problems - navigation and tourist information provision - in an integrated way. By *navigation*, we refer to the problem of finding appropriate destinations to go to and the task of wayfinding to reach them and by *tourist information provision* we refer to the problem of meeting the informational needs of a user about entities such as museums, statues and famous personalities. A dialogue system such as this could serve as a personal tour guide to pedestrian tourists as they walk around unknown cities. With the proliferation of smartphones, there has been a

number of mobile apps developed to address these problems. However these apps have the following problems: first, they demand the user's visual attention because they predominantly present information on a mobile screen. This can be dangerous in urban environments, as well as being distracting. Second, these apps address the problems of navigation and tourist information independently and therefore do not have a shared interaction context. This means that users cannot switch between information and navigation tasks in a natural and fluid manner.

User1: Take me to the National Museum.
System2: The National Museum is about 300m away..
System3: At the KFC, turn left on to South Bridge
<b>System4</b> : Near you is the statue of David Hume.
User2: Who is David Hume.
System5: David Hume was a Scottish philosopher....
User3: Tell me more about David Hume.
System6: He was one of the most important figures in..
System7: You should be able to see <b>the museum</b> ...
User4: Tell me more about <b>the museum</b> .
System8: <b>The National Museum of Scotland</b> is a....

Table 1: An example interaction with the evaluated system

In contrast to many existing mobile apps, Spacebook has a speech-only interface and addresses both problems in an integrated way. We conjecture that with a speech-only interface, users can immerse themselves in exploring the city, and that because of the shared context they can switch between navigation and tourist information tasks more easily. Using the navigational context, Spacebook pushes point-of-interest information which can then initiate tourist information tasks using the QA module. Table 1 presents an example interaction with our system showing the integrated use of navigation and question-answering capabil-

ities. Utterances *System4-8* show the system’s capability to push information about nearby points-of-interest (PoI) during a navigation task and answer followup questions using the QA system (in utterances *User2* and *User3*). The final 3 utterances show a natural switch between navigation to an entity and QA about that entity.

We investigate whether our system using a combination of geographical information system (GIS) and natural language processing (NLP) technologies would be a better companion to pedestrian city explorers than the current state-of-the-art mobile apps. We hypothesize that, (1) users will find our speech-only interface to navigation efficient as it allows them to navigate without having to repeatedly look at a map and (2), that users will find a dialogue interface which integrates touristic question-answering and navigation within a shared context to be useful for finding information about entities in the urban environment. We first present some related work in section 2. We describe the architecture of the system in section 3. We then present our experimental design, results and analysis in sections 5, 6 and 7.

## 2 Related work

Mobile apps such as Siri, Google Maps Navigation, Sygic, etc. address the problem of navigation while apps like Triposo, Guidepal, Wikihood, etc. address the problem of tourist information by presenting the user with descriptive information about various points of interest (PoI) in the city. While some exploratory apps present snippets of information about a precompiled list of PoIs, other apps dynamically generate a list of PoIs arranged based on their proximity to the users. Users can also obtain specific information about PoIs using Search apps. Also, since these navigation and exploratory/search apps do not address both problems in an integrated way, users need to switch between them and therefore lose interaction context.

While most apps address these two problems independently, some like Google Now, Google Field Trip, etc, mix navigation with exploration. But such apps present information primarily visually on the screen for the user to read. Some of these are available for download at the Google Play Android app store<sup>1</sup>. Several dialogue and natural language systems have addressed the issue

<sup>1</sup><https://play.google.com/store>

of pedestrian navigation (Malaka and Zipf, 2000; Raubal and Winter, 2002; Dale et al., 2003; Bartie and Mackaness, 2006; Shroder et al., 2011; Dethlefs and Cuayáhuitl, 2011). There has also been recent interest in shared tasks for generating navigation instructions in indoor and urban environments (Byron et al., 2007; Janarthanam and Lemon, 2011). Some dialogue systems deal with presenting information concerning points of interest (Ko et al., 2005; Kashioka et al., 2011) and interactive question answering (Webb and Webber, 2009).

In contrast, Spacebook has the objective of keeping the user’s cognitive load low and preventing users from being distracted (perhaps dangerously so) from walking in the city (Kray et al., 2003). Also, it allows users to interleave the two sub-tasks seamlessly and can keep entities discussed in both tasks in shared context (as shown in Table 1).

## 3 Architecture

The architecture of the Spacebook system is shown in figure 1. Our architecture brings together Spoken Dialogue Systems (SDS), Geographic Information Systems (GIS) and Question-Answering (QA) technologies (Janarthanam et al., 2012). Its essentially a spoken dialogue system (SDS) consisting of an automatic speech recogniser (ASR), a semantic parser, an Interaction Manager, an utterance generator and a text-to-speech synthesizer (TTS). The GIS modules in this architecture are the City Model, the Visibility Engine, and the Pedestrian tracker. Users communicate with the system using a smartphone-based client app (an Android app) that sends users’ position, pace rate, and spoken utterances to the system, and delivers synthesised system utterances to the user.

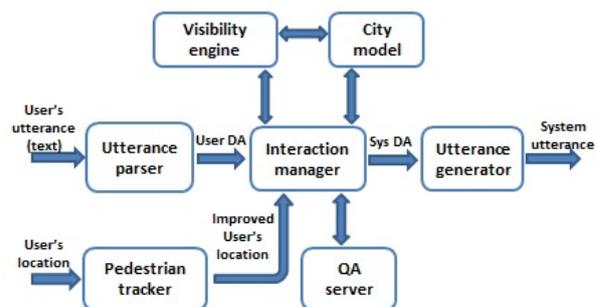

Figure 1: System Architecture

### 3.1 Dialogue interface

The dialogue interface consists of a speech recognition module, an utterance parser, an interaction manager, an utterance generator and a speech synthesizer. The Nuance 9 speech recogniser with a domain specific language model was used for speech recognition. The recognised speech is currently parsed using a rule-based parser into dialogue acts and semantic content.

The Interaction Manager (IM) is the central component of this architecture, which provides the user with navigational instructions, pushes PoI information and manages QA questions. It receives the user's input in the form of a dialogue act (DA), the user's location (latitude and longitude) and pace rate. Based on these inputs and the dialogue context, it responds with system output dialogue act, based on a dialogue policy. The IM initiates the conversation with a calibration phase where the user's initial location and orientation are obtained. The user can then initiate tasks that interest him/her. These tasks include searching for an entity (e.g. a museum or a restaurant), requesting navigation instructions to a destination, asking questions about the entities in the City Model, and so on. When the user is mobile, the IM identifies points of interest<sup>2</sup> on the route proximal to the user. We call this "PoI push". The user is encouraged to ask for more information if he/she is interested. The system also answers adhoc questions from the user (e.g. "Who is David Hume?", "What is the Old College?", etc) (see section 3.4).

Navigation instructions are given in-situ by observing user's position continuously, in relation to the next node (street junction) on the current planned route, and they are given priority if in conflict with a PoI push at the same time. Navigation instructions use landmarks near route nodes whenever possible (e.g. "When you reach Clydesdale Bank, keep walking forward"). The IM also informs when users pass by recognisable landmarks, just to reassure them that they are on track (e.g. "You will pass by Tesco on the right"). In addition to navigation instructions, the IM also answers users' questions concerning the route, his/her location, and location of and distance to the various entities. Finally, the IM uses the city model's Visibility Engine (VE) to determine whether the destination is visible to the user (see section 3.3).

<sup>2</sup>Using high scoring ones when there are many, based on tourist popularity ratings in the City Model.

The shared spatial and dialogue context employs a feature-based representation which is updated every 1 second (for location), and after every dialogue turn. Spatial context such as the user's coordinates, street names, PoIs and landmarks proximal to the user, etc are used by PoI pushing and navigation. The dialogue context maintains the history of landmarks and PoIs pushed, latest entities mentioned, etc to resolve anaphoric references in navigation and QA requests, and to deliver coherent dialogue responses. The IM resolves anaphoric references by keeping a record of entities mentioned in the dialogue context. It also engages in clarification sub-dialogues when the speech recognition confidence scores are low. The IM stores the name and type information for each entity (such as landmark, building, etc) mentioned in navigation instructions and PoI pushes. Subsequent references to these entities using expressions such as "the museum", "the cafe" etc are resolved by searching for the latest entity of the given type. Pronouns are resolved to the last mentioned entity.

The IM also switches between navigation, PoI push, and QA tasks in an intelligent manner by using the shared context to prioritise its utterances from these different tasks. The utterance generator is a Natural Language Generation module that translates the system DA into surface text which is converted into speech using the Cereproc Text-to-Speech Synthesizer using a Scottish female voice. The only changes made were minor adjustments to the pronunciation of certain place names.

### 3.2 Pedestrian tracker

Urban environments can be challenging with limited sky views, and hence limited line of sight to satellites, in deep urban corridors. There is therefore significant uncertainty about the user's true location reported by GNSS sensors on smartphones (Zandbergen and Barbeau, 2011). This module improves on the reported user position by combining smartphone sensor data (e.g. accelerometer) with map matching techniques, to determine the most likely location of the pedestrian (Bartie and Mackaness, 2012).

### 3.3 City Model

The City Model is a spatial database containing information about thousands of entities in the city of Edinburgh (Bartie and Mackaness, 2013). This data has been collected from a variety of exist-

ing resources such as Ordnance Survey, OpenStreetMap, Google Places, and the Gazetteer for Scotland. It includes the location, use class, name, street address, and where relevant other properties such as build date and tourist ratings. The model also includes a pedestrian network (streets, pavements, tracks, steps, open spaces) which is used by an embedded route planner to calculate minimal cost routes, such as the shortest path. The city model also consists of a Visibility Engine that identifies the entities that are in the user's *vista space* (Montello, 1993). To do this it accesses a *digital surface model*, sourced from LiDAR, which is a 2.5D representation of the city including buildings, vegetation, and land surface elevation. The Visibility Engine uses this dataset to offer a number of services, such as determining the line of sight from the observer to nominated points (e.g. which junctions are visible), and determining which entities within the city model are visible. Using these services, the IM determines if the destination is visible or not.

### 3.4 Question-Answering server

The QA server currently answers a range of *definition* and *biographical* questions such as, “Tell me more about the Scottish Parliament”, “Who was David Hume?”, “What is haggis?”, and requests to resume (eg. “Tell me more”). QA is also capable of recognizing out of scope requests, that is, either navigation-related questions that can be answered by computations from the City Model and dealt with elsewhere in the system (“How far away is the Scottish Parliament?”, “How do I get there?”), or exploration queries that cannot be handled yet (“When is the cannon gun fired from the castle?”). Question classification is entirely machine learning-based using the SMO algorithm (Keerthi et al., 1999) trained over 2013 annotated utterances. Once the question has been typed, QA proceeds to focus detection also using machine learning techniques (Mikhailian et al., 2009). Detected foci include possibly anaphoric expressions (“Who was he?”, “Tell me more about the castle”). These expressions are resolved against the dialogue history and geographical context. QA then proceeds to a textual search on texts from the Gazetteer of Scotland (Gittings, 2012) and Wikipedia, and definitions from WordNet glosses. The task is similar to TAC KBP 2013 Entity Linking Track and named en-

tity disambiguation (Cucerzan, 2007). Candidate answers are reranked using a trained confidence score with the top candidate used as the final answer. These are usually long, descriptive answers and are provided as a flow of sentence chunks that the user can interrupt (see table 2). The Interaction Manager queries the QA model and pushes information when a salient PoI is in the vicinity of the user.

<p><i>“Edinburgh’s most famous and historic thoroughfare, which has formed the heart of the Old Town since mediaeval times. The Royal Mile includes Castlehill, the Lawnmarket, the Canongate and the Abbey Strand, but, is officially known simply as the High Street.”</i></p>
--

Table 2: QA output: query on “Royal Mile”

### 3.5 Mobile client

The mobile client app, installed on an Android smartphone (Samsung Galaxy S3), connects the user to the dialogue system using a 3G data connection. The client senses the user’s location using positioning technology using GNSS satellites (GPS and GLONASS) which is sent to the dialogue system at the rate of one update every two seconds. It also sends pace rate of the user from the accelerometer sensor. In parallel, the client also places a phone call using which the user communicates with the dialogue system.

## 4 Baseline system

The baseline system chosen for evaluation was Samsung S-Voice, a state-of-the-art commercial smartphone speech interface. S-Voice is a Samsung Android mobile phone app that allows a user to use the functionalities of device using a speech interface. For example, the user can say “Call John” and it will dial John from the user’s contacts. It launches the Google Navigation app when users request directions and it activates Google Search for open ended touristic information questions. The Navigation app is capable of providing instructions in-situ using speech. We used the S-Voice system for comparison because it provided an integrated state-of-the-art interface to use both a navigation app and also an information-seeking app using the same speech interface. Users were encouraged to use these apps using speech but were allowed to use the GUI interface when using speech wasn’t working (e.g. misrecognition of local names). Users obtained the same kind of in-

formation (i.e. navigation directions, descriptions about entities such as people, places, etc) from the baseline system as they would from our system. However, our system interacted with the user using the speech modality only.

## 5 Experimental design

Spacebook and the baseline were evaluated in the summer of 2012. We evaluated both systems with 17 subjects in the streets of Edinburgh. There were 11 young subjects (between 20 and 26 years, mean=22 ± 2) and 6 older subjects (between 50 and 71 years, mean=61 ± 11). They were mostly native English speakers (88%). 59% of the users were regular smartphone users and their mean overall time spent in the city was 76 months. The test subjects had no previous experience with the proposed system. They were recruited via email adverts and mail shots. Subjects were given a task sheet with 8 tasks in two legs (4 tasks per leg). These tasks included both navigation and tourist information tasks (see table 3). Subjects used our system for one of the legs and the baseline system for the other and the order was balanced. Each leg took up to 30 mins to finish and the total duration including questionnaires was about 1.5 hours. Figure 2 shows the route taken by the subjects. The route is about 1.3 miles long. Subjects were followed by the evaluator who made notes on their behaviour (e.g. subject looks confused, subject looks at or manipulates the phone, subject looks around, etc).

Subjects filled in a demographic questionnaire prior to the experiment. After each leg, they filled in a system questionnaire (see appendix) rating their experience. After the end of the experiment, they filled out a comparative questionnaire and were debriefed. They were optionally asked to elaborate on their questionnaire ratings. Users were paid £20 after the experiment was over.

## 6 Results

Subjects were asked to identify tasks that they thought were successfully completed. The perceived task success rates of the two systems were compared for each task using the Chi square test. The results show that there is no statistically significant difference between the two systems in terms of perceived task success although the baseline system had a better task completion rate in tasks 1-3, 5 and 6. Our system performed better in

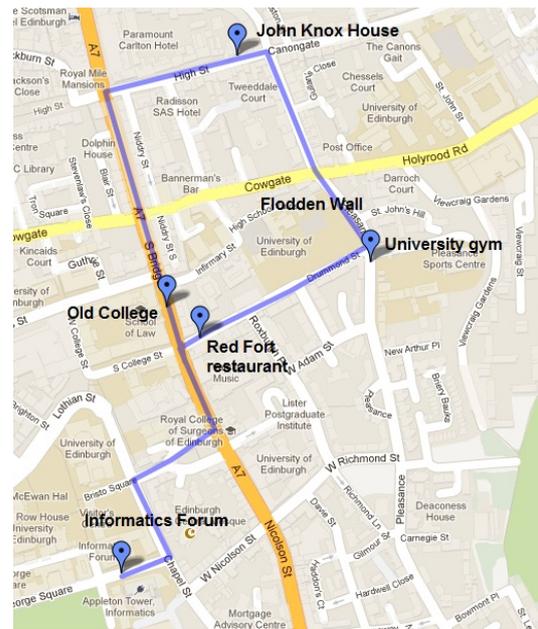

Figure 2: Task route

tourist information tasks (4, 7) (see table 4).

Task	Our system	Baseline	p
T1 (N)	77.7	100	0.5058
T2 (TI)	88.8	100	0.9516
T3 (N)	100	100	NA
T4 (TI)	100	87.5	0.9516
T5 (N+TI)	62.5	100	0.1654
T6 (N+TI)	87.5	100	0.9516
T7 (TI)	100	55.5	0.2926
T8 (N)	75.0	88.8	0.9105

Table 4: % Perceived Task success - task wise comparison (N - navigation task, TI - Tourist Information task)

The system questionnaires that were filled out by users after each leg were analysed. These consisted of questions concerning each system to be rated on a six point Likert scale (1-Strongly Disagree, 2-Disagree, 3-Somewhat Disagree, 4-Somewhat Agree, 5-Agree, 6-Strongly Agree). The responses were paired and tested using a Wilcoxon Sign Rank test. Median and Mode for each system and significance in differences are shown in table 5. Results show that although our system is not performing significantly better than the baseline system (SQ1-SQ10 except SQ7), users seem to find it more understanding (SQ7) and more interesting to interact with (SQ11) than the baseline. We grouped the subjects by age group and tested their responses. We found that the young subjects (age group 20-26), also felt that

<p>Leg 1</p> <p>(Task 1) Ask the system to guide you to the Red Fort restaurant.</p> <p>(Task 2) You've heard that Mary Queen of Scots lived in Edinburgh. they learned something new about the city using it (SQ12) ( $p < 0.05$ ) while the elderly (age group 50-71) didn't. We also found statistically significant differences in smartphone users rating for our system on their learning compared to the baseline (SQ12).

Subjects were also asked to choose between the two systems given a number of requirements such as ease of use, use for navigation, tourist information, etc. There was an option to rank the systems equally (i.e. a tie). They were presented with the same requirements as the system questionnaire with one additional question - "Overall which system do you prefer?" (CQ0). Users' choice of system based on a variety of requirements is shown in table 6. Users' choice counts were tested using Chi-square test. Significant differences were found in users' choice of system for navigation and tourist information requirements. Users preferred the baseline system for navigation (CQ2) and our system for touristic information (CQ3) on the city. Although there was a clear choice of systems based on the two tasks, there was no significant preference of one system over the other overall (CQ0). They chose our system as the most interesting system to interact with (CQ11) and that it was more informative than the baseline (CQ12). Figure 3 shows the relative frequency between user choices on comparative questions. Figure 3 shows the relative frequency between user choices on comparative questions.

## 7 Analysis

Users found it somewhat difficult to navigate using Spacebook (see comments in table 7). Although the perceived task success shows that our system was able to get the users to their destination and there was no significant difference between the two systems based on their questionnaire response on navigation, they pointed out a number of issues and suggested a number of modifications. Many

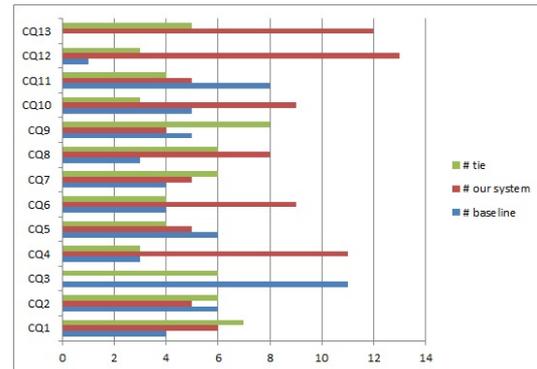

Figure 3: Responses to comparative questions

users noted that a visual map and the directional arrow in the baseline system was helpful for navigation. In addition, they noted that our system's navigation instructions were sometimes not satisfactory. They observed that there weren't enough instructions coming from the system at street junctions. They needed more confirmatory utterances (that they are walking in the right direction) (5 users) and quicker recovery and notification when walking the wrong way (5 users). They observed that the use of street names was confusing sometimes. Some users also wanted a route summary before the navigation instructions are given.

The problem with Spacebook's navigation policy was that it did not, for example, direct the user via easily visible landmarks (e.g. "Head towards the Castle"), and relies too much on street names. Also, due to the latency in receiving GPS information, the IM sometimes did not present instructions soon enough during evaluation. Sometimes it received erroneous GPS information and therefore got the user's orientation wrong. These problems will be addressed in the future version. Some users did find navigation instructions useful because of the use of proximal landmarks such

Table 6: User's choice on comparative questions (CQ are the same questions as SQ but requesting a ranking of the 2 systems)

as KFC, Tesco, etc. (popular chain stores). Some users also suggested that our system should have a map and that routes taken should be plotted on them for reference. Based on the ratings and observations made by the users, we conclude that our first hypothesis that Spacebook would be more efficient for navigation than the baseline because of its speech-only interface was inconclusive. We believe so because users' poor ratings for Spacebook may be due to the current choice of dialogue policy for navigation. It may be possible to reassure the user with a better dialogue policy with just the speech interface. However, this needs further investigation.

Users found the information-search task interesting and informative when they used Spacebook (see sample user comments in table 8). They also found push information on nearby PoIs unexpected and interesting as they would not have found them otherwise. Many users believed that this could be an interesting feature that could help tourists. They also found that asking questions and

finding answers was much easier with Spacebook compared to the baseline system, where sometimes users needed to type search keywords in. Another user observation was that they did not have to stop to listen to information presented by our system (as it was in speech) and could carry on walking. However, with the baseline system, they had to stop to read information off the screen. Although users in general liked the QA feature, many complained that Spacebook spoke too quickly when it was presenting answers. Some users felt that the system might lose context of the navigation task if presented with a PoI question. In contrast, some others noted Spacebook's ability to interleave the two tasks and found it to be an advantage.

Users' enthusiasm for our system was observed when (apart from the points of interest that were in the experimental task list) they also asked spontaneous questions about James Watt, the Talbot Rice gallery, the Scottish Parliament and Edinburgh Castle. Some of the PoIs that the system pushed information about were the Royal College of Surgeons, the Flodden Wall, the Museum of Childhood, and the Scottish Storytelling Centre. Our system answered a mean of 2.5 out of 6.55 questions asked by users in leg 1 and 4.88 out of 8.5 questions in leg 2. Please note that an utterance is sent to QA if it is not parsed by the parser and therefore some utterances may not be legitimate questions themselves. Users were pushed a mean of 2.88 and 6.37 PoIs during legs 1 and 2. There were a total of 17 "tell me more" requests requesting the system to present more information (mean=1.35 ± 1.57).

Evaluators who followed the subjects noted that the subjects felt difficulty using the baseline system as they sometimes struggled to see the screen

1. "It's useful when it says 'Keep walking' but it should say it more often."
2. "[Your system] not having a map, it was sometimes difficult to check how aware it was of my environment."
3. "[Google] seemed to be easier to follow as you have a map as well to help."
4. "It told me I had the bank and Kentucky Fried Chicken so I crossed the road because I knew it'd be somewhere over beside them. I thought 'OK, great. I'm going the right way,' but then it didn't say anything else. I like those kind of directions because when it said to go down Nicolson Street I was looking around trying to find a street sign."
5. "The system keeps saying 'when we come to a junction, I will tell you where to go', but I passed junctions and it didn't say anything. It should say 'when you need to change direction, I will tell you.'"
6. "I had to stop most of the times for the system to be aware of my position. If walking very slowly, its awareness of both landmarks and streets is excellent."

Table 7: Sample user comments on the navigation task

1. "Google doesn't \*offer\* any information. I would have to know what to ask for..."
2. "Since many information is given without being asked for (by your system), one can discover new places and landmarks even if he lives in the city. Great feature!!"
3. "I didn't feel confident to ask [your system] a question and still feel it would remember my directions"
4. "Google could only do one thing at a time, you couldn't find directions for a place whilst learning more."
5. "If she talked a little bit slower [I would use the system for touristic purposes]. She just throws masses of information really, really quickly."

Table 8: Sample user comments on the tourist information task

in bright sunlight. They sometimes had difficulty identifying which way to go based on the route plotted on the map. In comparison, subjects did not have to look at the screen when they used our system. Based on the ratings and observations made by the users about our system's tourist information features such as answering questions and pushing PoI information, we have support for our second hypothesis: that users find a dialogue interface which integrates question-answering and navigation within a shared context to be useful for finding information about entities in the urban environment.

## 8 Future plans

We plan to extend Spacebook's capabilities to address other challenges in pedestrian navigation and tourist information. Many studies have shown that visible landmarks provide better cues for navigation than street names (Ashweeni and Steed, 2006; Hiley et al., 2008). We will use visible landmarks identified using the visibility engine to make navigation instructions more effective, and we plan to include entities in dialogue and visual context as candidates for PoI push, and to implement an adaptive strategy that will estimate user interests and push information that is of interest to them. We are also taking advantage of user's local knowledge of the city to present navigation instructions only for the part of the route that the user does not have any knowledge of. These features, we believe, will make users' experience of

the interface more pleasant, useful and informative.

## 9 Conclusion

We presented a mobile dialogue app called Spacebook to support pedestrian users in navigation and tourist information gathering in urban environments. The system is a speech-only interface and addresses navigation and tourist information in an integrated way, using a shared dialogue context. For example, using the navigational context, Spacebook can push point-of-interest information which can then initiate touristic exploration tasks using the QA module.

We evaluated the system against a state-of-the-art baseline (Samsung S-Voice with Google Navigation and Search) with a group of 17 users in the streets of Edinburgh. We found that users found Spacebook interesting to interact with, and that it was their system of choice for touristic information exploration tasks. These results were statistically significant. Based on observations and user ratings, we conclude that our speech-only system was less preferred for navigation and more preferred for tourist information tasks due to features such as PoI pushing and the integrated QA module, when compared to the baseline system. Younger users, who used Spacebook, even felt that they learned new facts about the city.

## Abstract

Procedural dialog systems can help users achieve a wide range of goals. However, such systems are challenging to build, currently requiring manual engineering of substantial domain-specific task knowledge and dialog management strategies. In this paper, we demonstrate that it is possible to learn procedural dialog systems given only light supervision, of the type that can be provided by non-experts. We consider domains where the required task knowledge exists in textual form (*e.g.*, instructional web pages) and where system builders have access to statements of user intent (*e.g.*, search query logs or dialog interactions). To learn from such textual resources, we describe a novel approach that first automatically extracts task knowledge from instructions, then learns a dialog manager over this task knowledge to provide assistance. Evaluation in a Microsoft Office domain shows that the individual components are highly accurate and can be integrated into a dialog system that provides effective help to users.

## 1 Introduction

Procedural dialog systems aim to assist users with a wide range of goals. For example, they can guide visitors through a museum (Traum et al., 2012; Aggarwal et al., 2012), teach students physics (Steinhauser et al., 2011; Dzikovska et al., 2011), or enable interaction with a health care

U: "I want to add page numbers and a title"
S: "Top or Bottom of the page?"
U: "Top"
S: "Please select page design from the templates" (*System shows drop down menu*)
U: *User selects from menu*
S: "Enter header or footer content"
U: "C.V."
S: "Task completed."

Figure 1: An example dialog interaction between a system (S) and user (U) that can be automatically achieved by learning from instructional web page and query click logs.

system (Morbini et al., 2012; Rizzo et al., 2011). However, such systems are challenging to build, currently requiring expensive, expert engineering of significant domain-specific task knowledge and dialog management strategies.

In this paper, we present a new approach for learning procedural dialog systems from task-oriented textual resources in combination with light, non-expert supervision. Specifically, we assume access to task knowledge in textual form (*e.g.*, instructional web pages) and examples of user intent statements (*e.g.*, search query logs or dialog interactions). Such instructional resources are available in many domains, ranging from recipes that describe how to cook meals to software help web pages that describe how to achieve goals by interacting with a user interface.<sup>1</sup>

<sup>1</sup>ehow.com, wikianswers.com

There are two key challenges: we must (1) learn to convert the textual knowledge into a usable form and (2) learn a dialog manager that provides robust assistance given such knowledge. For example, Figure 1 shows the type of task assistance that we are targeting in the Microsoft Office setting, where the system should learn from web pages and search query logs. Our central contribution is to show that such systems can be built without the help of knowledge engineers or domain experts. We present new approaches for both of our core problems. First, we introduce a method for learning to map instructions to tree representations of the procedures they describe. Nodes in the tree represent points of interaction with the questions the system can ask the user, while edges represent user responses. Next, we present an approach that uses example user intent statements to simulate dialog interactions, and learns how to best map user utterances to nodes in these induced dialog trees. When combined, these approaches produce a complete dialog system that can engage in conversations by automatically moving between the nodes of a large collection of induced dialog trees.

Experiments in the Windows Office help domain demonstrate that it is possible to build an effective end-to-end dialog system. We evaluate the dialog tree construction and dialog management components in isolation, demonstrating high accuracy (in the 80-90% range). We also conduct a small-scale user study which demonstrates that users can interact productively with the system, successfully completing over 80% of their tasks. Even when the system does fail, it often does so in a graceful way, for example by asking redundant questions but still reaching the goal within a few additional turns.

## 2 Overview of Approach

Our task-oriented dialog system understands user utterances by mapping them to nodes in dialog trees generated from instructional text. Figure 2 shows an example of a set of instructions and the corresponding dialog tree. This section describes the problems that we must solve to enable such interactions, and outlines our approach for each.

**Knowledge Acquisition** We extract task knowledge from instructional text (*e.g.*, Figure 2, left) that describes (1) actions to be performed, such as clicking a button, and (2) places where input is needed from the user, for example to enter the

contents of the footer or header they are trying to create. We aim to convert this text into a form that will enable a dialog system to automatically assist with the described task. To this end, we construct *dialog trees* (*e.g.*, Figure 2, right) with nodes to represent entire documents (labeled as topics  $t$ ), nodes to represent user goals or intents ( $g$ ), and system action nodes ( $a$ ) that enable execution of specific commands. Finally, each node has an associated system action  $a_s$ , which can prompt user input (*e.g.*, with the question “Top or bottom of the page?”) and one or more user actions  $a_u$  that represent possible responses. All nodes connect to form a tree structure that follows the workflow described in the document. Section 3 presents a scalable approach for inducing dialog trees.

**Dialog Management** To understand user intent and provide task assistance, we need a dialog management approach that specifies what the system should do and say. We adopt a simple approach that at all times maintains an index into a node in a dialog tree. Each system utterance is then simply the action  $a_s$  for that node. However, the key challenge comes in interpreting user utterances. After each user statement, we must automatically update our node index. At any point, the user can state a general goal (*e.g.*, “I want to add page numbers”), refine their goal (*e.g.*, “in a footer”), or both (*e.g.*, “I want to add page numbers in the footer”). Users can also change their goals in the process of completing the tasks.

We develop a simple classification approach that is robust to these different types of user behavior. Specifically, we learn classifiers that, given the dialog interaction history, predict how to pick the next tree node from the space of all nodes in the dialog trees that define the task knowledge. We isolate two specific cases, classifying initial user utterances (Section 4) and classifying all subsequent utterances (Section 5). This approach allows us to isolate the difference in language for the two cases, and bias the second case to prefer tree nodes near the current one. The resulting approach allows for significant flexibility in traversing the dialog trees.

**Data and Evaluation** We collected a large set of such naturally-occurring web search queries that resulted in a user click on a URL in the Microsoft Office help domain.<sup>2</sup> We found that queries longer than 4-5 words often resembled natural language utterances that could be used for dialog interac-

<sup>2</sup><http://office.microsoft.com>

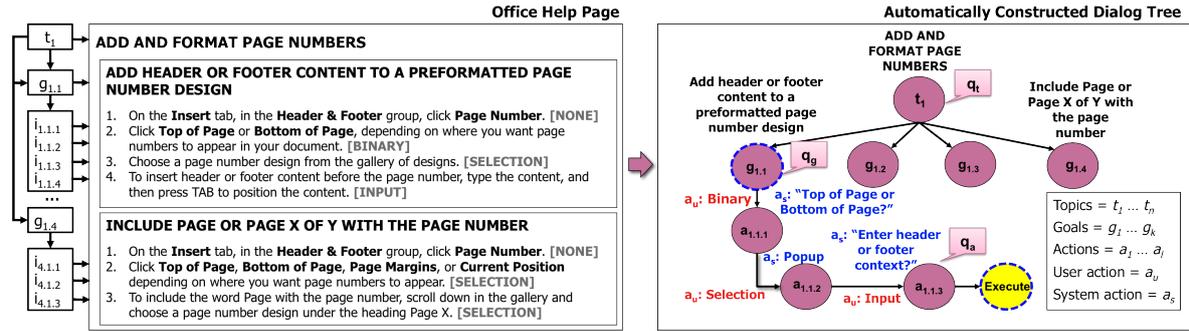

Figure 2: An example instructional text paired with a section of the corresponding dialog tree.

tions, for example *how do you add borders*, *how can I add a footer*, *how to insert continuous page numbers*, and *where is the header and footer*.

We also collected instructional texts from the web pages that describe how to solve 76 of the most pressing user goals, as indicated by query click log statistics. On average 1,000 user queries were associated with each goal. To some extent clickthroughs can be treated as a proxy for user frustration; popular search targets probably represent user pain points.

### 3 Building Dialog Trees from Instructions

Our first problem is to convert sets of instructions for user goals to dialog trees, as shown in Figure 2. These goals are broadly grouped into topics (instructional pages). In addition, we manually associate each node in a dialog tree with a training set of 10 queries. For the 76 goals (246 instructions) in our data, this annotation effort took a single annotator a total of 41 hours. Scaling this approach to the entire Office help domain would require a focused annotation effort. Crucially, though, this annotation work can be carried out by non-specialists, and could even be crowdsourced (Bernstein et al., 2010).

**Problem Definition** As input, we are given instructional text ( $p_1 \dots p_n$ ), comprised of topics ( $t_1 \dots t_n$ ) describing:

- (1) high-level user intents (e.g.,  $t_1$  – “add and format page numbers”)
- (2) goals ( $g_1, \dots, g_k$ ) that represent more specific user intents (e.g.,  $g_1$  – “add header or footer content to a preformatted page number design”,  $g_2$  – “place the page number in the side margin of the page”).

Given instructional text  $p_1 \dots p_n$  and queries  $q_1 \dots q_m$  per topic  $t_i$ , our goals are as follows:

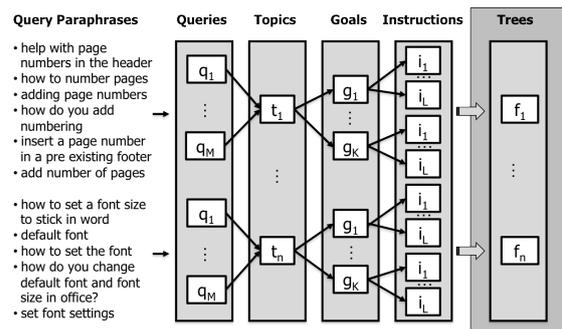

Figure 3: Relationships between user queries and OHP with goals, instructions and dialog trees.

- for every instructional page  $p_i$  extract a topic  $t_i$  and a set of goals  $g_1 \dots g_k$ ;
- for every goal  $g_j$  for a topic  $t_i$ , extract a set of instructions  $i_1 \dots i_l$ ;
- from topics, goals and instructions, construct dialog trees  $f_1 \dots f_n$  (one dialog tree per topic). Classify instructions to user interaction types thereby identifying system action nodes  $a_s^1 \dots a_s^l$ . Transitions between these nodes are the user actions  $a_u^1 \dots a_u^l$ .

Figure 2 (left) presents an example of a topic extracted from the help page, and a set of goals and instructions annotated with user action types.

In the next few sections of the paper, we outline an overall system component design demonstrating how queries and topics are mapped to the dialog trees in Figure 3. The figure shows *many-to-one* relations between queries and topics, *one-to-many* relations between topics and goals, goals and instructions, and *one-to-one* relations between topics and dialog trees.

**User Action Classification** We aim to classify instructional text ( $i_1 \dots i_l$ ) for every goal  $g_j$  in the decision tree into four categories: *binary*, *selection*, *input* or *none*.

Given a single instruction  $i$  with category  $a_u$ , we use a log-linear model to represent the distri-

bution over the space of possible user actions. Under this representation, the user action distribution is defined as:

$$p(a_u|i, \theta) = \frac{e^{\theta \cdot \phi(a_u, i)}}{\sum_{a'_u} e^{\theta \cdot \phi(a'_u, i)}}, \quad (1)$$

where  $\phi(a_u, i) \in \mathbb{R}^n$  is an  $n$ -dimensional feature representation and  $\vec{\theta}$  is a parameter vector we aim to learn. Features are indicator functions of properties of the instructions and a particular class. For smoothing we use a zero mean, unit variance Gaussian prior  $(0, 1)$  that penalizes  $\vec{\theta}$  for drifting too far from the mean, along with the following optimization function:

$$\begin{aligned} \log p(A_u, \theta|I) &= \log p(A_u|I, \theta) - \log p(\theta) = \\ &= \sum_{a_u, i \in (A_u, I)} p(a_u|i, \theta) - \sum_i \frac{(\theta - \mu_i)^2}{2\sigma_i^2} + k \end{aligned} \quad (2)$$

We use L-BFGS (Nocedal and Wright, 2000) as an optimizer.

**Experimental Setup** As described in Section 2, our dataset consists of 76 goals grouped into 30 topics (average 2-3 goals per topic) for a total of 246 instructions (average 3 instructions per goal). We manually label all instructions with user action  $a_u$  categories. The distribution over categories is *binary=14*, *input=23*, *selection=80* and *none=129*. The data is skewed towards the categories *none* and *selection*. Many instruction do not require any user input and can be done automatically, e.g., “On the Insert tab, in the Header and Footer group, click Page Number”. The example instructions with corresponding user action labels are shown in Figure 2 (left). Finally, we divide the 246 instructions into 2 sets: 80% training and 20% test, 199 and 47 instructions respectively.

**Results** We apply the user action type classification model described in the Eq.1 and Eq.2 to classify instructions from the test set into 4 categories. In Table 1 we report classification results for 2 baselines: a majority class and heuristic-based approach, and 2 models with different feature types: *ngrams* and *ngrams + stems*. For a heuristic baseline, we use simple lexical clues to classify instructions (e.g., *X or Y* for *binary*, *select Y* for *selection* and *type X, insert Y* for *input*). Table 1 summarizes the results of mapping instructional text to user actions.

Features	# Features	Accuracy
Baseline 1: Majority	–	0.53
Baseline 2: Heuristic	–	0.64
Ngrams	10,556	0.89
Ngrams + Stems	12,196	0.89

Table 1: Instruction classification results.

**Building the Dialog Trees** Based on the classified user action types, we identify system actions  $a_s^1 \dots a_s^l$  which correspond to 3 types of user actions  $a_s^1 \dots a_s^l$  (excluding *none* type) for every goal in a topic  $t_i$ . This involved associating all words from an instruction  $i_l$  with a system action  $a_s^l$ . Finally, for every topic we automatically construct a dialog tree as shown in Figure 2 (right). The dialog tree includes a topic  $t_1$  with goals  $g_1 \dots g_4$ , and actions (user actions  $a_u$  and system actions  $a_s$ ).

**Definition 1.** A dialog tree encodes a user-system dialog flow about a topic  $t_i$  represented as a directed unweighted graph  $f_i = (V, E)$  where topics, goals and actions are nodes of corresponding types  $\{t_1 \dots t_n\}, \{g_1 \dots g_k\}, \{a_1 \dots a_l\} \in V$ . There is a hierarchical dependency between topic, goal and action nodes. User interactions are represented by edges  $t_i \rightarrow \{g_1 \dots g_k\}, a_u^1 = (g_j, a_1) \dots a_u^l = (a_{k-1}, a_k) \in E$ .

For example, in the dialog tree in Figure 2 there is a relation  $t_1 \rightarrow g_4$  between the topic  $t_1$  “add and format page numbers” and the goal  $g_4$  “include page of page X of Y with the page number”. Moreover, in the dialog tree, the topic level node has one index  $i \in [1..n]$ , where  $n$  is the number of topics. Every goal node includes information about its parent (topic) node and has double index  $i.j$ , where  $j \in [1..k]$ . Finally, action nodes include information about their parent (goal) and grandparent (topic) nodes and have triple index  $i.j.z$ , where  $z \in [1..l]$ .

## 4 Understanding Initial Queries

This section presents a model for classifying initial user queries to nodes in a dialog tree, which allows for a variety of different types of queries. They can be under-specified, including information about a topic only (e.g., “add or delete page numbers”); partially specified, including information about a goal (e.g., “insert page number”); or over-specified, including information about an action (e.g., “page numbering at bottom page”).

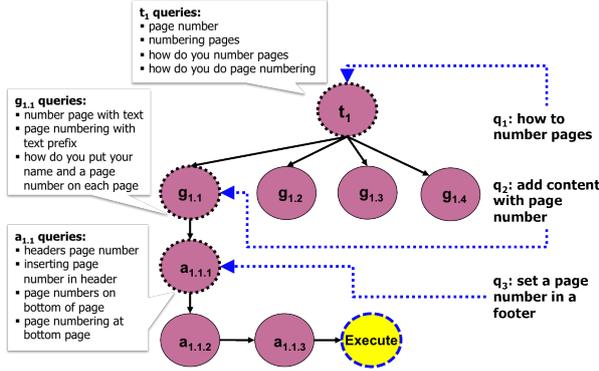

Figure 4: Mapping initial user queries to the nodes on different depth in a dialog tree.

**Problem Definition** Given an initial query, the dialog system initializes to a state  $s_0$ , searches for the deepest relevant node given a query, and maps the query to a node on a topic  $t_i$ , goal  $g_j$  or action  $a_k$  level in the dialog tree  $f_i$ , as shown in Figure 4.

More formally, as input, we are given automatically constructed dialog trees  $f_1 \dots f_n$  for instructional text (help pages) annotated with topic, goal and action nodes and associated with system actions as shown in Figure 2 (right). From the query logs, we associate queries with each node type: topic  $q_t$ , goal  $q_g$  and action  $q_a$ . This is shown in Figure 2 and 4. We join these dialog trees representing different topics into a *dialog network* by introducing a global root. Within the network, we aim to find (1) an initial dialog state  $s_0$  that maximizes the probability of state given a query  $p(s_0|q, \theta)$ ; and (2) the deepest relevant node  $v \in V$  on topic  $t_i$ , goal  $g_j$  or action  $a_k$  depth in the tree.

**Initial Dialog State Model** We aim to predict the best node in a dialog tree  $t_i, g_j, a_l \in V$  based on a user query  $q$ . A query-to-node mapping is encoded as an initial dialog state  $s_0$  represented by a binary vector over all nodes in the dialog network:

$$s_0 = [t_1, g_{1.1}, g_{1.2}, g_{1.2.1} \dots, t_n, g_{n.1}, g_{n.1.1}].$$

We employ a log-linear model and try to maximize initial dialog state distribution over the space of all nodes in a dialog network:

$$p(s_0|q, \theta) = \frac{e^{\sum_i \theta_i \phi_i(s_0, q)}}{\sum_{s'_0} e^{\sum_i \theta_i \phi_i(s'_0, q)}}, \quad (3)$$

Optimization follows Eq. 2.

We experimented with a variety of features. Lexical features included query *ngrams* (up to 3-grams) associated with every node in a dialog tree with removed stopwords and stemming query unigrams. We also used network structural features:

Features	Accuracy		
	Topic	Goal	Action
Random	0.10	0.04	0.04
TFIDF 1Best	0.81	0.21	0.45
Lexical (L)	0.92	0.66	0.63
L + 10TFIDF	0.94	0.66	0.64
L + 10TFIDF + PO	0.94	0.65	0.65
L + 10TFIDF + QO	0.95	0.72	0.69
All above + QHistO	0.96	0.73	0.71

Table 2: Initial dialog state classification results where L stands for lexical features, 10TFIDF - 10 best tf-idf scores, PO - prompt overlap, QO - query overlap, and QHistO - query history overlap.

tf-idf scores, query *ngram* overlap with the topic and goal descriptions, as well as system action prompts, and query *ngram* overlap with a history including queries from parent nodes.

**Experimental Setup** For each dialog tree, nodes corresponding to single instructions were hand-annotated with a small set of user queries, as described in Section 3. Approximately 60% of all action nodes have no associated queries<sup>3</sup> For the 76 goals, the resulting dataset consists of 972 node-query pairs, 80% training and 20% test.

**Results** The initial dialog state classification model of finding a single node given an initial query is described in Eq. 3.

We chose two simple baselines: (1) randomly select a node in a dialog network and (2) use a tf-idf 1-best model.<sup>4</sup> Stemming, stopword removal and including top 10 tf-idf results as features led to a 19% increase in accuracy on an action node level over baseline (2). Adding the following features led to an overall 26% improvement: query overlap with a system prompt (PO), query overlap with other node queries (QO), and query overlap with its parent queries (QHistO).

We present more detailed results for topic, goal and action nodes in Table 2. For nodes deeper in the network, the task of mapping a user query to an action becomes more challenging. Note, however, that the action node accuracy numbers actually un-

<sup>3</sup>There are multiple possible reasons for this: the software user interface may already make it clear how to accomplish this intent, the user may not understand that the software makes this fine-grained option available to them, or their experience with search engines may lead them to state their intent in a more coarse-grained way.

<sup>4</sup>We use cosine similarity to rank all nodes in a dialog network and select the node with the highest rank.

derstate the utility of the resulting dialog system. The reason is that even incorrect node assignments can lead to useful system performance. As long as a misclassification results being assigned to a too-high node within the correct dialog tree, the user will experience a graceful failure: they may be forced to answer some redundant questions, but they will still be able to accomplish the task.

## 5 Understanding Query Refinements

We also developed a classifier model for mapping followup queries to the nodes in a dialog network, while maintaining a dialog state that summarizes the history of the current interaction.

**Problem Definition** Similar to the problem definition in Section 4, we are given a network of dialog trees  $f_1 \dots f_n$  and a query  $q'$ , but in addition we are given the previous dialog state  $s$ , which contains the previous user utterance  $q$  and the last system action  $a_s$ . We aim to find a new dialog state  $s'$  that pairs a node from the dialog tree with updated history information, thereby undergoing a dialog state update.

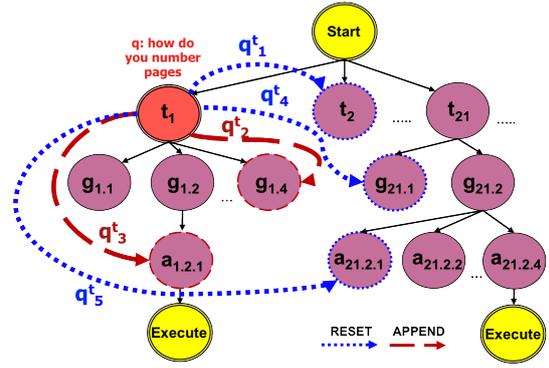

We learn a linear classifier that models  $p(s'|q', q, a_s, \theta)$ , the dialog state update distribution, where we constrain the new state  $s'$  to contain the new utterance  $q'$  we are interpreting. This distribution models 3 transition types: *append*, *override* and *reset*.

**Definition 2.** An *append* action defines a dialog state update when transitioning from a node to its children at any depth in the same dialog tree e.g.,  $t_i \rightarrow g_{i,j}$  (from a topic to a goal node),  $g_{i,j} \rightarrow a_{i,j,z}$  (from a goal to an action node) etc.

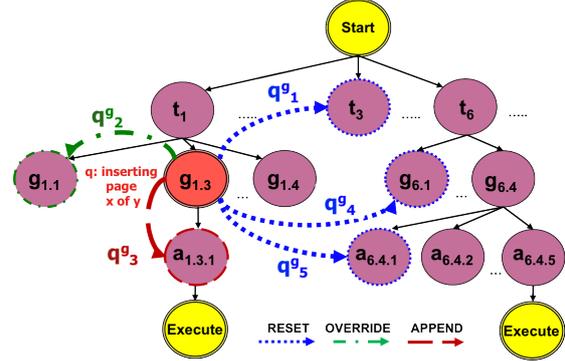

**Definition 3.** An *override* action defines a dialog state update when transitioning from a goal to its sibling node. It could also be from an action node<sup>5</sup> to another in its parent sibling node in the same dialog tree e.g.,  $g_{i,j-1} \rightarrow g_{i,j}$  (from one goal to another goal in the same topic tree),  $a_{i,j,z} \rightarrow a_{i,-j,z}$  (from an action node to another action node in a different goal in the same dialog tree) etc.

**Definition 4.** A *reset* action defines a dialog state update when transitioning from a node in a current dialog tree to any other node at any depth in a dialog tree other than the current dialog tree e.g.,  $t_i \rightarrow t_{-i}$ , (from one topic node to another topic

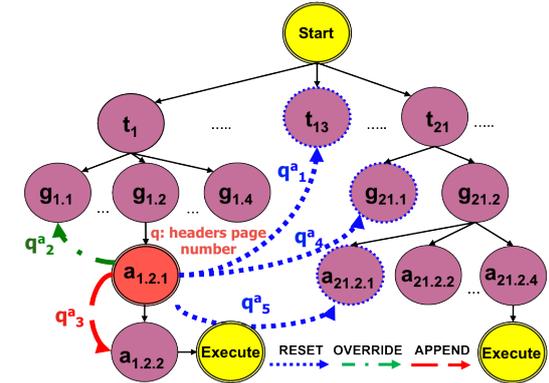

<sup>5</sup>A transition from  $a_{i,j,z}$  must be to a different goal or an action node in a different goal but in the same dialog tree.

(a) Updates from topic node  $t_i$

(b) Updates from goal node  $g_j$

(c) Updates from action node  $a_i$

Figure 5: Information state updates: append, reset and override updates based on Definition 2, 3 and 4, respectively, from topic, goal and action nodes.

node)  $t_i \rightarrow g_{-i,j}$  (from a topic node to a goal node in a different topic subtree), etc.

The *append* action should be selected when the user’s intent is to clarify a previous query (e.g., “insert page numbers”  $\rightarrow$  “page numbers in the footer”). An *override* action is appropriate when the user’s intent is to change a goal within the same topic (e.g., “insert page number  $\rightarrow$  “change page number”). Finally, a *reset* action should be used when the user’s intent is to restart the dialog (e.g., “insert page x of y”  $\rightarrow$  “set default font”). We present more examples for *append*, *override* and *reset* dialog state update actions in Table 3.

Previous Utterance, $q$	User Utterance, $q'$	Transition	Update Action, $a$
inserting page numbers	$q_1^t$ add a background	$t_i \rightarrow t_{-i}$	2, reset-T, reset
how to number pages	$q_2^t$ insert numbers on pages in margin	$t_i \rightarrow s_{i,j}$	1.4, append-G, append
page numbers	$q_3^t$ set a page number in a footer	$t_i \rightarrow a_{i,j,z}$	1.2.1, append-A, append
page number a document	$q_4^t$ insert a comment	$t_i \rightarrow g_{-i,j}$	21.1, reset-G, reset
page number	$q_5^t$ add a comment "redo"	$t_i \rightarrow a_{-i,j,z}$	21.2.1, reset-A, reset
page x of y	$q_1^g$ add a border	$g_{i,j} \rightarrow t_{-i}$	6, reset-T, reset
format page x of x	$q_2^g$ enter text and page numbers	$g_{i,j} \rightarrow g_{i,-j}$	1.1, override-G, override
enter page x of y	$q_3^g$ page x of y in footer	$g_{i,j} \rightarrow a_{i,j,z}$	1.3.1, append-A, append
inserting page x of y	$q_4^g$ setting a default font	$g_{i,j} \rightarrow g_{-i,j}$	6.1, reset-G, reset
showing page x of x	$q_5^g$ set default font and style	$g_{i,j} \rightarrow a_{-i,j,z}$	6.4.1, reset-A, reset
page numbers bottom	$q_1^a$ make a degree symbol	$a_{i,j,z} \rightarrow t_{-i}$	13, reset-T, reset
numbering at bottom page	$q_2^a$ insert page numbers	$a_{i,j,z} \rightarrow g_{i,-j}$	1.1, override-G, override
insert footer page numbers	$q_3^a$ page number design	$a_{i,j,z-1} \rightarrow a_{i,j,z}$	1.2.2, append-A, append
headers page number	$q_4^a$ comments in document	$a_{i,j,z} \rightarrow g_{-i,j}$	21.1, reset-G, reset
page number in a footer	$q_5^a$ changing initials in a comment	$a_{i,j,z} \rightarrow a_{-i,j,z}$	21.2.1, reset-A, reset

Table 3: Example  $q$  and  $q'$  queries for append, override and reset dialog state updates.

Figure 5 illustrates examples of *append*, *override* and *reset* dialog state updates. All transitions presented in Figure 5 are aligned with the example  $q$  and  $q'$  queries in Table 3.

**Dialog State Update Model** We use a log-linear model to maximize a dialog state distribution over the space of all nodes in a dialog network:

$$p(s'|q', q, a_s, \theta) = \frac{e^{\sum_i \theta_i \phi_i(s', q', a_s, q)}}{\sum_{s''} e^{\sum_i \theta_i \phi_i(s'', q', a_s, q)}}, \quad (4)$$

Optimization is done as described in Section 3.

**Experimental Setup** Ideally, dialog systems should be evaluated relative to large volumes of real user interaction data. Our query log data, however, does not include dialog turns, and so we turn to simulated user behavior to test our system.

Our approach, inspired by recent work (Schatzmann et al., 2006; Scheffler and Young, 2002; Georgila et al., 2005), involves simulating dialog turns as follows. To define a state  $s$  we sample a query  $q$  from a set of queries per node  $v$  and get a corresponding system action  $a_s$  for this node; to define a state  $s'$ , we sample a new query  $q'$  from another node  $v' \in V, v \neq v'$  which is sampled using a prior probability biased towards *append*:  $p(\text{append})=0.7$ ,  $p(\text{override})=0.2$ ,  $p(\text{reset})=0.1$ . This prior distribution defines a dialog strategy where the user primarily continues the current goal and rarely resets.

We simulate 1100 previous state and new query pairs for training and 440 pairs for testing. The features were lexical, including word ngrams, stems with no stopwords; we also tested network structure, such as:

- old  $q$  and new  $q'$  query overlap (QO);
- $q'$  overlap with a system prompt  $a_s$  (PO);

- $q'$  ngram overlap with all queries from the old state  $s$  (SQO);
- $q'$  ngram overlap with all queries from the new state  $s'$  (S'QO);
- $q'$  ngram overlap with all queries from the new state parents (S'ParQO).

**Results** Table 4 reports results for dialog state updates for topic, goal and action nodes. We also report performance for two types of dialog updates such as: *append* (App.) and *override* (Over.).

We found that the combination of lexical and query overlap with the previous and new state queries yielded the best accuracies: 0.95, 0.84 and 0.83 for topic, goal and action node level, respectively. As in Section 4, the accuracy on the topic level node was highest. Perhaps surprisingly, the reset action was perfectly predicted (accuracy is 100% for all feature combinations, not included in figure). The accuracies for *append* and *override* actions are also high (*append* 95%, *override* 90%).

Features	Topic	Goal	Action	App.	Over.
L	0.92	0.76	0.78	0.90	0.89
L+Q	0.93	0.80	0.80	0.92	0.83
L+P	0.93	0.80	0.79	0.91	0.85
L+Q+P	0.94	0.80	0.80	0.93	0.85
L+SQ	0.94	0.82	0.81	0.93	0.85
L+S'Q	0.93	0.80	0.80	0.91	<b>0.90</b>
L+S'+ParQ	0.94	0.80	0.80	0.91	0.86
L+Q+S'Q	0.94	0.81	0.81	0.91	0.88
L+SQ+S'Q	<b>0.95</b>	<b>0.84</b>	<b>0.83</b>	<b>0.94</b>	0.88

## 6 The Complete Dialog System

Following the overall setup described in Section 2, we integrate the learned models into a complete dialog system. To evaluate the quality of the interactions with this system, we performed a small scale user study, as described here.

**Experimental Setup** We randomly chose 8 goals, across topics, from the 76 used to train our models. For each goal, six users were shown a Microsoft Word document before and after the goal was executed. Users were allowed to interact with the system in an unconstrained manner providing a total of 48 interactions. If at any point they thought the system response was irrelevant to their intent, they could either rephrase or start over.

**User Study** We objectively measured task completion and the quality of individual system utterances. We also asked the users to rate the system (on a scale of 1-5, with 5 being best) on various measures, including whether the system asked relevant questions. Table 5 summarizes the results. In general, users were able to complete the tasks and were reasonably satisfied.

**Discussion** Figure 6 shows four example dialogs. User utterances ranged from single keywords to rich, sentence-like goal descriptions. For the shorter inputs, the system was generally able to identify a small cohort of high-probability intents. For longer inputs, especially with explicitly specified parameter settings, the system was usually able to elicit whatever additional information was required to complete the task. The majority of errors fell into two categories when the system:

- I. missed key information in the input and asked redundant questions – Figure 6 (C);
- II. failed to correctly identify the intent, and asked an irrelevant question – Figure 6 (D).

Table 5 shows the frequency of each error type.

Objective Measures	Observed Rates	
User achieved task	83%	
System asked irrelevant questions	19%	
System asked redundant questions	18%	
User Satisfaction	Score	Std.Dev.
Overall satisfaction	3.42	0.49
Questions were relevant	4.17	0.41
Ambiguity was managed	4.00	0.89

## 7 Related work

To the best of our knowledge, this paper presents the first effort to induce full procedural dialog systems from instructional text and query click logs.

**Grounded Language Learning** There has been significant interest in grounded language learning. Perhaps the most closely related work learns to understand instructions and automati-

cally complete the tasks they describe (Branavan et al., 2009; Vogel and Jurafsky, 2010; Kushman et al., 2009; Branavan et al., 2010; Artzi and Zettlemoyer, 2013). However, these approaches did not model user interaction. There are also many related approaches for other grounded language problems, including understanding game strategy guides (Branavan et al., 2011), modeling users goals in a Windows domain (Horvitz et al., 1998), learning from conversational interaction (Artzi and Zettlemoyer, 2011), learning to sportscast (Chen and Mooney, 2011), learning from event streams (Liang et al., 2009), and learning paraphrases from crowdsourced captions of video snippets (Chen and Dolan, 2011).

**Dialog Generation from Text** Similarly to Piwek’s work (2007; 2010; 2011), we study extracting dialog knowledge from documents (monologues or instructions). However, Piwek’s approach generates static dialogs, for example to generate animations of virtual characters having a conversation. There is no model of dialog management or user interaction, and the approach does not use any machine learning. In contrast, to the best of our knowledge, we are the first to demonstrate it is possible to learn complete, interactive dialog systems using instructional texts (and non-expert annotation).

**Learning from Web Query Logs** Web query logs have been extensively studied. For example, they are widely used to represent user intents in spoken language dialogs (Tür et al., 2011; Celikyilmaz et al., 2011; Celikyilmaz and Hakkani-Tur, 2012). Web query logs are also used in many other NLP tasks, including entity linking (Pantel et al., 2012) and training product and job intent classifiers (Li et al., 2008).

**Dialog Modeling and User Simulation** Many existing dialog systems learn dialog strategies from user interactions (Young, 2010; Rieser and Lemon, 2008). Moreover, dialog data is often limited and, therefore, user simulation is commonly used (Scheffler and Young, 2002; Schatzmann et al., 2006; Georgila et al., 2005).

Our overall approach is also related to many other dialog management approaches, including those that construct dialog graphs from dialog data via clustering (Lee et al., 2009), learn information state updates using discriminative classification models (Hakkani-Tur et al., 2012; Mairesse et al.,

2009), optimize dialog strategy using reinforcement learning (RL) (Scheffler and Young, 2002; Rieser and Lemon, 2008), or combine RL with information state update rules (Heeman, 2007). However, our approach is unique in the use of inducing task and domain knowledge with light supervision to assist the user with many goals.

## 8 Conclusions and Future Work

This paper presented a novel approach for automatically constructing procedural dialog systems with light supervision, given only textual resources such as instructional text and search query click logs. Evaluations demonstrated highly accurate performance, on automatic benchmarks and through a user study.

Although we showed it is possible to build complete systems, more work will be required to scale the approach to new domains, scale the complexity of the dialog manager, and explore the range of possible textual knowledge sources that could be incorporated. We are particularly interested in scenarios that would enable end users to author new goals by writing procedural instructions in natural language.

## Acknowledgments

## Abstract

Social media platforms have enabled people to freely express their views and discuss issues of interest with others. While it is important to discover the topics in discussions, it is equally useful to mine the nature of such discussions or debates and the behavior of the participants. There are many questions that can be asked. One key question is whether the participants give reasoned arguments with justifiable claims via constructive debates or exhibit dogmatism and egotistic clashes of ideologies. The central idea of this question is *tolerance*, which is a key concept in the field of communications. In this work, we perform a computational study of tolerance in the context of online discussions. We aim to identify tolerant vs. intolerant participants and investigate how disagreement affects tolerance in discussions in a quantitative framework. To the best of our knowledge, this is the first such study. Our experiments using real-life discussions demonstrate the effectiveness of the proposed technique and also provide some key insights into the psycholinguistic phenomenon of tolerance in online discussions.

## 1 Introduction

Social media platforms have enabled people from anywhere in the world to express their views and discuss any issue of interest in online discussions/debates. Existing works in this context include recognition of support and oppose camps (Agrawal et al., 2003), mining of authorities and subgroups (Mayfield and Rosè, 2011; Abu-Jbara et al. (2012), dialogue act segmentation and classification (Morbini and Sagae, 2011; Boyer et al., 2011), etc.

This paper probes further to study a different and important angle, i.e., the psycholinguistic phenomenon of *tolerance* in online discussions. Tolerance is an important concept in the field of communications. It is a subfacet of deliberation which refers to critical thinking and exchange of rational arguments on an issue among participants that seek to achieve consensus/solution

(Habermas, 1984).

Perhaps the most widely accepted definition of tolerance is that of Gastil (2005; 2007), who defines tolerance as a means to engage (in written or spoken communication) in critical thinking, judicious argument, sound reasoning, and justifiable claims through constructive discussion as opposed to mere coercion/egotistic clashes of ideologies.

In this work, we adopt this definition, and also employ the following characteristics of tolerance (also known as “code of conduct”) (Crocker, 2005; Gutmann and Thompson, 1996) to guide our work.

*Reciprocity*: Each member (or participant) offers proposals and justifications in terms that others could understand and accept.

*Publicity*: Each member engages in a process that is transparent to all and each member knows with whom he is agreeing or disagreeing.

*Accountability*: Each member gives acceptable and sound reasons to others on the various claims or proposals suggested by him.

*Mutual respect and civic integrity*: Each member’s speech should be morally acceptable, i.e., using proper language irrespective of agreement or disagreement of views.

The issue of tolerance has been actively researched in the field of communications for the past two decades, and has been investigated in multiple dimensions. However, existing studies are typically qualitative and focus on theorizing the socio-linguistic aspects of tolerance (more details in §2).

With the rapid growth of social media, the large volumes of online discussions/debates offer a golden opportunity to investigate people’s implicit psyche in discussions quantitatively based on the real-life data, i.e., their tolerance levels and their arguing nature, which are of fundamental interest to several fields, e.g., communications, marketing, politics, and sociology (Dahlgren, 2005; Gastil, 2005; Moxey and

Sanford, 2000). Communication and political scholars are hopeful that technologies capable of identifying tolerance levels of people on social issues (often discussed in online discussions) can render vital statistics which can be used in predicting political outcomes in elections and helpful in tailoring voting campaigns and agendas to maximize winning chances (Dahlgren, 2002).

**Objective:** The objective of this work is two-fold:

1. Identifying tolerant and intolerant participants in discussions.
2. Analyzing how disagreement affects tolerance and estimating the tipping point of such effects.

To the best of our knowledge, these tasks have not been attempted quantitatively before. The first task is a classification/prediction problem. Due to the complex and interactive nature of discussions, the traditional n-gram features are no longer sufficient for accurate classification. We thus propose a generative model, called DTM, to discover some key pieces of information which characterize the nature of discussions and their participants, e.g., the arguing nature (agreeing vs. disagreeing), topic and expression distributions. These allow us to generate a set of novel features from the estimated latent variables of DTM capable of capturing authors' tolerance psyche during discussions. The features are then used in learning to identify tolerant and intolerant authors. Our experimental results show that the proposed approach is effective and outperforms several strong baselines significantly.

The second task studies the interplay of tolerance and disagreement. It is well-known that tolerance facilitates constructive disagreements, but sustained disagreements often result in a transition to destructive disagreement leading to polarization and intolerance (Dahlgren, 2005). An interesting question is: What is the tipping point of disagreement to exhibit intolerance? We take a Bayesian approach to seek an answer and discover issue-specific tipping points. Our empirical results discover some interesting relationships which are supported by theoretical studies in psychology and linguistic communications.

Finally, this work also produces an annotated corpus of tolerant and intolerant users in online discussions across two domains: politics and religion. We believe this is the first such dataset and will be a valuable resource to the community.

## 2 Related Work

Although limited work has been done on analysis of tolerance in online discussions, there are several general research areas that are related to our work.

**Communications:** Tolerance has been an active research area in the field of communications for the past two decades. Ryfe (2005) provided a comprehensive survey of the literature. The topic has been studied in multiple dimensions, e.g., opinion and attitude (Luskin et al., 2004; Price et al., 2002), public engagement (Escobar, 2012), psychoanalysis (Slavin and Kriegman, 1992), argument repertoire (Cappella et al., 2002), etc.

Tolerance has also been investigated in the domain of political communications with an emphasis on political sophistication (Gastil and Dillard, 1999), civic culture (Dahlgren, 2002), and democracy (Fishkin, 1991). These existing works study tolerance from the qualitative perspective. Our focus is quantitative analysis.

**Sentiment analysis:** Sentiment analysis determines positive or negative opinions expressed on topics (Liu, 2012; Pang and Lee, 2008). Main tasks include aspect extraction (Hu and Liu, 2004; Popescu and Etzioni, 2005; Mukherjee and Liu, 2012c; Chen et al., 2013), opinion polarity identification (Hassan and Radev, 2010; Choi and Cardie, 2010) and subjectivity analysis (Wiebe, 2000). Although related, tolerance is different from sentiment. Sentiments are mainly indicated by sentiment terms (e.g., *great*, *good*, *bad*, and *poor*). Tolerance in discussions refers to the reception of certain views and often indicated by agreement and disagreement expressions and other features (§5).

**Online discussions or debates:** Several works put authors in debate into support and oppose camps. Agrawal et al. (2003) used a graph based method, and Murakami and Raymond (2010) used a rule-based method. In (Mukherjee and Liu, 2012a), contention points were identified, in (Mukherjee and Liu, 2012b), various expressions in review comment discussions were mined, and in (Galley et al., 2004; Hillard et al., 2003), speaker utterances were classified into agreement, disagreement, and backchannel classes. Also related are studies on linguistic style accommodation (Mukherjee and Liu, 2012d) and user pair interactions (Mukherjee and Liu, 2013) in online debates. However, these works do not consider tolerance analysis in debate discussions, which is the focus of this work.

In a similar vein, several classification methods have been proposed to recognize opinion stances and speaker sides in online debates (Somasundaran and Wiebe, 2009; Thomas et al., 2006; Bansal et al., 2008; Burfoot et al., 2011; Yessenalina et al., 2010). Lin and Hauptmann (2006) also proposed a method to identify opposing perspectives. Abu-Jbara et al. (2012) identified subgroups. Kim and Hovy (2007) studied election prediction by analyzing online discussions. Other related works studying dialogue and discourse in discussions include authority recognition (Mayfield and Rosè, 2011), dialogue act segmentation and classification (Morbini and Sagae, 2011; Boyer et al., 2011), discourse structure prediction (Wang et al., 2011).

All these prior works are valuable. But they are not designed to identify tolerance or to analyze tipping points of disagreements for intolerance in discussions which are the focus of this work.

### 3 Discussion/Debate Data

For this research, we used discussion posts from Volconvo.com. This forum is divided into various domains: Politics, Religion, Science, etc. Each domain consists of multiple discussion threads. Each thread consists of a list of posts. Our experimental data is from two domains, Politics and Religion. The data is summarized in Table 1(a). In this work, the terms users, authors and participants are used interchangeably. The full data is used for modeling, but 436 and 501 authors from Politics and Religion domains were manually labeled as being tolerant or intolerant (Table 1(c)) respectively for classification experiments.

Two judges (graduate students) were used to label the data. The judges are fluent in English and were briefed on the definition of tolerance (see §1). From each domain (Politics, Religion), we randomly sampled authors having not more than 60 posts in order to reduce the labeling burden as the judges need to read all posts and see all interactions of each author before providing a label. Given all posts by an author,  $a$  and his/her associated interactions (posts by other authors replying or quoting  $a$ ), the judges were asked to provide a label for author  $a$  as being *tolerant* or *intolerant*. In our labeling, we found that users strongly exhibit one dominant trait: tolerant or intolerant, as our data consists of topics like elections, immigration, theism, terrorism, and vegetarianism across politics and religion domains,

Domain	Posts	Authors	Cohen's $\kappa$	Tol.	Intol.	Total
Politics	48605	1027	0.74	213	223	436
Religion	66835	1370	0.77	207	294	501

(a) Full Data (b) Agreement (c) Labeled data

Table 1: Data statistics (Tol: Tolerant users; Intol: Intolerant users. Total = Tol. + Intol).

which are often heated and thus attract people with pre-determined, strong, and polarized stances<sup>1</sup>.

The judges worked in isolation (to prevent bias) during annotation/labeling and were also asked to provide a short reason for their judgment. The agreement statistics using Cohen's kappa are given in Table 1(b), which shows substantial agreements according to the scale<sup>2</sup> in (Landis and Koch, 1977). This shows that tolerance as defined in §1 is quite decisive and one can decide whether a debater is exhibiting tolerant vs. intolerant quite well. To account for disagreements in labels, the judges discussed their reasons to reach a consensus. The final labeled data is reported in Table 1(c).

### 4 Model

We now present our generative model to capture the key aspects of discussions/debates and their intricate relationships, which enable us to (1) design sophisticated features for classification and (2) perform an in-depth analysis of the interplay of disagreement and tolerance. The model is called Debate Topic Model (DTM).

DTM is a semi-supervised generative model motivated by the joint occurrence of various topics; and agreement and disagreement expressions (abbreviated AD-expressions hereon) in debate posts. A typical debate post mentions a few topics (using similar topical terms) and expresses some viewpoints with one or more AD-expression types (Agreement and Disagreement) using semantically related expressions. This observation forms the basis of the generative process of our model where documents (posts) are represented as admixtures of latent topics and AD-expression types (Agreement and Disagreement). This key observation and the motivation of modeling debates are from our previous work in (Mukherjee and Liu, 2012a). In the new set-

<sup>1</sup> These hardened perspectives are theoretically supported by the polarization effect (Sunstein, 2002), and the hostile media effect, a scenario where partisans rigidly hold on to their stances (Hansen and Hyunjung, 2011).

<sup>2</sup> Agreement levels are as follows.  $\kappa \in [0, 0.2]$ : Poor,  $\kappa \in (0.2, 0.4]$ : Fair,  $\kappa \in (0.4, 0.6]$ : Moderate,  $\kappa \in (0.6, 0.8]$ : Substantial, and  $\kappa \in (0.8, 1.0]$ : Almost perfect agreement.

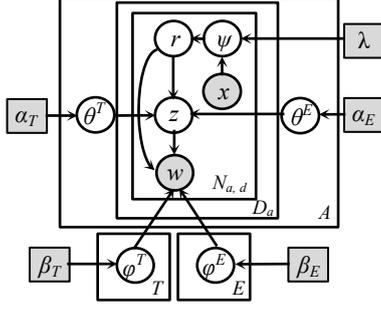

Figure 1: Plate notation of DTM

Variable/Function	Description
$a; A; d$	An author $a$ ; set of all authors; document, $d$
$(a, d); D_a$	Post $d$ by author $a$ ; Set of all posts by $a$
$T; E; V$	# of topics; expression types; vocabulary
$w_{a,d,j}; N_{a,d}$	$j^{\text{th}}$ term in $(a, d)$ ; Total # of terms in $(a, d)$
$\psi_{a,d,j}$	Distribution over topics and AD-expressions
$x_{a,d,j}$	Associated feature context of observed $w_{a,d,j}$
$\lambda$	Learned Max-Ent parameters
$r_{a,d,j} \in \{\hat{t}, \hat{e}\}$	Binary indicator/switch variable (topic ( $\hat{t}$ ) or AD-expression ( $\hat{e}$ )) for $w_{a,d,j}$
$\theta_a^T; \theta_a^E(\theta_{a,Ag}^E, \theta_{a,DisAg}^E)$	$a$ 's distribution over topics; expression types (Agreement: $\theta_{a,Ag}^E$ , Disagreement: $\theta_{a,DisAg}^E$ )
$\theta_{a,d}^T; \theta_{a,d}^E$	Topic distribution of post $d$ by author $a$ ; Probability mass of topic $t$ in $\theta_{a,d}^T$ .
$\theta_{a,d,e}^E; \theta_{a,d,e \in \{Ag, DisAg\}}^E$	Expression type distribution of post $d$ by author $a$ ; Corresponding probability masses of Agreement: $\theta_{a,d,e=Ag}^E$ and Disagreement in $\theta_{a,d,e=DisAg}^E$ .
$z_{a,d,j}$	Topic/Expression type of $w_{a,d,j}$
$\phi_t^T; \phi_e^E$	Topic $t$ 's; Expression type $e$ 's distribution over vocabulary terms
$\alpha^T; \alpha^E; \beta^T; \beta^E$	Dirichlet priors of $\theta_a^T; \theta_a^E; \phi_t^T; \phi_e^E$
$n_{a,t}^{AT}; n_{a,e}^{AE}$	# of times topic $t$ ; expression type $e$ assigned to $a$
$n_{t,v}^{TV}; n_{e,v}^{EV}$	# of times term $v$ appears in topic $t$ ; expression type $e$

Table 2: List of notations

ting, we model topics and debate expression distributions specific to authors as this work is concerned with modeling authors' (in)tolerance nature. Making latent variable  $\theta^E$  and  $\theta^T$  author specific facilitates modeling user behaviors (§5.3).

Assume we have  $t_{1..T}$  topics and  $e_{1..E}$  expression types in our corpus. In our case of debate posts, based upon reading various posts, we hypothesize that  $E = 2$  as in debates as we mostly find 2 dominant expression types: Agreement and Disagreement. Meanings of variables used in the following discussion are detailed in Table 2.

In this work, a document/post is viewed as a bag of  $n$ -grams and we use terms to denote both words (unigrams) and phrases ( $n$ -grams)<sup>3</sup>. DTM is a switching graphical model performing a switch between topics and AD-expressions similar to that in (Zhao et al., 2010). The switch is done using a learned maximum entropy (Max-Ent) model. The rationale here is that topical and AD-expression terms usually play different syntactic roles in a sentence. Topical terms (e.g., "U.S. elections," "government," "income tax") tend to be noun and noun phrases while expression terms ("I refute," "how can you say," "I'd agree") usually contain pronouns, verbs, wh-determiners, and modals. In order to utilize the part-of-speech (POS) tag information, we place the topic/AD-expression distribution,  $\psi_{a,d,j}$  (the prior over the indicator variable  $r_{a,d,j}$ ) in the term plate (Figure 1) and set it using a Max-Ent model conditioned on the observed context  $x_{a,d,j}$  associated with  $w_{a,d,j}$  and the learned Max-Ent parameters  $\lambda$  (details in §4.1). In this work, we use both lexical and POS features of the previous, current and next POS tags/lexemes of the term  $w_{a,d,j}$  as the contextual information, i.e.,

$$x_{a,d,j} = [POS_{w_{a,d,j-1}}, POS_{w_{a,d,j}}, POS_{w_{a,d,j+1}}, w_{a,d,j-1}, w_{a,d,j}, w_{a,d,j+1}],$$

which is used to produce feature functions for Max-Ent. For phrasal terms ( $n$ -grams), all POS tags and lexemes of  $w_{d,j}$  are considered as contextual information for computing feature functions in Max-Ent. DTM has the following generative process:

- A. For each AD-expression type  $e$ , draw  $\phi_e^E \sim \text{Dir}(\beta^E)$
- B. For each topic  $t$ , draw  $\phi_t^T \sim \text{Dir}(\beta^T)$
- C. For each author  $a \in \{1 \dots A\}$ :
  - i. Draw  $\theta_a^E \sim \text{Dir}(\alpha^E)$
  - ii. Draw  $\theta_a^T \sim \text{Dir}(\alpha^T)$
  - iii. For each document/post  $d \in \{1 \dots D_a\}$ :
    - I. For each term  $w_{a,d,j}, j \in \{1 \dots N_{a,d}\}$ :
      - a. Set  $\psi_{a,d,j} \leftarrow \text{MaxEnt}(x_{a,d,j}; \lambda)$
      - b. Draw  $r_{a,d,j} \sim \text{Bernoulli}(\psi_{a,d,j})$
      - c. if ( $r_{a,d,j} = \hat{e}$ ) //  $w_{a,d,j}$  is an AD-expression term  
Draw  $z_{a,d,j} \sim \text{Mult}(\theta_{a,d,j}^E)$   
else //  $r_{a,d,j} = \hat{t}$ ,  $w_{a,d,j}$  is a topical term  
Draw  $z_{a,d,j} \sim \text{Mult}(\theta_a^T)$
      - d. Emit  $w_{a,d,j} \sim \text{Mult}(\phi_{z_{a,d,j}}^{r_{a,d,j}})$

#### 4.1 Inference

We employ posterior inference using Monte Car-

<sup>3</sup> Topics in most topic models (e.g., LDA (Blei et al., 2003)) are unigram distributions and a document is treated as an exchangeable bag-of-words. This offers a computational advantage over models considering word orders (Wallach, 2006). As our goal is to enhance the expressiveness of DTM (rather than "modeling" word order), we use 1-4 grams preserving the advantages of exchangeable modeling.

Disagreement expressions ( $\varphi_{e=Disagreement}^E$ )
I, disagree, I don't, I disagree, <b>argument</b> , reject, <b>claim</b> , I reject, I refute, <b>and</b> , <b>your</b> , I refuse, <b>won't</b> , <b>the claim</b> , nonsense, <i>I contest</i> , dispute, <b>I think</b> , completely disagree, don't accept, don't agree, incorrect, <b>doesn't</b> , <i>hogwash</i> , <i>I don't buy your</i> , <i>I really doubt</i> , your nonsense, <b>true</b> , <i>can you prove</i> , argument fails, <i>you fail to</i> , <b>your assertions</b> , <i>bullshit</i> , <i>sheer nonsense</i> , <i>doesn't make sense</i> , <i>you have no clue</i> , <i>how can you say</i> , <i>do you even</i> , <i>contradict yourself</i> , ...
Agreement expressions ( $\varphi_{e=Agreement}^E$ )
agree, <b>I</b> , correct, yes, true, accept, I agree, <b>don't</b> , indeed correct, <b>your</b> , <b>point</b> , <b>that</b> , I concede, is valid, <b>your claim</b> , <b>not really</b> , <i>would agree</i> , <b>might</b> , <i>agree completely</i> , yes indeed, absolutely, you're correct, <i>valid point</i> , <b>argument</b> , <b>the argument</b> , proves, <i>do accept</i> , support, agree with you, <i>rightly said</i> , <b>personally</b> , well put, <i>I do support</i> , <i>personally agree</i> , <b>doesn't necessarily</b> , exactly, <i>very well put</i> , absolutely correct, <i>kudos</i> , <i>point taken</i> , ...

Table 3: Top terms (comma delimited) of two expression types. **Red (bold)** terms denote possible errors. *Blue (italics)* terms are newly discovered; rest (black) terms have been used in Max-Ent training.

lo Gibbs sampling. Denoting the random variables  $\{w, z, r\}$  by singular scripts  $\{w_k, z_k, r_k\}, k_{1...K}$ , where  $K = \sum_a \sum_d N_{a,d}$ , a single iteration consists of performing the following sampling:

$$p(z_k = t, r_k = \hat{t} | W_{-k}, Z_{-k}, R_{-k}, w_k = v) \propto \frac{\exp(\sum_{i=1}^n \lambda_i f_i(x_{a,d,j}, \hat{t}))}{\sum_{y \in \{\hat{t}, \bar{t}\}} \exp(\sum_{i=1}^n \lambda_i f_i(x_{a,d,j}, y))} \times \frac{n_{a,t,-k}^{AT} + \alpha^T}{n_{a,(\cdot)-k}^{AT} + T\alpha^T} \times \frac{n_{t,v,-k}^{TV} + \beta^T}{n_{t,(\cdot)-k}^{TV} + V\beta^T} \quad (1)$$

$$p(z_k = e, r_k = \hat{e} | W_{-k}, Z_{-k}, R_{-k}, w_k = v) \propto \frac{\exp(\sum_{i=1}^n \lambda_i f_i(x_{a,d,j}, \hat{e}))}{\sum_{y \in \{\hat{e}, \bar{e}\}} \exp(\sum_{i=1}^n \lambda_i f_i(x_{a,d,j}, y))} \times \frac{n_{a,e,-k}^{AE} + \alpha^E}{n_{a,(\cdot)-k}^{AE} + E\alpha^E} \times \frac{n_{e,v,-k}^{EV} + \beta^E}{n_{e,(\cdot)-k}^{EV} + V\beta^E} \quad (2)$$

where  $k = (a, d, j)$  denotes the  $j^{th}$  term of document  $d$  by author  $a$  and the subscript  $-k$  denotes assignments excluding the term at  $(a, d, j)$ . Omission of the latter index denoted by  $(\cdot)$  represents the marginalized sum over the latter index. Count variables are detailed in Table 1 (last two rows).  $\lambda_{1...n}$  are the parameters of the learned Max-Ent model corresponding to the  $n$  binary feature functions  $f_{1...n}$  for Max-Ent. The learned Max-Ent  $\lambda$  parameters in conjunction with the observed context,  $x_{a,d,j}$  feed the supervision signal for updating the topic/expression switch parameter,  $r$  in equations (1) and (2).

The hyper-parameters for the model were set to the values  $\beta^T = \beta^E = 0.1$  and  $\alpha_T = 50/T$ ,  $\alpha_E = 50/E$ , suggested in (Griffiths and Steyvers, 2004). Model parameters were estimated after 5000 Gibbs iterations with a burn-in of 1000 iterations. The Max-Ent parameters  $\lambda$  were learned using 500 labeled terms in each domain (politics:- topical: 376 and AD-expression: 124; religion:- topical: 349 and AD-expression: 151) appearing at least 10 times in debate threads other than the data in Table 1 (we do so since the

data in Table 1(c) is later used in the classification experiments in §6.1).

Table 3 lists some top AD-expressions discovered by DTM. We see that DTM can cluster many correct AD-expressions, e.g., “I disagree”, “I refute”, “don’t accept”, etc. in disagreement; and “I agree”, “you’re correct”, “agree with you”, etc. in agreement. Further, it also discovers highly specific and more distinctive expressions beyond those used in Max-Ent training (marked *blue* in italics), e.g., “I don’t buy your”, “can you prove”, “you fail to”, and “you have no clue” in disagreement; and phrases like “valid point”, “rightly said”, “I do support”, and “very well put” in agreement. In §6.1, we will see that these AD-expressions serve as high quality features for predicting tolerance.

Lastly, we note that DTM also estimates several pieces of useful information (e.g., AD-expressions, posterior estimates of author’s arguing nature,  $\theta_a^E$ ; latent topics and expressions,  $\varphi_t^T$ ;  $\varphi_e^E$ , etc.). These will be used to produce a rich set of user behavioral features for characterizing tolerance in §5.3.

## 5 Feature Engineering

We now propose features which will be used for model building to classify tolerant and intolerant authors in Table 1(c). We use three sets of features.

### 5.1 Language based Features of Tolerance

**Word and POS n-grams:** As tolerance in communication is directly reflected in language usage, word  $n$ -grams are obvious features. We also use POS tags (obtained using Stanford Tagger<sup>4</sup>) as features. The rationale of using POS tag based features is that intolerant communications are often characterized by hate/egotistic speech which have pronounced use of specific part of speech (e.g., pronouns) (Zingo, 1998).

**Heuristic Factor Analysis:** In psycholinguistics, factor analysis refers to the process of finding groups of semantically similar linguistic constructs (words/phrases). It is also called meaning extraction in (Chung and Pennebaker, 2007). As tolerance in discussions is characterized by reasoned expressions which often accompany sourcing (e.g., providing a hyperlink, making an attempt to clarify with some evidence, etc.), we compiled a list of reasoned and sourced expressions (shown in Table 4) from prior works

<sup>4</sup> <http://nlp.stanford.edu/software/tagger.shtml>

Factor: Reasoning words/phrases
because, because of, since, reason, reason being, reason is, reason why, due to, owing to, as in, therefore, thus, henceforth, hence, implies, implies that, implying, hints, hinting, hints towards, it follows that, it turns out, conclude, consequence, consequently, the cause, rationale, the rationale, justification, the justification, provided, premise, assumption, on the proviso, in spite, ...
Factor: Sourcing words/phrases
<i>presence of hyperlinks/urls</i> , source, reference, for example, for instance, namely, to explain, to detail, to clarify, to elucidate, to illustrate, to be precise, furthermore, moreover, apart from, besides, we find, ...

Table 4: Heuristic Factor Analysis (HFA). Words/Phrases in each factor compiled from prior works in psycholinguistics.

(Chung and Pennebaker, 2007; Flor and Hadar, 2005; Moxey and Sanford, 2000; Pennebaker, et al., 2007).

## 5.2 Debate Expression Features

**AD-expressions:** As we have seen in §4, DTM can discover specific agreement and disagreement expressions in debates. We use these expressions as another feature set. Estimated AD-expressions (Table 3) serve as a principled way of performing factor analysis in debates instead of heuristic factor analysis as in Table 4 used in prior works.

As the AD-expression types are modeled as Dirichlet distributions ( $\varphi^E \sim \text{Dir}(\beta^E)$ ), due to the smoothing effect, each term in the vocabulary has some non-zero probability mass associated with the expression types. To ensure that the discovered expressions are representative AD-expressions, we only consider the terms in  $\varphi^E$  with  $p(v|e) = \varphi_{e,v}^E > 0.001$  as probability masses lower than 0.001 are more due to the smoothing effect of Dirichlet distribution than true correlation.

## 5.3 User Behavioral Features

Here we propose several features of user interaction which reflect the socio-psychological state of tolerance while participating in discussions. We note that these features rely on the posterior estimates of latent variables  $\theta^E$ ,  $z$ , and  $r$  in DTM (§4) and are thus difficult to obtain without modeling.

**Overall Arguing Nature:** The posterior on  $\theta_a^E$  (Table 2) for each author,  $a$  gives an estimate of  $a$ 's overall arguing nature (agreeing or disagreeing). We use the probability mass assigned to each arguing nature type as a user behavioral feature. This gives us two features  $f_1, f_2$  as fol-

lows:

$$f_1(a) = \theta_{a,Ag}^E; f_2(a) = \theta_{a,DisAg}^E \quad (3)$$

**Behavioral Response:** As intolerant users are likely to attract more disagreement, it is naturally useful to estimate the response (agreeing vs. disagreeing) a user receives from other users. For computing behavioral response, we first use the posterior on  $z$  to compute the distribution of AD-expressions (i.e., the relative probability masses of agreeing and disagreeing expressions) in a document  $d$  by an author  $a$  as follows:

$$\theta_{a,d,Ag}^E = \frac{|\{j|z_{a,d,j}=Ag, 1 \leq j \leq N_{a,d}\}|}{|\{j|r_{a,d,j}=\hat{e}, 1 \leq j \leq N_{a,d}\}|},$$

$$\theta_{a,d,DisAg}^E = \frac{|\{j|z_{a,d,j}=DisAg, 1 \leq j \leq N_{a,d}\}|}{|\{j|r_{a,d,j}=\hat{e}, 1 \leq j \leq N_{a,d}\}|} \quad (4)$$

Now to get the overall behavioral response of an author,  $a$  we take the expected value of the agreeing and disagreeing responses that  $a$  received from other authors  $a'$  who replied to or quoted  $a$ 's posts. The expectations below are taken over all posts  $d'$  by  $a'$  which reply/quote posts of  $a$ .

$$f_3(a) = E[\theta_{a',d',Ag}^E]; f_4(a) = E[\theta_{a',d',DisAg}^E] \quad (5)$$

**Equality of Speech:** In communication literature (Dahlgren, 2005; Habermas, 1984), equality is theorized as an essential element of tolerance. Each participant must be able to participate on an equal footing with others without anybody dominating the discussion. In online debates, we can measure this phenomenon using the following feature:

$$f_5(a) = E\left[\left(\frac{\# \text{ of posts by } a \text{ in thread } l}{\# \text{ of posts in thread } l}\right) E[\theta_{a,d,DisAg}^E]\right] \quad (6)$$

where the inner expectation is taken over all posts of  $a$  in thread  $l$  and the outer expectation is taken over all threads  $l$  in which  $a$  participated. The above definition computes the aggressive posting behavior of author  $a$  whereby he tries to dominate the thread by posting more than others. The aggressive posting behavior is weighted by author's disagreeing nature because a person usually exhibits a dominating nature when he pushes hard to establish his ideology (which is often in disagreement with others) (Moxey and Sanford, 2000).

**Topic Shifts:** An interesting phenomenon of human (social) psyche is that when people are unable to logically argue their stances and feel they are losing the debate, they often try to belittle/deride others by pulling unrelated topics into discussion (Slavin and Kriegman, 1992). This is

referred to as topic shifts. Topic shifts thus have a relation with tolerance in deliberation. Stromer-Galley (2005) reported that if the discussion is off topic, then tolerance or deliberation cannot meet its objective of deep consideration of an issue. Hence, the average topic shifts of an author,  $a$  across various posts in a thread can serve as a good feature for measuring tolerance. We use the posterior on per-document topic distribution,  $\theta_{a,d,t}^T = \frac{|\{j|z_{a,d,j}=t, 1 \leq j \leq N_{a,d}\}|}{|\{j|r_{a,d,j}=\hat{t}, 1 \leq j \leq N_{a,d}\}|}$  to measure topic shifts using KL-Divergence as follows:

$$f_6 = E \left[ \text{avg}_{d,d' \in \text{thread } l} \left( D_{KL}(\theta_{a,d}^T || \theta_{a,d'}^T) \right) \right] \quad (7)$$

We first compute author,  $a$ 's average topic shifts in a thread,  $l$  which measures his topic shifts in  $l$ . But this only gives us his behavior in one thread. To capture his overall behavior, we take the expected value of this behavior over all threads in which  $a$  participated. We take average KL-divergence (KL-Div.) over all pairs of posts by  $a$  in a given thread to account for the asymmetry of KL-Div.

Finally, we note that by no means do we claim that the mere presence and a large value of any of the above features imply that a user is intolerant or tolerant. They are indicators of the phenomenon of tolerance in discussions/debates. The actual prediction is done using the learned models in §6.1.

## 6 Experimental Evaluation

We now detail the experiments that investigate the strengths of features in §5. In particular, we first consider the task of classifying whether an author is tolerant or intolerant in discussions. Then, we analyze how disagreement affects tolerance.

### 6.1 Tolerant and Intolerant Classification

Here, we show that the features in §5 can help build accurate models for predicting tolerance. We employ a linear kernel<sup>5</sup> SVM (using the SVM<sup>Light</sup> system (Joachims, 1999)) and report 5-fold cross validation (CV) results on the task of predicting the socio-psychological nature of users' communication: tolerant vs. intolerant in politics and religion domains (Table 1(c)). Note that for each fold of 5-fold CV, DTM was run on the full data of each domain (Table 1(a)) excluding the users (and their associated posts) in the test set of that fold for generating the features of the training instances (users). The learned DTM

<sup>5</sup> Other kernels (rbf, poly, sigmoid) did not perform as well.

was then fitted (using the approach in (Hofmann, 1999)) to the test set users and their posts for generating the features of the test instances.

To investigate the effectiveness of the proposed framework, we incrementally add feature sets starting with the baseline features. Word unigrams and bigrams (inclusive of unigrams)<sup>6</sup> serve as our first baseline (B1a, B1b). Word + POS bigrams is our second baseline (B2). "Word" in B2 uses bigrams as B1b gives better results. B2 + Heuristic Factor Analysis (HFA) (Table 4) serve as our third baseline (B3). Table 5 shows the experiment results. We note the following:

1. Across both domains, adding POS bigrams slightly improves classification accuracy and F<sub>1</sub>-score beyond standard word unigrams and bigrams. Feature selection using information gain (IG) does not help much.
2. Using heuristic factor analyses (HFA) of reasoned and sourced expressions (Table 4) brings about 1% and 2% improvement in accuracy in politics and religion domains respectively.
3. Debate expression features (DE) in §5.2 and user behavioral features (UB) in §5.3 produced from DTM progressively improve classification accuracies by 4% and 8% in politics domains and 5% and 6% in religion domains. The improvements are also statistically significant.

In summary, we can see that modeling made a major impact. It improved the accuracy by about 10% than traditional unigram and bigram baselines. This shows that the debate expressions and user behaviors computed using the DTM model can capture various dimensions of (in)tolerance not captured by n-grams.

### 6.2 How Disagreement affects Tolerance?

We now quantitatively study the effect of disagreement on tolerance. We recall from §1 that tolerance indicates constructive discussion and allows disagreement. Some level of disagreement is often times an integral component of deliberation and tolerance (Cappella et al., 2002).

Disagreements, however, can be either constructive or destructive. The distinction is that the former is aimed at arriving at a consensus or solution, while the latter leads to polarization and intolerance (Sunstein, 2002). It was also shown in (Dahlgren, 2005) that sustained disa-

<sup>6</sup> Higher order  $n$ -grams did not result in better results.

Feature Setting	Politics				Religion			
	Precision	Recall	F <sub>1</sub>	Accuracy	Precision	Recall	F <sub>1</sub>	Accuracy
B1a: Word unigrams	64.1	86.3	73.7	70.1	61.9	86.8	72.6	71.9
Word unigram + IG	64.5	86.2	73.9	70.2	62.7	86.9	72.9	71.9
B1b: Word bigrams	66.8	87.8	75.9	72.4	64.9	89.1	75.9	75.1
B2: W+POS bigrams	68.5	86.8	76.4	73.7	66.6	88.4	76.8	76.7
B3: B2 + HFA(Table 4)	69.2	90.5	78.1	75.2	66.4	90.6	76.8	77.5
B3 + DE (§5.2)	74.7	91.3	<b>82.4†</b>	<b>79.5†</b>	70.2	92.8	<b>80.8†</b>	<b>82.1†</b>
B3 + DE + UB (§5.3)	76.1	92.2	<b>83.1‡</b>	<b>83.2‡</b>	71.7	93.4	<b>82.1‡</b>	<b>83.3‡</b>

Table 5: Precision, Recall, F<sub>1</sub> score on the tolerant class, and Accuracy for different feature settings across 2 domains. DE: Debate expression features (AD-expressions, Table3, §5.2). UB: User behavioral features (§5.3). Improvements in F<sub>1</sub> and Accuracy using DTM features (beyond baselines, B1-B3) are statistically significant (†:  $p < 0.02$ ; ‡:  $p < 0.01$ ) using paired  $t$ -test with 5-fold CV.

Thread/Issue	# Posts	# Users	% InTol.	$E[\theta_{a,d,DisAg}^E]$	$\tau$	$p$ -value
Repeal Healthcare	1823	33	39.9	0.57	0.65	0.02
Europe’s Collapse	1824	33	42.5	0.61	0.61	0.01
Obama Euphoria	1244	26	30.7	0.66	0.71	0.01
Socialism	831	49	44.8	0.69	0.48	0.03
Abortion	1232	58	48.4	0.78	0.37	0.01

Table 6: Tipping points of disagreements for intolerance ( $\tau$ ) of different issues.  $E[\theta_{a,d,DisAg}^E]$ : the expected disagreement over all posts in each issue/thread, # Posts: the total number of posts, # Users: the total number of users/authors, % Intol: % of intolerant users in each thread,  $\tau$ : the estimated tipping point, and  $p$ -value: computed from two-tailed Fisher’s exact test.

greement often takes a transition towards destructive disagreement and is likely to lead to intolerance. Similar phenomena was also identified in psychology literature (Critchley, 1964). In such cases, the participants often stubbornly stick to an extreme attitude, which eventually results in intolerance and defeats the very purpose of deliberative discussion.

An intriguing research question is: What is the relationship between disagreement and intolerance? The question is interesting from both the communication and psycholinguistic perspectives. The best of our knowledge, this is the first attempt towards seeking an answer. We work in the context of five issues/threads in real-life online debates. To derive quantitative and definite conclusions, it is required to perform the following tasks:

- For each issue, empirically investigate *in expectation* the *tipping point* of disagreement beyond which a user tends to be intolerant.
- Further, investigate the *confidence* on the estimated tipping point (i.e., what is the likelihood that the estimated tipping point is statistically significant instead of chance alone).

We formalize the above tasks in the Bayesian setting. Recall from Table 2 of §4, that  $\theta_{a,Ag}^E$  (respectively,  $\theta_{a,DisAg}^E$ ) are the estimates of agreeing and disagreeing nature of an author and  $\theta_{a,Ag}^E + \theta_{a,DisAg}^E = 1$ . Let  $TP(\tau)$  denote the event that *in*

*expectation* a threshold value of  $0 < \tau < 1$  serves as a tipping point of disagreement beyond which intolerance is exhibited. Note that we emphasize the term “in expectation” (taken over all authors). We do not mean that every author whose disagreement,  $\theta_{a,DisAg}^E > \tau$ , is intolerant. The empirical likelihood of  $TP(\tau)$  can be expressed by the following probability expression:

$$\mathcal{L}(TP(\tau)) = E[P(\theta_{a,DisAg}^E > \tau | a = I) - P(\theta_{a,DisAg}^E > \tau | a = T)] \quad (8)$$

The events  $a = I$  and  $a = T$  denote that author  $a$  is intolerant and tolerant respectively. The expectation is taken over authors. Showing that  $\tau$  indeed serves as the tipping point of disagreement to exhibit intolerance corresponds to rejecting the null hypothesis that the probabilities in (8) are equal. We employ a Fisher’s exact test to test significance and report confidence measures (using  $p$ -values) for the tipping point thresholds. The results are shown in Table 6.

The threshold  $\tau$  is computed using the entropy method in (Fayyad and Irani, 1993) as follows: We first fit our previously learned model (using the data in Table 1 (a)) to the new threads in Table 6 and its users and posts to obtain the estimates of  $\theta_{a,DisAg}^E$  and other latent variables for feature generation. The learned classifier in §6.1 is used to predict the nature of users (tolerant vs.

intolerant) in the new threads<sup>7</sup>. Then, for each user we have his predicted deliberative (social) psyche (Tolerant vs. Intolerant) and also his overall disagreeing nature exhibited in that thread (the posterior on  $\theta_{a,DisAg}^E \in [0, 1]$ ). For a thread, tolerant and intolerant users (data points) span the range [0, 1] attaining different values for  $\theta_{a,DisAg}^E$ . Each candidate tipping point of disagreement,  $0 \leq \tau' \leq 1$  results in a binary partition of the range with each partition containing some proportion of tolerant and intolerant users. We compute the entropy of the partition for every candidate tipping point in the range [0, 1]. The final tipping point threshold,  $\tau$  is chosen such that it minimizes the partition entropy based on the binary cut-point method in (Fayyad and Irani, 1993).

Since we perform a thread level analysis, the results in Table 6 are thread/issue specific. We note the following from Table 6:

1. Across all threads/issues, we find that the expected disagreement over all posts,  $d$ ,  $E[\theta_{a,d,DisAg}^E] > 0.5$  showing that in discussions of the reported issues, disagreement predominates.
2.  $E[\theta_{a,d,DisAg}^E]$  also gives an estimate of overall *heat* in the issue being discussed. We find sensitive issues like *abortion* and *socialism* being more heated than *healthcare*, *Obama*, etc.
3. The percentage of intolerant users increases with the expected overall disagreement in the issue except for the issue *Obama euphoria*.
4. The estimated tipping point of disagreement to exhibit intolerance,  $\tau$  happens to vary inversely with the expected disagreement,  $E[\theta_{a,d,DisAg}^E]$  except the issue *Obama euphoria*. This reflects that as overall disagreement in the issue increases, the tipping point of intolerance decreases, i.e., due to high discussion heat, people are likely to turn intolerant even with relatively small amount of disagreement. This finding dovetails with prior studies in psychology (Rokeach and Fruchter, 1956) that heated discussions are likely to reduce thresh-

<sup>7</sup> Although this prediction may not be perfect, it can be regarded as considerably reliable to study the trend of tolerance across different issues as our classifier (in §6.1) attains a high (83%) classification accuracy using the full feature set. As judging all users across all threads would require reading about 7000 posts, for confirmation, we randomly sampled 30 authors across various threads for labeling by our judges. 28 out of 30 predictions produced by the classifier correlated with the judges' labels, which should be sufficiently accurate for our analysis.

olds of reception leading to dogmatism, egotism, and intolerance. Table 6 shows that for moderately heated issues (*healthcare*, *Europe's collapse*), in expectation, author's disagreement  $\theta_{a,DisAg}^E$  should exceed 61-65% to exhibit intolerance. However, for sensitive issues, we find that the tipping point is much lower, *abortion*: 37%; *socialism*: 48%.

5. The issue *Obama Euphoria* is an exception to other issues' trends. Even though in expectation, it has  $E[\theta_{a,d,DisAg}^E] = 66\%$  overall disagreement, the percentage of intolerant users remains the lowest (30%) and the tipping point attains a highest value ( $\tau = 0.71$ ), showing more tolerance on the issue. A plausible reason could be that Obama is somewhat more liked and hence attracts less intolerance from users<sup>8</sup>.
6. The  $p$ -values of the estimated tipping points,  $\tau$  across all issues are statistically significant at 98-99% confidence levels.

## 7 Conclusion

This work performed a deep analysis of the sociopsychological and psycholinguistic phenomenon of tolerance in online discussions, which is an important concept in the field of communications. A novel framework is proposed, which is capable of characterizing and classifying tolerance in online discussions. Further, a novel technique was also proposed to quantitatively evaluate the interplay of tolerance and disagreement. Our empirical results using real-life online discussions render key insights into the psycholinguistic process of tolerance and dovetail with existing theories in psychology and communications. To the best of our knowledge, this is the first such quantitative study. In our future work, we want to further this research and study the role of diversity of opinions in the context of tolerance and its relation to polarization.

## Acknowledgments

This work was supported in part by a grant from National Science Foundation (NSF) under grant no. IIS-1111092.

<sup>8</sup> This observation may be linked to the political phenomenon of "democratic citizenship through exposure to diverse perspectives" (Mutz, 2006) where it was shown that exposure to heterogeneous opinions (i.e., greater disagreement), often enhances tolerance.

## Abstract

Repeating experiments is an important instrument in the scientific toolbox to validate previous work and build upon existing work. We present two concrete use cases involving key techniques in the NLP domain for which we show that reproducing results is still difficult. We show that the deviation that can be found in reproduction efforts leads to questions about how our results should be interpreted. Moreover, investigating these deviations provides new insights and a deeper understanding of the examined techniques. We identify five aspects that can influence the outcomes of experiments that are typically not addressed in research papers. Our use cases show that these aspects may change the answer to research questions leading us to conclude that more care should be taken in interpreting our results and more research involving systematic testing of methods is required in our field.

## 1 Introduction

Research is a collaborative effort to increase knowledge. While it includes validating previous approaches, our experience is that most research output in our field focuses on presenting new approaches, and to a somewhat lesser extent building upon existing work.

In this paper, we argue that the value of research that attempts to replicate previous approaches goes beyond simply *validating* what is already known. It is also an essential aspect for *building upon* existing approaches. Especially when validation

fails or variations in results are found, systematic testing helps to obtain a clearer picture of both the approach itself and of the meaning of state-of-the-art results leading to a *better insight* into the quality of new approaches in relation to previous work.

We support our claims by presenting two use cases that aim to reproduce results of previous work in two key NLP technologies: measuring WordNet similarity and Named Entity Recognition (NER). Besides highlighting the difficulty of repeating other researchers' work, new insights about the approaches emerged that were not presented in the original papers. This last point shows that reproducing results is not merely part of good practice in science, but also an essential part in gaining a better understanding of the methods we use. Likewise, the problems we face in reproducing previous results are not merely frustrating inconveniences, but also pointers to research questions that deserve deeper investigation.

We investigated five aspects that cause experimental variation that are not typically described in publications: **preprocessing** (e.g. tokenisation), **experimental setup** (e.g. splitting data for cross-validation), **versioning** (e.g. which version of WordNet), **system output** (e.g. the exact features used for individual tokens in NER), and **system variation** (e.g. treatment of ties).

As such, reproduction provides a platform for systematically testing individual aspects of an approach that contribute to a given result. What is the influence of the size of the dataset, for example? How does using a different dataset affect the results? What is a reasonable divergence between different runs of the same experiment? Finding answers to these questions enables us to better interpret our state-of-the-art results.

Moreover, the experiments in this paper show that even while strictly trying to replicate a previous experiment, results may vary up to a point where they lead to different answers to the main question addressed by the experiment. The WordNet similarity experiment use case compares the performance of different similarity measures. We will show that the answer as to which measure works best changes depending on factors such as the gold standard used, the strategy towards part-of-speech or the ranking coefficient, all aspects that are typically not addressed in the literature.

The main contributions of this paper are the following:

- 1) An in-depth analysis of two reproduction use cases in NLP
- 2) New insights into the state-of-the-art results for WordNet similarities and NER, found because of problems in reproducing prior research
- 3) A categorisation of aspects influencing reproduction of experiments and suggestions on testing their influence systematically

The code, data and experimental setup for the WordNet experiments are available at <http://github.com/antske/WordNetSimilarity>, and for the NER experiments at <http://github.com/Mvanerp/NER>. The experiments presented in this paper have been repeated by colleagues not involved in the development of the software using the code included in these repositories. The remainder of this paper is structured as follows. In Section 2, previous work is discussed. Sections 3 and 4 describe our real-world use cases. In Section 5, we present our observations, followed by a more general discussion in Section 6. In Section 7, we present our conclusions.

## 2 Background

This section provides a brief overview of recent work addressing reproduction and benchmark results in computer science related studies and discusses how our research fits in the overall picture.

Most researchers agree that validating results entails that a method should lead to the same overall conclusions rather than producing the exact same numbers (Drummond, 2009; Dalle, 2012; Buchert and Nussbaum, 2012, etc.). In other words, we should strive to *reproduce* the same answer to a research question by different means,

perhaps by re-implementing an algorithm or evaluating it on a new (in domain) data set. *Replication* has a somewhat more limited aim, and simply involves running the exact same system under the same conditions in order to get the exact same results as output.

According to Drummond (2009) replication is not interesting, since it does not lead to new insights. On this point we disagree with Drummond (2009) as replication allows us to: 1) validate prior research, 2) improve on prior research without having to rebuild software from scratch, and 3) compare results of reimplementations and obtain the necessary insights to perform reproduction experiments. The outcome of our use cases confirms the statement that deeper insights into an approach can be obtained when all resources are available, an observation also made by Ince et al. (2012).

Even if exact replication is not a goal many strive for, Ince et al. (2012) argue that insightful reproduction can be an (almost) impossible undertaking without the source code being available. Moreover, it is not always clear where replication stops and reproduction begins. Dalle (2012) distinguishes levels of reproducing results related to how close they are to the original work and how each contributes to research. In general, an increasing awareness of the importance of reproduction research and open code and data can be observed based on publications in high-profile journals (e.g. Nature (Ince et al., 2012)) and initiatives such as myExperiment.<sup>1</sup>

Howison and Herbsleb (2013) point out that, even though this is important, often not enough (academic) credit is gained from making resources available. What is worse, the same holds for research that investigates existing methods rather than introducing new ones, as illustrated by the question that is found on many review forms ‘how novel is the presented approach?’. On the other hand, initiatives for journals addressing exactly this issue (Neylon et al., 2012) and tracks focusing on results verification at conferences such as VLDB<sup>2</sup> show that this opinion is not universal.

A handful of use cases on reproducing or replicating results have been published. Louridas and Gousios (2012) present a use case revealing that source code alone is not enough for reproducing

<sup>1</sup><http://www.myexperiment.org>

<sup>2</sup><http://www.vldb.org/2013/>

results, a point that is also made by Mende (2010) who provides an overview of all information required to replicate results.

The experiments in this paper provide use cases that confirm the points brought out in the literature mentioned above. This includes both observations that a detailed level of information is required for truly insightful reproduction research as well as the claim that such research leads to better understanding of our techniques. Furthermore, the work in this paper relates to Bikel (2004)'s work. He provides all information needed in addition to Collins (1999) to replicate Collins' benchmark results. Our work is similar in that we also aim to fill in the blanks needed to replicate results. It must be noted, however, that the use cases in this paper have a significantly smaller scale than Bikel's.

Our research distinguishes itself from previous work, because it links the challenges of reproduction to what they mean for reported results beyond validation. Ruml (2010) mentions variations in outcome as a reason not to emphasise comparisons to benchmarks. Vanschoren et al. (2012) propose to use experimental databases to systematically test variations for machine learning, but neither links the two issues together. Raeder et al. (2010) come closest to our work in a critical study on the evaluation of machine learning. They show that choices in the methodology, such as data sets, evaluation metrics and type of cross-validation can influence the conclusions of an experiment, as we also find in our second use case. However, they focus on the problem of evaluation and recommendations on how to achieve consistent reproducible results. Our contribution is to investigate how much results vary. We cannot control how fellow researchers carry out their evaluation, but if we have an idea of the variations that typically occur within a system, we can better compare approaches for which not all details are known.

### 3 WordNet Similarity Measures

Patwardhan and Pedersen (2006) and Pedersen (2010) present studies where the output of a variety of WordNet similarity and relatedness measures are compared. They rank Miller and Charles (1991)'s set (henceforth "*mc-set*") of 30 word pairs according to their semantic relatedness with several WordNet similarity measures.

Each measure ranks the *mc-set* of word pairs and these outputs are compared to Miller and

Charles (1991)'s gold standard based on human rankings using the Spearman's Correlation Coefficient (Spearman, 1904,  $\rho$ ). Pedersen (2010) also ranks the original set of 65 word pairs ranked by humans in an experiment by Rubenstein and Goodenough (1965) (*rg-set*) which is a superset of Miller and Charles's set.

#### 3.1 Replication Attempts

This research emerged from a project running a similar experiment for Dutch on Cornetto (Vossen et al., 2013). First, an attempt was made to reproduce the results reported in Patwardhan and Pedersen (2006) and Pedersen (2010) on the English WordNet using their WordNet::Similarity web-interface.<sup>3</sup> Results differed from those reported in the aforementioned works, even when using the same versions as the original, WordNet::Similarity-1.02 and WordNet 2.1 (Patwardhan and Pedersen, 2006) and WordNet::Similarity-2.05 and WordNet 3.0 (Pedersen, 2010), respectively.<sup>4</sup>

The fact that results of similarity measures on WordNet can differ even while the same software and same versions are used indicates that properties which are not addressed in the literature may influence the output of similarity measures. We therefore conducted a range of experiments that, in addition to searching for the right settings to replicate results of previous research, address the following questions:

- 1) Which properties have an impact on the performance of WordNet similarity measures?
- 2) How much does the performance of individual measures vary?
- 3) How do commonly used measures compare when the variation of their performance are taken into account?

#### 3.2 Methodology and first observations

The questions above were addressed in two stages. In the first stage, Fokkens, who was not involved in the first replication attempt implemented a script to calculate similarity measures using WordNet::Similarity. This included similarity measures introduced by Wu and Palmer (1994) (*wup*),

<sup>3</sup>Obtained from <http://talisker.d.umn.edu/cgi-bin/similarity/similarity.cgi>, WordNet::Similarity version 2.05. This web interface has now moved to <http://maraca.d.umn.edu>

<sup>4</sup>WordNet::Similarity were obtained <http://search.cpan.org/dist/WordNet-Similarity/>.

Leacock and Chodorow (1998) (*lch*), Resnik (1995) (*res*), Jiang and Conrath (1997) (*jcn*), Lin (1998) (*lin*), Banerjee and Pedersen (2003) (*lesk*), Hirst and St-Onge (1998) (*hso*) and Patwardhan and Pedersen (2006) (*vector* and *vpairs*) respectively.

Consequently, settings and properties were changed systematically and shared with Pedersen who attempted to produce the new results with his own implementations. First, we made sure that the script implemented by Fokkens could produce the same WordNet similarity scores for each individual word pair as those used to calculate the ranking on the *mc-set* by Pedersen (2010). Finally, the gold standard and exact implementation of the Spearman ranking coefficient were compared.

Differences in results turned out to be related to variations in the **experimental setup**. First, we made different assumptions on the restriction of part-of-speech tags (henceforth “PoS-tag”) considered in the comparison. Miller and Charles (1991) do not discuss how they deal with words with more than one PoS-tag in their study. Pedersen therefore included all senses with any PoS-tag in his study. The first replication attempt had restricted PoS-tags to nouns based on the idea that most items are nouns and subjects would be primed to primarily think of the noun senses. Both assumptions are reasonable. Pos-tags were not restricted in the second replication attempt, but because of a bug in the code only the first identified PoS-tag (“noun” in all cases) was considered. We therefore mistakenly assumed that PoS-tag restrictions did not matter until we compared individual scores between Pedersen and the replication attempts.

Second, there are two gold standards for the Miller and Charles (1991) set: one has the scores assigned during the original experiment run by Rubenstein and Goodenough (1965), the other has the scores assigned during Miller and Charles (1991)’s own experiment. The ranking correlation between the two sets is high, but they are not identical. Again, there is no reason why one gold standard would be a better choice than the other, but in order to replicate results, it must be known which of the two was used. Third, results changed because of differences in the treatment of ties while calculating Spearman  $\rho$ . The influence of the exact gold standard and calculation of Spearman  $\rho$  could only be found because Pedersen could pro-

measure	Spearman $\rho$		Kendall $\tau$		ranking variation
	min	max	min	max	
path based similarity					
path	0.70	0.78	0.55	0.62	1-8
wup	0.70	0.79	0.53	0.61	1-6
lch	0.70	0.78	0.55	0.62	1-7
path based information content					
res	0.65	0.75	0.26	0.57	4-11
lin	0.49	0.73	0.36	0.53	6-10
jcn	0.46	0.73	0.32	0.55	5, 7-11
path based relatedness					
hso	0.73	0.80	0.36	0.41	1-3,5-10
dictionary and corpus based relatedness					
vpairs	0.40	0.70	0.26	0.50	7-11
vector	0.48	0.92	0.33	0.76	1,2,4,6-11
lesk	0.66	0.83	-0.02	0.61	1-8,11,12

Table 1: Variation WordNet measures’ results

vide the output of the similarity measures he used to calculate the coefficient. It is unlikely we would have been able to replicate his results at all without the output of this intermediate step. Finally, results for *lch*, *lesk* and *wup* changed according to measure specific configuration settings such as including a PoS-tag specific root node or turning on normalisation.

In the second stage of this research, we ran experiments that systematically manipulate the influential factors described above. In this experiment, we included both the *mc-set* and the complete *rg-set*. The implementation of Spearman  $\rho$  used in Pedersen (2010) assigned the lowest number in ranking to ties rather than the mean, resulting in an unjustified drop in results for scores that lead to many ties. We therefore experimented with a different correlation measure, Kendall tau coefficient (Kendall, 1938,  $\tau$ ) rather than two versions of Spearman  $\rho$ .

### 3.3 Variation per measure

All measures varied in their performance. The complete outcome of our experiments (both the similarity measures assigned to each pair as well as the output of the ranking coefficients) are included in the data set provided at <http://github.com/antske/WordNetSimilarity>. Table 1 presents an overview of the main point we wish to make through this experiment: the minimal and maximal results according to both ranking coefficients. Results for similarity measures varied from 0.06-0.42 points for Spearman  $\rho$  and from 0.05-0.60 points for Kendall  $\tau$ . The last column indicates the variation of performance of a measure

compared to the other measures, where 1 is the best performing measure and 12 is the worst.<sup>5</sup> For instance, `path` has been best performing measure, second best, eighth best and all positions in between, `vector` has ranked first, second and fourth, but also occupied all positions from six to eleven.

In principle, it is to be expected that numbers are not exactly the same while evaluating against a different data set (the *mc-set* versus the *rg-set*), taking a different set of synsets to evaluate on (changing PoS-tag restrictions) or changing configuration settings that influence the similarity score. However, a variation of up to 0.44 points in Spearman  $\rho$  and 0.60 in Kendall  $\tau$ <sup>6</sup> leads to the question of how indicative these results really are. A more serious problem is the fact that the comparative performance of individual measure changes. Which measure performs best depends on the evaluation set, ranking coefficient, PoS-tag restrictions and configuration settings. This means that the answer to the question of which similarity measure is best to mimic human similarity scores depends on aspects that are often not even mentioned, let alone systematically compared.

### 3.4 Variation per category

For each influential category of experimental variation, we compared the variation in Spearman  $\rho$  and Kendall  $\tau$ , while similarity measure and other influential categories were kept stable. The categories we varied include WordNet and WordNet::Similarity version, the gold standard used to evaluate, restrictions on PoS-tags, and measure specific configurations. Table 2 presents the maximum variation found across measures for each category. The last column indicates how often the ranking of a specific measure changed as the category changed, e.g. did the measure ranking third using specific configurations, PoS-tag restrictions and a specific gold standard using WordNet 2.1 still rank third when WordNet 3.0 was used instead? The number in parentheses next to the ‘different ranks’ in the table presents the total number of scores investigated. Note that this number changes for each category, because we com-

<sup>5</sup>Some measures ranked differently as their individual configuration settings changed. In these cases, the measure was included in the overall ranking multiple times, which is why there are more ranking positions than measures.

<sup>6</sup>Section 3.4 explains why the variation in Kendall is this extreme and  $\rho$  is more appropriate for this task.

Variation	Maximum difference		Different rank (tot)
	Spearman $\rho$	Kendall $\tau$	
WN version	0.44	0.42	223 (252)
gold standard	0.24	0.21	359 (504)
PoS-tag	0.09	0.08	208 (504)
configuration	0.08	0.60	37 (90)

Table 2: Variations per category

pared two WordNet versions (WN version), three gold standard and PoS-tag restriction variations and configuration only for the subset of scores where configuration matters.

There are no definite statements to make as to which version (Patwardhan and Pedersen (2006) vs Pedersen (2010)), PoS-tag restriction or configuration gives the best results. Likewise, while most measures do better on the smaller data set, some achieve their highest results on the full set. This is partially due to the fact that ranking coefficients are sensitive to outliers. In several cases where PoS-tag restrictions led to different results, only one pair received a different score. For instance, `path` assigns a relatively high score to the pair *chord-smile* when verbs are included, because the hierarchy of verbs in WordNet is relatively flat. This effect is not observed in `wup` and `lch` which correct for the depth of the hierarchy. On the other hand, `res`, `lin` and `jcn` score better on the same set when verbs are considered, because they cannot detect any relatedness for the pair *crane-implement* when restricted to nouns.

On top of the variations presented above, we notice a discrepancy between the two coefficients. Kendall  $\tau$  generally leads to lower coefficient scores than Spearman  $\rho$ . Moreover, they each give different relative indications: where `lesk` achieves its highest Spearman  $\rho$ , it has an extremely low Kendall  $\tau$  of 0.01. Spearman  $\rho$  uses the difference in rank as its basis to calculate a correlation, where Kendall  $\tau$  uses the number of items with the correct rank. The low Kendall  $\tau$  for `lesk` is the result of three pairs receiving a score that is too high. Other pairs that get a relatively accurate score are pushed one place down in rank. Because only items that receive the exact same rank help to increase  $\tau$ , such a shift can result in a drastic drop in the coefficient. In our opinion, Spearman  $\rho$  is therefore preferable over Kendall  $\tau$ . We included  $\tau$ , because many authors do not mention the ranking coefficient they use (cf. Budanitsky and Hirst (2006), Resnik (1995)) and both  $\rho$  and  $\tau$  are com-

monly used coefficients.

Except for WordNet, which Budanitsky and Hirst (2006) hold accountable for minor variations in a footnote, the influential categories we investigated in this paper, to our knowledge, have not yet been addressed in the literature. Cramer (2008) points out that results from WordNet-Human similarity correlations lead to scattered results reporting variations similar to ours, but she compares studies using different measures, data and experimental setup. This study shows that even if the main properties are kept stable, results vary enough to change the identity of the measure that yields the best performance. Table 1 reveals a wide variation in ranking relative to alternative approaches. Results in Table 2 show that it is common for the ranking of a score to change due to variations that are not at the core of the method.

This study shows that it is far from clear how different WordNet similarity measures relate to each other. In fact, we do not know how we can obtain the best results. This is particularly challenging, because the ‘best results’ may depend on the intended use of the similarity scores (Meng et al., 2013). This is also the reason why we presented the maximum variation observed, rather than the average or typical variation (mostly below 0.10 points). The experiments presented in this paper resulted in a vast amount of data. An elaborate analysis of this data is needed to get a better understanding of how measures work and why results vary to such an extent. We leave this investigation to future work. If there is one take-home message from this experiment, it is that one should experiment with parameters such as restrictions on PoS-tags or configurations and determine which score to use depending on what it is used for, rather than picking something that did best in a study using different data for a different task and may have used a different version of WordNet.

## 4 Reproducing a NER method

Freire et al. (2012) describe an approach to classifying named entities in the cultural heritage domain. The approach is based on the assumption that domain knowledge, encoded in complex features, can aid a machine learning algorithm in NER tasks when only little training data is available. These features include information about person and organisation names, locations, as well as PoS-tags. Additionally, some general features

are used such as a window of three preceding and two following tokens, token length and capitalisation information. Experiments are run in a 10-fold cross-validation setup using an open source machine learning toolkit (McCallum, 2002).

### 4.1 Reproducing NER Experiments

This experiment can be seen as a real-world case of *the sad tale of the Ziggiebottom tagger* (Pedersen, 2008). The (fictional) Ziggiebottom tagger is a tagger with spectacular results that looks like it will solve some major problems in your system. However, the code is not available and a new implementation does not yield the same results. The original authors cannot provide the necessary details to reproduce their results, because most of the work has been done by a PhD student who has finished and moved on to something else. In the end, the newly implemented Ziggiebottom tagger is not used, because it does not lead to the promised better results and all effort went to waste.

Van Erp was interested in the NER approach presented in Freire et al. (2012). Unfortunately, the code could not be made available, so she decided to reimplement the approach. Despite feedback from Freire about particular details of the system, results remained 20 points below those reported in Freire et al. (2012) in overall F-score (Van Erp and Van der Meij, 2013).

The reimplementing process involved choices about seemingly small details such as rounding to how many decimals, how to tokenise or how much data cleanup to perform (normalisation of non-alphanumeric characters for example). Trying different parameter combinations for feature generation and the algorithm never yielded the exact same results as Freire et al. (2012). The results of the best run in our first reproduction attempt, together with the original results from Freire et al. (2012) are presented in Table 3. Van Erp and Van der Meij (2013) provide an overview of the implementation efforts.

### 4.2 Following up from reproduction

Since the experiments in Van Erp and Van der Meij (2013) introduce several new research questions regarding the influence of data cleaning and the limitations of the dataset, we performed some additional experiments.

First, we varied the tokenisation, removing non-alphanumeric characters from the data set. This yielded a significantly smaller data set (10,442

	(Freire et al., 2012) results			Van Erp and Van der Meij’s replication results		
	Precision	Recall	$F_{\beta=1}$	Precision	Recall	$F_{\beta=1}$
LOC (388)	92%	55%	69	77.80%	39.18%	52.05
ORG (157)	90%	57%	70	65.75%	30.57%	41.74
PER (614)	91%	56%	69	73.33%	37.62%	49.73
Overall (1,159)	91%	55%	69	73.33%	37.19%	49.45

Table 3: Precision, recall and  $F_{\beta=1}$  scores for the original experiments from Freire et al. 2012 and our replication of their approach as presented in Van Erp and Van der Meij (2013)

tokens vs 12,510), and a 15 point drop in overall F-score. Then, we investigated whether variation in the cross-validation splits made any difference as we noticed that some NEs were only present in particular fields in the data, which can have a significant impact on a small dataset. We inspected the difference between different cross-validation folds by computing the standard deviations of the scores and found deviations of up to 25 points in F-score between the 10 splits. In the general setup, database records were randomly distributed over the folds and cut off to balance the fold sizes. In a different approach to dividing the data by distributing individual sentences from the records over the folds, performance increases by 8.57 points in overall F-score to 58.02. This is not what was done in the original Freire et al. (2012) paper, but shows that the results obtained with this dataset are quite fragile.

As we worried about the complexity of the feature set relative to the size of the data set, we deviated somewhat from Freire et al. (2012)’s experiments in that we switched some features on and off. Removal of complex features pertaining to the window around the focus token improved our results by 3.84 points in overall F-score to 53.39. The complex features based on VIAF,<sup>7</sup> GeoNames<sup>8</sup> and WordNet do contribute to the classification in the Mallet setup as removing them and only using the focus token, window and generic features causes a slight drop in overall F-score from 49.45 to 47.25.

When training the Stanford NER system (Finkel et al., 2005) on just the tokens from the Freire data set and the parameters from english.all.3class.distsim.prop (included in the Stanford NER release, see also Van Erp and Van der Meij (2013)), our F-scores come very close to those reported by Freire et al. (2012), but mostly with a higher recall and lower precision. It is puzzling that the Stanford system obtains such high

results with only very simple features, whereas for Mallet the complex features show improvement over simpler features. This leads to questions about the differences between the CRF implementations and the influence of their parameters, which we hope to investigate in future work.

### 4.3 Reproduction difficulties explained

Several reasons may be the cause of why we fail to reproduce results. As mentioned, not all resources and data were available for this experiment, thus causing us to navigate in the dark as we could not reverse-engineer intermediate steps, but only compare to the final precision, recall and F-scores.

The experiments follow a general machine learning setup consisting roughly of four steps: preprocess data, generate features, train model and test model. The novelty and replication problems lie in the first three steps. How the data was preprocessed is a major factor here. The data set consisted of XML files marked up with inline named entity tags. In order to generate machine learning features, this data has to be tokenised, possibly cleaned up and the named entity markup had to be converted to a token-based scheme. Each of these steps can be carried out in several ways, and choices made here can have great influence on the rest of the pipeline.

Similar choices have to be made for preprocessing external resources. From the descriptions in the original paper, it is unclear how records in VIAF and GeoNames were preprocessed, or even which versions of these resources were used. Preprocessing and calculating occurrence statistics over VIAF takes 30 hours for each run. It is thus not feasible to identify the main potential variations without the original data to verify this preparatory step.

Numbers had to be rounded when generating the features, leading to the question of how many decimals are required to be discriminative without creating an overly sparse dataset. Freire recalls that encoding features as multi-value discrete fea-

<sup>7</sup><http://www.viaf.org>

<sup>8</sup><http://www.geonames.org>

tures versus several boolean features can have significant impact. These settings are not mentioned in the paper, making reproduction very difficult.

As the project in which the original research was performed has ended, and there is no central repository where such information can be retrieved, we are left to wonder how to reuse this approach in order to further domain-specific NER.

## 5 Observations

In this section, we generalise the observations from our use cases to the main categories that can influence reproduction.

Despite our efforts to describe our systems as clearly as possible, details that can make a tremendous difference are often omitted in papers. It will be no surprise to researchers in the field that **pre-processing** of data can make or break an experiment.

The choice of which steps we perform, and how each of these steps is carried out exactly are part of our **experimental setup**. A major difference in the results for the NER experiments was caused by variations in the way in which we split the data for cross-validation.

As we fine-tune our techniques, software gets updated, data sets are extended or annotation bugs are fixed. In the WordNet experiment, we found that there were two different gold standard data sets. There are also different versions of WordNet, and the WordNet::Similarity packages. Similarly for the NER experiment, GeoNames, VIAF and Mallet are updated regularly. It is therefore critical to pay attention to **versioning**.

Our experiments often consist of several different steps whose outputs may be difficult to retrace. In order to check the output of a reproduction experiment at every step of the way, **system output** of experiments, including intermediate steps, is vital. The WordNet replication was only possible, because Pedersen could provide the similarity scores of each word pair. This enabled us to compare the intermediate output and identify the source of differences in output.

Lastly, there may be inherent **system variations** in the techniques used. Machine learning algorithms may for instance use coin flips in case of a tie. This was not observed in our experiments, but such variations may be determined by running an experiment several times and taking the average over the different runs (cf. Raeder et al. (2010)).

All together, these observations show that sharing data and software play a key role in gaining insight into how our methods work. Vanschoren et al. (2012) propose a setup that allows researchers to provide their full experimental setup, which should include exact steps followed in preprocessing the data, documentation of the experimental setup, exact versions of the software and resources used and experimental output. Having access to such a setup allows other researchers to validate research, but also tweak the approach to investigate system variation, systematically test the approach in order to learn its limitations and strengths and ultimately improve on it.

## 6 Discussion

Many of the aspects addressed in the previous section such as preprocessing are typically only mentioned in passing, or not at all. There is often not enough space to capture all details, and they are generally not the core of the research described. Still, our use cases have shown that they can have a tremendous impact on reproduction, and can even lead to different conclusions. This leads to serious questions on how we can interpret our results and how we can compare the performance of different methods. Is an improvement of a few per cent really due to the novelty of the approach if larger variations are found when the data is split differently? Is a method that does not quite achieve the highest reported state-of-the-art result truly less good? What does a state-of-the-art result mean if it is only tested on one data set?

If one really wants to know whether a result is better or worse than the state-of-the-art, the range of variation within the state-of-the-art must be known. Systematic experiments such as the ones we carried out for WordNet similarity and NER, can help determine this range. For results that fall within the range, it holds that they can only be judged by evaluations going beyond comparing performance numbers, i.e. an evaluation of how the approach achieves a given result and how that relates to alternative approaches.

Naturally, our use cases do not represent the entire gamut of research methodologies and problems in the NLP community. However, they do represent two core technologies and our observations align with previous literature on replication and reproduction.

Despite the systematic variation we employed

in our experiments, they do not answer all questions that the problems in reproduction evoked. For the WordNet experiments, deeper analysis is required to gain full understanding of how individual influential aspects interact with each measurement. For the NER experiments, we are yet to identify the cause of our failure to reproduce.

The considerable time investment required for such experiments forms a challenge. Due to pressure to publish or other time limitations, they cannot be carried out for each evaluation. Therefore, it is important to share our experiments, so that other researchers (or students) can take this up. This could be stimulated by instituting reproduction tracks in conferences, thus rewarding systematic investigation of research approaches. It can also be aided by adopting initiatives that enable authors to easily include data, code and/or workflows with their publications such as the PLOS/figshare collaboration.<sup>9</sup> We already do a similar thing for our research problems by organising challenges or shared tasks, why not extend this to systematic testing of our approaches?

## 7 Conclusion

We have presented two reproduction use cases for the NLP domain. We show that repeating other researchers' experiments can lead to new research questions and provide new insights into and better understanding of the investigated techniques.

Our WordNet experiments show that the performance of similarity measures can be influenced by the PoS-tags considered, measure specific variations, the rank coefficient and the gold standard used for comparison. We not only find that such variations lead to different numbers, but also different rankings of the individual measures, i.e. these aspects lead to a different answer to the question as to which measure performs best. We did not succeed in reproducing the NER results of Freire et al. (2012), showing the complexity of what seems a straightforward reproduction case based on a system description and training data only. Our analyses show that it is still an open question whether additional complex features improve domain specific NER and that this may partially depend on the CRF implementation.

Some observations go beyond our use cases. In particular, the fact that results vary significantly

<sup>9</sup><http://blogs.plos.org/plos/2013/01/easier-access-to-plos-data/>

because of details that are not made explicit in our publications. Systematic testing can provide an indication of this variation. We have classified relevant aspects in five categories occurring across subdisciplines of NLP: **preprocessing, experimental setup, versioning, system output, and system variation.**

We believe that knowing the influence of different aspects in our experimental workflow can help increase our understanding of the robustness of the approach at hand and will help understand the meaning of the state-of-the-art better. Some techniques are reused so often (the papers introducing WordNet similarity measures have around 1,000-2,000 citations each as of February 2013, for example) that knowing their strengths and weaknesses is essential for optimising their use.

As mentioned many times before, sharing is key to facilitating reuse, even if the code is imperfect and contains hacks and possibly bugs. In the end, the same holds for software as for documentation: *it is like sex: if it is good, it is very good and if it is bad, it is better than nothing!*<sup>10</sup> But most of all: when reproduction fails, regardless of whether original code or a reimplementations was used, valuable insights can emerge from investigating the cause of this failure. So don't let your failing reimplementations of the *Zigglebottom* tagger collect dust on a shelf while others reimplement their own failing *Zigglebottoms*. As a community, we need to know where our approaches fail, as much –if not more– as where they succeed.

## Acknowledgments

We would like to thank the anonymous reviewers for their eye to detail and useful comments to make this a better paper. We furthermore thank Ruben Izquierdo, Lourens van der Meij, Christoph Zwirello, Rebecca Dridan and the Semantic Web Group at VU University for their help and useful feedback. # Evaluating Text Segmentation using Boundary Edit Distance

Chris Fournier

University of Ottawa  
Ottawa, ON, Canada

cfour037@eecs.uottawa.ca

## Abstract

This work proposes a new segmentation evaluation metric, named *boundary similarity* (B), an inter-coder agreement coefficient adaptation, and a confusion-matrix for segmentation that are all based upon an adaptation of the boundary edit distance in Fournier and Inkpen (2012). Existing segmentation metrics such as  $P_k$ , WindowDiff, and Segmentation Similarity (S) are all able to award partial credit for near misses between boundaries, but are biased towards segmentations containing few or tightly clustered boundaries. Despite S's improvements, its normalization also produces cosmetically high values that overestimate agreement & performance, leading this work to propose a solution.

## 1 Introduction

Text segmentation is the task of splitting text into segments by placing boundaries within it. Segmentation is performed for a variety of purposes and is often a pre-processing step in a larger task. E.g., text can be topically segmented to aid video and audio retrieval (Franz et al., 2007), question answering (Oh et al., 2007), subjectivity analysis (Stoyanov and Cardie, 2008), and even summarization (Haghighi and Vanderwende, 2009).

A variety of segmentation granularities, or atomic units, exist, including segmentations at the morpheme (e.g., Sirts and Alumäe 2012), word (e.g., Chang et al. 2008), sentence (e.g., Reynar and Ratnaparkhi 1997), and paragraph (e.g., Hearst 1997) levels. Between each atomic unit lies the potential to place a boundary. Segmentations can also represent the structure of text as being organized linearly (e.g., Hearst 1997), hierarchically (e.g., Eisenstein 2009), etc. Theoretically, segmentations could also contain varying bound-

ary types, e.g., two boundary types could differentiate between act and scene breaks in a play.

Because of its value to natural language processing, various text segmentation tasks have been automated such as topical segmentation—for which a variety of automatic segmenters exist (e.g., Hearst 1997, Malioutov and Barzilay 2006, Eisenstein and Barzilay 2008, and Kazantseva and Szpakowicz 2011). This work addresses how to best select an automatic segmenter and which segmentation metrics are most appropriate to do so.

To select an automatic segmenter for a particular task, a variety of segmentation evaluation metrics have been proposed, including  $P_k$  (Beeferman and Berger, 1999, pp. 198–200), WindowDiff (WD; Pevzner and Hearst 2002, p. 10), and most recently Segmentation Similarity (S; Fournier and Inkpen 2012, p. 154–156). Each of these metrics have a variety of flaws:  $P_k$  and WindowDiff both under-penalize errors at the beginning of segmentations (Lamprier et al., 2007) and have a bias towards favouring segmentations with few or tightly-clustered boundaries (Niekrasz and Moore, 2010), while S produces overly optimistic values due to its normalization (shown later).

To overcome the flaws of existing text segmentation metrics, this work proposes a new series of metrics derived from an adaptation of boundary edit distance (Fournier and Inkpen, 2012, p. 154–156). This new metric is named *boundary similarity* (B). A confusion matrix to interpret segmentation as a classification problem is also proposed, allowing for the computation of information retrieval (IR) metrics such as precision and recall.<sup>1</sup>

In this work: §2 reviews existing segmentation metrics; §3 proposes an adaptation of *boundary edit distance*, a new normalization of it, a new confusion matrix for segmentation, and an inter-

<sup>1</sup>An implementation of boundary edit distance, boundary similarity, B-precision, and B-recall, etc. is provided at <http://nlp.chrisfournier.ca/>

coder agreement coefficient adaptation; §4 compares existing segmentation metrics to those proposed herein; §5 evaluates S and B based inter-coder agreement; and §6 compares B, S, and WD while evaluating automatic segmenters.

## 2 Related Work

### 2.1 Segmentation Evaluation

Many early studies evaluated automatic segmenters using information retrieval (IR) metrics such as precision, recall, etc. These metrics looked at segmentation as a binary classification problem and were very harsh in their comparisons—no credit was awarded for nearly missing a boundary.

Near misses occur frequently in segmentation—although manual coders often agree upon the bulk of where segment lie, they frequently disagree upon the exact position of boundaries (Artstein and Poesio, 2008, p. 40). To attempt to overcome this issue, both Passonneau and Litman (1993) and Hearst (1993) conflated multiple manual segmentations into one that contained only those boundaries which the majority of coders agreed upon. IR metrics were then used to compare automatic segmenters to this majority solution. Such a majority solution is unsuitable, however, because it does not contain actual subtopic breaks, but instead the conflation of a collection of potentially disagreeing solutions. Additionally, the definition of what constitutes a majority is subjective (e.g., Passonneau and Litman (1993, p. 150), Litman and Passonneau (1995), Hearst (1993, p. 6) each used  $4/7$ ,  $3/7$ , and  $> 50\%$ , respectively).

To address the issue of awarding partial credit for an automatic segmenter nearly missing a boundary—without conflating segmentations, Beeferman and Berger (1999, pp. 198–200) proposed a new metric named  $P_k$ . Pevzner and Hearst (2002, pp. 3–4) explain  $P_k$  well: a window of size  $k$ —where  $k$  is half of the mean manual segmentation length—is slid across both automatic and manual segmentations. A penalty is awarded if the window’s edges are found to be in differing or the same segments within the manual segmentation and the automatic segmentation disagrees.  $P_k$  is the sum of these penalties over all windows. Measuring the proportion of windows in error allows  $P_k$  to penalize a fully missed boundary by  $k$  windows, whereas a nearly missed boundary is penalized by the distance that it is offset.

$P_k$  was not without issue, however. Pevzner

and Hearst (2002, pp. 5–10) identified that  $P_k$ : i) penalizes false negatives (FNs)<sup>2</sup> more than false positives (FPs); ii) does not penalize full misses within  $k$  units of a reference boundary; iii) penalize near misses too harshly in some situations; and iv) is sensitive to internal segment size variance.

To solve  $P_k$ ’s issues, Pevzner and Hearst (2002, pp. 10) proposed a modification referred to as WindowDiff (WD). Its major difference is in how it decides to penalized windows: within a window, if the number of boundaries in the manual segmentation ( $M_{ij}$ ) differs from the number of boundaries in the automatic segmentation ( $A_{ij}$ ), then a penalty is given. The ratio of penalties over windows then represents the degree of error between the segmentations, as in Equation 1. This change better allowed WD to: i) penalize FPs and FNs more equally;<sup>3</sup> ii) Not skip full misses; iii) Less harshly penalize near misses; and iv) Reduce its sensitivity to internal segment size variance.

$$WD(M, A) = \frac{1}{N - k} \sum_{i=1, j=i+k}^{N-k} (|M_{ij} - A_{ij}| > 0) \quad (1)$$

WD did not, however, solve all of the issues related to window-based segmentation comparison. WD, and inherently  $P_k$ : i) Penalize errors less at the beginning and end of segmentations (Lamprier et al., 2007); ii) Are biased towards favouring automatic segmentations with either few or tightly-clustered boundaries (Niekrasz and Moore, 2010); iii) Calculate window size  $k$  inconsistently;<sup>4</sup> iv) Are not symmetric<sup>5</sup> (meaning that they cannot be used to produce a pairwise mean of multiple manual segmentations<sup>6</sup>).

Segmentation Similarity (S; Fournier and Inkpen 2012, pp. 154–156) took a different approach to comparing segmentations. Instead of using windows, the work proposes a new restricted edit distance called *boundary edit distance* which differentiates between full and near misses. S then

<sup>2</sup>I.e., a boundary present in the manual but not the automatic segmentation, and the reverse for a false positive.

<sup>3</sup>Georgescul et al. (2006, p. 48) noted that WD interprets a near miss as a FP probabilistically more than as a FN.

<sup>4</sup> $k$  must be an integer, but half of a mean may be a fraction, thus rounding must be used, but no rounding method is specified. It is also not specified whether  $k$  should be set once during a study or recalculated for each comparison—this work assumes the latter.

<sup>5</sup>Window size is calculated only upon the manual segmentation, meaning that one must be a manual and other an automatic segmentation.

<sup>6</sup>This also means that WD and  $P_k$  cannot be adapted to compute inter-coder agreement coefficients.

normalizes the counts of full and near misses identified by boundary edit distance, as shown in Equation 2, where  $s_a$  and  $s_b$  are the segmentations,  $n_t$  is the maximum distance that boundaries may span to be considered a near miss,  $\text{edits}(s_a, s_b, n_t)$  is the edit distance, and  $\text{pb}(D)$  is the number of potential boundaries in a document  $D$  ( $\text{pb}(D) = |D| - 1$ ).

$$S(s_a, s_b, n_t) = 1 - \frac{|\text{edits}(s_a, s_b, n_t)|}{\text{pb}(D)} \quad (2)$$

Boundary edit distance models full misses as the addition/deletion of a boundary, and near misses as  $n$ -wise transpositions. An  $n$ -wise transposition is the act of swapping the position of a boundary with an empty position such that it matches a boundary in the segmentation compared against (up to a spanning distance of  $n_t$ ).  $S$  also scales the severity of a near miss by the distance over which it is transposed, allowing it to scale the penalty of a near misses much like WD.  $S$  is also symmetric, allowing it to be used in pairwise means and inter-coder agreement coefficients.

The usage of an edit distance that supported transpositions to compare segmentations was an advancement over window-based methods, but boundary edit distance and its normalization  $S$  are not without problems, specifically: i) This edit distance uses string reversals ( $ABCD \implies DCBA$ ) to perform transpositions, making it cumbersome to analyse individual pairs of boundaries between segmentations; ii)  $S$  is sensitive to variations in the total size of a segmentation, leading it to favour very sparse segmentations with few boundaries; iii)  $S$  produces cosmetically high values, making it difficult to interpret and causing over-estimation of inter-coder agreement. In this work, these deficiencies are demonstrated and a new set of metrics are proposed as replacements.

## 2.2 Inter-Coder Agreement

Inter-coder agreement coefficients are used to measure whether a group of human judges (i.e. coders) agree with each other greater than chance. Such coefficients are used to determine the reliability and replicability of the coding scheme and instructions used to collect manual codings (Carletta, 1996). Although direct interpretation of such coefficients is difficult, they are an invaluable tool when comparing segmentation data that has been collected with differing labels and when estimating the replicability of a study. A variety of inter-

coder agreement coefficients exist, but this work focuses upon a selection of those discussed by Artstein and Poesio (2008), specifically: Scott's  $\pi$  (Scott, 1955) Fleiss' multi- $\pi$  ( $\pi^*$ , Fleiss 1971)<sup>7</sup>, Cohen's  $\kappa$  (Cohen, 1960), and multi- $\kappa$  ( $\kappa^*$ , Davies and Fleiss 1982). Their general forms are shown in Equation 3, where  $A_a$  represents actual agreement, and  $A_e$  expected (i.e., chance) agreement between coders.

$$\kappa, \pi, \kappa^*, \text{ and } \pi^* = \frac{A_a - A_e}{1 - A_e} \quad (3)$$

When calculating agreement between manual segmenters, boundaries are considered labels and their positions the decisions. Unfortunately, because of the frequency of near misses that occur in segmentation, using such labels and decisions causes inter-coder agreement coefficients to drastically underestimate actual agreement—much like how automatic segmenter performance is underestimated when segmentation is treated as a binary classification problem. Hearst (1997, pp. 53–54) attempted to adapt  $\pi^*$  to award partial credit for near misses by using the percentage agreement metric of Gale et al. (1992, p. 254) to compute actual agreement—which conflates multiple manual segmentations together according to whether a majority of coders agree upon a boundary or not. Unfortunately, such a method of computing agreement grossly inflates results, and “the statistic itself guarantees at least 50% agreement by only pairing off coders against the majority opinion” (Isard and Carletta, 1995, p. 63).

Fournier and Inkpen (2012, pp. 154–156) proposed using pairwise mean  $S$  for actual agreement to allow inter-coder agreement coefficients to award partial credit for near misses. Unfortunately, because  $S$  produces cosmetically high values, it also causes inter-coder agreement coefficients to drastically overestimates actual agreement. This work demonstrates this deficiency and proposes and evaluates a solution.

## 3 A New Proposal for Edit-Based Text Segmentation Evaluation

In this section, a new boundary edit distance based segmentation metric and confusion matrix is proposed to solve the deficiencies of  $S$  for both segmentation comparison and inter-coder agreement.

<sup>7</sup>Sometimes referred to as  $K$  (Siegel and Castellan, 1988).

### 3.1 Boundary Edit Distance

In this section, Boundary Edit Distance (BED; as proposed in Fournier and Inkpen 2012, pp. 154–156) is introduced in more detail, and a few terminological and conceptual changes are made.

Boundary Edit Distance uses three main edit operations to model segmentation differences:

- Additions/deletions (AD; referred to originally as substitutions) for full misses;
- Substitutions (S; not shown for brevity) for confusing one boundary type with another;
- $n$ -wise transpositions (T) for near misses.

These edit operations are symmetric and operate upon the set of boundaries that occur at each potential boundary position in a pair of segmentations. An example of how these edit operations are applied<sup>8</sup> is shown in Figure 1, where a near miss (T), a matching pair of boundaries (M), and two full misses (ADs) are shown with the maximum distance that a transposition can span ( $n_t$ ) set to 2 potential boundaries (i.e., only adjacent positions can be transposed).

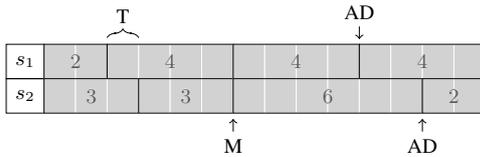

Figure 1: Boundary edit operations

In Figure 1, the location of the errors is clearly shown. Importantly, however, pairs of boundaries between the segmentations can be seen that represent the decisions made, and the correctness of these decisions. Imagine that  $s_1$  is a manual segmentation, and  $s_2$  is an automatic segmenter’s hypothesis. The transposition is a partially correct decision, or boundary pair. The match is a correct boundary pair. The additions/deletions, however, could be one of two erroneous decisions: to not place an expected boundary (FN), or to place a superfluous boundary (FP).<sup>9</sup>

This work proposes assigning a correctness score for each boundary pair/decision (shown in Table 1) and then using the mean of this score as a normalization of boundary edit distance. This interpretation intuitively relates boundary edit distance to coder judgements, making it ideal for

<sup>8</sup>A complete explanation of Boundary Edit Distance is detailed in Fournier (2013, Section 4.1.2).

<sup>9</sup>Also note that the ADs are close together, and if  $n_t > 2$ , then they would be considered a T, and not two ADs—this is one way to award partial credit for near misses.

calculating actual agreement in inter-coder agreement coefficients and comparing segmentations.

Pair	Correctness
Match	1
Addition/deletion	0
Transposition	$1 - w_{t\_span}(T_e, n_t)$
Substitution	$1 - w_{s\_ord}(S_e, T_b)$

Table 1: Correctness of boundary pair

### 3.2 Boundary Similarity

The new boundary edit distance normalization proposed herein is referred to as *boundary similarity* (B). Assuming that boundary edit distance produces sets of edit operations where  $A_e$  is the set of additions/deletions,  $T_e$  the set of  $n$ -wise transpositions,  $S_e$  the set of substitutions, and  $B_M$  the set of matching boundary pairs, boundary similarity can be defined as shown in Equation 4—one minus the incorrectness of each boundary pair over the total number of boundary pairs.

$$B(s_1, s_2, n_t) = 1 - \frac{|A_e| + w_{t\_span}(T_e, n_t) + w_{s\_ord}(S_e, T_b)}{|A_e| + |T_e| + |S_e| + |B_M|} \quad (4)$$

This form, one minus a penalty function, was chosen so that it was easier to compare against other penalty functions considered (not shown here for brevity). This normalization was also chosen because it is equivalent to mean boundary pair correctness and so that it ranges in value from 0 to 1. In the worst case, a segmentation comparison will result in no matches, no near misses, no substitutions, and  $X$  full misses, i.e.,  $|A_e| = X$  and all other terms in Equation 4 are zero, meaning that:

$$\begin{aligned} B &= 1 - \frac{X + 0 + 0}{X + 0 + 0 + 0} \\ &= 1 - X/X = 1 - 1 = 0 \end{aligned}$$

In the best case, a segmentation comparison will result in  $X$  matches, no near misses, no substitutions, and no full misses, i.e.,  $|B_M| = X$  and all other terms in Equation 4 are zero, meaning that:

$$\begin{aligned} B &= 1 - \frac{0 + 0 + 0}{0 + 0 + 0 + X} \\ &= 1 - 0/X = 1 - 0 = 1 \end{aligned}$$

For all other scenarios, varying numbers of matches, near misses, substitutions and full misses will result in values of B between 0 and 1.

Equation 4 takes two segmentations (in any order), and the maximum transposition spanning distance ( $n_t$ ). This distance represents the greatest offset between boundary positions that could be considered a near miss and can be used to scale

the severity of a near miss. A variety of scaling functions could be used, and this work arbitrarily chooses a simple fraction to represent each transposition’s severity in terms of its distance from its paired boundary over  $n_t$  plus a constant  $w_t$  (0 by default), as shown in Equation 5.

$$w_t\text{-span}(T_e, n_t) = \sum_{j=1}^{|T_e|} \left( w_t + \frac{\text{abs}(T_e[j][1] - T_e[j][2])}{n_t - 1} \right) \quad (5)$$

If multiple boundary types are used, then substitution edit operations would occur when one boundary type was confused with another. Assigning each boundary type  $t_b \in T_b$  a number on an ordinal scale, substitutions can be weighted by their distance on this scale over the maximum distance plus a constant  $w_s$  (0 by default), as shown in Equation 6.

$$w_s\text{-ord}(S_e, T_b) = \sum_{j=1}^{|S_e|} \left( w_s + \frac{\text{abs}(S_e[j][1] - S_e[j][2])}{\max(T_b) - \min(T_b)} \right) \quad (6)$$

These scaling functions allow for edit penalties to range from 0 to  $w_s/t$  plus some linear distance.

### 3.3 A Confusion Matrix for Segmentation

The mean correctness of each pair (i.e., B) gives an indication of just how similar one segmentation is to another, but what if one wants to identify some specific attributes of the performance of an automatic segmenter? Is the segmenter confusing one boundary type with another, or is it very precise but has poor recall? The answers to these questions can be obtained by looking at text segmentation as a multi-class classification problem.

This work proposes using a task’s set of boundary types ( $T_b$ ) and the lack of a boundary ( $\emptyset$ ) to represent the set of segmentation classes in a boundary classification problem. Using these classes, a confusion matrix (defined in Equation 7) can be created which sums boundary pair correctness so that information-retrieval metrics can be calculated that award partial credit to near misses by scaling edits operations.

$$\text{CM}(a, p) = \begin{cases} |B_{M,a}| + w_s\text{-ord}(S_e^{a,p}, T_b) \\ \quad + w_t\text{-span}(T_e^{a,p}, n_t) & \text{if } a = p \\ w_s\text{-ord}(S_e^{a,p}, T_b) \\ \quad + w_t\text{-span}(T_e^{a,p}, n_t) & \text{if } a \neq p \\ |A_{e,a}| & \text{if } p = \emptyset \\ |A_{e,p}| & \text{if } a = \emptyset \end{cases} \quad (7)$$

An example confusion matrix is shown in Figure 2 from which IR metrics such as precision, recall, and  $F_\beta$ -measure can be computed (referred to as B-precision, B-recall, etc.).

		Actual	
		B	Non-B
Predicted	B	CM(1, 1)	CM( $\emptyset$ , 1)
	Non-B	CM(1, $\emptyset$ )	CM( $\emptyset$ , $\emptyset$ )

Figure 2: Example confusion matrix ( $T_b = \{1\}$ )

### 3.4 B-Based Inter-coder Agreement

Fournier and Inkpen (2012, p. 156–157) adapted four inter-coder agreement formulations provided by Artstein and Poesio (2008) to use S to award partial credit for near misses, but because S produces cosmetically high agreement values they grossly overestimate agreement. To solve this issue, this work instead proposes using micro-average B (i.e., mean boundary pair correctness over all documents and codings compared) to solve this issue (demonstrated in §5) because it does not over-estimate actual agreement (demonstrated in §4 and 5).

## 4 Discussion of Segmentation Metrics

Before analysing how each metric compares to each other upon a large data set, it would be useful to investigate how they act on a smaller scale. To that end, this section discusses how each metric interprets a set of hypothetical segmentations of an excerpt of a poem by Coleridge (1816, pp. 55–58) titled *Kubla Khan* (shown in Figure 3)—chosen arbitrarily for its brevity (and beauty). These segmentations are topical and at the line-level.

1. In Xanadu did Kubla Khan
2. A stately pleasure-dome decree:
3. Where Alph, the sacred river, ran
4. Through caverns measureless to man
5. Down to a sunless sea.
6. So twice five miles of fertile ground
7. With walls and towers were girdled round:
8. And here were gardens bright with sinuous rills,
9. Where blossomed many an incense-bearing tree;
10. And here were forests ancient as the hills,
11. Enfolding sunny spots of greenery.

Figure 3: Excerpt from the poem *Kubla Khan* (Coleridge, 1816, pp. 55–58) with line numbers

Topical segmentations of this poem are difficult to produce because there is still some structural form (i.e., punctuation) which may dictate where a boundary lies, but the imagery, places, times, and subjects of the poem appear to twist and wind like a vision in a dream. Thus, placing a topical boundary in this text is a highly subjective task. One hypothetical topical segmentation of the excerpt is shown in Figure 4. In this section, a variety of

contrived automatic segmentations are compared to this manual segmentation to illustrate how each metric reacts to different mistakes.

Lines	Description
1–2	Kubla Khan and his decree
3–5	Waterways
6–11	Fertile ground and greenery

Figure 4: A hypothetical manual segmentation

Assuming that Figure 4 represents an acceptable manual segmentation ( $m$ ), how would each metric react to an automatic segmentation ( $a$ ) that combines the segments 1–2 and 3–5 together? This would represent a full miss, or a false negative, as shown in Figure 5. S interprets these segmentations as being quite similar, yet, the automatic segmentation is missing a boundary. B and  $1-WD$ ,<sup>10</sup> in this case, better reflect this error.

$m$	■	■	■	■	■	■	■	■	■	■	$s$	$B$	$1-WD$
$a$	■	■	■	■	■	■	■	■	■	■	0.9	0.5	0.777
$k = 2$													

Figure 5: False negative

How would each metric react to an automatic segmentation that is very close to placing the boundaries correctly, but makes the slight mistake of thinking that the segment on waterways (3–5) ends a bit too early? This would represent a near miss, as shown in Figure 6. S and  $1-WD$  incorrectly interpret this error as being equivalent to the previous false negative—a troubling result. Segmentation comparison metrics should be able to discern between the full and a near miss shown in these two figures, and an automatic segmenter that nearly misses a boundary should be awarded a better score than one which fully misses a boundary—B recognizes this and awards the near miss a higher score.

$m$	■	■	■	■	■	■	■	■	■	■	$s$	$B$	$1-WD$
$a$	■	■	■	■	■	■	■	■	■	■	0.9	0.75	0.777
$k = 2$													

Figure 6: Near miss

How would each metric react to an automatic segmentation that adds an additional boundary between line 8 and 9? This would not be ideal because such a boundary falls in the middle of a cohesive description of a garden, representing

<sup>10</sup>WD is reported as  $1-WD$  because WD is normally a penalty metric where a value of 0 is ideal, unlike S and B. Additionally,  $k = 2$  for all examples in this section because WD computes  $k$  from the manual segmentation  $m$ , which does not change in these examples.

a full miss, or false positive, as in Figure 7. S and  $1-WD$  incorrectly interpret this error as being equivalent to the previous two errors—an even more troubling result. In this case, there are two matching boundaries and a pair that do not match, which is arguably preferable to the full miss and one match in Figure 5, but not to the match and near miss in Figure 6. B recognizes this, and awards a higher score to this automatic segmenter than that in Figure 5, but below Figure 6.

$m$	■	■	■	■	■	■	■	■	■	■	$s$	$B$	$1-WD$
$a$	■	■	■	■	■	■	■	■	■	■	0.9	0.666	0.777
$k = 2$													

Figure 7: False positive

How would each metric react to an automatic segmentation that compensates for its lack of precision by spuriously adding boundaries in clusters around where it thinks that segments should begin or end? This is shown in Figure 8. This kind of behaviour is finally penalized differently by S and  $1-WD$  (unlike the other errors shown in this section), but it only barely results in a dip in their values. B also penalizes this behaviour, but does so much more harshly—in B’s interpretation, this is as egregious as committing a false negative (e.g., Figure 5)—an arguably correct interpretation, if the evaluation desires to maximize similarity with a manual segmentation.

$m$	■	■	■	■	■	■	■	■	■	■	$s$	$B$	$1-WD$
$a$	■	■	■	■	■	■	■	■	■	■	0.8	0.5	0.666
$k = 2$													

Figure 8: Cluster of false positives

These short demonstrations of how S, B, and  $1-WD$  interpret error should lead one to conclude that: i) WD can penalize near misses to the same degree as full misses—overly harshly; ii) Both S and WD are not very discriminating when small segments are analysed; and iii) B is the only one of the three metrics that is able to often discriminate between these situations. B, if used to rank these automatic segmenters, would rank them from best to worst performing as: the near miss, false positive, and then a tie between the false negative and cluster of false positives—a reasonable ranking in the context of an evaluation seeking similarity with a manual segmentation.

## 5 Segmentation Agreement

Having a bit more confidence in B compared to S and WD on a small scale from the previous sec-

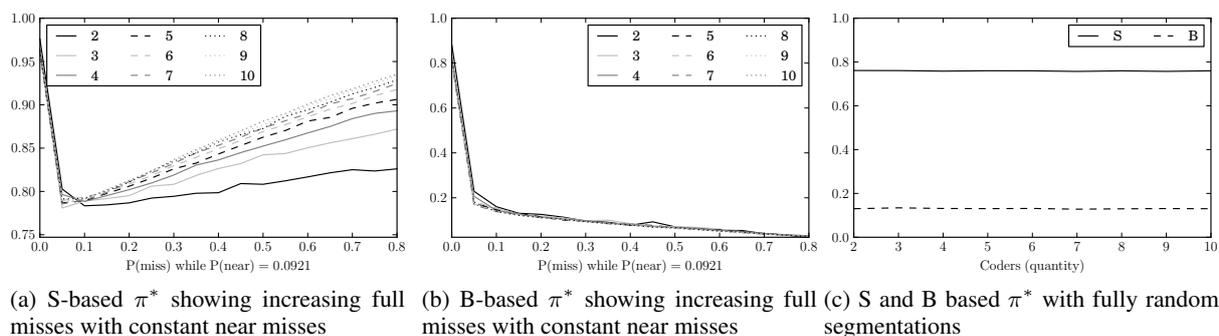

Figure 9: Artificial data sets illustrating how  $\pi$  adapted to use either S or B reacts to increasing full misses and random segmentations and varying numbers of coders

tion, it makes sense to analyse some larger data sets. Two such data sets are The Stargazer data set collected by Hearst (1997) and The Moonstone data set collected by Kazantseva and Szpakowicz (2012). Both are linear topical segmentations at the paragraph level with only one boundary type, but that is where their similarities end.

The Stargazer text is a science magazine article titled “Stargazers look for life” (Baker, 1990) segmented by 7 coders and was one of twelve articles chosen for its length (between 1,800 and 2,500 words) and for having little structural demarcation. “The Moonstone” is a 19<sup>th</sup> century romance novel by Collins (1868) segmented by 4–6 coders per chapter; of its 23 chapters, 2 were coded in a pilot study and another 20 were coded individually by 27 undergraduate English students in 5 groups.

For the Stargazer data set, using S-based  $\pi^*$ , an inter-coder agreement coefficient of 0.7562 is obtained—a reasonable level by content analysis standards. Unfortunately, this value is highly inflated, and B-based  $\pi^*$  gives a much more conservative coefficient at 0.4405. For the Moonstone data set, the agreement coefficients for each group of 4–6 coders using S-based  $\pi^*$  is again over-inflated at 0.91, 0.92, 0.90, 0.94, 0.83. B-based  $\pi^*$  instead reports that the coefficients should be 0.20, 0.18, 0.40, 0.38, 0.23.

Which of these coefficients should be trusted? Is agreement in these data sets high or low? To help answer that, this work looks at how the coders in the data sets behaved. If the segmenters in the Moonstone data set truly agreed with each other, then they should have all behaved similarly. One measure of coder behaviour is the frequency that they placed boundaries (normalized by their opportunity to place boundaries, i.e. the sum of the potential boundaries in the chapters that each segmented). This normalized frequency is shown per

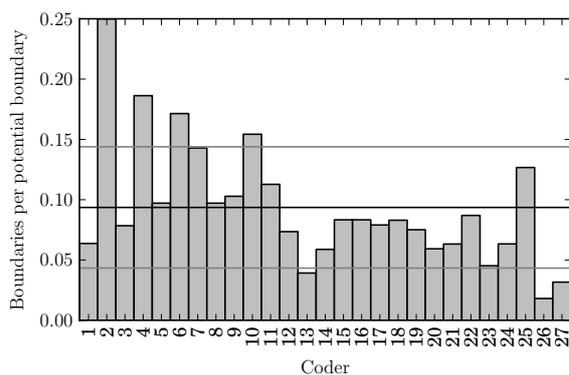

Figure 11: Normalized boundaries placed by each coder in the Moonstone data set (with mean $\pm$ SD)

coder in Figure 11 for The Moonstone data set, along with bars indicating the mean and one standard deviation above and below. As can be seen, the coders fluctuated wildly in the frequency with which they placed boundaries—some (e.g., coder 7) to degrees exceeding 2 standard deviations. The Moonstone data set as a whole does not exhibit coders who behaved similarly, supporting the assertion by B-based  $\pi^*$  that these coders do not agree well (though pockets of agreement exist).

How can it be demonstrated that S-based agreement over-estimates agreement, and B-based agreement does not? One way to demonstrate this is through simulation. By estimating parameters from the large Moonstone data set such as the distribution of internal segment sizes produced by all coders, a random segmentation of the novel with similar characteristics can be created. From this single random segmentation, other segmentation can be created with a probability of either placing an offset boundary (i.e., a near miss) or placing an extra/omitting a boundary (i.e., a full miss)—a pseudo-coding. Manipulating these probabilities and keeping the probability of a near miss at a constant natural level should produce a slowly declin-

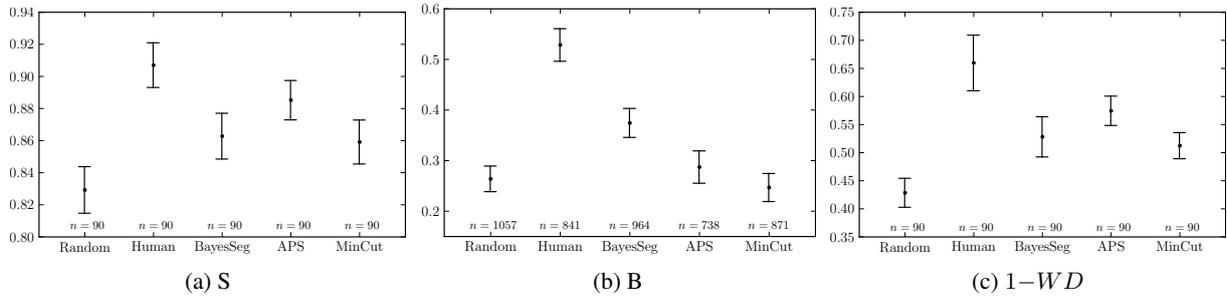

Figure 10: Mean performance of 5 segmenters using varying metrics with 95% confidence intervals

ing amount of agreement which is unaffected by the number of pseudo-coders. This is not apparent, however, for S-based  $\pi^*$  in Figure 9a; as the probability of a full miss increases, agreement appears to rise and varies depending upon the number of pseudo-coders. B-based  $\pi^*$  however shows declining agreement and little to no variation depending upon the number of pseudo-coders, as shown in Figure 9b.

If instead of creating pseudo-coders from a random segmentation a series of random segmentations with the same parameters were generated, a properly functioning inter-coder agreement coefficient should report some agreement (due to the similar parameters used to create the segmentations) but it should be quite low. Figure 9c shows this, and that S-based  $\pi^*$  drastically over-estimates what should be very low agreement whereas B-based  $\pi^*$  properly reports low agreement.

From these demonstrations, it is evident that S-based inter-coder agreement coefficients drastically over-estimate agreement, as does S itself in pairwise mean form. B-based coefficients, however, properly discriminate between levels of agreement regardless of the number of coders and do not over-estimate.

## 6 Evaluation of Automatic Segmenters

Having looked at how S, WD, and B perform at a small scale in §4 and on larger data set in §5, this section demonstrates the use of these metrics to evaluate some automatic segmenters. Three automatic segmenters were trained—or had their parameters estimated upon—The Moonstone data set, including MinCut; (Malioutov and Barzilay, 2006), BayesSeg; (Eisenstein and Barzilay, 2008), and APS (Kazantseva and Szpakowicz, 2011).

To put this evaluation into context, an upper and lower bound were also created comprised of a random coder from the manual data (Human) and a

random segmenter (Random), respectively. These automatic segmenters, and the upper and lower bounds, were created, trained, and run by another researcher (Anna Kazantseva) with their labels removed during the development of the metrics detailed herein (to improve the impartiality of these analyses). An ideal segmentation evaluation metric should, in theory, place the three automatic segmenters between the upper and lower bounds in terms of performance if the metrics, and the segmenters, function properly.

The mean performance of the upper and lower bounds upon the test set of the Moonstone data set using S, B, and WD are shown in Figure 10a–10c along with 95% confidence intervals. Despite the difference in the scale of their values, both S and WD performed almost identically, placing the three automatic segmenters between the upper and lower bounds as expected. For S, statistically significant differences<sup>11</sup> ( $\alpha = 0.05$ ) were found between all segmenters except between APS–human and MinCut–BayesSeg, and WD could only find significant differences between the automatic segmenters and the upper and lower bounds. B, however, shows a marked deviation, and places MinCut and APS statistically significantly below the random baseline with only BayesSeg between the upper and lower bounds—to a significant degree.

Why would pairwise mean B act in such an unexpected manner? The answer lies in a further analysis using the confusion matrix proposed earlier to calculate B-precision and B-recall (as shown in Table 2). From the values in Table 2, all three automatic segmenters appear to have B-precision above the baseline and below the upper bound, but the B-recall of both APS and MinCut is below that of the random baseline (illustrated

<sup>11</sup>Using Kruskal-Wallis rank sum multiple comparison tests (Siegel and Castellan, 1988, pp. 213-214) for S and WD and the Wilcoxon-Nemenyi-McDonald-Thompson test (Hollander and Wolfe, 1999, p. 295) for B.

	B	$n$	B-P	B-R	B-F <sub>1</sub>	TP	FP	FN	TN
Random	$0.2640 \pm 0.0129$	1057	0.3991	0.4673	0.4306	279.0	420	318	4236.0
Human	$0.5285 \pm 0.0164$	841	0.6854	0.7439	0.7135	444.5	204	153	4451.5
BayesSeg	$0.3745 \pm 0.0146$	964	0.5247	0.6224	0.5694	361.0	327	219	4346.0
APS	$0.2873 \pm 0.0163$	738	0.6773	0.3403	0.4530	212.0	101	411	4529.0
MinCut	$0.2468 \pm 0.0141$	871	0.4788	0.3496	0.4041	215.0	234	400	4404.0

Table 2: Mean performance of 5 segmenters using micro-average B, B-precision (B-P), B-recall (B-R), and B-F<sub>β</sub>-measure (B-F<sub>1</sub>) along with the associated confusion matrix values for 5 segmenters

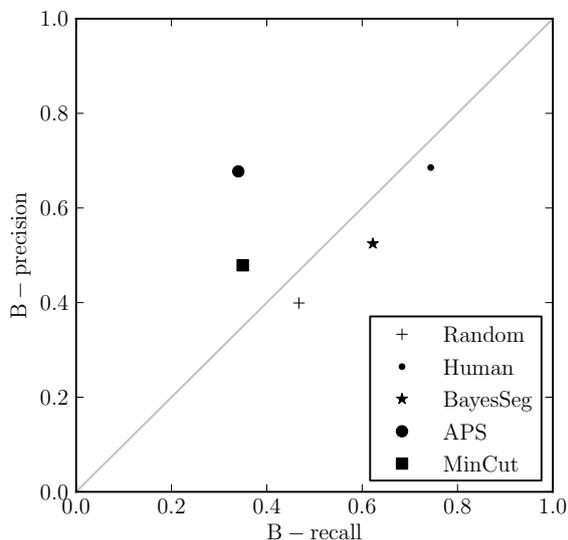

Figure 12: Mean B-precision versus B-recall of 5 automatic segmenters

in Figure 12). These automatic segmenters were developed and performance tuned using WD, thus it would be expected that they would perform as they did according to WD, but the evaluation using B highlights WD’s bias towards sparse segmentations (i.e., those with low B-recall)—a failing that S also appears to share. Mean B shows an unbiased ranking of these automatic segmenters in terms of the upper and lower bounds. B, then, should be preferred over S and WD for an unbiased segmentation evaluation that assumes that similarity to a human solution is the best measure of performance for a task.

## 7 Conclusions

In this work, a new segmentation evaluation metric, referred to as *boundary similarity* (B) is proposed as an unbiased metric, along with a boundary-edit-distance-based (BED-based) confusion matrix to compute predictably biased IR metrics such as precision and recall. Additionally, a method of adapting inter-coder agreement coefficients to award partial credit for near misses is proposed that uses B as opposed to S for actual agreement so as to not over-estimate agreement.

B overcomes the cosmetically high values of S and, the bias towards segmentations with few or tightly-clustered boundaries of WD—manifesting in this work as a bias towards precision over recall for both WD and S. When such precision is desirable, however, B-precision can be computed from a BED-based confusion matrix, along with other IR metrics. WD and  $P_k$  should not be preferred because their biases do not occur consistently in all scenarios, whereas BED-based IR metrics offer expected biases built upon a consistent, edit-based, interpretation of segmentation error.

B also allows for an intuitive comparison of boundary pairs between segmentations, as opposed to the window counts of WD or the simplistic edit count normalization of S. When an unbiased segmentation evaluation metric is desired, this work recommends the usage of B and the use of an upper and lower bound to provide context. Otherwise, if the evaluation of a segmentation task requires some biased measure, the predictable bias of IR metrics computed from a BED-based confusion matrix is recommended. For all evaluations, however, a justification for the biased/unbiased metrics used should be given, and more than one metric should be reported so as to allow a reader to ascertain for themselves whether a particular automatic segmenter’s bias in some manner is cause for concern or not.

## 8 Future Work

Future work includes adapting this work to analyse hierarchical segmentations and using it to attempt to explain the low inter-coder agreement coefficients reported in topical segmentation tasks.

## Acknowledgements

I would like to thank Anna Kazantseva for her invaluable feedback and data. Additionally, I would like to thank my thesis committee members—Stan Szpakowicz, James Green, and Xiaodan Zhu—for their feedback along with my supervisor Diana Inkpen and colleague Martin Scaiano.

## Abstract

Query segmentation, like text chunking, is the first step towards query understanding. In this study, we explore the effectiveness of crowdsourcing for this task. Through carefully designed control experiments and Inter Annotator Agreement metrics for analysis of experimental data, we show that crowdsourcing may not be a suitable approach for query segmentation because the crowd seems to have a very strong bias towards dividing the query into roughly equal (often only two) parts. Similarly, in the case of hierarchical or nested segmentation, turkers have a strong preference towards balanced binary trees.

## 1 Introduction

*Text chunking* of Natural Language (NL) sentences is a well studied problem that is an essential pre-processing step for many NLP applications (Abney, 1991; Abney, 1995). In the context of Web search queries, *query segmentation* is similarly the first step towards analysis and understanding of queries (Hagen et al., 2011). The task in both the cases is to divide the sentence or the query into contiguous *segments* or chunks of words such that the words from a segment are related to each other more strongly than words from different segments (Bendersky et al., 2009). It is typically assumed that the segments are structurally and semantically coherent and, therefore, the information contained in them can be processed holistically.

Table 2: Example of nested segmentation by Turkers.  $f$  is the frequency of annotations.

A majority of work on query segmentation relies on manually segmented queries by human experts for training and evaluation of segmentation algorithms. These are typically small datasets and even with detailed annotation guidelines and/or close supervision, low Inter Annotator Agreement (IAA) remains an issue. For instance, Table 1 illustrates the variation in flat segmentation by 10 annotators. This confusion is mainly because the definition of a segment in a query is ambiguous and of an unspecified granularity. This is further compounded by the fact that other than easily recognizable and agreed upon segments such as Named Entities or Multi-Word Expressions, there is no established notion of linguistic grouping such as phrases and clauses in a query.

Although there is little work on the use of crowdsourcing for query segmentation (Hagen et al., 2011; Hagen et al., 2012), the idea that the

crowd could be a potential (and cheaper) source for reliable segmentation seems a reasonable assumption. The need for larger datasets makes this an attractive proposition. Also, a larger number of annotations could be appropriately distilled to obtain better quality segmentations.

In this paper we explore crowdsourcing as an option for query segmentation through experiments designed using Amazon Mechanical Turk (AMT)<sup>1</sup>. We compare the results against gold datasets created by trained annotators. We address the issues pertaining to disagreements due to both ambiguity and granularity and attempt to objectively quantify their role in IAA. To this end, we also conduct similar annotation experiments for NL sentences and randomly generated queries. While queries are not as structured as NL sentences they are not simply a set of random words. Thus, it is necessary to compare query segmentation to the über-structure of NL sentences as well as the unter-structure of random  $n$ -grams. This has important implications for understanding any inherent biases annotators may have as a result of the apparent lack of structure of the queries.

To quantify the effect of granularity on segmentation, we also ask annotators to provide hierarchical or nested segmentations for real and random queries, as well as sentences. Following Abney’s (1992) proposal for hierarchical chunking of NL, we ask the annotators to group *exactly two* words or segments at a time to recursively form bigger segments. The concept is illustrated in Fig. 1. Table 2 shows annotations from 10 Turkers. It is important to constrain the joining of exactly two segments or words at a time to avoid the issue of fuzziness in granularity. We shall refer to this style of annotation as *Nested segmentation*, whereas the non-hierarchical non-constrained chunking will be referred to as *Flat segmentation*.

Through statistical analysis of the experimental data we show that crowdsourcing may not be the best practice for query segmentation, not only because of ambiguity and granularity issues, but because there exist very strong biases amongst annotators to divide a query into two roughly equal parts that result in misleadingly high agreements. As a part of our analysis framework, we introduce a new IAA metric for comparison across flat and nested segmentations. This versatile metric can be

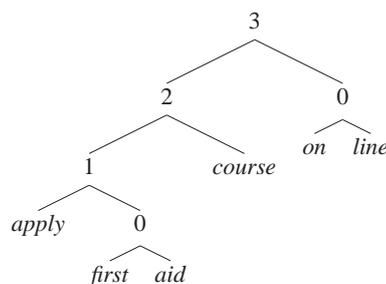

Figure 1: Nested Segmentation: Illustration.

readily adapted for measuring IAA for other linguistic annotation tasks, especially when done using crowdsourcing.

The rest of the paper is organized as follows. Sec 2 provides a brief overview of related work. Sec 3 describes the experiment design and procedure. In Sec 4, we introduce a new metric for IAA, that could be uniformly applied across flat and nested segmentations. Results of the annotation experiments are reported in Sec 5. In Sec 6, we analyze the possible statistical and linguistic biases in annotation. Sec 7 concludes the paper by summarizing the work and discussing future research directions. All the annotated datasets used in this research are freely available for non-commercial research purposes<sup>2</sup>.

## 2 Related Work

Query segmentation was introduced by Risvik et. al. (2003) as a possible means to improve Information Retrieval. Since then there has been a significant amount of research exploring various algorithms for this task and its use in IR (see Hagen et. al. (2011) for a survey). Most of the research and evaluation considers query segmentation as a process analogous to identification of phrases within a query which when put within double-quotes (implying exact matching of the quoted phrase in the document) leads to better IR performance. However, this is a very restricted view of the process and does not take into account the full potential of query segmentation.

A more generic notion of segments leads to diverse and ambiguous definitions, making its evaluation a hard problem (see Saha Roy et. al. (2012) for a discussion on issues with evaluation). Most automatic segmentation techniques (Bergsma and Wang, 2007; Tan and Peng, 2008; Zhang et al.,

<sup>2</sup>Related datasets and supplementary material can be accessed from <http://bit.ly/161Gkk9> or can be obtained by directly emailing the authors.

<sup>1</sup><http://www.mturk.com/mturk/welcome>

2009; Brenes et al., 2010; Hagen et al., 2011; Li et al., 2011) have so far been evaluated only against a small set of human-annotated queries (Bergsma and Wang, 2007). The reported low IAA for such datasets casts serious doubts on the reliability of annotation and the performance of the algorithms evaluated on them (Hagen et al., 2011; Saha Roy et al., 2012).

To address the problem of data scarcity, Hagen et al. (2011) have created larger annotated datasets through crowdsourcing<sup>3</sup>. However, in their approach the crowd is provided with a few (four) possible segmentations of a query to choose from (known through a personal communication with a authors). Thus, it presupposes an automatic process that can generate the correct segmentation of a query within top few options. It is far from obvious how to generate these initial segmentations in a reliable manner. This may also result in an over-optimistic IAA. An ideal segmentation should be based on the annotators' own interpretation of the query. Nevertheless, if large scale data has to be procured, crowdsourcing seems to be the only efficient and effective model for this task, and has been proven to be so for other IR and linguistic annotations; see Carvalho et al. (2011) for examples of crowdsourcing for IR resources and (Snow et al., 2008; Callison-Burch, 2009) for language resources.

In the context of NL text, segmentation has been traditionally referred to as *chunking* and is a well-studied problem. Abney (1991; 1992; 1995) defines a chunk as a sub-tree within a syntactic phrase structure tree corresponding to Noun, Prepositional, Adjectival, Adverbial and Verb Phrases. Similarly, Bharati et al (1995) defines it as Noun Group and Verb Group based only on local surface information. However, cognitive and annotation experiments for chunking of English (Abney, 1992) and other language text (Bali et al., 2009) have shown that native speakers agree on major clause and phrase boundaries, but may not do so on more fine-grained chunks. One important implication of this is that annotators are expected to agree more on the higher level boundaries for nested segmentation than the lower ones. We note that hierarchical query segmentation was proposed for the first time by Huang et al. (2010), where the authors recursively split a query (or its fragment) into exactly two parts and evaluate the

final output against human annotations.

### 3 Experiments

The annotation experiments have been designed to systematically study the various aspects of query segmentation. In order to verify the effectiveness and reliability of crowdsourcing, we designed an AMT experiment for flat segmentation of Web search queries. As a baseline, we would like to compare these annotations with those from human experts trained for the task. We shall refer to this baseline as the *Gold annotation set*. Since we believe that the issue of granularity could be the prime reason for previously reported low IAA for segmentation, we also designed AMT-based nested segmentation experiments for the same set of queries, and obtained the corresponding gold annotations.

Finally, to estimate the role of ambiguity inherent in the structure of Web search queries on IAA, we conducted two more control experiments, both through crowdsourcing. First, flat and nested segmentation of well-formed English, i.e., NL sentences of similar length distribution; and second, flat and nested segmentation of randomly generated queries. Higher IAA for NL sentences would lead us to conclude that ambiguity and lack of structure in queries is the main reason for low agreements. On the other hand high or comparable IAA for random queries would mean that annotations have strong biases.

Thus, we have the following four pairs of annotation experiments: flat and nested segmentation of queries from crowdsourcing, corresponding flat and nested gold annotations, flat and nested segmentation of English sentences from crowdsourcing, and flat and nested segmentations for randomly generated queries through crowdsourcing.

#### 3.1 Dataset

For our experiments, we need a set of Web search queries and well-formed English sentences. Furthermore, for generating the random queries, we will use search query logs to learn  $n$ -gram models. In particular, we use the following datasets:

**Q500, QG500:** Saha Roy et al. (2012) released a dataset of 500 queries, 5 to 8 words long, for evaluation of various segmentation algorithms. This dataset has flat segmentations from three annotators obtained under controlled experimental settings, and can be considered as *Gold* annota-

<sup>3</sup><http://www.webis.de/research/corpora>

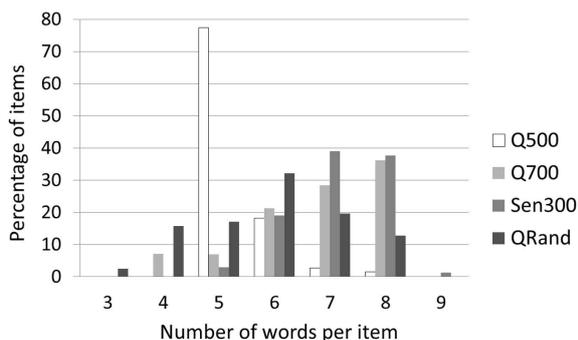

Figure 2: Length distribution of datasets.

tions. Hence, we select this set for our experiments as well. We procured the corresponding nested segmentation for these queries from two human experts, who are regular search engine users, between 20 and 30 years old, and familiar with various linguistic annotation tasks. They annotated the data under supervision. They were trained and paid for the task. We shall refer to the set of flat and nested gold annotations as **QG500**, whereas **Q500** will be reserved for AMT experiments.

**Q700:** Since 500 queries may not be enough for reliable conclusion and since the queries may not have been chosen specifically for the purpose of annotation experiments, we expanded the set with another 700 queries sampled from a slice of the query logs of Bing Australia<sup>4</sup> containing 16.7 million queries issued over a period of one month (May 2010). We picked, uniformly at random, queries that are 4 to 8 words long, have only English letters and numerals, and a high *click entropy* because “a query with a larger click entropy value is more likely to be an informational or ambiguous query” (Dou et al., 2008). **Q500** consists of tailish queries with frequency between 5 and 15 that have at least one multiword named entity; but unlike the case of **Q700**, click-entropy was not considered during sampling. As we shall see, this difference is clearly reflected in the results.

**S300:** We randomly selected 300 English sentences from a collection of full texts of public domain books<sup>5</sup> that were 5 to 15 words long, and checked them for well-formedness. This set will be referred to as **S300**.

**QRand:** Instead of generating search queries by throwing in words randomly, we thought it will be more interesting to explore annotation of

Parameter	Flat Details	Nested Details

Turker location	United States of America	

Table 3: Specifics of the HITs for AMT.

queries generated using  $n$ -gram models for  $n = 1, 2, 3$ . We estimated the models from the Bing Australia log of 16.7 million queries. We generated 250 queries each of desired length distribution using the 1, 2 and 3-gram models. We shall refer to these as **U250**, **B250**, **T250** (for Uni, Bi and Trigram) respectively, and the whole dataset as **QRand**. Fig. 2 shows the query and sentence length distribution for the various sets.

### 3.2 Crowdsourcing Experiments

We used AMT to get our annotations through crowdsourcing. Pilot experiments were carried out to test the instruction set and examples presented. Based on the feedback, the precise instructions for the final experiments were designed.

Two separate AMT Human Intelligence Tasks (HITs) were designed for flat and nested query segmentation. Also, the experiments for queries (**Q500+Q700**) were conducted separately from **S300** and **QRand**. Thus, we had six HITs in all. The concept of flat and nested segmentation was introduced to the Turkers with the help of examples presented in two short videos<sup>6</sup>. When in doubt regarding the meaning of a query, the Turkers were advised to issue the query on a search engine of their choice and find out its possible interpretation(s). Note that we intentionally kept definitions of flat and nested segmentation fuzzy because (a) it would require very long instruction manuals to cover all possible cases and (b) Turkers do not tend to read verbose and complex instructions. Table 3 summarizes other specifics of HITs.

*Honey pots* or trap questions whose answers are known a priori are often included in a HIT to identify turkers who are unable to solve the task appropriately leading to incorrect annotations. However, this trick cannot be employed in our case because there is no notion of an absolutely correct segmentation. We observe that even with unambiguous queries, even expert annotators may dis-

<sup>4</sup><http://www.bing.com/?cc=au>

<sup>5</sup><http://www.gutenberg.org>

<sup>6</sup>Flat: <http://youtu.be/eMeLjJivIh0>, Nested: <http://youtu.be/xE3rwANbFvU>

agree on some of the segment boundaries. Hence, we decided to include annotations from all the turkers, except for those that were syntactically ill-formed (e.g., non-binary nested segmentation).

## 4 Inter Annotator Agreement

*Inter Annotator Agreement* is the only way to judge the reliability of annotated data in absence of an end application. Therefore, before we can venture into analysis of the experimental data, we need to formalize the notion of IAA for flat and nested queries. The task is non-trivial for two reasons. First, traditional IAA measures are defined for a fixed set of annotators. However, for crowdsourcing based annotations, different annotators might have annotated different parts of the dataset. For instance, we observed that a total of 128 turkers have provided the flat annotations for **Q700**, when we had only asked for 10 annotations per query. Thus, on average, a turker has annotated only 7.81% of the 700 queries. In fact, we found that 31 turkers had annotated less than 5 queries. Hence, measures such as Cohen’s  $\kappa$  (1960) cannot be directly applied in this context because for crowdsourced annotations, we cannot meaningfully compute annotator-specific distribution of the labels and biases.

Second, most of the standard annotation metrics do not generalize for flat segmentation and trees. Artstein and Poesio (2008) provides a comprehensive survey of the IAA metrics and their usage in NLP. They note that all the metrics assume that a fixed set of labels are used for items. Therefore, it is far from obvious how to compare chunking or segmentation that *covers* the whole text or that might have *overlapping* units as in the case of nested segmentation. Furthermore, we would like to compare the reliability of flat and nested segmentation, and therefore, ideally we would like to have an IAA metric that can be meaningfully applied to both of these cases.

After considering various measures, we decided to appropriately generalize one of the most versatile and effective IAA metrics proposed till date, the Krippendorff’s  $\alpha$  (2004). To be consistent with prior work, we will stick to the notation used in Artstein and Poesio (2008) and redefine the  $\alpha$  in the context of flat and nested segmentation. Note that though the notations introduced here will be from the perspective of queries, it is equally applicable to sentences and the generalization is

straightforward.

### 4.1 Notations and Definitions

Let  $Q$  be the set of all queries with cardinality  $q$ . A query  $q \in Q$  can be represented as a sequence of  $|q|$  words:  $w_1 w_2 \dots w_{|q|}$ . We introduce  $|q| - 1$  random variables,  $b_1, b_2, \dots, b_{|q|-1}$ , such that  $b_i$  represents the boundary between the words  $w_i$  and  $w_{i+1}$ . A flat or nested segmentation of  $q$ , represented by  $q_j$ ,  $j$  varying from 1 to total number of annotations  $c$ , is a particular instantiation of these boundary variables as described below.

*Definition.* A *flat segmentation*,  $q_j$  can be uniquely defined by a binary assignment of the boundary variables  $b_{j,i}$ , where  $b_{j,i} = 1$  iff  $w_i$  and  $w_{i+1}$  belong to two different flat segments. Otherwise,  $b_{j,i} = 0$ . Thus,  $q$  has  $2^{|q|-1}$  possible flat segmentations.

*Definition.* A *nested segmentation*  $q_j$  can also be uniquely defined by assigning non-negative integers to the boundary variables such that  $b_{j,i} = 0$  iff words  $w_i$  and  $w_{i+1}$  form an atomic segment (i.e., they are grouped together), else  $b_{j,i} = 1 + \max(\text{left}_i, \text{right}_i)$ , where  $\text{left}_i$  and  $\text{right}_i$  are the heights of the largest subtrees ending at  $w_i$  and beginning at  $w_{i+1}$  respectively.

This numbering scheme for nested segmentation can be understood through Fig. 1. Every internal node of the binary tree corresponding to the nested segmentation is numbered according to its height. The lowest internal nodes, both of whose children are query words, are assigned a value of 0. Other internal nodes get a value of one greater than the height of its higher child. Since every internal node corresponds to a boundary, we assign the height of the node to the corresponding boundaries. The number of unique nested segmentations of a query of length  $|q|$  is its corresponding *Catalan number*<sup>7</sup>.

Boundary variables for flat and nested segmentation are illustrated with an example of each kind in Tables 1 and 2 (last column).

### 4.2 Krippendorff’s $\alpha$ for Segmentation

Krippendorff’s  $\alpha$  (Krippendorff, 2004) is an extremely versatile agreement coefficient, which is based on the assumption that the expected agreement is calculated by looking at the overall distribution of judgments without regard to which annotator produced them (Artstein and Poesio, 2008).

<sup>7</sup><http://goo.gl/vKQvK>

Hence, it is appropriate for crowdsourced annotation, where the judgments come from a large number of unrelated annotators. Moreover, it allows for different magnitudes of disagreement, which is a useful feature as we might want to differentially penalize disagreements at various levels of the tree for nested segmentation.

$\alpha$  is defined as

$$\alpha = 1 - \frac{D_o}{D_e} = 1 - \frac{s_{within}^2}{s_{total}^2} \quad (1)$$

where  $D_o$  and  $D_e$  are, respectively, the observed and expected disagreements that are measured by  $s_{within}^2$  – the variance within the annotation of an item and  $s_{total}^2$  – variance across annotations of all items. We adapt the equations presented in pp.565-566 of Artstein and Poesio (2008) for measuring these quantities for queries:

$$s_{within}^2 = \frac{1}{2\mathbf{q}\mathbf{c}(\mathbf{c}-1)} \sum_{q \in Q} \sum_{m=1}^{\mathbf{c}} \sum_{n=1}^{\mathbf{c}} d(q_m, q_n) \quad (2)$$

$$s_{total}^2 = \frac{1}{2\mathbf{q}\mathbf{c}(\mathbf{q}\mathbf{c}-1)} \sum_{q \in Q} \sum_{m=1}^{\mathbf{c}} \sum_{q' \in Q} \sum_{n=1}^{\mathbf{c}} d(q_m, q'_n) \quad (3)$$

where,  $d(q_m, q'_n)$  is a distance metric for the agreement between annotations  $q_m$  and  $q'_n$ .

We define two different distance metrics  $d_1$  and  $d_2$  that are applicable to flat and nested segmentation. We shall first define these metrics for comparing queries with equal length (i.e.,  $|q| = |q'|$ ):

$$d_1(q_m, q'_n) = \frac{1}{|q|-1} \sum_{i=1}^{|q|-1} |b_{m,i} - b'_{n,i}| \quad (4)$$

$$d_2(q_m, q'_n) = \frac{1}{|q|-1} \sum_{i=1}^{|q|-1} |b_{m,i}^2 - (b'_{n,i})^2| \quad (5)$$

While  $d_1$  penalizes all disagreements equally,  $d_2$  penalizes disagreements higher up the tree more.  $d_2$  might be a desirable metric for nested segmentation, because research on sentence chunking shows that annotators agree more on clause or major phrase boundaries, even though they may not always agree on intra-clausal or intra-phrasal boundaries (Bali et al., 2009). Note that for flat segmentation,  $d_1$  and  $d_2$  are identical, and hence we will denote them as  $d$ .

We propose the following extension to these metrics for queries of unequal lengths. Without

loss of generality, let us assume that  $|q| < |q'|$ .  $k$  is 1 or 2;  $r = |q'| - |q| + 1$ .

$$d_k(q_m, q'_n) = \frac{1}{r(|q|-1)} \sum_{a=0}^{r-1} \sum_{i=1}^{|q|-1} |b_{m,i}^k - (b'_{n,i+a})^k| \quad (6)$$

### 4.3 IAA under Random Bias Assumption

Krippendorff’s  $\alpha$  uses the cross-item variance as an estimate of chance agreement, which is reliable in general. However, this might result in misleadingly low values of IAA, especially when the items in the set are indeed expected to have similar annotations. To resolve this, we also compute the chance agreement under a random bias model. The random model assumes that *all the structural annotations of  $q$  are equiprobable*. For flat segmentation, it boils down to the fact that all the  $2^{|q|-1}$  annotations are equally likely, which is equivalent to the assumption that any boundary variable  $b_i$  has 0.5 probability of being 0 and 0.5 for 1.

Analytical computation of the expected probability distributions of  $d_1(q_m, q_n)$  and  $d_2(q_m, q_n)$  is harder for nested segmentation. Therefore, we programmatically generate all possible trees for  $q$ , which is again dependent only on  $|q|$  and compute  $d_1$  and  $d_2$  between all pairs of trees, from which the expected distributions can be readily estimated. Let us denote this expected cumulative probability distribution for flat segmentation as  $P_d(x; |q|)$  = the probability that for a pair of randomly chosen flat segmentations of  $q$ ,  $q_m$  and  $q_n$ ,  $d(q_m, q_n) \geq x$ . Likewise, let  $P_{d_1}(x; |q|)$  and  $P_{d_2}(x; |q|)$  be the respective probabilities that for any two nested segmentations  $q_m$  and  $q_n$  of  $q$ , the following holds:  $d_1(q_m, q_n) \geq x$  and  $d_2(q_m, q_n) \geq x$ .

We define the IAA under random bias model as ( $k$  is 1, 2 or null):

$$S = \frac{1}{\mathbf{q}\mathbf{c}^2} \sum_{q \in Q} \sum_{m=1}^{\mathbf{c}} \sum_{n=1}^{\mathbf{c}} P_{d_k}(d_k(q_m, q_n); |q|) \quad (7)$$

Thus,  $S$  is the expected probability of observing a similar or worse agreement by random chance, averaged over all pairs of annotations for all queries, and not a chance corrected IAA metric such as  $\alpha$ . Thus,  $S = 1$  implies that the observed agreement is *almost always better than* that by random chance and  $S = 0.5$  and 0 respectively imply that the observed agreement is *as good as* and *almost always worse than* that by random chance. We

Dataset	Flat	Nested	
	$d_1$	$d_1$	$d_2$
Q700	0.21(0.59)	0.21(0.89)	0.16(0.68)
Q500	0.22(0.62)	0.15(0.70)	0.15(0.44)
QG500	0.61(0.88)	0.66(0.88)	0.67(0.80)
S300	0.27(0.74)	0.18(0.94)	0.14(0.75)
U250	0.23(0.89)	0.42(0.90)	0.30(0.78)
B250	0.22(0.86)	0.34(0.88)	0.22(0.71)
T250	0.20(0.86)	0.44(0.89)	0.34(0.76)

Table 4: Agreement Statistics:  $\alpha(S)$ .

also note that a high value of  $S$  and low value of  $\alpha$  indicate that though the annotators agree on the judgment of individual items, they also tend to agree on judgments of two different items, which in turn, could be due to strong annotator biases or due to lack of variability of the dataset.

In the supplementary material, computations of  $\alpha$  and  $S$  have been explained in further details through worked out examples. Tables for the expected distributions of  $d$ ,  $d_1$  and  $d_2$  under the random annotation assumption are also available.

## 5 Results

Table 4 reports the values of  $\alpha$  and  $S$  for flat and nested segmentation on the various datasets. For nested segmentation, the values were computed for two different distance metrics  $d_1$  and  $d_2$ . As expected, the highest value of  $\alpha$  for both flat and nested segmentation is observed for gold annotations. An  $\alpha > 0.6$  indicates quite good IAA, and thus, reliable annotations. Higher  $\alpha$  for nested segmentation **QG500** than flat further validates our initial postulate that nested segmentation may reduce disagreement from granularity issues inherent in the definition of flat segmentation.

Opposite trends are observed for **Q700**, **Q500** and **S300**, where  $\alpha$  for flat is the highest, followed by that for nested using  $d_1$ , and then  $d_2$ . Moreover, except for flat segmentation of sentences,  $\alpha$  lies between 0.14 and 0.22, which is quite low. This clearly shows that segmentation, either flat or nested, cannot be reliably procured through crowdsourcing. Lower  $\alpha$  for  $d_2$  than  $d_1$  further indicates that annotators disagree more for higher levels of the trees, contrary to what we had expected. However, nearly equal IAA for sentences and queries implies that low agreement may not be an outcome of inherent ambiguity in the structure

of queries. Slightly higher  $\alpha$  for flat segmentation and a much higher  $\alpha$  for nested segmentation of **QRand** reinforce the fact that low IAA is not due to a lack of structure in queries.

It is interesting to note that  $\alpha$  for nested segmentation of **S300** and all segmentations of **QRand** are low or medium despite the fact that  $S$  is very high in all these cases. Thus, it is clear that annotators have a strong bias towards certain structures across queries. In the next section, we will analyze some of these biases. We also computed the IAA between **QG500** and **Q500**, and found  $\alpha = 0.27$ . This is much lower than  $\alpha$  for **QG500**, though slightly higher than that for **Q500**. We did not observe any significant variation in agreement with respect to the length of the queries.

## 6 Biases in Annotation

The IAA statistics clearly show that there are certain strong biases in both flat and nested query segmentation, especially those obtained through crowdsourcing. To identify these biases, we went through the annotations and came up with possible hypotheses, which we tried to verify through statistical analysis of the data. Here, we report the most prominent biases that were thus discovered.

**Bias 1:** *During flat segmentation, annotators prefer dividing the query into two segments of roughly equal length.*

As discussed earlier, one of the major problems of flat segmentation is the fuzziness in granularity. In our experiments, we intentionally left the decision of whether to go for fine or coarse-grained segmentation to the annotator. However, it is surprising to observe that annotators typically divide the query into two segments (see Fig. 3, plots A1 and A2), and at times three, but hardly ever more than three. This bias is observed across queries, sentences and random queries, where the percentage of annotations with 2 or 3 segments are greater than 83%, 91% and 96% respectively. This bias is most strongly visible for **QRand** because the lack of syntactic or semantic cohesion between the words provides no clue for segmentation.

Furthermore, we observe that typically segments tend to be of equal length. For this, we computed standard deviations (sd) of segment lengths for all annotations having 2 or 3 segments; the distribution of sd is shown in Fig. 3, plots B1 and B2. We observe that for all datasets, sd lies mainly between 0.5 and 1 (for perspective, consider a query

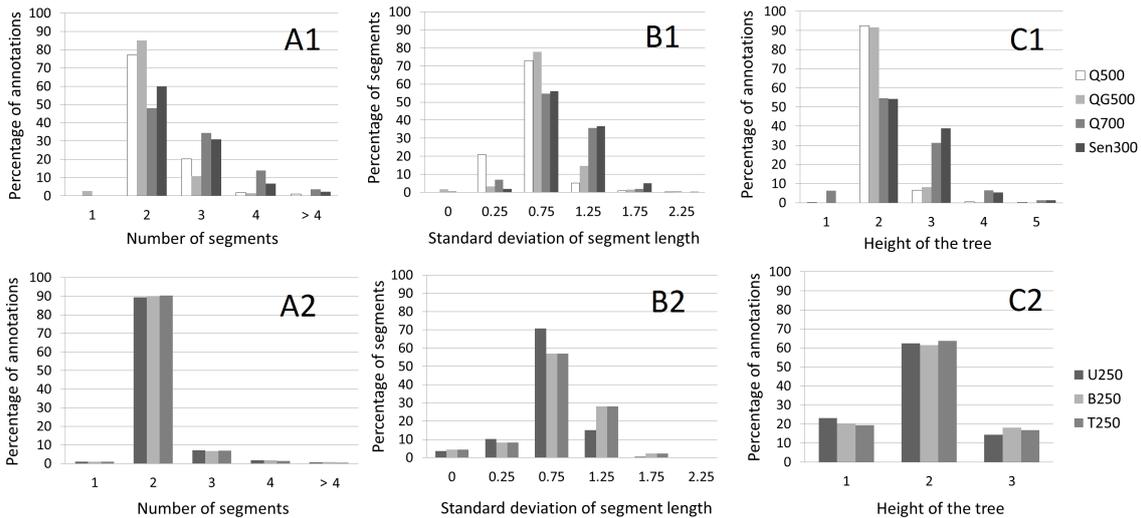

Figure 3: Analysis of annotation biases: A1, A2 – number of segments per flat segmentation vs. length; B1, B2 – standard deviation of segment length for flat segmentation; C1, C2 – distribution of the tree heights in nested segmentation.

Length	Expected	Q500	QG500	Q700	S300	QRand
5	2.57	2.00	2.02	2.08	2.02	2.01
6	3.24	2.26	2.23	2.23	2.24	2.02
7	3.88	2.70	2.71	2.67	2.55	2.62
8	4.47	2.89	2.68	2.72	2.72	2.35

Table 5: Average height for nested segmentation.

with 7 words; with two segments of length 3 and 4 the sd is 0.5, and for 2 and 5, the sd is 1.5), implying that segments are roughly of equal length.

It is likely that due to this bias, the  $S$  or observed agreement is moderately high for queries and very high for sentences, but then it also leads to high agreement across different queries and sentences (i.e., high  $s_{total}^2$ ) especially when they are of equal length, which in turn brings down the value of  $\alpha$  – the true agreement after bias correction.

**Bias 2:** *During nested segmentation, annotators prefer balanced binary trees.*

Quite analogous to bias 1, for nested segmentation we observe that annotators tend to prefer more balanced binary trees. Fig. 3 plots C1 and C2 show the distribution of the tree heights for various cases and Table 5 reports the corresponding average height of the trees for queries and sentences of various lengths and the the expected value of the height if all trees were equally likely. The observed heights are much lower than the expected values clearly implying the preference of the annotators for more balanced trees.

Thus, the crowd seems to choose the middle

path, avoiding extremes and hence may not be a reliable source of annotation for query segmentation. It can be argued that similar biases are also observed for gold annotations, and therefore, probably it is the inherent structure of the queries and sentences that lead to such biased distribution of segmentation patterns. However, note that  $\alpha$  for **QG500** is much higher than all other cases, which shows that the true agreement between gold annotators is immune to such biases or skewed distributions in the datasets. Furthermore, high values of  $\alpha$  for **QRand** despite the very strong biases in annotation shows that there perhaps is very little choice that the annotators have while segmenting randomly generated queries. On the other hand, the textual coherence of the real queries and sentences provide many different choices for segmentation and the Turker typically gets carried away by these biases, leading to low  $\alpha$ .

**Bias 3:** *Phrase structure drives segmentation only when reconcilable with Bias 1.* Whenever the sentence or query has a verb phrase (VP) spanning roughly half of it, annotators seem to chunk before the VP as one would expect, quite as often as just after the verb, which is quite unexpected. For instance, the sentence `A gentle sarcasm ruffled her anger. gathers as many as eight flat annotations with a boundary between sarcasm and ruffled, and four with a boundary between ruffled and her.` However, if the VP is very short consisting of a single

Position	Q500	QG500	Q700	S300	QRand

None	50.34	56.85	35.74	35.84	39.81
Right	23.86	21.50	19.02	12.52	15.23
Left	18.08	15.97	40.59	45.96	21.21

Table 6: Percentages of positions of segment boundaries with respect to prepositions. Prepositions occurring in the beginning or end of a query/sentence have been excluded from the analysis; hence, numbers in a column do not total 100.

verb, as in `A fleeting and furtive air of triumph erupted.`, annotators seem to attempt for a balanced annotation due to **Bias 1**. As a clear middle boundary is not present in such sentences, the annotations show a lot more variation and disagreement. For instance, only 1 out of 10 annotations had a boundary before `erupted` in the above example. In fact, at least one annotation had a boundary after each word in the sentence, with no clear majority.

**Bias 4:** *Prepositions influence segment boundaries differently for queries and sentences.* We automatically labeled all the prepositions in the flat annotations and classified them according to the criterion of whether a boundary was placed immediately before or after it, or on both sides or neither side. The statistics, reported in Table 6, show that for NL sentences a majority of the boundaries are present before the preposition, marking the beginning of a prepositional phrase. However, for queries, a much richer pattern emerges depending on the specific preposition. For instance, `to`, `of` and `for` are often chunked with the previous word (e.g., `how to | choose a bike size, birthday party ideas for | one year old`). We believe that this difference is because in sentences due to the presence of a verb, the PP has a well-defined head, lack of which leads to preposition in queries getting chunked with words that form more commonly seen patterns (e.g., `flights to and tickets for`).

Bias 3 and 4 present the complex interpretation of the structure of queries by the annotators which could be due to some emerging cognitive model of queries among the search engine users. This is a fascinating and unexplored aspect of query structures that demands deeper investigation through cognitive and psycholinguistic experiments.

## 7 Conclusion

We have studied various aspects of query segmentation through crowdsourcing by designing and conducting suitable experiments. Analysis of experimental data leads us to conclude the following: (a) crowdsourcing may not be a very effective way to collect judgments for query segmentation; (b) addressing fuzziness of granularity for flat segmentation by introducing strict binary nested segments does not lead to better agreement in crowdsourced annotations, though it definitely improves the IAA for gold standard segmentations, implying that low IAA in flat segmentation among experts is primarily an effect of unspecified granularity of segments; (c) low IAA is not due to the inherent structural ambiguity in queries as this holds true for sentences as well; (d) there are strong biases in crowdsourced annotations, mostly because turkers prefer more balanced segment structures; and (e) while annotators are by and large guided by linguistic principles, application of these principles differ between query and NL sentences and also closely interact with other biases.

One of the important contributions of this work is the formulation of a new IAA metric for comparing across flat and nested segmentations, especially for crowdsourcing based annotations. Since trees are commonly used across various linguistic annotations, this metric can have wide applicability. The metric, moreover, can be easily adapted to other annotation schemes as well by defining an appropriate distance metric between annotations. Since large scale data for query segmentation is very useful, it would be interesting to see if the problem can be rephrased to the Turkers in a way so as to obtain more reliable judgments. Yet a deeper question is regarding the theoretical status of query structure, which though in an emergent state is definitely an operating model for the annotators. Our future work in this area would specifically target understanding and formalization of the theoretical model underpinning a query.

## Acknowledgments

We thank Ed Cutrell and Andrew Cross, Microsoft Research Lab India, for their help in setting up the AMT experiments. We would also like to thank Anusha Suresh, IIT Kharagpur, India, for helping us with data preparation.

## Abstract

In Community question answering (QA) sites, malicious users may provide deceptive answers to promote their products or services. It is important to identify and filter out these deceptive answers. In this paper, we first solve this problem with the traditional supervised learning methods. Two kinds of features, including textual and contextual features, are investigated for this task. We further propose to exploit the user relationships to identify the deceptive answers, based on the hypothesis that similar users will have similar behaviors to post deceptive or authentic answers. To measure the user similarity, we propose a new user preference graph based on the answer preference expressed by users, such as “helpful” voting and “best answer” selection. The user preference graph is incorporated into traditional supervised learning framework with the graph regularization technique. The experiment results demonstrate that the user preference graph can indeed help improve the performance of deceptive answer prediction.

## 1 Introduction

Currently, Community QA sites, such as Yahoo! Answers<sup>1</sup> and WikiAnswers<sup>2</sup>, have become one of the most important information acquisition methods. In addition to the general-purpose web search engines, the Community QA sites have emerged as popular, and often effective, means of information seeking on the web. By posting questions for other participants to answer, users can obtain answers to their specific questions. The Community QA

sites are growing rapidly in popularity. Currently there are hundreds of millions of answers and millions of questions accumulated on the Community QA sites. These resources of past questions and answers are proving to be a valuable knowledge base. From the Community QA sites, users can directly get the answers to meet some specific information need, rather than browse the list of returned documents to find the answers. Hence, in recent years, knowledge mining in Community QA sites has become a popular topic in the field of artificial intelligence (Adamic et al., 2008; Wei et al., 2011).

However, some answers may be deceptive. In the Community QA sites, there are millions of users each day. As the answers can guide the user’s behavior, some malicious users are motivated to give deceptive answers to promote their products or services. For example, if someone asks for recommendations about restaurants in the Community QA site, the malicious user may post a deceptive answer to promote the target restaurant. Indeed, because of lucrative financial rewards, in several Community QA sites, some business owners provide incentives for users to post deceptive answers for product promotion.

There are at least two major problems that the deceptive answers cause. On the user side, the deceptive answers are misleading to users. If the users rely on the deceptive answers, they will make the wrong decisions. Or even worse, the promoted link may lead to illegitimate products. On the Community QA side, the deceptive answers will hurt the health of the Community QA sites. A Community QA site without control of deceptive answers could only benefit spammers but could not help askers at all. If the asker was cheated by the provided answers, he will not trust and visit this site again. Therefore, it is a fundamental task to predict and filter out the deceptive answers.

In this paper, we propose to predict deceptive

<sup>1</sup><http://answers.yahoo.com>

<sup>2</sup><http://wiki.answers.com>

answer, which is defined as the answer, whose purpose is not only to answer the question, but also to promote the authors' self-interest. In the first step, we consider the deceptive answer prediction as a general binary-classification task. We extract two types of features: one is textual features from answer content, including unigram/bigram, URL, phone number, email, and answer length; the other is contextual features from the answer context, including the relevance between answer and the corresponding question, the author of the answer, answer evaluation from other users and duplication with other answers. We further investigate the user relationship for deceptive answer prediction. We assume that similar users tend to have similar behaviors, i.e. posting deceptive answers or posting authentic answers. To measure the user relationship, we propose a new user preference graph, which is constructed based on the answer evaluation expressed by users, such as "helpful" voting and "best answer" selection. The user preference graph is incorporated into traditional supervised learning framework with graph regularization, which can make answers, from users with same preference, tend to have the same category (deceptive or authentic). The experiment results demonstrate that the user preference graph can further help improve the performance for deceptive answer prediction.

## 2 Related Work

In the past few years, it has become a popular task to mine knowledge from the Community QA sites. Various studies, including retrieving the accumulated question-answer pairs to find the related answer for a new question, finding the expert in a specific domain, summarizing single or multiple answers to provide a concise result, are conducted in the Community QA sites (Jeon et al., 2005; Adamic et al., 2008; Liu et al., 2008; Song et al., 2008; Si et al., 2010a; Figueroa and Atkinson, 2011). However, an important issue which has been neglected so far is the detection of deceptive answers. If the acquired question-answer corpus contains many deceptive answers, it would be meaningless to perform further knowledge mining tasks. Therefore, as the first step, we need to predict and filter out the deceptive answers. Among previous work, answer quality prediction (Song et al., 2010; Harper et al., 2008; Shah and Pomerantz, 2010; Ishikawa et al., 2010) is most related to the deceptive answer prediction task. But these are

still significant differences between two tasks. Answer quality prediction measures the overall quality of the answers, which refers to the accuracy, readability, completeness of the answer. While the deceptive answer prediction aims to predict if the main purpose of the provided answer is only to answer the specific question, or includes the user's self-interest to promote something. Some of the previous work (Song et al., 2010; Ishikawa et al., 2010; Bian et al., 2009) views the "best answer" as high quality answers, which are selected by the askers in the Community QA sites. However, the deceptive answer may be selected as high-quality answer by the spammer, or because the general users are misled. Meanwhile, some answers from non-native speakers may have linguistic errors, which are low-quality answers, but are still authentic answers. Our experiments also show that answer quality prediction is much different from deceptive answer prediction.

Previous QA studies also analyze the user graph to investigate the user relationship (Jurczyk and Agichtein, 2007; Liu et al., 2011). They mainly construct the user graph with asker-answerer relationship to estimate the expertise score in Community QA sites. They assume the answerer is more knowledgeable than the asker. However, we don't care which user is more knowledgeable, but are more likely to know if two users are both spammers or authentic users. In this paper, we propose a novel user preference graph based on their preference towards the target answers. We assume that the spammers may collaboratively promote the target deceptive answers, while the authentic users may generally promote the authentic answers and demote the deceptive answers. The user preference graph is constructed based on their answer evaluation, such as "helpful" voting or "best answer" selection.

## 3 Proposed Features

We first view the deceptive answer prediction as a binary-classification problem. Two kinds of features, including textual features and contextual features, are described as follows:

### 3.1 Textual Features

We first aim to predict the deceptive answer by analyzing the answer content. Several textual features are extracted from the answer content:

#### 3.1.1 Unigrams and Bigrams

The most common type of feature for text classification is the bag-of-words. We use an effective

feature selection method  $\chi^2$  (Yang and Pedersen, 1997) to select the top 200 unigrams and bigrams as features. The top ten unigrams related to deceptive answers are shown on Table 1. We can see that these words are related to the intent for promotion.

professional	service	advice	address
site	telephone	therapy	recommend
hospital	expert		

Table 1: Top 10 Deceptive Related Unigrams

### 3.1.2 URL Features

Some malicious users may promote their products by linking a URL. We find that URL is good indicator for deceptive answers. However, some URLs may provide the references for the authentic answers. For example, if you ask the weather in mountain view, someone may just post the link to "http://www.weather.com/". Therefore, besides the existence of URL, we also use the following URL features:

- 1). Length of the URLs: we observe that the longer urls are more likely to be spam.
- 2). PageRank Score: We employ the PageRank (Page et al., 1999) score of each URL as popularity score.

### 3.1.3 Phone Numbers and Emails

There are a lot of contact information mentioned in the Community QA sites, such as phone numbers and email addresses, which are very likely to be deceptive, as good answers are found to be less likely to refer to phone numbers or email addresses than the malicious ones. We extract the number of occurrences of email and phone numbers as features.

### 3.1.4 Length

We have also observed some interesting patterns about the length of answer. Deceptive ones tend to be longer than authentic ones. This can be explained as the deceptive answers may be well prepared to promote the target. We also employ the number of words and sentences in the answer as features.

## 3.2 Contextual Features

Besides the answer textual features, we further investigate various features from the context of the target answer:

### 3.2.1 Question Answer Relevance

The main characteristic of answer in Community QA site is that the answer is provided to answer the corresponding question. We can use the corresponding question as one of the context features by measuring the relevance between the answer and the question. We employ three different models for Question-Answer relevance:

#### Vector Space Model

Each answer or question is viewed as a word vector. Given a question  $q$  and the answer  $a$ , our vector model uses weighted word counts(e.g.TF-IDF) as well as the cosine similarity ( $q \cdot a$ ) of their word vectors as relevant function (Salton and McGill, 1986). However, vector model only consider the exact word match, which is a big problem, especially when the question and answer are generally short compared to the document. For example, Barack Obama and the president of the US are the same person. But the vector model would indicate them to be different. To remedy the word-mismatch problem, we also look for the relevance models in higher semantic levels.

#### Translation Model

A translation model is a mathematical model in which the language translation is modeled in a statistical way. The probability of translating a source sentence (as answer here) into target sentence (as question here) is obtained by aligning the words to maximize the product of all the word probabilities. We train a translation model (Brown et al., 1990; Och and Ney, 2003) using the Community QA data, with the question as the target language, and the corresponding best answer as the source language. With translation model, we can compute the translation score for new question and answer.

#### Topic Model

To reduce the false negatives of word mismatch in vector model, we also use the topic models to extend matching to semantic topic level. The topic model, such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003), considers a collection of documents with  $K$  latent topics, where  $K$  is much smaller than the number of words. In essence, LDA maps information from the word dimension to a semantic topic dimension, to address the shortcomings of the vector model.

### 3.2.2 User Profile Features

We extract several user's activity statistics to construct the user profile features, including the level

of the user in the Community QA site, the number of questions asked by this user, the number of answers provided by this user, and the best answer ratio of this user.

### 3.2.3 User Authority Score

Motivated by expert finding task (Jurczyk and Agichtein, 2007; Si et al., 2010a; Li et al., 2011), the second type of author related feature is authority score, which denotes the expertise score of this user. To compute the authority score, we first construct a directed user graph with the user interactions in the community. The nodes of the graph represent users. An edge between two users indicates a contribution from one user to the other. Specifically, on a Q&A site, an edge from A to B is established when user B answered a question asked by A, which shows user B is more likely to be an expert than A. The weight of an edge indicates the number of interactions. We compute the user’s authority score (AS) based on the link analysis algorithm *PageRank*:

$$AS(u_i) = \frac{1-d}{N} + d \sum_{u_j \in M(u_i)} \frac{AS(u_j)}{L(u_j)} \quad (1)$$

where  $u_1, \dots, u_N$  are the users in the collection,  $N$  is the total number of users,  $M(u_i)$  is the set of users whose answers are provided by user  $u_i$ ,  $L(u_i)$  is the number of users who answer  $u_i$ ’s questions,  $d$  is a damping factor, which is set as 0.85. The authority score can be computed iteratively with random initial values.

### 3.2.4 Robot Features

The third type of author related feature is used for detecting whether the author is a robot, which are scripts crafted by malicious users to automatically post answers. We observe that the distributions of the answer-posting time are very different between general user and robot. For example, some robots may make posts continuously and mechanically, hence the time increment may be smaller than human users who would need time to think and process between two posts. Based on this observation, we design a time sequence feature for robot detection. For each author, we can get a list of time points to post answers,  $T = \{t_0, t_1, \dots, t_n\}$ , where  $t_i$  is the time point when posting the  $i$ th answer. We first convert the time sequence  $T$  to time interval sequence  $\Delta T = \{\Delta t_0, \Delta t_1, \dots, \Delta t_{n-1}\}$ , where  $\Delta t_i = t_{i+1} - t_i$ . Based on the interval sequences for all users, we then construct a matrix  $X_{m \times b}$  whose rows correspond to users and

columns correspond to interval histogram with predefined range. We can use each row vector as time sequence pattern to detect robot. To reduce the noise and sparse problem, we use the dimension reduction techniques to extract the latent semantic features with Singular Value Decomposition (SVD) (Deerwester et al., 1990; Kim et al., 2006).

### 3.2.5 Evaluation from Other Users

In the Community QA sites, other users can express their opinions or evaluations on the answer. For example, the asker can choose one of the answers as best answer. We use a bool feature to denote if this answer is selected as the best answer. In addition, other users can label each answer as “helpful” or “not helpful”. We also use this helpful evaluation by other users as the contextual feature, which is defined as the ratio between the number of “helpful” votes and the number of total votes.

### 3.2.6 Duplication with Other Answers

The malicious user may post the pre-written product promotion documents to many answers, or just change the product name. We also compute the similarity between different answers. If the two answers are totally same, but the question is different, these answer is potentially as a deceptive answer. Here, we don’t want to measure the semantic similarity between two answers, but just measure if two answers are similar to the word level, therefore, we apply BleuScore (Papineni et al., 2002), which is a standard metric in machine translation for measuring the overlap between n-grams of two text fragments  $r$  and  $c$ . The duplication score of each answer is the maximum BleuScore compared to all other answers.

## 4 Deceptive Answer Prediction with User Preference Graph

Besides the textual and contextual features, we also investigate the user relationship for deceptive answer prediction. We assume that similar users tend to perform similar behaviors (posting deceptive answers or posting authentic answers). In this section, we first show how to compute the user similarity (user preference graph construction), and then introduce how to employ the user relationship for deceptive answer prediction.

### 4.1 User Preference Graph Construction

In this section, we propose a new user graph to describe the relationship among users. Figure 1 (a) shows the general process in a question answering

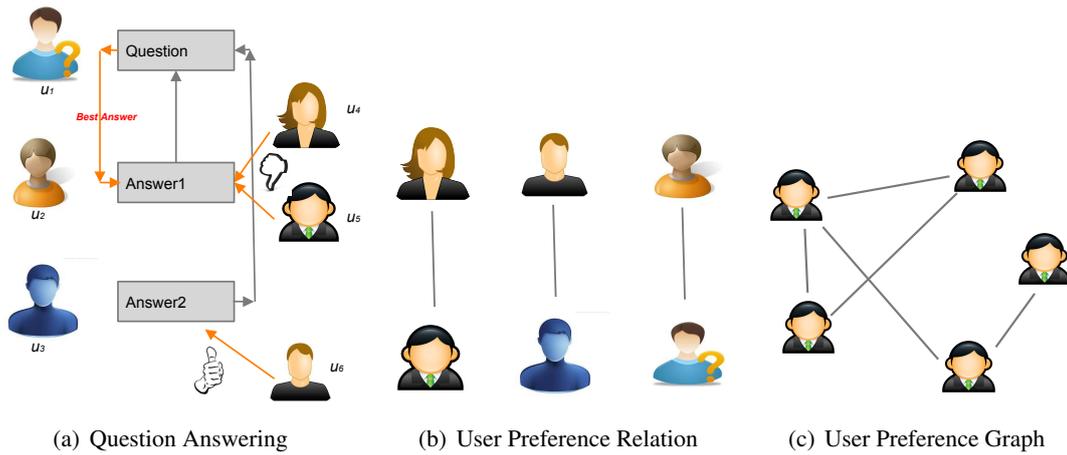

Figure 1: User Preference Graph Construction

thread. The asker, i.e.  $u_1$ , asks a question. Then, there will be several answers to answer this question from other users, for example, answerers  $u_2$  and  $u_3$ . After the answers are provided, users can also vote each answer as “helpful” or “not helpful” to show their evaluation towards the answer. For example, users  $u_4, u_5$  vote the first answer as “not helpful”, and user  $u_6$  votes the second answer as “helpful”. Finally, the asker will select one answer as the best answer among all answers. For example, the asker  $u_1$  selects the first answer as the “best answer”.

To mine the relationship among users, previous studies mainly focus on the asker-answerer relationship (Jurczyk and Agichtein, 2007; Liu et al., 2011). They assume the answerer is more knowledgeable than the asker. Based on this assumption, they can extract the expert in the community, as discussed in Section 3.2.3. However, we don’t care which user is more knowledgeable, but are more interested in whether two users are both malicious users or authentic users. Here, we propose a new user graph based on the user preference. The preference is defined based on the answer evaluation. If two users show same preference towards the target answer, they will have the user-preference relationship. We mainly use two kinds of information: “helpful” evaluation and “best answer” selection. If two users give same “helpful” or “not helpful” to the target answer, we view these two users have same user preference. For example, user  $u_4$  and user  $u_5$  both give “not helpful” evaluation towards the first answer, we can say that they have same user preference. Besides the real “helpful” evaluation, we also assume the author of the answer gives the “helpful” evalu-

ation to his or her own answer. Then if user  $u_6$  give “helpful” evaluation to the second answer, we will view user  $u_6$  has same preference as user  $u_3$ , who is the author of the second answer. We also can extract the user preference with “best answer” selection. If the asker selects the “best answer” among all answers, we will view that the asker has same preference as the author of the “best answer”. For example, we will view user  $u_1$  and user  $u_2$  have same preference.

Based on the two above assumptions, we can extract three user preference relationships (with same preference) from the question answering example in Figure 1 (a):  $u_4 \sim u_5, u_3 \sim u_6, u_1 \sim u_2$ , as shown in Figure 1 (b). After extracting all user preference relationships, we can construct the user preference graph as shown in Figure 1 (c). Each node represents a user. If two users have the user preference relationship, there will be an edge between them. The edge weight is the number of user preference relationships.

In the Community QA sites, the spammers mainly promote their target products by promoting the deceptive answers. The spammers can collaboratively make the deceptive answers look good, by voting them as high-quality answer, or selecting them as “best answer”. However, the authentic users generally have their own judgements to the good and bad answers. Therefore, the evaluation towards the answer reflects the relationship among users. Although there maybe noisy relationship, for example, an authentic user may be cheated, and selects the deceptive answer as “best answer”, we hope the overall user preference relation can perform better results than previous user interaction graph for this task.

## 4.2 Incorporating User Preference Graph

To use the user graph, we can just compute the feature value from the graph, and add it into the supervised method as the features introduced in Section 3. Here, we propose a new technique to employ the user preference graph. We utilize the graph regularizer (Zhang et al., 2006; Lu et al., 2010) to constrain the supervised parameter learning. We will introduce this technique based on a commonly used model  $f(\cdot)$ , the linear weight model, where the function value is determined by linear combination of the input features:

$$f(\mathbf{x}_i) = \mathbf{w}^T \cdot \mathbf{x}_i = \sum_k w_k \cdot x_{ik} \quad (2)$$

where  $\mathbf{x}_i$  is a  $K$  dimension feature vector for the  $i$ th answer, the parameter value  $w_k$  captures the effect of the  $k$ th feature in predicting the deceptive answer. The best parameters  $\mathbf{w}^*$  can be found by minimizing the following objective function:

$$\Omega_1(\mathbf{w}) = \sum_i L(\mathbf{w}^T \mathbf{x}_i, y_i) + \alpha \cdot |\mathbf{w}|_F^2 \quad (3)$$

where  $L(\mathbf{w}^T \mathbf{x}_i, y_i)$  is a loss function that measures discrepancy between the predicted label  $\mathbf{w}^T \cdot \mathbf{x}_i$  and the true label  $y_i$ , where  $y_i \in \{+1, -1\}$ . The common used loss functions include  $L(p, y) = (p - y)^2$  (least square),  $L(p, y) = \ln(1 + \exp(-py))$  (logistic regression). For simplicity, here we use the least square loss function.  $|\mathbf{w}|_F^2 = \sum_k w_k^2$  is a regularization term defined in terms of the Frobenius norm of the parameter vector  $\mathbf{w}$  and plays the role of penalizing overly complex models in order to avoid fitting.

We want to incorporate the user preference relationship into the supervised learning framework. The hypothesis is that similar users tend to have similar behaviors, i.e. posting deceptive answers or authentic answers. Here, we employ the user preference graph to denote the user relationship. Based on this intuition, we propose to incorporate the user graph into the linear weight model with graph regularization. The new objective function is changed as:

$$\Omega_2(\mathbf{w}) = \sum_i L(\mathbf{w}^T \mathbf{x}_i, y_i) + \alpha \cdot |\mathbf{w}|_F^2 + \beta \sum_{u_i, u_j \in N_u} \sum_{x \in A_{u_i}, y \in A_{u_j}} w_{u_i, u_j} (f(x) - f(y))^2 \quad (4)$$

where  $N_u$  is the set of neighboring user pairs in user preference graph, i.e. the user pairs with same

preference.  $A_{u_i}$  is the set of all answers posted by user  $u_i$ .  $w_{u_i, u_j}$  is the weight of edge between  $u_i$  and  $u_j$  in user preference graph. In the above objective function, we impose a user graph regularization term

$$\beta \sum_{u_i, u_j \in N_u} \sum_{x \in A_{u_i}, y \in A_{u_j}} w_{u_i, u_j} (f(x) - f(y))^2$$

to minimize the answer authenticity difference among users with same preference. This regularization term smoothes the labels on the graph structure, where adjacent users with same preference tend to post answers with same label.

## 5 Experiments

### 5.1 Experiment Setting

#### 5.1.1 Dataset Construction

In this paper, we employ the Confucius (Si et al., 2010b) data to construct the deceptive answer dataset. Confucius is a community question answering site, developed by Google. We first crawled about 10 million question threads within a time range. Among these data, we further sample a small data set, and ask three trained annotators to manually label the answer as deceptive or not. If two or more people annotate the answer as deceptive, we will extract this answer as a deceptive answer. In total, 12446 answers are marked as deceptive answers. Similarly, we also manually annotate 12446 authentic answers. Finally, we get 24892 answers with deceptive and authentic labels as our dataset. With our labeled data, we employ supervised methods to predict deceptive answers. We conduct 5-fold cross-validation for experiments. The larger question threads data is employed for feature learning, such as translation model, and topic model training.

#### 5.1.2 Evaluation Metrics

The evaluation metrics are *precision*, *recall* and *F-score* for authentic answer category and deceptive answer category:  $precision = \frac{S_p \cap S_c}{S_p}$ ,  $recall = \frac{S_p \cap S_c}{S_c}$ , and  $F = \frac{2 * precision * recall}{precision + recall}$ , where  $S_c$  is the set of gold-standard positive instances for the target category,  $S_p$  is the set of predicted results. We also use the *accuracy* as one metric, which is computed as the number of answers predicted correctly, divided by the number of total answers.

	Deceptive Answer			Authentic Answer			Overall
	Prec.	Rec.	F-Score	Prec.	Rec.	F-Score	Acc.
Random	0.50	0.50	0.50	0.50	0.50	0.50	0.50
Unigram/Bigram (UB)	0.61	0.71	0.66	0.66	0.55	0.60	0.63
URL	0.93	0.26	0.40	0.57	0.98	0.72	0.62
Phone/Mail	0.94	0.15	0.25	0.53	0.99	0.70	0.57
Length	0.56	0.91	0.69	0.76	0.28	0.41	0.60
All Textual Features	0.64	0.67	0.66	0.66	0.63	0.64	0.65
QA Relevance	0.66	0.57	0.61	0.62	0.71	0.66	0.64
User Profile	0.62	0.53	0.57	0.59	0.67	0.63	0.60
User Authority	0.54	0.80	0.65	0.62	0.33	0.43	0.56
Robot	0.66	0.62	0.64	0.61	0.66	0.64	0.64
Answer Evaluation	0.55	0.53	0.54	0.55	0.57	0.56	0.55
Answer Duplication	0.69	0.71	0.70	0.70	0.68	0.69	0.69
All Contextual Feature	0.78	0.74	0.76	0.75	0.79	0.77	0.77
Textual + Contextual	0.80	0.82	0.81	0.82	0.79	0.80	0.81

Table 2: Results With Textual and Contextual Features

## 5.2 Results with Textual and Contextual Features

We tried several different classifiers, including SVM, ME and the linear weight models with least square and logistic regression. We find that they can achieve similar results. For simplicity, the linear weight with least square is employed in our experiment. Table 2 shows the experiment results. For textual features, it achieves much better result with unigram/bigram features than the random guess. This is very different from the answer quality prediction task. The previous studies (Jeon et al., 2006; Song et al., 2010) find that the word features can’t improve the performance on answer quality prediction. However, from Table 1, we can see that the word features can provide some weak signals for deceptive answer prediction, for example, words “recommend”, “address”, “professional” express some kinds of promotion intent. Besides unigram and bigram, the most effective textual feature is URL. The phone and email features perform similar results with URL. The observation of length feature for deceptive answer prediction is very different from previous answer quality prediction. For answer quality prediction, length is an effective feature, for example, long-length provides very strong signals for high-quality answer (Shah and Pomerantz, 2010; Song et al., 2010). However, for deceptive answer prediction, we find that the long answers are more potential to be deceptive. This is because most of deceptive answers are well prepared for product

promotion. They will write detailed answers to attract user’s attention and promote their products. Finally, with all textual features, the experiment achieves the best result, 0.65 in accuracy.

For contextual features, we can see that, the most effective contextual feature is answer duplication. The malicious users may copy the prepared deceptive answers or just simply edit the target name to answer different questions. Question-answer relevance and robot are the second most useful single features for deceptive answer prediction. The main characteristics of the Community QA sites is to accumulate the answers for the target questions. Therefore, all the answers should be relevant to the question. If the answer is not relevant to the corresponding question, this answer is more likely to be deceptive. Robot is one of main sources for deceptive answers. It automatically post the deceptive answers to target questions. Here, we formulate the time series as interval sequence. The experiment result shows that the robot indeed has his own posting behavior patterns. The user profile feature also can contribute a lot to deceptive answer prediction. Among the user profile features, the user level in the Community QA site is a good indicator. The other two contextual features, including user authority and answer evaluation, provide limited improvement. We find the following reasons: First, some malicious users post answers to various questions for product promotion, but don’t ask any question. From Equation 1, when iteratively computing the

	Deceptive Answer			Authentic Answer			Overall
	Prec.	Rec.	F-Score	Prec.	Rec.	F-Score	Acc.
Interaction Graph as Feature	0.80	0.82	0.81	0.82	0.79	0.80	0.81
Interaction Graph as Regularizer	0.80	0.83	0.82	0.82	0.80	0.81	0.82
Preference Graph as Feature	0.79	0.83	0.81	0.82	0.78	0.80	0.81
Preference Graph as Regularizer	0.83	0.86	0.85	0.85	0.83	0.84	0.85

Table 3: Results With User Preference Graph

final scores, the authority scores for these malicious users will be accumulated to large values. Therefore, it is hard to distinguish whether the high authority score represents real expert or malicious user. Second, the “best answer” is not a good signal for deceptive answer prediction. This may be selected by malicious users, or the authentic asker was misled, and chose the deceptive answer as “best answer”. This also demonstrates that the deceptive answer prediction is very different from the answer quality prediction. When combining all the contextual features, it can achieve the overall accuracy 0.77, which is much better than the textual features. Finally, with all the textual and contextual features, we achieve the overall result, 0.81 in accuracy.

### 5.3 Results with User Preference Graph

Table 3 shows the results with user preference graph. We compare with several baselines. Interaction graph is constructed by the asker-answerer relationship introduced in Section 3.2.3. When using the user graph as feature, we compute the authority score for each user with PageRank as shown in Equation 1. We also incorporating the interaction graph with a regularizer as shown in Equation 4. Note that we didn’t consider the edge direction when using interaction graph as a regularizer. From the table, we can see that when incorporating user preference graph as a feature, it can’t achieve a better result than the interaction graph. The reason is similar as the interaction graph. The higher authority score may be boosted by other spammer, and can’t be a good indicator to distinguish deceptive and authentic answers. When we incorporate the user preference graph as a regularizer, it can achieve about 4% further improvement, which demonstrates that the user evaluation towards answers, such as “helpful” voting and “best answer” selection, is a good signal to generate user relationship for deceptive answer prediction, and the graph regularization is an effective technique to incorporate the user prefer-

ence graph. We also analyze the parameter sen-

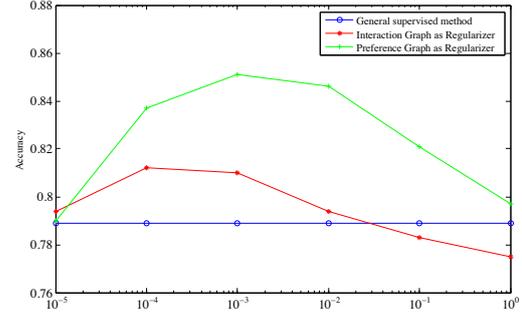

Figure 2: Results with different values of  $\beta$

sitivity.  $\beta$  is the tradeoff weight for graph regularization term. Figure 2 shows the results with different values of  $\beta$ . We can see that when  $\beta$  ranges from  $10^{-4} \sim 10^{-2}$ , the deceptive answer prediction can achieve best results.

## 6 Conclusions and Future Work

In this paper, we discuss the deceptive answer prediction task in Community QA sites. With the manually labeled data set, we first predict the deceptive answers with traditional classification method. Two types of features, including textual features and contextual features, are extracted and analyzed. We also introduce a new user preference graph, constructed based on the user evaluations towards the target answer, such as “helpful” voting and “best answer” selection. A graph regularization method is proposed to incorporate the user preference graph for deceptive answer prediction. The experiments are conducted to discuss the effects of different features. The experiment results also show that the method with user preference graph can achieve more accurate results for deceptive answer prediction.

In the future work, it is interesting to incorporate more features into deceptive answer prediction. It is also important to predict the deceptive question threads, which are posted and answered both by malicious users for product promotion. Malicious user group detection is also an important task in the future.

## Abstract

In this paper, we explore the utility of *intra-* and *inter-sentential causal relations* between terms or clauses as evidence for answering why-questions. To the best of our knowledge, this is the first work that uses both intra- and inter-sentential causal relations for why-QA. We also propose a method for assessing the appropriateness of causal relations as answers to a given question using the semantic orientation of *excitation* proposed by Hashimoto et al. (2012). By applying these ideas to Japanese why-QA, we improved precision by 4.4% against all the questions in our test set over the current state-of-the-art system for Japanese why-QA. In addition, unlike the state-of-the-art system, our system could achieve very high precision (83.2%) for 25% of all the questions in the test set by restricting its output to the confident answers only.

## 1 Introduction

“Why-question answering” (why-QA) is a task to retrieve answers from a given text archive for a why-question, such as “Why are tsunamis generated?” The answers are usually text fragments consisting of one or more sentences. Although much research exists on this task (Girju, 2003; Higashinaka and Isozaki, 2008; Verberne et al., 2008; Verberne et al., 2011; Oh et al., 2012), its performance remains much lower than that of the state-of-the-art factoid QA systems, such as IBM’s Watson (Ferrucci et al., 2010).

In this work, we propose a quite *straightforward* but *novel* approach for such difficult why-QA task. Consider the sentence **A1** in Table 1, which represents the causal relation between the cause, “the ocean’s water mass ..., waves are gen-

<b>A1</b>	[Tsunamis that can cause large coastal inundation are generated] <sub>effect</sub> <u>because</u> [the ocean’s water mass is displaced and, much like throwing a stone into a pond, waves are generated.] <sub>cause</sub>
<b>A2</b>	[Earthquake causes seismic waves which set up the water in motion with a large force.] <sub>cause</sub> <u>This causes</u> [a tsunami]. <sub>effect</sub>
<b>A3</b>	[Tsunamis] <sub>effect</sub> <u>are caused by</u> [the sudden displacement of huge volumes of water.] <sub>cause</sub>
<b>A4</b>	[Tsunamis weaken as they pass through forests] <sub>effect</sub> <u>because</u> [the hydraulic resistance of the trees diminish their energy.] <sub>cause</sub>
<b>A5</b>	[Automakers in Japan suspended production for an array of vehicles] <sub>effect</sub> <u>because</u> [the magnitude 9 earthquake and tsunami hit their country on Friday, March 11, 2011.] <sub>cause</sub>

Table 1: Examples of intra/inter-sentential causal relations. Cause and effect parts of each causal relation, marked with  $[..]_{cause}$  and  $[..]_{effect}$ , are connected by the underlined cue phrases for causality, such as *because*, *this causes*, and *are caused by*.

erated,” and its effect, “Tsunamis ... are generated.” This is a good answer to the question, “Why are tsunamis generated?”, since the effect part is more or less equivalent to the (propositional) content of the question. Our method finds text fragments that include such causal relations with an effect part that resembles a given question and provides them as answers.

Since this idea looks quite intuitive, many people would probably consider it as a solution to why-QA. However, to our surprise, we could not find any previous work on why-QA that took this approach. Some methods utilized the causal relations between terms as evidence for finding answers (i.e., matching a cause term with an answer text and its effect term with a question) (Girju, 2003; Higashinaka and Isozaki, 2008). Other approaches utilized such clue terms for causality as “because” as evidence for finding answers (Murata et al., 2007). However, these algorithms did not check whether an answer candidate, i.e., a text fragment that may be provided as an answer, explicitly contains a complex causal relation sen-

tence with the effect part that resembles a question. For example, **A5** in Table 1 is an incorrect answer to “Why are tsunamis generated?”, but these previous approaches would probably choose it as a proper answer due to “because” and “earthquake” (i.e., a cause of tsunamis). At least in our experimental setting, our approach outperformed these simpler causality-based QA systems.

Perhaps this approach was previously deemed infeasible due to two non-trivial technical challenges. The first challenge is to accurately identify a wide range of causal relations like those in Table 1 in answer candidates. To meet this challenge, we developed a sequence labeling method that identifies not only *intra-sentential causal relations*, i.e., the causal relations between two terms/phrases/clauses expressed in a single sentence (e.g., **A1** in Table 1), but also the *inter-sentential causal relations*, which are the causal relations between two terms/phrases/clauses expressed in two adjacent sentences (e.g., **A2**) in a given text fragment.

The second challenge is assessing the appropriateness of each identified causal relation as an answer to a given question. This is important since the causal relations identified in the answer candidates may have nothing to do with a given question. In this case, we have to reject these causal relations because they are inappropriate as an answer to the question. When a single answer candidate contains many causal relations, we also have to select the appropriate ones. Consider the causal relations in **A1–A4**. Those in **A1–A3** are appropriate answers to “Why are tsunamis generated?”, but not the one in **A4**. To assess the appropriateness, the system must recognize *textual entailment*, i.e., “tsunamis (are) generated” in the question is entailed by all “tsunamis are generated” in **A1**, “cause a tsunami” in **A2** and “tsunamis are caused” in **A3** but not by “tsunamis weaken” in **A4**. This quite difficult task is currently being studied by many researchers in the RTE field (Androutsopoulos and Malakasiotis, 2010; Dagan et al., 2010; Shima et al., 2011; Bentivogli et al., 2011). To meet this challenge, we developed a relatively simple method that can be seen as a lightweight approximation for this difficult RTE task, using excitation polarities (Hashimoto et al., 2012).

Through our experiments on Japanese why-QA, we show that a combination of the above methods

can improve why-QA accuracy. In addition, our proposed method can be successfully combined with other approaches to why-QA and can contribute to higher accuracy. As a final result, we improved the precision by 4.4% against all the questions in our test set over the current state-of-the-art system of Japanese why-QA (Oh et al., 2012). The difference in the performance became much larger when we only compared the highly confident answers of each system. When we made our system provide only its confident answers according to their confidence score given by our system, the precision of these confident answers was 83.2% for 25% of all the questions in our test set. In the same setting, the precision of the state-of-the-art system (Oh et al., 2012) was only 62.4%.

## 2 Related Work

Although there were many previous works on the acquisition of intra- and inter-sentential causal relations from texts (Khoo et al., 2000; Girju, 2003; Inui and Okumura, 2005; Chang and Choi, 2006; Torisawa, 2006; Blanco et al., 2008; De Saeger et al., 2009; De Saeger et al., 2011; Riaz and Girju, 2010; Do et al., 2011; Radinsky et al., 2012), their application to why-QA was limited to causal relations between terms (Girju, 2003; Higashinaka and Isozaki, 2008).

As previous attempts to improve why-QA performance, such semantic knowledge as WordNet synsets (Verberne et al., 2011), semantic word classes (Oh et al., 2012), sentiment analysis (Oh et al., 2012), and causal relations between terms (Girju, 2003; Higashinaka and Isozaki, 2008) has been used. These previous studies took basically bag-of-words approaches and used the semantic knowledge to identify certain semantic associations using terms and n-grams. On the other hand, our method explicitly identifies intra- and inter-sentential causal relations between terms/phrases/clauses that have complex structures and uses the identified relations to answer a why-question. In other words, our method considers more complex linguistic structures than those used in the previous studies. Note that our method can complement the previous approaches. Through our experiments, we showed that it is possible to achieve a higher precision by combining our proposed method with bag-of-words approaches considering semantic word classes and sentiment analysis in our previous work (Oh et al.,

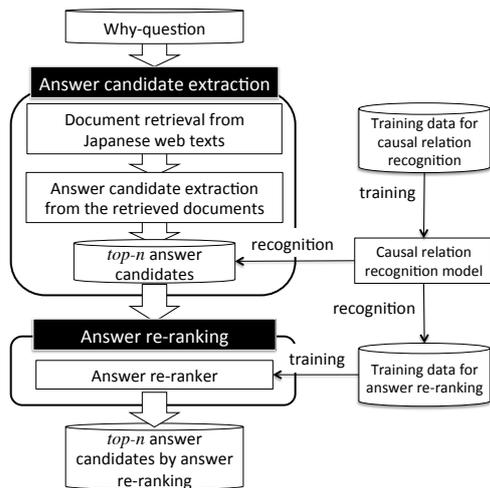

Figure 1: System architecture

2012).

### 3 System Architecture

We first describe the system architecture of our QA system before describing our proposed method. It is composed of two components: answer candidate extraction and answer re-ranking (Fig. 1). This architecture is basically the same as that used in our previous work (Oh et al., 2012). We extended our previous work by introducing causal relations recognized from answer candidates to the answer re-ranking. The features used in our previous work are very different from those in this work, and we found that combining both improves accuracy.

**Answer candidate extraction:** In our previous work, we implemented the method of Murata et al. (2007) for our answer candidate extractor. We retrieved documents from Japanese web texts using *Boolean AND* and *OR* queries generated from the content words in why-questions. Then we extracted passages of five sentences from these retrieved documents and ranked them with the ranking function proposed by Murata et al. (2007). This method ranks a passage higher when it contains more query terms that are closer to each other in the passage. We used a set of clue terms, including the Japanese counterparts of *cause* and *reason*, as query terms for the ranking. The top ranked passages are regarded as *answer candidates* in the answer re-ranking. See Murata et al. (2007) for more details.

**Answer re-ranking:** Re-ranking the answer candidates is done by a supervised classifier (SVMs) (Vapnik, 1995). In our previous work, we

employed three types of features for training the re-ranker: morphosyntactic features ( $n$ -grams of morphemes and syntactic dependency chains), semantic word class features (semantic word classes obtained by automatic word clustering (Kazama and Torisawa, 2008)) and sentiment polarity features (word and phrase polarities). Here, we used semantic word classes and sentiment polarities for identifying such semantic associations between a why-question and its answer as “if a disease’s name appears in a question, then answers that include nutrient names are more likely to be correct” by semantic word classes and “if something undesirable happens, the reason is often also something undesirable” by sentiment polarities. In this work, we propose causal relation features generated from intra- and inter-sentential causal relations in answer candidates and use them along with the features proposed in our previous work for training our re-ranker.

### 4 Causal Relations for Why-QA

We describe causal relation recognition in Section 4.1 and describe the features (of our re-ranker) generated from causal relations in Section 4.2.

#### 4.1 Causal Relation Recognition

We restrict causal relations to those expressed by such cue phrases for causality as (the Japanese counterparts of) *because* and *as a result* like in the previous work (Khoo et al., 2000; Inui and Okumura, 2005) and recognize them in the following two steps: extracting causal relation candidates and recognizing causal relations from these candidates.

##### 4.1.1 Extracting Causal Relation Candidates

We identify cue phrases for causality in answer candidates using the regular expressions in Table 2. Then, for each identified cue phrase, we extract three sentences as a causal relation candidate, where one contains the cue phrase and the other two are the previous and next sentences in the answer candidates. When there is more than one cue phrase in an answer candidate, we use all of them for extracting the causal relation candidates, assuming that each of the cue phrases is linked to different causal relations. We call a cue phrase used for extracting a causal relation candidate a *c-marker* (*causality marker*) of the candidate to distinguish it from the other cue phrases in the same causal relation candidate.

Regular expressions	Examples
(D の)? ため P?	ため (for), のため (for), そのため (as a result), のために (for)
ので	ので (since or because of)
こと (から で)	ことから (from the fact that), ことで (by the fact that)
(から ため) C	からだ (because), ためた (It is because)
D? RCT (P C)+	理由は (the reason is), 原因だ (is the cause), この理由から (from this reason)

Table 2: Regular expressions for identifying cue phrases for causality. **D**, **P** and **C** represent demonstratives (e.g., この (this) and その (that)), postpositions (including case markers such as が (nominative), の (genitive)), and copula (e.g., です (is) and である (is)) in Japanese, respectively. **RCT**, which represents Japanese terms meaning *reason*, *cause*, or *thanks to*, is defined as follows: **RCT** = {理由 (reason), 原因 (cause), 要因 (cause), 引き金 (cause), おかげ (thanks to), せい (thanks to), わけ (reason)}.

#### 4.1.2 Recognizing Causal Relations

Next, we recognize the spans of the cause and effect parts of a causal relation linked to a c-marker. We regard this task as a sequence labeling problem and use Conditional Random Fields (CRFs) (Lafferty et al., 2001) as a machine learning framework. In our task, CRFs take three sentences of a causal relation candidate as input and generate their cause-effect annotations with a set of possible cause-effect IOB labels, including Begin-Cause (B-C), Inside-Cause (I-C), Begin-Effect (B-E), Inside-Effect (I-E), and Outside (O). Fig 2 shows an example of such sequence labeling. Although this example is about sequential labeling shown on English sentences for ease of explanation, it was actually done on Japanese sentences.

We used the three types of feature sets in Table 3 for training the CRFs, where  $j$  is in the range of  $i - 4 \leq j \leq i + 4$  for current position  $i$  in a causal relation candidate.

Type	Features
Morphological feature	$m_j, m_j^{j+1}, pos_j, pos_j^{j+1}$
Syntactic feature	$s_j, s_j^{j+1}, b_j, b_j^{j+1}$
C-marker feature	$(m_j, cm), (m_j^{j+1}, cm)$ $(s_j, cm), (s_j^{j+1}, cm)$

Table 3: Features for training CRFs, where  $x_j^{j+1} = x_j x_{j+1}$

**Morphological features:**  $m_j$  and  $pos_j$  in Table 3 represent the  $j^{th}$  morpheme and the POS tag.

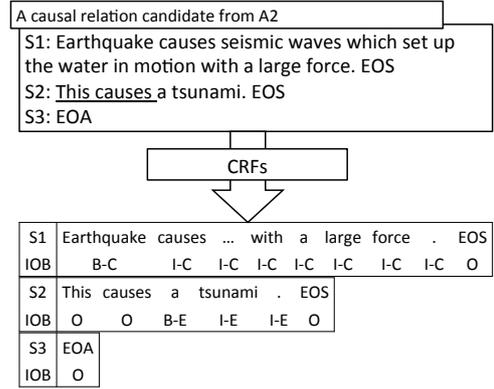

Figure 2: Recognizing causal relations by sequence labeling: Underlined text *This causes* represents a c-marker, and EOS and EOA represent *end-of-sentence* and *end-of-answer candidates*.

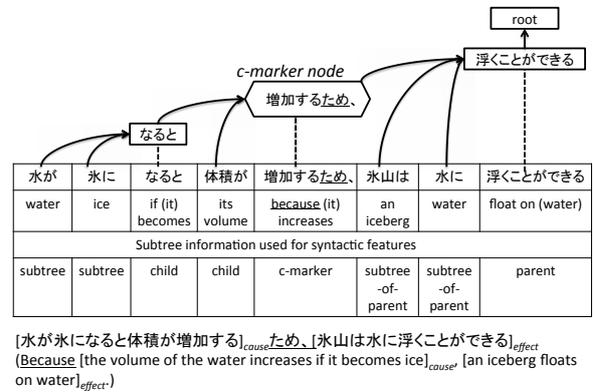

Figure 3: Example of syntactic information related to a c-marker used for syntactic features

We use JUMAN<sup>1</sup>, a Japanese morphological analyzer, for generating our morphological features.

**Syntactic features:** The span of the causal relations in a given causal relation candidate strongly depends on the c-marker in the candidate. Especially for intra-sentential causal relations, their cause and effect parts often appear in the subtrees of the c-marker's node or those of the c-marker's parent node in a syntactic dependency tree structure. Fig. 3 shows an example that follows this observation, where the c-marker node is represented in a hexagon and the other nodes are in a rectangle. Note that each node in Fig. 3 is a word phrase (called a *bunsetsu*), which is the smallest unit of syntactic analysis in Japanese. A *bunsetsu* is a syntactic constituent composed of a content word and several function words such as postpositions and case markers. Syntactic dependency is represented by an arrow in Fig. 3. For example, there is syntactic dependency from word phrase 水が

<sup>1</sup> <http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?JUMAN>

(water) になると (if (it) becomes), i.e., 水が<sup>dep</sup> になると. We encode this subtree information into  $s_j$ , which is the syntactic information of a word phrase to which the  $j^{\text{th}}$  morpheme belongs.  $s_j$  only has one of six values: 1) the c-marker’s node (*c-marker*), 2) the c-marker’s child node (*child*), 3) the c-marker’s parent node (*parent*), 4) in the c-marker’s subtree but not the c-marker’s child node (*subtree*), 5) in the subtree of the c-marker’s parent node but not the c-marker’s node (*subtree-of-parent*) and 6) the others (*others*).  $b_j$  is the word phrase information of the  $j^{\text{th}}$  morpheme ( $m_j$ ) that represents whether  $m_j$  is in the beginning or inside a word phrase. For generating our syntactic features, we use KNP<sup>2</sup>, a Japanese syntactic dependency parser.

**C-marker features:** As our c-marker features, we use a pair composed of c-marker  $cm$  and one of the following:  $m_j$ ,  $m_j^{j+1}$ ,  $s_j$ , or  $s_j^{j+1}$ .

## 4.2 Causal Relation Features

We use terms, partial trees (in a syntactic dependency tree structure), and the semantic orientation of excitation (Hashimoto et al., 2012) to assess the appropriateness of each causal relation obtained by our causal relation recognizer as an answer to a given question. Finding answers with term matching and partial tree matching has been used in the literature of question answering (Girju, 2003; Narayanan and Harabagiu, 2004; Moschitti et al., 2007; Higashinaka and Isozaki, 2008; Verberne et al., 2008; Surdeanu et al., 2011; Verberne et al., 2011; Oh et al., 2012), while that with the excitation polarity is proposed in this work.

We use three types of features. Each feature type expresses the causal relations in an answer candidate that are determined to be appropriate as answers to a given question by term matching ( $tf_1$ – $tf_4$ ), partial tree matching ( $pf_1$ – $pf_4$ ) and excitation polarity matching ( $ef_1$ – $ef_4$ ). We call these causal relations used for generating our causal relation features *candidates of an appropriate causal relation* in this section. Note that if one answer candidate has more than one candidate of an appropriate causal relation found by one matching method, we generated features for each appropriate candidate and merged all of them for the answer candidate.

Type	Description
$tf_1$	word $n$ -grams of causal relations
$tf_2$	word class version of $tf_1$
$tf_3$	indicator for the existence of candidates of an appropriate causal relation identified by term matching in an answer candidate
$tf_4$	number of matched terms in candidates of an appropriate causal relation
$pf_1$	syntactic dependency $n$ -grams ( $n$ dependency chain) of causal relations
$pf_2$	word class version of $pf_1$
$pf_3$	indicator for the existence of candidates of an appropriate causal relation identified by partial tree matching in an answer candidate
$pf_4$	number of matched partial trees in candidates of an appropriate causal relation
$ef_1$	types of noun-polarity pairs shared by causal relations and the question
$ef_2$	$ef_1$ coupled with each noun’s word class
$ef_3$	indicator for the existence of candidates of an appropriate causal relation identified by excitation polarity matching in an answer candidate
$ef_4$	number of noun-polarity pairs shared by the question and the candidates of an appropriate causal relation

Table 4: Causal relation features:  $n$  in  $n$ -grams is  $n = \{2, 3\}$  and  $n$ -grams in an effect part are distinguished from those in a cause part.

### 4.2.1 Term Matching

Our term matching method judges that a causal relation is a candidate of an appropriate causal relation if its effect part contains at least one content word (nouns, verbs, and adjectives) in the question. For example, all the causal relations of **A1**–**A4** in Table 1 are candidates of an appropriate causal relation to the question, “Why is a tsunami generated?”, by term matching with question term *tsunami*.

$tf_1$ – $tf_4$  are generated from candidates of an appropriate causal relation identified by term matching. The  $n$ -grams of  $tf_1$  and  $tf_2$  are restricted to those containing at least one content word in a question. We distinguish this matched word from the other words by replacing it with QW, a special symbol representing a word in the question. For example, word 3-gram “this/cause/QW” is extracted from *This causes tsunamis* in **A2** for “Why is a tsunami generated?” Further, we create a word class version of word  $n$ -grams by converting the words in these word  $n$ -grams into their corresponding word class using the semantic word classes (500 classes for 5.5 million nouns) from our previous work (Oh et al., 2012). These word classes were created by applying the automatic word clustering method of Kazama and Torisawa (2008) to 600 million Japanese web pages. For example, the word class version of word 3-gram

<sup>2</sup> <http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?KNP>

“this/cause/QW” is “this/cause/QW,WC<sub>tsunami</sub>”, where WC<sub>tsunami</sub> represents the word class of a tsunami.  $tf_3$  is a binary feature that indicates the existence of candidates of an appropriate causal relation identified by term matching in an answer candidate.  $tf_4$  represents the degree of the relevance of the candidates of an appropriate causal relation measured by the number of matched terms: one, two, and more than two.

### 4.2.2 Partial Tree Matching

Our partial tree matching method judges a causal relation as a candidate of an appropriate causal relation if its effect part contains at least one partial tree in a question, where the partial tree covers more than one content word. For example, only the causal relation **A1** among **A1–A4** is a candidate of an appropriate causal relation for question “Why are tsunamis generated?” by partial tree matching because only its effect part contains partial tree “tsunamis  $\xrightarrow{dep}$  (are) generated” of the question.

$pf_1$ – $pf_4$  are generated from candidates of an appropriate causal relation identified by the partial tree matching. The syntactic dependency  $n$ -grams in  $pf_1$  and  $pf_2$  are restricted to those that contain at least one content word in a question. We distinguish this matched content word from the other content words in the  $n$ -gram by converting it to QW, which represents a content word in the question. For example, syntactic dependency 2-gram “QW  $\xrightarrow{dep}$  cause” and its word class version “QW,WC<sub>tsunami</sub>  $\xrightarrow{dep}$  cause” are extracted from *Tsunamis that can cause* in **A1**.  $pf_3$  is a binary feature that indicates whether an answer candidate contains candidates of an appropriate causal relation identified by partial tree matching.  $pf_4$  represents the degree of the relevance of the candidate of an appropriate causal relation measured by the number of matched partial trees: one, two, and more than two.

### 4.2.3 Excitation Polarity Matching

Hashimoto et al. (2012) proposed a semantic orientation called *excitation polarities*. It classifies predicates with their argument position (called *templates*) into *excitatory*, *inhibitory* and *neutral*. In the following, we denote a template as “[*argument position, predicate*].” According to Hashimoto’s definition, excitatory templates imply that the function, effect, purpose, or the role of

an entity filling an argument position in the templates is activated/enhanced. On the contrary, inhibitory templates imply that the effect, purpose or the role of an entity is deactivated/suppressed. Neutral templates are those that neither activate nor suppress the function of an argument.

We assume that the *meanings* of a text can be *roughly* captured by checking whether each noun in the text is *activated* or *suppressed* in the sense of the excitation polarity framework, where the activation and suppression of each entity (or noun) can be detected by looking at the excitation polarities of the templates that are filled by the entity. For instance, effect part “tsunamis that can cause large coastal inundation are generated” of **A1** roughly means that “tsunamis” are *activated* and “inundation” is (or can be) *activated*. This activation/suppression configuration of the nouns is *consistent* with sentence “tsunamis are caused” in which “tsunamis” are *activated*. This consistency suggests that **A1** is a good answer to question “Why are tsunamis caused?”, although the “tsunamis” are modified by different predicates; “cause” and “generate.” On the other hand, effect part “tsunamis weaken as they pass through forests” of **A4** implies that “tsunamis” are *suppressed*. This suggests that **A4** is not a good answer to “Why are tsunamis caused?” Note that the consistency checking between activation/suppression configurations of nouns<sup>3</sup> in texts can be seen as a rough but lightweight approximation of the recognition of textual entailments or paraphrases.

Following the definition of excitation polarity in Hashimoto et al. (2012), we manually classified templates<sup>4</sup> to each polarity type and obtained 8,464 excitatory templates, such as [が, 増える] ([subject, increase]) and [が, 向上する] ([subject, improve]), 2,262 inhibitory templates, such as [を, 防ぐ] ([object, prevent]) and [が, 死ぬ] ([subject, die]), and 7,230 neutral templates such as [を, 考える] ([object, consider]). With these templates, we obtain activation/suppression configurations (including neutral) for the nouns in the causal relations in the answer candidates and ques-

<sup>3</sup> Because the activation/suppression configurations of nouns come from an excitation polarity of templates, “[*argument position, predicate*],” the semantics of verbs in the templates are implicitly considered in this consistency checking.

<sup>4</sup> Varga et al. (2013) has used the same templates as ours, except they restricted their excitation/inhibitory templates to those whose polarity is consistent with that given by the automatic acquisition method of Hashimoto et al. (2012).

tions.

Next, we assume that a causal relation is appropriate as an answer to a question if the effect part of the causal relation and the question share at least one common noun with the same polarity. More detailed information concerning the configurations of all the nouns in all the candidates of an *appropriate* causal relation (including their cause parts) and the question are encoded into our feature set  $ef_1$ – $ef_4$  in Table 4 and the final judgment is done by our re-ranker.

For generating  $ef_1$  and  $ef_2$ , we classified all the nouns coupled with activation/suppression/neutral polarities in a causal relation into three types: SAME (the question contains the same noun with the same polarity), DiffPOL (the question contains the same noun with different polarity), and OTHER (the others).  $ef_1$  indicates whether each type of noun-polarity pair exists in a causal relation. Note that the types for the effect and cause parts are represented in distinct features.  $ef_2$  is the same as  $ef_1$  except that the types are augmented with the word classes of the corresponding nouns. In other words,  $ef_2$  indicates whether each type of noun-polarity pair exists in the causal relation for each word class.  $ef_3$  indicates the existence of candidates of an appropriate causal relation identified by this matching scheme, and  $ef_4$  represents the number of noun-polarity pairs shared by the question and the candidates of an appropriate causal relations (one, two, and more than two).

## 5 Experiments

We experimented with causal relation recognition and why-QA with our causal relation features.

### 5.1 Data Set for Why-Question Answering

For our experiments, we used the same why-QA data set as the one used in our previous work (Oh et al., 2012). This why-QA data set is composed of 850 Japanese why-questions and their top-20 answer candidates obtained by answer candidate extraction from 600 million Japanese web pages. Three annotators checked the top-20 answer candidates of these 850 questions and the final judgment was made by their majority vote. Their inter-rater agreement by Fleiss’ kappa reported in Oh et al. (2012) was substantial ( $\kappa = 0.634$ ). Among the 850 questions, 250 why-questions were extracted from the Japanese version of *Yahoo! Answers*, and another 250 were created by annotators. In

our previous work, we evaluated the system with these 500 questions and their answer candidates as training and test data in 10-fold cross-validation. The other 350 why-questions were manually built from passages describing the causes or reasons of events/phenomena. These questions and their answer candidates were used as additional training data for testing subsamples in each fold during the 10-fold cross-validation. In our why-QA experiments, we evaluated our why-QA system with the same settings.

### 5.2 Data Set for Causal Relation Recognition

We built a data set composed of manually annotated causal relations for evaluating our causal relation recognition. As source data for this data set, we used the same 10-fold data that we used for evaluating our why-QA (500 questions and their answer candidates). We extracted the causal relation candidates from the answer candidates in each fold, and then our annotator (not an author) manually marked the span of the cause and effect parts of a causal relation for each causal relation candidate, keeping in mind that the causal relation must be expressed in terms of a c-marker in a given causal relation candidate. Finally, we had a data set made of 16,051 causal relation candidates, 8,117 of which had a true causal relation; the number of intra- and inter-sentential causal relations were 7,120 and 997, respectively.

Note that this data set can be partitioned into ten folds by using the 10-fold partition of its source data. We performed 10-fold cross validation to evaluate our causal relation recognition with this 10-fold data.

### 5.3 Causal Relation Recognition

We used CRF++<sup>5</sup> for training our causal relation recognizer. In our evaluation, we judged a system’s output as correct if both spans of the cause and effect parts overlapped those in the gold standard. Evaluation was done by precision, recall, and  $F_1$ .

	Precision	Recall	$F_1$
BASELINE	41.9	61.0	49.7
INTRA-SENT	84.5	75.4	79.7
INTER-SENT	80.2	52.6	63.6
ALL	83.8	71.1	77.0

Table 5: Results of causal relation recognition (%)

Table 5 shows the result. BASELINE represents

<sup>5</sup> <http://code.google.com/p/crfpp/>

the result for our baseline system that recognizes a causal relation by simply taking the two phrases adjacent to a c-marker (i.e., before and after) as cause and effect parts of the causal relation. We assumed that the system had an oracle for judging correctly whether each phrase is a cause part or an effect part. In other words, we judged that a causal relation recognized by BASELINE is correct if both cause and effect parts in the gold standard are adjacent to a c-marker. INTRA-SENT and INTER-SENT represent the results for intra- and inter-sentential causal relations and ALL represents the result for the both causal relations by our method. From these results, we confirmed that our method recognized both intra- and inter-sentential causal relations with over 80% precision, and it significantly outperformed our baseline system in both precision and recall rates.

	Precision	Recall	$F_1$
ALL-“MORPH”	80.8	66.4	72.9
ALL-“SYNTACTIC”	82.9	67.0	74.1
ALL-“C-MARKER”	76.3	51.4	61.4
ALL	<b>83.8</b>	<b>71.1</b>	<b>77.0</b>

Table 6: Ablation test results for causal relation recognition (%)

We also investigated the contribution of the three types of features used in our causal relation recognition to the performance. We evaluated the performance when we removed one of the three types of features (ALL-“MORPH”, ALL-“SYNTACTIC” and ALL-“C-MARKER”) and compared the results in these settings with the one when all the feature sets were used (ALL). Table 6 shows the result. We confirmed that all the feature sets improved the performance, and we got the best performance when using all of them. We used the causal relations obtained from the 10-fold cross validation for our why-QA experiments.

#### 5.4 Why-Question Answering

We performed why-QA experiments to confirm the effectiveness of intra- and inter-sentential causal relations in a why-QA task. In this experiment, we compared five systems: four baseline systems (MURATA, OURCF, OH and OH+PREVCF) and our proposed method (PROPOSED).

MURATA corresponds to our answer candidate extraction.

OURCF uses a re-ranker trained with only our

causal relation features.

OH, which represents our previous work (Oh et al., 2012), has a re-ranker trained with morphosyntactic, semantic word class, and sentiment polarity features.

OH+PREVCF is a system with a re-ranker trained with the features used in OH and with the causal relation feature proposed in Higashinaka and Isozaki (2008). The causal relation feature includes an indicator that determines whether the causal relations between two terms appear in a question-answer pair; cause in an answer and its effect in a question. We acquired the causal relation instances (between terms) from 600 million Japanese web pages using the method of De Saeger et al. (2009) and exploited the *top-100,000* causal relation instances in this system.

PROPOSED has a re-ranker trained with our causal relation features as well as the three types of features proposed in Oh et al. (2012). Comparison between OH and PROPOSED reveals the contribution of our causal relation features to why-QA.

We used TinySVM<sup>6</sup> with a linear kernel for training the re-rankers in OURCF, OH, OH+PREVCF and PROPOSED. Evaluation was done by P@1 (Precision of the top-answer) and Mean Average Precision (MAP); they are the same measures used in Oh et al. (2012). P@1 measures how many questions have a correct top-answer candidate. MAP measures the overall quality of the top-20 answer candidates. As mentioned in Section 5.1, we used 10-fold cross-validation with the same setting as the one used in Oh et al. (2012) for our experiments.

	P@1	MAP
MURATA	22.2	27.0
OURCF	27.8	31.4
OH	37.4	39.1
OH+PREVCF	37.4	38.9
PROPOSED	<b>41.8</b>	<b>41.0</b>

Table 7: Why-QA results (%)

Table 7 shows the evaluation results. Our proposed method outperformed the other four systems and improved P@1 by 4.4% over OH, which is the-state-of-the-art system for Japanese why-

<sup>6</sup> <http://chasen.org/~taku/software/TinySVM/>

QA. OURCF showed the performance improvement over MURATA. Although this suggests the effectiveness of our causal relation features, the overall performance of OURCF was lower than that of OH. OH+PREVCF outperformed neither OH nor PROPOSED. This suggests that our approach is more effective than previous causality-based approaches (Girju, 2003; Higashinaka and Isozaki, 2008), at least in our setting.

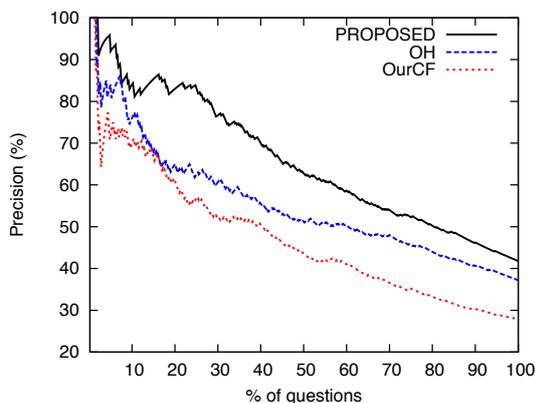

Figure 4: Effect of causal relation features on the top-answers

We also compared *confident* answers of OURCF, OH, and PROPOSED by making each system provide only the  $k$  confident top-answers (for  $k$  questions) selected by their SVM scores given by each system’s re-ranker. This reduces the number of questions that can be answered by a system, but the top-answers become more reliable as  $k$  decreases. Fig. 4 shows this result, where the  $x$  axis represents the percentage of questions (against all the questions in our test set) whose top-answers are given by each system, and the  $y$  axis represents the precision of the top-answers at a certain point on the  $x$  axis. When both systems provided top-answers for 25% of all the questions in our test set, our method achieved 83.2% precision, which is much higher than OH’s (62.4%). This experiment confirmed that our causal relation features were also effective in improving the quality of the highly confident answers.

However, the high precision by our method was bound to confident answers for a small number of questions, and the difference in the precision between OH and PROPOSED in Fig. 4 became smaller as we considered more answers with lower confidence. We think that one of the reasons is the relatively small coverage of the excitation polarity lexicon, a core resource in our excitation polarity

matching. We are planning to enlarge the lexicon to deal with this problem.

Next, we investigated the contribution of the intra- and inter-sentential causal relations to the performance of our method. We used only one of the two types of causal relations for generating causal relation features (INTRA-SENT and INTER-SENT) for training our re-ranker and compared the results in these settings with the one when both were used (ALL (PROPOSED)). Table 8 shows the result. Both intra- and inter-sentential causal relations contributed to the performance improvement.

	P@1	MAP
INTER-SENT	39.0	39.7
INTRA-SENT	40.4	40.5
ALL (PROPOSED)	<b>41.8</b>	<b>41.0</b>

Table 8: Results with/without intra- and inter-sentential causal relations (%)

We also investigated the contributions of the three types of causal relation features by ablation tests (Table 9). When we do not use the features by excitation polarity matching (ALL- $\{ef_1-ef_4\}$ ), the performance is the worst. This implies that the contribution of excitation polarity matching exceeds the other two.

	P@1	MAP
ALL- $\{tf_1-tf_4\}$	40.8	40.7
ALL- $\{pf_1-pf_4\}$	41.0	40.9
ALL- $\{ef_1-ef_4\}$	39.6	40.5
ALL (PROPOSED)	<b>41.8</b>	<b>41.0</b>

Table 9: Ablation test results for why-QA (%)

## 6 Conclusion

In this paper, we explored the utility of intra- and inter-sentential causal relations for ranking answer candidates to why-questions. We also proposed a method for assessing the appropriateness of causal relations as answers to a given question using the semantic orientation of excitation. Through experiments, we confirmed that these ideas are effective for improving why-QA, and our proposed method achieved 41.8% P@1, which is 4.4% improvement over the current state-of-the-art system of Japanese why-QA. We also showed that our system achieved 83.2% precision for its confident answers, when it only provided its confident answers for 25% of all the questions in our test set.

## Abstract

In this paper, we study the *answer sentence selection* problem for question answering. Unlike previous work, which primarily leverages syntactic analysis through dependency tree matching, we focus on improving the performance using models of lexical semantic resources. Experiments show that our systems can be consistently and significantly improved with rich lexical semantic information, regardless of the choice of learning algorithms. When evaluated on a benchmark dataset, the MAP and MRR scores are increased by 8 to 10 points, compared to one of our baseline systems using only surface-form matching. Moreover, our best system also outperforms previous work that makes use of the dependency tree structure by a wide margin.

## 1 Introduction

Open-domain question answering (QA), which fulfills a user's information need by outputting direct answers to natural language queries, is a challenging but important problem (Etzioni, 2011). State-of-the-art QA systems often implement a complicated pipeline architecture, consisting of question analysis, document or passage retrieval, answer selection and verification (Ferrucci, 2012; Moldovan et al., 2003). In this paper, we focus on one of the key subtasks – *answer sentence selection*. Given a question and a set of candidate sentences, the task is to choose the *correct* sentence that contains the exact answer and can sufficiently support the answer choice. For instance, although both of the following sentences contain the answer “Jack Lemmon” to the question “Who won the best actor Oscar in 1973?” only the first sentence is correct.

**A1:** Jack Lemmon won the Academy Award for Best Actor for Save the Tiger (1973).

**A2:** Oscar winner Kevin Spacey said that Jack Lemmon is remembered as always making time for other people.

One of the benefits of answer sentence selection is that the output can be provided directly to the user. Instead of outputting only the answer, returning the whole sentence often adds more value as the user can easily verify the correctness without reading a lengthy document.

Answer sentence selection can be naturally reduced to a semantic text matching problem. Conceptually, we would like to measure how close the question and sentence can be *matched* semantically. Due to the variety of word choices and inherent ambiguities in natural languages, bag-of-words approaches with simple surface-form word matching tend to produce brittle results with poor prediction accuracy (Bilotti et al., 2007). As a result, researchers put more emphasis on exploiting both the syntactic and semantic structure in questions/sentences. Representative examples include methods based on deeper semantic analysis (Shen and Lapata, 2007; Moldovan et al., 2007) and on tree edit-distance (Punyakank et al., 2004; Heilman and Smith, 2010) and quasi-synchronous grammar (Wang et al., 2007) that match the dependency parse trees of questions and sentences. However, such approaches often require more computational resources. In addition to applying a syntactic or semantic parser during run-time, finding the best matching between structured representations of sentences is not trivial. For example, the computational complexity of tree matching is  $O(V^2L^4)$ , where  $V$  is the number of nodes and  $L$  is the maximum depth (Tai, 1979).

Instead of focusing on the high-level semantic representation, we turn our attention in this work to improving the shallow semantic compo-

ment, *lexical semantics*. We formulate answer selection as a semantic matching problem with a latent word-alignment structure as in (Chang et al., 2010) and conduct a series of experimental studies on leveraging recently proposed lexical semantic models. Our main contributions in this work are two key findings. First, by incorporating the abundant information from a variety of lexical semantic models, the answer selection system can be enhanced substantially, regardless of the choice of learning algorithms and settings. Compared to the previous work, our latent alignment model improves the result on a benchmark dataset by a wide margin – the mean average precision (MAP) and mean reciprocal rank (MRR) scores are increased by 25.6% and 18.8%, respectively. Second, while the latent alignment model performs better than unstructured models, the difference diminishes after adding the enhanced lexical semantics information. This may suggest that compared to introducing complex structured constraints, incorporating shallow semantic information is both more effective and computationally inexpensive in improving the performance, at least for the specific word alignment model tested in this work.

The rest of the paper is structured as follows. We first survey the related work in Sec. 2. Sec. 3 defines the problem of answer sentence selection, along with the high-level description of our solution. The enhanced lexical semantic models and the learning frameworks we explore are presented in Sec. 4 and Sec. 5, respectively. Our experimental results on a benchmark QA dataset is shown in Sec. 6. Finally, Sec. 7 concludes the paper.

## 2 Related Work

While the task of question answering has a long history dated back to the dawn of artificial intelligence, early systems like STUDENT (Winograd, 1977) and LUNAR (Woods, 1973) are typically designed to demonstrate natural language understanding for a small and specific domain. The Text REtrieval Conference (TREC) Question Answering Track was arguably the first large-scale evaluation of open-domain question answering (Voorhees and Tice, 2000). The task is designed in an information retrieval oriented setting. Given a factoid question along with a collection of documents, a system is required to return the exact answer, along with the document that supports the answer. In contrast, the Jeopardy! TV

quiz show provides another open-domain question answering setting, in which IBM’s Watson system famously beat the two highest ranked players (Ferrucci, 2012). Questions in this game are presented in a statement form and the system needs to identify the true question and to give the exact answer. A short sentence or paragraph to justify the answer is not required in either TREC-QA or Jeopardy!

As any QA system can virtually be decomposed into two major high-level components, *retrieval* and *selection* (Echihabi and Marcu, 2003), the answer selection problem is clearly critical. Limiting the scope of an answer to a sentence is first highlighted by Wang et al. (2007), who argued that it was more informative to present the whole sentence instead of a short answer to users.

Observing the limitations of the bag-of-words models, Wang et al. (2007) proposed a syntax-driven approach, where each pair of question and sentence are matched by their dependency trees. The mapping is learned by a generative probabilistic model based on a Quasi-synchronous Grammar formulation (Smith and Eisner, 2006). This approach was later improved by Wang and Manning (2010) with a tree-edit CRF model that learns the latent alignment structure. In contrast, general tree matching methods based on tree-edit distance have been first proposed by Punyakanok et al. (2004) for a similar answer selection task. Heilman and Smith (2010) proposed a discriminative approach that first computes a tree kernel function between the dependency trees of the question and candidate sentence, and then learns a classifier based on the tree-edit features extracted.

Although lexical semantic information derived from WordNet has been used in some of these approaches, the research has mainly focused on modeling the mapping between the syntactic structures of questions and sentences, produced from syntactic analysis. The potential improvement from enhanced lexical semantic models seems to have been deliberately overlooked.<sup>1</sup>

## 3 Problem Definition

We consider the answer selection problem in a supervised learning setting. For a set of questions  $\{q_1, \dots, q_m\}$ , each question  $q_i$  is associated with a list of labeled candidate answer sentences

---

<sup>1</sup>For example, Heilman and Smith (2010) emphasized that “The tree edit model, which does not use lexical semantics knowledge, produced the best result reported to date.”

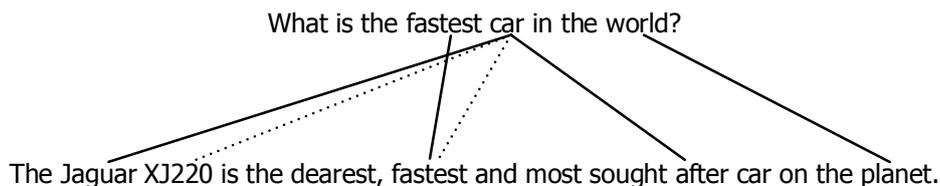

Figure 1: An example pair of question and answer sentence, adapted from (Harabagiu and Moldovan, 2001). Words connected by solid lines are clear synonyms or hyponym/hypernym; words with weaker semantic association are linked by dashed lines.

$\{(y_{i_1}, s_{i_1}), (y_{i_1}, s_{i_2}), \dots, (y_{i_n}, s_{i_n})\}$ , where  $y_{i_j} = 1$  indicates that sentence  $s_{i_j}$  is a correct answer to question  $q_i$ , and 0 otherwise. Using this labeled data, our goal is to learn a probabilistic classifier to predict the label of a new, unseen pair of question and sentence.

Fundamentally, what the classifier predicts is whether the sentence “matches” the question semantically. In other words, does  $s$  have the answer that satisfies the semantic constraints provided in the question? Without representing the question and sentence in logic or syntactic trees, we take a *word-alignment* view for solving this problem. We assume that there is an underlying structure  $h$  that describes how  $q$  and  $s$  can be associated through the relations of the words in them. Figure 1 illustrates this setting using a revised example from (Harabagiu and Moldovan, 2001). In this figure, words connected by solid lines are clear synonyms or hyponym/hypernym; words connected by dashed lines indicate that they are weakly related. With this alignment structure, features like the degree of mapping or whether all the content words in the question can be mapped to some words in the sentence can be extracted and help improve the classifier. Notice that the structure representation in terms of word-alignment is fairly general. For instance, if we assume a naive complete bipartite matching, then effectively it reduces to the simple bag-of-words model.

Typically, the “ideal” alignment structure is not available in the data, and previous work exploited mostly syntactic analysis (e.g., dependency trees) to reveal the latent mapping structure. In this work, we focus our study on leveraging the low-level semantic cues from recently proposed lexical semantic models. As will be shown in our experiments, such information not only improves a latent structure learning method, but also makes a simple

bipartite matching approach extremely strong.<sup>2</sup>

## 4 Lexical Semantic Models

In this section, we introduce the lexical semantic models we adopt for solving the semantic matching problem in answer selection. To go beyond the simple, limited surface-form matching, we aim to pair words that are semantically related, specifically measured by models of word relations including *synonymy/antonymy*, *hyponymy/hyponymy* (the Is-A relation) and general *semantic word similarity*.

### 4.1 Synonymy and Antonymy

Among all the word relations, *synonymy* is perhaps the most basic one and needs to be handled reliably. Although sets of synonyms can be easily found in thesauri or WordNet synsets, such resources typically cover only strict synonyms. When comparing two words, it is more useful to estimate the *degree* of synonymy as well. For instance, *ship* and *boat* are not strict synonyms because a ship is usually viewed as a large boat. Knowing that two words are somewhat synonymous could be valuable in determining whether they should be mapped.

In order to estimate the degree of synonymy, we leverage a recently proposed polarity-inducing latent semantic analysis (PILSA) model (Yih et al., 2012). Given a thesaurus, the model first constructs a *signed d-by-n* co-occurrence matrix  $W$ , where  $d$  is the number of word groups and  $n$  is the size of the vocabulary. Each row consists of a

<sup>2</sup>Proposed by an anonymous reviewer, one justification of this word-alignment approach, where syntactic analysis plays a less important role, is that there are often few sensible combinations of words. For instance, knowing only the set of words {“car”, “fastest”, “world”}, one may still guess correctly the question “What is the fastest car in the world?”

group of synonyms and antonyms of a particular sense and each column represents a unique word. Values of the elements in each row vector are the TFIDF values of the corresponding words in this group. The notion of *polarity* is then induced by making the values of words in the antonym groups negative, and the matrix is generalized by a low-rank approximation derived by singular-value decomposition (SVD) in the end. This design has an intriguing property – if the cosine score of two column vectors are positive, then the two corresponding words tend to be synonymous; if it's negative, then the two words are antonymous. The degree is measured by the absolute value.

Following the setting described in (Yih et al., 2012), we construct a PILSA model based on the Encarta thesaurus and enhance it with a discriminative projection matrix training method. The estimated degrees of both synonymy and antonymy are used our experiments.<sup>3</sup>

## 4.2 Hypernymy and Hyponymy

The *Class-Inclusion* or *Is-A* relation is commonly observed between words in questions and answer sentences. For example, to correctly answer the question “What color is Saturn?”, it is crucial that the selected sentence mentions a specific kind of color, as in “Saturn is a giant gas planet with brown and beige clouds.” Another example is “Who wrote Moonlight Sonata?”, where *compose* in “Ludwig van Beethoven composed the Moonlight Sonata in 1801.” is one kind of *write*.

Traditionally, WordNet taxonomy is the linguistic resource for identifying hypernyms and hyponyms, applied broadly to many NLP problems. However, WordNet has a number of well-known limitations including its rather limited or skewed concept distribution and the lack of the coverage of the *Is-A* relation (Song et al., 2011). For instance, when a word refers to a named entity, the particular sense and meaning is often not encoded. As a result, relations such as “Apple” *is-a* “company” and “Jaguar” *is-a* “car” cannot be found in WordNet. Similar to the case in synonymy, the *Is-A* relation defined in WordNet does not provide a native, real-valued degree of the relation, which can only be roughly approximated using the number of links on the taxonomy path connecting two

<sup>3</sup>Mapping two antonyms may be desired if one of them is in the scope of negation (Morante and Blanco, 2012; Blanco and Moldovan, 2011). However, we do not attempt to resolve the negation scope in this work.

concepts (Resnik, 1995).

In order to remedy these issues, we augment WordNet with the *Is-A* relations found in Probase (Wu et al., 2012). Probbase is a knowledge base that establishes connections between 2.7 million concepts, discovered automatically by applying Hearst patterns (Hearst, 1992) to 1.68 billion Web pages. Its abundant concept coverage distinguishes it from other knowledge bases, such as Freebase (Bollacker et al., 2008) and WikiTaxonomy (Ponzetto and Strube, 2007). Based on the frequency of term co-occurrences, each *Is-A* relation from Probbase is associated with a probability value, indicating the degree of the relation.

We verified the quality of Probbase *Is-A* relations using a recently proposed SemEval task of relational similarity (Jurgens et al., 2012) in a companion paper (Zhila et al., 2013), where a subset of the data is to measure the degree of two words having a *class-inclusion* relation. Probbase’s prediction correlates well with the human annotations and achieves a high Spearman’s rank correlation coefficient score,  $\rho = 0.619$ . In comparison, the previous best system (Rink and Harabagiu, 2012) in the task only reaches  $\rho = 0.233$ . These appealing qualities make Probbase a robust lexical semantic model for hypernymy/hyponymy.

## 4.3 Semantic Word Similarity

The third lexical semantic model we introduce targets a general notion of *word similarity*. Unlike synonymy and hyponymy, word similarity is only loosely defined when two words can be associated by some implicit relation.<sup>4</sup> The general word similarity model can be viewed as a “back-off” solution when the exact lexical relation (e.g., *part-whole* and *attribute*) is not available or cannot be accurately detected.

Among various word similarity models (Agirre et al., 2009; Reisinger and Mooney, 2010; Gabilovich and Markovitch, 2007; Radinsky et al., 2011), the vector space models (VSMs) based on the idea of *distributional similarity* (Turney and Pantel, 2010) are often used as the core component. Inspired by (Yih and Qazvinian, 2012), which argues the importance of incorporating heterogeneous vector space models for measuring word similarity, we leverage three different VSMs in this work: Wiki term-vectors, recurrent neural

<sup>4</sup>Instead of making the distinction, *word similarity* here refers to the larger set of relations commonly covered by *word relatedness* (Budanitsky and Hirst, 2006).

network language model (RNNLM) and a concept vector space model learned from click-through data. Semantic word similarity is estimated using the cosine score of the corresponding word vectors in these VSMs.

Contextual term-vectors created using the Wikipedia corpus have shown to perform well on measuring word similarity (Reisinger and Mooney, 2010). Following the setting suggested by Yih and Qazvinian (2012), we create term-vectors representing about 1 million words by aggregating terms within a window of  $[-10, 10]$  of each occurrence of the target word. The vectors are further refined by applying the same vocabulary and feature pruning techniques.

A recurrent neural network language model (Mikolov et al., 2010) aims to estimate the probability of observing a word given its preceding context. However, one by-product of this model is the word embedding learned in its hidden-layer, which can be viewed as capturing the word meaning in some latent, conceptual space. As a result, vectors of related words tend to be close to each other. For this word similarity model, we take a 640-dimensional version of RNNLM vectors, which is trained using the Broadcast News corpus of 320M words.<sup>5</sup>

The final word relatedness model is a projection model learned from the click-through data of a commercial search engine (Gao et al., 2011). Unlike the previous two models, which are created or trained using a text corpus, the input for this model is pairs of aggregated queries and titles of pages users click. This parallel data is used to train a projection matrix for creating the mapping between words in queries and documents based on user feedback, using a Siamese neural network (Yih et al., 2011). Each row vector of this matrix is the dense vector representation of the corresponding word in the vocabulary. Perhaps due to its unique information source, we found this particular word embedding seems to complement the other two VSMs and tends to improve the word similarity measure in general.

## 5 Learning QA Matching Models

In this section, we investigate the effectiveness of various learning models for matching questions and sentences, including the *bag-of-words* setting

<sup>5</sup><http://www.fit.vutbr.cz/~imikolov/rnnlm/>

and the framework of learning latent structures.

### 5.1 Bag-of-Words Model

The bag-of-words model treats each question and sentence as an unstructured bag of words. When comparing a question with a sentence, the model first matches each word in the question to each word in the sentence. It then aggregates features extracted from each of these word pairs to represent the whole question/sentence pair. A binary classifier can be trained easily using any machine learning algorithm in this standard supervised learning setting.

Formally, let  $x = (q, s)$  be a pair of question  $q$  and sentence  $s$ . Let  $V_q = \{w_{q_1}, w_{q_2}, \dots, w_{q_m}\}$  and  $V_s = \{w_{s_1}, w_{s_2}, \dots, w_{s_n}\}$  be the sets of words in  $q$  and  $s$ , respectively. Given a word pair  $(w_q, w_s)$ , where  $w_q \in V_q$  and  $w_s \in V_s$ , feature functions  $\phi_1, \dots, \phi_d$  map it to a  $d$ -dimensional real-valued feature vector.

We consider two aggregate functions for defining the feature vectors of the whole question/answer pair: *average* and *max*.

$$\Phi_{avg_j}(q, s) = \frac{1}{mn} \sum_{\substack{w_q \in V_q \\ w_s \in V_s}} \phi_j(w_q, w_s) \quad (1)$$

$$\Phi_{max_j}(q, s) = \max_{\substack{w_q \in V_q \\ w_s \in V_s}} \phi_j(w_q, w_s) \quad (2)$$

Together, each question/sentence pair is represented by a  $2d$ -dimensional feature vector.

We tested two learning algorithms in this setting: *logistic regression* and *boosted decision trees* (Friedman, 2001). The former is the log-linear model widely used in the NLP community and the latter is a robust non-linear learning algorithm that has shown great empirical performance.

The bag-of-words model does not require an additional inference stage as in structured learning, which may be computationally expensive. Nevertheless, its lack of structure information could limit the expressiveness of the model and make it difficult to capture more sophisticated semantics in the sentences. To address this concern, we investigate models of learning latent structures next.

### 5.2 Learning Latent Structures

One obvious issue of the bag-of-words model is that words in the unrelated part of the sentence may still be paired with words in the question, which introduces noise to the final feature vector.

This is observed in many question/sentence pairs, such as the one below.

**Q:** Which was the first movie that James Dean was in?

**A:** James Dean, who began as an actor on TV dramas, didn't make his screen debut until 1951's "Fixed Bayonet."

While this sentence correctly answers the question, the fact that James Dean began as a TV actor is unrelated to the question. As a result, an "ideal" word alignment structure should not link words in this clause to those in the question. In order to leverage the latent structured information, we adapt a recently proposed framework of *learning constrained latent representations* (LCLR) (Chang et al., 2010). LCLR can be viewed as a variant of Latent-SVM (Felzenszwalb et al., 2009) with different learning formulations and a general inference framework. The idea of LCLR is to replace the decision function of a standard linear model  $\theta^T \phi(x)$  with

$$\arg \max_h \theta^T \phi(x, h), \quad (3)$$

where  $\theta$  represents the weight vector and  $h$  represents the latent variables.

In this answer selection task,  $x = (q, s)$  represents a pair of question  $q$  and candidate sentence  $s$ . As described in Sec. 3,  $h$  refers to the latent alignment between  $q$  and  $s$ . The intuition behinds Eq. (3) is: candidate sentence  $s$  correctly answers question  $q$  if and only if the decision can be supported by the *best* alignment  $h$ .

The objective function of LCLR is defined as:

$$\begin{aligned} \min_{\theta} \quad & \frac{1}{2} \|\theta\|^2 + C \sum_i \xi_i^2 \\ \text{s.t.} \quad & \xi_i \geq 1 - y_i \max_h \theta^T \phi(x, h) \end{aligned}$$

Note that the alignment is latent, so LCLR uses the binary labels in the training data as feedback to find the alignment for each example.

The computational difficulty of the inference problem (Eq. (3)) largely depends on the constraints we enforce in the alignment. Complicated constraints may result in a difficult inference problem, which can be solved by integer linear programming (Roth and Yih, 2007). In this work, we considered several sets of constraints for the alignment task, including a two-layer phrase/word

alignment structure, but found that they generally performed the same. Therefore, we chose the many-to-one alignment<sup>6</sup>, where inference can be solved exactly using a simple greedy algorithm.

## 6 Experiments

We present our experimental results in this section by first introducing the data and evaluation metrics, followed by the results of existing systems and some baseline methods. We then show the positive impact of adding information of word relations from various lexical semantics models, with some discussion on the limitation of the word-matching approach.

### 6.1 Data & Evaluation Metrics

The answer selection dataset we used was originally created by Wang et al. (2007) based on the QA track of past Text REtrieval Conferences (TREC-QA). Questions in this dataset are short factoid questions, such as "What is Crips' gang color?" In average, each question is associated with approximately 33 answer candidate sentences. A pair of question and sentence is judged positive if the sentence contains the exact answer key *and* can provide sufficient context as supporting evidence.

The training set of the data contains manually labeled 5,919 question/sentence pairs from TREC 8-12. The development and testing sets are both from TREC 13, which contain 1,374 and 1,866 pairs, respectively. The task is treated as a sentence ranking problem for each question and thus evaluated in Mean Average Precision (MAP) and Mean Reciprocal Rank (MRR), using the official TREC evaluation program. Following (Wang et al., 2007), candidate sentences with more than 40 words are removed from evaluation, as well as questions with only positive or negative candidate sentences.

### 6.2 Baseline Methods

Several systems have been proposed and tested using this dataset. Wang et al. (2007) presented a generative probabilistic model based on a Quasi-synchronous Grammar formulation and was later improved by Wang and Manning (2010) with a tree-edit CRF model that learns the latent alignment structure. In contrast, Heilman and

<sup>6</sup>Each word in the question needs to be linked to a word in the sentence. Each word in the sentence can be linked to zero or multiple words in the question.

System	MAP	MRR
Wang et al. (2007)	0.6029	0.6852
Heilman and Smith (2010)	0.6091	0.6917
Wang and Manning (2010)	0.5951	0.6951

Table 1: Test set results of existing methods, taken from Table 3 of (Wang and Manning, 2010).

Baseline	Dev		Test	
	MAP	MRR	MAP	MRR
Random	0.5243	0.5816	0.4708	0.5286
Word Cnt	0.6516	0.7216	0.6263	0.6822
Wgt Word Cnt	0.7112	0.7880	0.6531	0.7071

Table 2: Results of three baseline methods.

Smith (2010) proposed a discriminative approach that first computes a tree kernel function between the dependency trees of the question and candidate sentence, and then learns a classifier based on the tree-edit features extracted. Table 1 summarizes their results on the test set. All these systems incorporated lexical semantics features derived from WordNet and named entity features.

In order to further estimate the difficulty of this task and dataset, we tested three simple baselines. The first is *random scoring*, which simply assigns a random score to each candidate sentence. The second one, *word count*, is to count how many words in the question that also occur in the answer sentence, after removing stopwords<sup>7</sup>, and lowering the case. Finally, the last baseline method, *weighted word count*, is basically the same as identical word matching, but the count is re-weighted using the IDF value of the question word. This is similar to the BM25 ranking function (Robertson et al., 1995). The results of these three methods are shown in Table 1.

Somewhat surprisingly, we find that *word count* is fairly strong and performs comparably to previous systems.<sup>8</sup> In addition, weighting the question words with their IDF values further improves the results.

### 6.3 Incorporating Rich Lexical Semantics

We test the effectiveness of adding rich lexical semantics information by creating examples of different feature sets. As described in Sec. 5,

<sup>7</sup>We used a list of 101 stopwords, including articles, pronouns and punctuation.

<sup>8</sup>The finding has been confirmed by the lead author of (Wang et al., 2007).

all the features are based on the properties of the pair of a word from the question and a word from the candidate sentence. Stopwords are first removed from both questions and sentences and all words are lower-cased. Features used in the experiments can be categorized into six types: identical word matching (I), lemma matching (L), WordNet (WN), enhanced Lexical Semantics (LS), Named Entity matching (NE) and Answer type checking (Ans). Inspired by the *weighted word count* baseline, all features except (Ans) are weighted by the IDF value of the question word. In other words, the IDF values help decide the importance of word pairs to the model.

Starting from the our baseline model, *weighted word count*, the identical word matching (I) feature checks whether the pair of words are the same. Instead of checking the surface form of the word, lemma matching (L) verifies whether the two words have the same lemma form. Arguably the most common source of word relations, WordNet (WN) provides the primitive features of whether two words could belong to the same synset in WordNet, could be antonyms and whether one is a hypernym of the other. Alternatively, the enhanced lexical semantics (LS) features apply the models described in Sec. 4 to the word pair and use their estimated degree of synonymy, antonymy, hyponymy and semantic relatedness as features. Named entity matching (NE) checks whether two words are individually part of some named entities with the same type. Finally, when the question word is the WH-word, we check if the paired word belongs to some phrase that has the correct answer type using simple rules, such as “*Who* should link to a word that is part of a named entity of type *Person*.” We created examples in each round of experiments by augmenting these features in the same order, and observed how adding different information helped improve the model performance.

Three models are included in our study. For the unstructured, bag-of-words setting, we tested logistic regression (LR) and boosted decision trees (BDT). As mentioned in Sec. 5, the features for the whole question/sentence pair are the *average* and *max* of features of all the word pairs. For the structured-output setting, we used the framework of learning constrained latent representation (LCLR) and required that each question word needed to be mapped to a word in the sentence.

Feature set	LR		BDT		LCLR	
	MAP	MRR	MAP	MRR	MAP	MRR
1: I	0.6531	0.7071	0.6323	0.6898	0.6629	0.7279
2: I+L	0.6744	0.7223	0.6496	0.6923	0.6815	0.7270
3: I+L+WN	0.7039	0.7705	0.6798	0.7450	0.7316	0.7921
4: I+L+WN+LS	0.7339	0.8107	0.7523	0.8455	0.7626	0.8231
5: All	0.7374	0.8171	0.7495	0.8450	0.7648	0.8255

Table 3: Test results of various models and feature groups. Logistic regression (LR) and boosted decision trees (BDT) are the two unstructured models. LCLR is the algorithm for learning latent structures. Feature groups are identical word matching (I), lemma matching (L), WordNet (WN) and enhanced Lexical Semantics (LS). *All* includes these four plus Named Entity matching (NE) and Answer type checking (Ans).

Hyper-parameters are selected using the ones that achieve the best MAP score on the development set. Results of these models and feature sets are presented in Table 3.

We make two observations from the results. First, while incorporating more information of the word pairs in general helps, it is clear that mapping words beyond surface-form matching with the help of WordNet (Line #3 vs. #2) is important. Moreover, when richer information from other lexical semantic models is available, the performance can be further improved (Line #4 vs. #3). Overall, by simply incorporating more information on word relations, we gain approximately 10 points in both MAP and MRR compared to surface-form matching (Line #4 vs. #2), consistently across all three models. However, adding more information like named entity matching and answer type verification does not seem to help much (Line #5 vs. #4). Second, while the structured-output model usually performs better than both unstructured models (LCLR vs. LR & BDT), the performance gain diminishes after more information of word pairs is available (e.g., Lines #4 and #5).

#### 6.4 Limitation of Word Matching Models

Although we have demonstrated the benefits of leveraging various lexical semantic models to help find the association between words, the problem of question answering is nevertheless far from solved using the word-based approach. Examining the output of the LCLR model with all features on the development set, we found that there were three main sources of errors, including uncovered or inaccurate entity relations, the lack of robust question analysis and the need of high-level semantic

representation and inference. While the first two can be improved by, say, using a better named entity tagger, incorporating other knowledge bases and building a question classifier, how to solve the third problem is tricky. Below is an example:

**Q:** In what film is Gordon Gekko the main character?

**A:** He received a best actor Oscar in 1987 for his role as Gordon Gekko in “Wall Street”.

This is a correct answer sentence because “winning a best actor Oscar” implies that the role Gordon Gekko is the main character. It is hard to believe that a pure word-matching model would be able to solve this type of “inferential question answering” problem.

## 7 Conclusions

In this paper, we present an experimental study on solving the answer selection problem using enhanced lexical semantic models. Following the word-alignment paradigm, we find that the rich lexical semantic information improves the models consistently in the unstructured bag-of-words setting and also in the framework of learning latent structures. Another interesting finding we have is that while the latent structured model, LCLR, performs better than the other two unstructured models, the difference diminishes after more information, including the enhanced lexical semantic knowledge and answer type verification, has been incorporated. This may suggest that adding shallow semantic information is more effective than introducing complex structured constraints, at least for the specific word alignment model we experimented with in this work.

In the future, we plan to explore several directions. First, although we focus on improving TREC-style open-domain question answering in this work, we would like to apply the proposed technology to other QA scenarios, such as community-based QA (CQA). For instance, the sentence matching technique can help map a given question to some questions in an existing CQA database (e.g., Yahoo! Answers). Moreover, the answer sentence selection scheme could also be useful in extracting the most related sentences from the answer text to form a summary answer. Second, because the task of answer sentence selection is very similar to paraphrase detection (Dolan et al., 2004) and recognizing textual entailment (Dagan et al., 2006), we would like to investigate whether systems for these tasks can be improved by incorporating enhanced lexical semantic knowledge as well. Finally, we would like to improve our system for the answer sentence selection task and for question answering in general. In addition to following the directions suggested by the error analysis presented in Sec. 6.4, we plan to use logic-like semantic representations of questions and sentences, and explore the role of lexical semantics for handling questions that require inference.

## Acknowledgments

We are grateful to Mengqiu Wang for providing the dataset and helping clarify some issues in the experiments. We also thank Chris Burges and Hoi-fung Poon for valuable discussion and the anonymous reviewers for their useful comments.

# Syntactic Patterns versus Word Alignment: Extracting Opinion Targets from Online Reviews

Kang Liu, Liheng Xu and Jun Zhao

National Laboratory of Pattern Recognition  
Institute of Automation, Chinese Academy of Sciences

## Abstract

Mining opinion targets is a fundamental and important task for opinion mining from online reviews. To this end, there are usually two kinds of methods: syntax based and alignment based methods. Syntax based methods usually exploited syntactic patterns to extract opinion targets, which were however prone to suffer from parsing errors when dealing with online informal texts. In contrast, alignment based methods used word alignment model to fulfill this task, which could avoid parsing errors without using parsing. However, there is no research focusing on which kind of method is more better when given a certain amount of reviews. To fill this gap, this paper empirically studies how the performance of these two kinds of methods vary when changing the size, domain and language of the corpus. We further combine syntactic patterns with alignment model by using a partially supervised framework and investigate whether this combination is useful or not. In our experiments, we verify that our combination is effective on the corpus with small and medium size.

## 1 Introduction

With the rapid development of Web 2.0, huge amount of user reviews are springing up on the Web. Mining opinions from these reviews become more and more urgent since that customers expect to obtain fine-grained information of products and manufacturers need to obtain immediate feedbacks from customers. In opinion mining, extracting opinion targets is a basic subtask. It is to extract a list of the objects which users express their opinions on and can provide the prior information of targets for opinion mining. So this task

has attracted many attentions. To extract opinion targets, pervious approaches usually relied on opinion words which are the words used to express the opinions (Hu and Liu, 2004a; Popescu and Etzioni, 2005; Liu et al., 2005; Wang and Wang, 2008; Qiu et al., 2011; Liu et al., 2012). Intuitively, opinion words often appear around and modify opinion targets, and there are opinion relations and associations between them. If we have known some words to be opinion words, the words which those opinion words modify will have high probability to be opinion targets.

Therefore, identifying the aforementioned opinion relations between words is important for extracting opinion targets from reviews. To fulfill this aim, previous methods exploited the words co-occurrence information to indicate them (Hu and Liu, 2004a; Hu and Liu, 2004b). Obviously, these methods cannot obtain precise extraction because of the diverse expressions by reviewers, like long-span modified relations between words, etc. To handle this problem, several methods exploited syntactic information, where several heuristic patterns based on syntactic parsing were designed (Popescu and Etzioni, 2005; Qiu et al., 2009; Qiu et al., 2011). However, the sentences in online reviews usually have informal writing styles including grammar mistakes, typos, improper punctuation etc., which make parsing prone to generate mistakes. As a result, the syntax-based methods which heavily depended on the parsing performance would suffer from parsing errors (Zhang et al., 2010). To improve the extraction performance, we can only employ some exquisite high-precision patterns. But this strategy is likely to miss many opinion targets and has lower recall with the increase of corpus size. To resolve these problems, Liu et al. (2012) formulated identifying opinion relations between words as an monolingual alignment process. A word can find its corresponding modifiers by using a word alignment

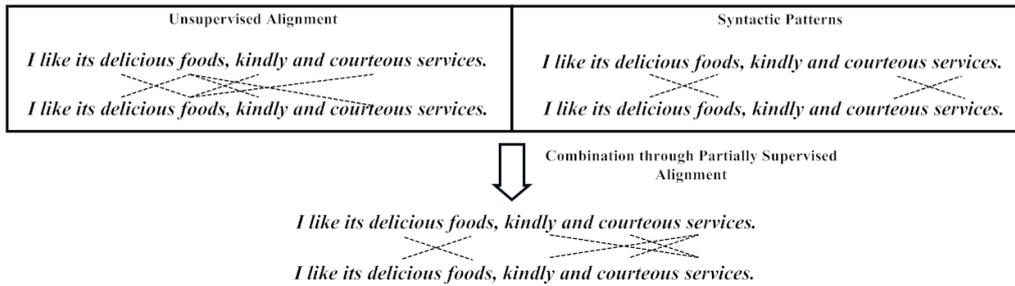

Figure 1: Mining Opinion Relations between Words using Partially Supervised Alignment Model

model (WAM). Without using syntactic parsing, the noises from parsing errors can be effectively avoided. Nevertheless, we notice that the alignment model is a statistical model which needs sufficient data to estimate parameters. When the data is insufficient, it would suffer from data sparseness and may make the performance decline.

Thus, from the above analysis, we can observe that the size of the corpus has impacts on these two kinds of methods, which arises some important questions: how can we make selection between syntax based methods and alignment based method for opinion target extraction when given a certain amount of reviews? And which kind of methods can obtain better extraction performance with the variation of the size of the dataset? Although (Liu et al., 2012) had proved the effectiveness of WAM, they mainly performed experiments on the dataset with medium size. We are still curious about that when the size of dataset is larger or smaller, can we obtain the same conclusion? To our best knowledge, these problems have not been studied before. Moreover, opinions may be expressed in different ways with the variation of the domain and language of the corpus. When the domain or language of the corpus is changed, what conclusions can we obtain? To answer these questions, in this paper, we adopt a unified framework to extract opinion targets from reviews, in the key component of which we vary the methods between syntactic patterns and alignment model. Then we run the whole framework on the corpus with different size (from #500 to #1,000,000), domain (three domains) and language (Chinese and English) to empirically assess the performance variations and discuss which method is more effective.

Furthermore, this paper naturally addresses another question: is it useful for opinion targets extraction when we combine syntactic patterns and word alignment model into a unified model? To

this end, we employ a partially supervised alignment model (PSWAM) like (Gao et al., 2010; Liu et al., 2013). Based on the exquisitely designed high-precision syntactic patterns, we can obtain some precisely modified relations between words in sentences, which provide a portion of links of the full alignments. Then, these partial alignment links can be regarded as the constrains for a standard unsupervised word alignment model. And each target candidate would find its modifier under the partial supervision. In this way, the errors generated in standard unsupervised WAM can be corrected. For example in Figure 1, “*kindly*” and “*courteous*” are incorrectly regarded as the modifiers for “*foods*” if the WAM is performed in an whole unsupervised framework. However, by using some high-precision syntactic patterns, we can assert “*courteous*” should be aligned to “*services*”, and “*delicious*” should be aligned to “*foods*”. Through combination under partial supervision, we can see “*kindly*” and “*courteous*” are correctly linked to “*services*”. Thus, it’s reasonable to expect to yield better performance than traditional methods. As mentioned in (Liu et al., 2013), using PSWAM can not only inherit the advantages of WAM: effectively avoiding noises from syntactic parsing errors when dealing with informal texts, but also can improve the mining performance by using partial supervision. However, is this kind of combination always useful for opinion target extraction? To access this problem, we also make comparison between PSWAM based method and the aforementioned methods in the same corpora with different size, language and domain. The experimental results show the combination by using PSWAM can be effective on dataset with small and medium size.

## 2 Related Work

Opinion target extraction isn't a new task for opinion mining. There are much work focusing on this task, such as (Hu and Liu, 2004b; Ding et al., 2008; Li et al., 2010; Popescu and Etzioni, 2005; Wu et al., 2009). Totally, previous studies can be divided into two main categories: supervised and unsupervised methods.

In supervised approaches, the opinion target extraction task was usually regarded as a sequence labeling problem (Jin and Huang, 2009; Li et al., 2010; Ma and Wan, 2010; Wu et al., 2009; Zhang et al., 2009). It's not only to extract a lexicon or list of opinion targets, but also to find out each opinion target mentions in reviews. Thus, the contextual words are usually selected as the features to indicate opinion targets in sentences. And classical sequence labeling models are used to train the extractor, such as CRFs (Li et al., 2010), HMM (Jin and Huang, 2009) etc.. Jin et al. (2009) proposed a lexicalized HMM model to perform opinion mining. Both Li et al. (2010) and Ma et al. (2010) used CRFs model to extract opinion targets in reviews. Specially, Li et al. proposed a Skip-Tree CRF model for opinion target extraction, which exploited three structures including linear-chain structure, syntactic structure, and conjunction structure. However, the main limitation of these supervised methods is the need of labeled training data. If the labeled training data is insufficient, the trained model would have unsatisfied extraction performance. Labeling sufficient training data is time and labor consuming. And for different domains, we need label data independently, which is obviously impracticable.

Thus, many researches focused on unsupervised methods, which are mainly to extract a list of opinion targets from reviews. Similar to ours, most approaches regarded opinion words as the indicator for opinion targets. (Hu and Liu, 2004a) regarded the nearest adjective to an noun/noun phrase as its modifier. Then it exploited an association rule mining algorithm to mine the associations between them. Finally, the frequent explicit product features can be extracted in a bootstrapping process by further combining item's frequency in dataset. Only using nearest neighbor rule to mine the modifier for each candidate cannot obtain precise results. Thus, (Popescu and Etzioni, 2005) used syntax information to extract opinion targets, which designed some syntactic patterns to capture

the modified relations between words. The experimental results showed that their method had better performance than (Hu and Liu, 2004a). Moreover, (Qiu et al., 2011) proposed a Double Propagation method to expand sentiment words and opinion targets iteratively, where they also exploited syntactic relations between words. Specially, (Qiu et al., 2011) didn't only design syntactic patterns for capturing modified relations, but also designed patterns for capturing relations among opinion targets and relations among opinion words. However, the main limitation of Qiu's method is that the patterns based on dependency parsing tree may miss many targets for the large corpora. Therefore, Zhang et al. (2010) extended Qiu's method. Besides the patterns used in Qiu's method, they adopted some other special designed patterns to increase recall. In addition they used the HITS (Kleinberg, 1999) algorithm to compute opinion target confidences to improve the precision. (Liu et al., 2012) formulated identifying opinion relations between words as an alignment process. They used a completely unsupervised WAM to capture opinion relations in sentences. Then the opinion targets were extracted in a standard random walk framework where two factors were considered: opinion relevance and target importance. Their experimental results have shown that WAM was more effective than traditional syntax-based methods for this task. (Liu et al., 2013) extend Liu's method, which is similar to our method and also used a partially supervised alignment model to extract opinion targets from reviews. We notice these two methods ((Liu et al., 2012) and (Liu et al., 2013)) only performed experiments on the corpora with a medium size. Although both of them proved that WAM model is better than the methods based on syntactic patterns, they didn't discuss the performance variation when dealing with the corpora with different sizes, especially when the size of the corpus is less than 1,000 and more than 10,000. Based on their conclusions, we still don't know which kind of methods should be selected for opinion target extraction when given a certain amount of reviews.

## 3 Opinion Target Extraction Methodology

To extract opinion targets from reviews, we adopt the framework proposed by (Liu et al., 2012), which is a graph-based extraction framework and

has two main components as follows.

1) **The first component** is to capture opinion relations in sentences and estimate associations between opinion target candidates and potential opinion words. In this paper, we assume opinion targets to be nouns or noun phrases, and opinion words may be adjectives or verbs, which are usually adopted by (Hu and Liu, 2004a; Qiu et al., 2011; Wang and Wang, 2008; Liu et al., 2012). And a potential opinion relation is comprised of an opinion target candidate and its corresponding modified word.

2) **The second component** is to estimate the confidence of each candidate. The candidates with higher confidence scores than a threshold will be extracted as opinion targets. In this procedure, we formulate the associations between opinion target candidates and potential opinion words in a bipartite graph. A random walk based algorithm is employed on this graph to estimate the confidence of each target candidate.

In this paper, we fix the method in the second component and vary the algorithms in the first component. In the first component, we respectively use syntactic patterns and unsupervised word alignment model (WAM) to capture opinion relations. In addition, we employ a partially supervised word alignment model (PSWAM) to incorporate syntactic information into WAM. In experiments, we run the whole framework on the different corpora to discuss which method is more effective. In the following subsections, we will present them in detail.

### 3.1 The First Component: Capturing Opinion Relations and Estimating Associations between Words

#### 3.1.1 Syntactic Patterns

To capture opinion relations in sentences by using syntactic patterns, we employ the manual designed syntactic patterns proposed by (Qiu et al., 2011). Similar to Qiu, only the syntactic patterns based on the direct dependency are employed to guarantee the extraction qualities. The direct dependency has two types. The first type indicates that one word depends on the other word without any additional words in their dependency path. The second type denotes that two words both depend on a third word directly. Specifically, we employ Minipar<sup>1</sup> to parse sentences. To further make syn-

tactic patterns precisely, we only use a few dependency relation labels outputted by Minipar, such as mod, pnm, subj, desc etc. To make a clear explanation, we give out some syntactic pattern examples in Table 1. In these patterns, *OC* is a potential opinion word which is an adjective or a verb. *TC* is an opinion target candidate which is a noun or noun phrase. The item on the arrows means the dependency relation type. The item in parenthesis denotes the part-of-speech of the other word. In these examples, the first three patterns are based on the first direct dependency type and the last two patterns are based on the second direct dependency type.

Pattern#1: <OC> $\xrightarrow{mod}$ <TC>
Example: This phone has an <i>amazing design</i>
Pattern#2: <TC> $\xrightarrow{obj}$ <OC>
Example: I <i>like</i> this <i>phone</i> very much
Pattern#3: <OC> $\xrightarrow{pnm}$ <TC>
Example: the <i>buttons</i> <i>easier</i> to use
Pattern#4: <OC> $\xrightarrow{mod}$ (NN) $\xleftarrow{subj}$ <TC>
Example: <i>IPhone</i> is a <i>revolutionary</i> smart phone
Pattern#5: <OC> $\xrightarrow{pred}$ (VBE) $\xleftarrow{subj}$ <TC>
Example: The <i>quality</i> of LCD is <i>good</i>

Table 1: Some Examples of Used Syntactic Patterns

#### 3.1.2 Unsupervised Word Alignment Model

In this subsection, we present our method for capturing opinion relations using unsupervised word alignment model. Similar to (Liu et al., 2012), every sentence in reviews is replicated to generate a parallel sentence pair, and the word alignment algorithm is applied to the monolingual scenario to align a noun/noun phrase with its modifiers. We select IBM-3 model (Brown et al., 1993) as the alignment model. Formally, given a sentence  $S = \{w_1, w_2, \dots, w_n\}$ , we have

$$P_{ibm3}(A|S) \propto \prod_{i=1}^N n(\phi_i|w_i) \prod_{j=1}^N t(w_j|w_{a_j}) d(j|a_j, N) \quad (1)$$

where  $t(w_j|w_{a_j})$  models the co-occurrence information of two words in dataset.  $d(j|a_j, N)$  models word position information, which describes the probability of a word in position  $a_j$  aligned with a word in position  $j$ . And  $n(\phi_i|w_i)$  describes the ability of a word for modifying (being modified by) several words.  $\phi_i$  denotes the number of words

<sup>1</sup><http://webdocs.cs.ualberta.ca/lindek/minipar.htm>

that are aligned with  $w_i$ . In our experiments, we set  $\phi_i = 2$ .

Since we only have interests on capturing opinion relations between words, we only pay attentions on the alignments between opinion target candidates (nouns/noun phrases) and potential opinion words (adjectives/verbs). If we directly use the alignment model, a noun (noun phrase) may align with other unrelated words, like prepositions or conjunctions and so on. Thus, we set constrains on the model: 1) Alignment links must be assigned among nouns/noun phrases, adjectives/verbs and null words. Aligning to null words means that this word has no modifier or modifies nothing; 2) Other unrelated words can only align with themselves.

### 3.1.3 Combining Syntax-based Method with Alignment-based Method

In this subsection, we try to combine syntactic information with word alignment model. As mentioned in the first section, we adopt a partially supervised alignment model to make this combination. Here, the opinion relations obtained through the high-precision syntactic patterns (Section 3.1.1) are regarded as the ground truth and can only provide a part of full alignments in sentences. They are treated as the constrains for the word alignment model. Given some partial alignment links  $\hat{A} = \{(k, a_k) | k \in [1, n], a_k \in [1, n]\}$ , the optimal word alignment  $A^* = \{(i, a_i) | i \in [1, n], a_i \in [1, n]\}$  can be obtained as  $A^* = \underset{A}{\operatorname{argmax}} P(A|S, \hat{A})$ , where  $(i, a_i)$  means that a noun (noun phrase) at position  $i$  is aligned with its modifier at position  $a_i$ .

Since the labeled data provided by syntactic patterns is not a full alignment, we adopt a EM-based algorithm, named as constrained hill-climbing algorithm (Gao et al., 2010), to estimate the parameters in the model. In the training process, the constrained hill-climbing algorithm can ensure that the final model is marginalized on the partial alignment links. Particularly, in the E step, their method aims to find out the alignments which are consistent to the alignment links provided by syntactic patterns, where there are main two steps involved.

1) *Optimize towards the constraints.* This step aims to generate an initial alignments for alignment model (IBM-3 model in our method), which can be close to the constraints. First, a simple alignment model (IBM-1, IBM-2, HMM etc.) is

trained. Then, the evidence being inconsistent to the partial alignment links will be got rid of by using the move operator  $m_{i,j}$  which changes  $a_j = i$  and the swap operator  $s_{j_1, j_2}$  which exchanges  $a_{j_1}$  and  $a_{j_2}$ . The alignment is updated iteratively until no additional inconsistent links can be removed.

2) *Towards the optimal alignment under the constraints.* This step aims to optimize towards the optimal alignment under the constraints which starts from the aforementioned initial alignments. Gao et.al. (2010) set the corresponding cost value of the invalid move or swap operation in  $M$  and  $S$  to be negative, where  $M$  and  $S$  are respectively called Moving Matrix and Swapping Matrix, which record all possible move and swap costs between two different alignments. In this way, the invalid operators will never be picked which can guarantee that the final alignment links to have high probability to be consistent with the partial alignment links provided by high-precision syntactic patterns.

Then in M-step, evidences from the neighbor of final alignments are collected so that we can produce the estimation of parameters for the next iteration. In the process, those statistics which come from inconsistent alignment links aren't be picked up. Thus, we have

$$P(w_i | w_{a_i}, \hat{A}) = \begin{cases} \lambda, & \text{otherwise} \\ P(w_i | w_{a_i}) + \lambda, & \text{inconsistent with } \hat{A} \end{cases} \quad (2)$$

where  $\lambda$  means that we make soft constraints on the alignment model. As a result, we expect some errors generated through high-precision patterns (Section 3.1.1) may be revised in the alignment process.

## 3.2 Estimating Associations between Words

After capturing opinion relations in sentences, we can obtain a lot of word pairs, each of which is comprised of an opinion target candidate and its corresponding modified word. Then the conditional probabilities between potential opinion target  $w_t$  and potential opinion word  $w_o$  can be estimated by using maximum likelihood estimation. Thus, we have  $P(w_t | w_o) = \frac{\operatorname{Count}(w_t, w_o)}{\operatorname{Count}(w_o)}$ , where  $\operatorname{Count}(\cdot)$  means the item's frequency information.  $P(w_t | w_o)$  means the conditional probabilities between two words. At the same time, we can obtain conditional probability  $P(w_o | w_t)$ . Then,

similar to (Liu et al., 2012), the association between an opinion target candidate and its modifier is estimated as follows.  $Association(w_t, w_o) = (\alpha \times P(w_t|w_o) + (1 - \alpha) \times P(w_o|w_t))^{-1}$ , where  $\alpha$  is the harmonic factor. We set  $\alpha = 0.5$  in our experiments.

### 3.3 The Second Component: Estimating Candidate Confidence

In the second component, we adopt a graph-based algorithm used in (Liu et al., 2012) to compute the confidence of each opinion target candidate, and the candidates with higher confidence than the threshold will be extracted as the opinion targets. Here, opinion words are regarded as the important indicators. We assume that two target candidates are likely to belong to the similar category, if they are modified by similar opinion words. Thus, we can propagate the opinion target confidences through opinion words.

To model the mined associations between words, a bipartite graph is constructed, which is defined as a weighted undirected graph  $G = (V, E, W)$ . It contains two kinds of vertex: opinion target candidates and potential opinion words, respectively denoted as  $v_t \in V$  and  $v_o \in V$ . As shown in Figure 2, the white vertices represent opinion target candidates and the gray vertices represent potential opinion words. An edge  $e_{v_t, v_o} \in E$  between vertices represents that there is an opinion relation, and the weight  $w$  on the edge represents the association between two words.

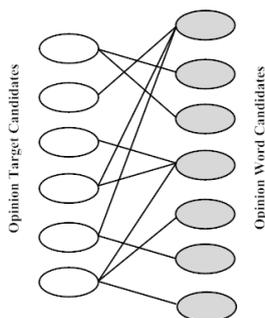

Figure 2: Modeling Opinion Relations between Words in a Bipartite Graph

To estimate the confidence of each opinion target candidate, we employ a random walk algorithm on our graph, which iteratively computes the weighted average of opinion target confidences from neighboring vertices. Thus we have

$$C^{i+1} = (1 - \beta) \times M \times M^T \times C^i + \beta \times I \quad (3)$$

where  $C^{i+1}$  and  $C^i$  respectively represent the opinion target confidence vector in the  $(i + 1)^{th}$  and  $i^{th}$  iteration.  $M$  is the matrix of word associations, where  $M_{i,j}$  denotes the association between the opinion target candidate  $i$  and the potential opinion word  $j$ . And  $I$  is defined as the prior confidence of each candidate for opinion target. Similar to (Liu et al., 2012), we set each item in  $I_v = \frac{tf(v)idf(v)}{\sum_v tf(v)idf(v)}$ , where  $tf(v)$  is the term frequency of  $v$  in the corpus, and  $idf(v)$  is computed by using the Google n-gram corpus<sup>2</sup>.  $\beta \in [0, 1]$  represents the impact of candidate prior knowledge on the final estimation results. In experiments, we set  $\beta = 0.4$ . The algorithm run until convergence which is achieved when the confidence on each node ceases to change in a tolerance value.

## 4 Experiments

### 4.1 Datasets and Evaluation Metrics

In this section, to answer the questions mentioned in the first section, we collect a large collection named as *LARGE*, which includes reviews from three different domains and different languages. This collection was also used in (Liu et al., 2012). In the experiments, reviews are first segmented into sentences according to punctuation. The detailed statistical information of the used collection is shown in Table 2, where Restaurant is crawled from the Chinese Web site: [www.dianping.com](http://www.dianping.com). The Hotel and MP3 are used in (Wang et al., 2011), which are respectively crawled from [www.tripadvisor.com](http://www.tripadvisor.com) and [www.amazon.com](http://www.amazon.com). For each dataset, we perform random sampling to generate testing set with different sizes, where we use sampled subsets with  $\#sentences = 5 \times 10^2, 10^3, 5 \times 10^3, 10^4, 5 \times 10^4, 10^5$  and  $10^6$  sentences respectively. Each

Domain	Language	Sentence	Reviews
<b>Restaurant</b>	Chinese	1,683,129	395,124
<b>Hotel</b>	English	1,855,351	185,829
<b>MP3</b>	English	289,931	30,837

Table 2: Experimental Dataset

sentence is tokenized, part-of-speech tagged by using Stanford NLP tool<sup>3</sup>, and parsed by using Minipar toolkit. And the method of (Zhu et al., 2009) is used to identify noun phrases.

<sup>2</sup><http://books.google.com/ngrams/datasets>

<sup>3</sup><http://nlp.stanford.edu/software/tagger.shtml>

We select precision and recall as the metrics. Specifically, to obtain the ground truth, we manually label all opinion targets for each subset. In this process, three annotators are involved. First, every noun/noun phrase and its contexts in review sentences are extracted. Then two annotators were required to judge whether every noun/noun phrase is opinion target or not. If a conflict happens, a third annotator will make judgment for final results. The average inter-agreements is 0.74. We also perform a significant test, i.e., a t-test with a default significant level of 0.05.

## 4.2 Compared Methods

We select three methods for comparison as follows.

- **Syntax**: It uses syntactic patterns mentioned in Section 3.1.1 in the first component to capture opinion relations in reviews. Then the associations between words are estimated and the graph based algorithm proposed in the second component (Section 3.3) is performed to extract opinion targets.
- **WAM**: It is similar to **Syntax**, where the only difference is that **WAM** uses unsupervised WAM (Section 3.1.2) to capture opinion relations.
- **PSWAM** is similar to **Syntax** and **WAM**, where the difference is that **PSWAM** uses the method mentioned in Section 3.1.3 to capture opinion relations, which incorporates syntactic information into word alignment model by using partially supervised framework.

The experimental results on different domains are respectively shown in Figure 3, 4 and 5.

## 4.3 Syntax based Methods vs. Alignment based Methods

Comparing **Syntax** with **WAM** and **PSWAM**, we can obtain the following observations:

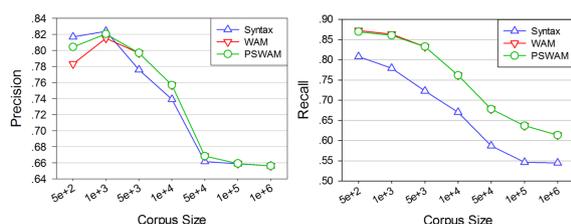

Figure 3: Experimental results on Restaurant

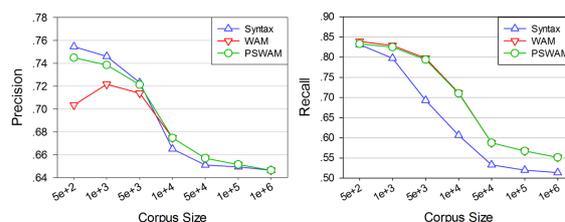

Figure 4: Experimental results on Hotel

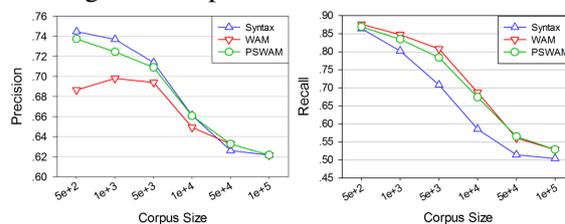

Figure 5: Experimental results on MP3

1) When the size of the corpus is small, **Syntax** has better precision than alignment based methods (**WAM** and **PSWAM**). We believe the reason is that the high-precision syntactic patterns employed in **Syntax** can effectively capture opinion relations in a small amount of texts. In contrast, the methods based on word alignment model may suffer from data sparseness for parameter estimation, so the precision is lower.

2) However, when the size of the corpus increases, the precision of **Syntax** decreases, even worse than alignment based methods. We believe it's because more noises were introduced from parsing errors with the increase of the size of the corpus, which will have more negative impacts on extraction results. In contrast, for estimating the parameters of alignment based methods, the data is more sufficient, so the precision is better compared with syntax based method.

3) We also observe that recall of **Syntax** is worse than other two methods. It's because the human expressions of opinions are diverse and the manual designed syntactic patterns are limited to capture all opinion relations in sentences, which may miss an amount of correct opinion targets.

4) It's interesting that the performance gap between these three methods is smaller with the increase of the size of the corpus (more than 50,000). We guess the reason is that when the data is sufficient enough, we can obtain sufficient statistics for each opinion target. In such situation, the graph-based ranking algorithm in the second component will be apt to be affected by the frequency information, so the final performance could not be sensitive to the performance of opinion relations iden-

tification in the first component. Thus, in this situation, we can get conclusion that there is no obviously difference on performance between syntax-based approach and alignment-based approach.

5) From the results on dataset with different languages and different domains, we can obtain the similar observations. It indicates that choosing either syntactic patterns or word alignment model for extracting opinion targets can take a few consideration on the language and domain of the corpus.

Thus, based on the above observations, we can draw the following conclusions: making chooses between different methods is only related to the size of the corpus. The method based on syntactic patterns is more suitable for small corpus ( $\#sentences < 5 \times 10^3$  shown in our experiments). And word alignment model is more suitable for medium corpus ( $5 \times 10^3 < \#sentences < 5 \times 10^4$ ). Moreover, when the size of the corpus is big enough, the performance of two kinds of methods tend to become the same ( $\#sentences \geq 10^5$  shown in our experiments).

#### 4.4 Is It Useful Combining Syntactic Patterns with Word Alignment Model

In this subsection, we try to see whether combining syntactic information with alignment model by using PSWAM is effective or not for opinion target extraction. From the results in Figure 3, 4 and 5, we can see that **PSWAM** has the similar recall compared with **WAM** in all datasets. **PSWAM** outperforms **WAM** on precision in all dataset. But the precision gap between **PSWAM** and **WAM** decreases when the size of the corpus increases. When the size is larger than  $5 \times 10^4$ , the performance of these two methods is almost the same. We guess the reason is that more noises from parsing errors will be introduced by syntactic patterns with the increase of the size of corpus, which have negative impacts on alignment performance. At the same time, as mentioned above, a great deal of reviews will bring sufficient statistics for estimating parameters in alignment model, so the roles of partial supervision from syntactic information will be covered by frequency information used in our graph based ranking algorithm.

**Compared with State-of-the-art Methods.** However, it's not say that this combination is not useful. From the results, we still see that **PSWAM** outperforms **WAM** in all datasets on

precision when size of corpus is smaller than  $5 \times 10^4$ . To further prove the effectiveness of our combination, we compare **PSWAM** with some state-of-the-art methods, including **Hu** (Hu and Liu, 2004a), which extracted frequent opinion target words based on association mining rules, **DP** (Qiu et al., 2011), which extracted opinion targets through syntactic patterns, and **LIU** (Liu et al., 2012), which fulfilled this task by using unsupervised WAM. The parameter settings in these baselines are the same as the settings in the original papers. Because of the space limitation, we only show the results on Restaurant and Hotel, as shown in Figure 6 and 7.

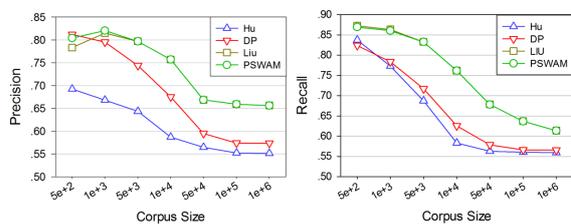

Figure 6: Compared with the State-of-the-art Methods on Restaurant

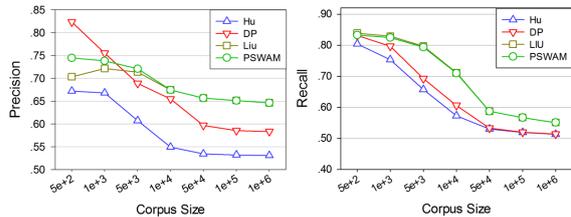

Figure 7: Compared with the State-of-the-art Methods on Hotel

From the experimental results, we can obtain the following observations. **PSWAM** outperforms other methods in most datasets. This indicates that our method based on PSWAM is effective for opinion target extraction. Especially compared **PSWAM** with **LIU**, both of which are based on word alignment model, we can see **PSWAM** identifies opinion relations by performing WAM under partial supervision, which can effectively improve the precision when dealing with small and medium corpus. However, these improvements are limited when the size of the corpus increases, which has the similar observations obtained above.

**The Impact of Syntactic Information on Word Alignment Model.** Although we have prove the effectiveness of PSWAM in the corpus with small and medium size, we are still curious about how the performance varies when we incor-

porate different amount of syntactic information into WAM. In this experiment, we rank the used syntactic patterns mentioned in Section 3.1.1 according to the quantities of the extracted alignment links by these patterns. Then, to capture opinion relations, we respectively use top N syntactic patterns according to frequency mentioned above to generate partial alignment links for PSWAM in section 3.1.3. We respectively define  $N=[1,7]$ . The larger is N, the more syntactic information is incorporated. Because of the space limitation, only the average performance of all dataset is shown in Figure 8.

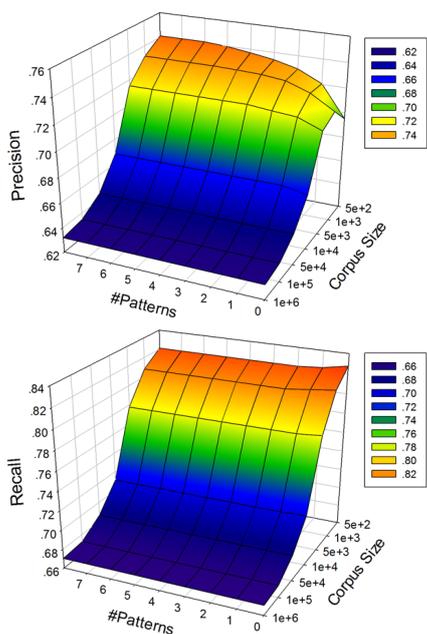

Figure 8: The Impacts of Different Syntactic Information on Word Alignment Model

In Figure 8, we can observe that the syntactic information mainly have effect on precision. When the size of the corpus is small, the opinion relations mined by high-precision syntactic patterns are usually correct, so incorporating more syntactic information can improve the precision of word alignment model more. However, when the size of the corpus increases, incorporating more syntactic information has little impact on precision.

## 5 Conclusions and Future Work

This paper discusses the performance variation of syntax based methods and alignment based methods on opinion target extraction task for the dataset with different sizes, different languages and different domains. Through experimental results, we can see that choosing which method is not related

with corpus domain and language, but strongly associated with the size of the corpus. We can conclude that syntax-based method is likely to be more effective when the size of the corpus is small, and alignment-based methods are more useful for the medium size corpus. We further verify that incorporating syntactic information into word alignment model by using PSWAM is effective when dealing with the corpora with small or medium size. When the size of the corpus is larger and larger, the performance gap between syntax based, WAM and PSWAM will decrease.

In future work, we will extract opinion targets based on not only opinion relations. Other semantic relations, such as the topical associations between opinion targets (or opinion words) should also be employed. We believe that considering multiple semantic associations will help to improve the performance. In this way, how to model heterogenous relations in a unified model for opinion targets extraction is worthy to be studied.

## Abstract

This paper proposes a novel two-stage method for mining opinion words and opinion targets. In the first stage, we propose a *Sentiment Graph Walking* algorithm, which naturally incorporates syntactic patterns in a Sentiment Graph to extract opinion word/target candidates. Then random walking is employed to estimate confidence of candidates, which improves extraction accuracy by considering confidence of patterns. In the second stage, we adopt a self-learning strategy to refine the results from the first stage, especially for filtering out high-frequency noise terms and capturing the long-tail terms, which are not investigated by previous methods. The experimental results on three real world datasets demonstrate the effectiveness of our approach compared with state-of-the-art unsupervised methods.

## 1 Introduction

Opinion mining not only assists users to make informed purchase decisions, but also helps business organizations understand and act upon customer feedbacks on their products or services in real-time. Extracting opinion words and opinion targets are two key tasks in opinion mining. Opinion words refer to those terms indicating positive or negative sentiment. Opinion targets represent aspects or attributes of objects toward which opinions are expressed. Mining these terms from reviews of a specific domain allows a more thorough understanding of customers' opinions.

Opinion words and opinion targets often co-occur in reviews and there exist modified relations (called *opinion relation* in this paper) between them. For example, in the sentence “It has a clear screen”, “clear” is an opinion word and “screen” is

an opinion target, and there is an opinion relation between the two words. It is natural to identify such opinion relations through common syntactic patterns (also called *opinion patterns* in this paper) between opinion words and targets. For example, we can extract “clear” and “screen” by using a syntactic pattern “Adj-*{mod}*-Noun”, which captures the opinion relation between them. Although previous works have shown the effectiveness of syntactic patterns for this task (Qiu et al., 2009; Zhang et al., 2010), they still have some limitations as follows.

**False Opinion Relations:** As an example, the phrase “everyday at school” can be matched by a pattern “Adj-*{mod}*-(Prep)-*{pcomp-n}*-Noun”, but it doesn't bear any sentiment orientation. We call such relations that match opinion patterns but express no opinion *false opinion relations*. Previous pattern learning algorithms (Zhuang et al., 2006; Kessler and Nicolov, 2009; Jijkoun et al., 2010) often extract opinion patterns by frequency. However, some high-frequency syntactic patterns can have very poor precision (Kessler and Nicolov, 2009).

**False Opinion Targets:** In another case, the phrase “wonderful time” can be matched by an opinion pattern “Adj-*{mod}*-Noun”, which is widely used in previous works (Popescu and Etzioni, 2005; Qiu et al., 2009). As can be seen, this phrase does express a positive opinion but unfortunately “time” is not a valid opinion target for most domains such as MP3. Thus, *false opinion targets* are extracted. Due to the lack of ground-truth knowledge for opinion targets, non-target terms introduced in this way can be hardly filtered out.

**Long-tail Opinion Targets:** We further notice that previous works prone to extract opinion targets with high frequency (Hu and Liu, 2004; Popescu and Etzioni, 2005; Qiu et al., 2009; Zhu et al., 2009), and they often have difficulty in identifying the infrequent or *long-tail opinion targets*.

To address the problems stated above, this paper proposes a two-stage framework for mining opinion words and opinion targets. The underlying motivation is analogous to the novel idea “Mine the Easy, Classify the Hard” (Dasgupta and Ng, 2009). In our first stage, we propose a *Sentiment Graph Walking* algorithm to cope with the false opinion relation problem, which mines easy cases of opinion words/targets. We speculate that it may be helpful to introduce a confidence score for each pattern. Concretely, we create a *Sentiment Graph* to model opinion relations among opinion word/target/pattern candidates and apply random walking to estimate confidence of them. Thus, confidence of pattern is considered in a unified process. Patterns that often extract false opinion relations will have low confidence, and terms introduced by low-confidence patterns will also have low confidence accordingly. This could potentially improve the extraction accuracy.

In the second stage, we identify the hard cases, which aims to filter out false opinion targets and extract long-tail opinion targets. Previous supervised methods have been shown to achieve state-of-the-art results for this task (Wu et al., 2009; Jin and Ho, 2009; Li et al., 2010). However, the big challenge for fully supervised method is the lack of annotated training data. Therefore, we adopt a **self-learning strategy**. Specifically, we employ a semi-supervised classifier to refine the target results from the first stage, which uses some highly confident target candidates as the initial labeled examples. Then opinion words are also refined.

Our main contributions are as follows:

- We propose a *Sentiment Graph Walking* algorithm to mine opinion words and opinion targets from reviews, which naturally incorporates confidence of syntactic pattern in a graph to improve extraction performance. To our best knowledge, the incorporation of pattern confidence in such a Sentiment Graph has never been studied before for opinion words/targets mining task (Section 3).
- We adopt a self-learning method for refining opinion words/targets generated by *Sentiment Graph Walking*. Specifically, it can remove high-frequency noise terms and capture long-tail opinion targets in corpora (Section 4).
- We perform experiments on three real world datasets, which demonstrate the effectiveness of our method compared with state-of-the-art unsupervised methods (Section 5).

## 2 Related Work

In opinion words/targets mining task, most unsupervised methods rely on identifying opinion relations between opinion words and opinion targets. Hu and Liu (2004) proposed an association mining technique to extract opinion words/targets. The simple heuristic rules they used may potentially introduce many false opinion words/targets. To identify opinion relations more precisely, subsequent research work exploited syntax information. Popescu and Etzioni (2005) used manually compiled syntactic patterns and Pointwise Mutual Information (PMI) to extract opinion words/targets. Qiu et al. (2009) proposed a bootstrapping framework called *Double Propagation* which introduced eight heuristic syntactic rules. While manually defining syntactic patterns could be time-consuming and error-prone, we learn syntactic patterns automatically from data.

There have been extensive works on mining opinion words and opinion targets by syntactic pattern learning. Riloff and Wiebe (2003) performed pattern learning through bootstrapping while extracting subjective expressions. Zhuang et al. (2006) obtained various dependency relationship templates from an annotated movie corpus and applied them to supervised opinion words/targets extraction. Kobayashi et al. (2007) adopted a supervised learning technique to search for useful syntactic patterns as contextual clues. Our approach is similar to (Wiebe and Riloff, 2005) and (Xu et al., 2013), all of which apply syntactic pattern learning and adopt self-learning strategy. However, the task of (Wiebe and Riloff, 2005) was to classify sentiment orientations in sentence level, while ours needs to extract more detailed information in term level. In addition, our method extends (Xu et al., 2013), and we give a more complete and in-depth analysis on the aforementioned problems in the first section. There were also many works employed graph-based method (Li et al., 2012; Zhang et al., 2010; Hassan and Radev, 2010; Liu et al., 2012), but none of previous works considered confidence of patterns in the graph.

In supervised approaches, various kinds of models were applied, such as HMM (Jin and Ho, 2009), SVM (Wu et al., 2009) and CRFs (Li et al., 2010). The downside of supervised methods was the difficulty of obtaining annotated training data in practical applications. Also, classifiers trained

on one domain often fail to give satisfactory results when shifted to another domain. Our method does not rely on annotated training data.

### 3 The First Stage: Sentiment Graph Walking Algorithm

In the first stage, we propose a graph-based algorithm called *Sentiment Graph Walking* to mine opinion words and opinion targets from reviews.

#### 3.1 Opinion Pattern Learning for Candidates Generation

For a given sentence, we first obtain its dependency tree. Following (Hu and Liu, 2004; Popescu and Etzioni, 2005; Qiu et al., 2009), we regard all adjectives as opinion word candidates (OC) and all nouns or noun phrases as opinion target candidates (TC). A statistic-based method in (Zhu et al., 2009) is used to detect noun phrases. Then candidates are replaced by wildcards “<OC>” or “<TC>”. Figure 1 gives a dependency tree example generated by Minipar (Lin, 1998).

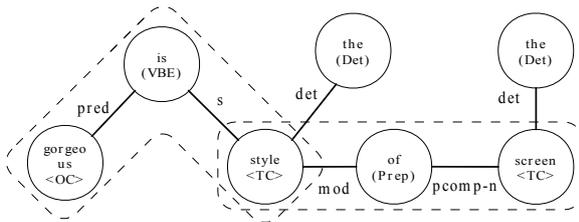

Figure 1: The dependency tree of the sentence “The style of the screen is gorgeous”.

We extract two kinds of opinion patterns: “OC-TC” pattern and “TC-TC” pattern. The “OC-TC” pattern is the shortest path between an OC wildcard and a TC wildcard in dependency tree, which captures opinion relation between an opinion word candidate and an opinion target candidate. Similarly, the “TC-TC” pattern captures opinion relation between two opinion target candidates.<sup>1</sup> Words in opinion patterns are replaced by their POS tags, and we constrain that there are at most two words other than wildcards in each pattern. In Figure 1, there are two opinion patterns marked out by dash lines: “<OC>{pred}{VBE}{s}<TC>” for the “OC-TC” type and “<TC>{mod}{(Prep)}{pcomp-n}<TC>” for the “TC-TC” type. After all pat-

<sup>1</sup>We do not identify the opinion relation “OC-OC” because this relation is often unreliable.

terns are generated, we drop those patterns with frequency lower than a threshold  $F$ .

#### 3.2 Sentiment Graph Construction

To model the opinion relations among opinion words/targets and opinion patterns, a graph named as *Sentiment Graph* is constructed, which is a weighted, directed graph  $G = (V, E, W)$ , where

- $V = \{V_{oc} \cup V_{tc} \cup V_p\}$  is the set of vertices in  $G$ , where  $V_{oc}$ ,  $V_{tc}$  and  $V_p$  represent the set of opinion word candidates, opinion target candidates and opinion patterns, respectively.
- $E = \{E_{po} \cup E_{pt}\} \subseteq \{V_p \times V_{oc}\} \cup \{V_p \times V_{tc}\}$  is the weighted, bi-directional edge set in  $G$ , where  $E_{po}$  and  $E_{pt}$  are mutually exclusive sets of edges connecting opinion word/target vertices to opinion pattern vertices. Note that there are no edges between  $V_{oc}$  and  $V_{tc}$ .
- $W : E \rightarrow \mathbb{R}^+$  is the weight function which assigns non-negative weight to each edge. For each  $(e : v_a \rightarrow v_b) \in E$ , where  $v_a, v_b \in V$ , the weight function  $w(v_a, v_b) = freq(v_a, v_b) / freq(v_a)$ , where  $freq(\cdot)$  is the frequency of a candidate extracted by opinion patterns or co-occurrence frequency between two candidates.

Figure 2 shows an example of Sentiment Graph.

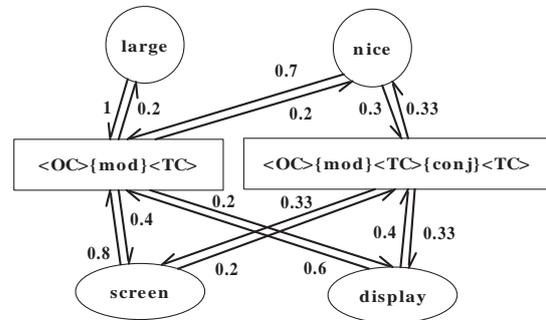

Figure 2: An example of Sentiment Graph.

#### 3.3 Confidence Estimation by Random Walking with Restart

We believe that considering confidence of patterns can potentially improve the extraction accuracy. Our intuitive idea is: (i) If an opinion word/target is with higher confidence, the syntactic patterns containing this term are more likely to be used to express customers’ opinion. (ii) If an opinion pattern has higher confidence, terms extracted by this pattern are more likely to be correct. It’s a reinforcement process.

We use Random Walking with Restart (RWR) algorithm to implement our idea described above. Let  $\mathbf{M}_{oc.p}$  denotes the transition matrix from  $V_{oc}$  to  $V_p$ , for  $v_o \in V_{oc}, v_p \in V_p$ ,  $\mathbf{M}_{oc.p}(v_o, v_p) = w(v_o, v_p)$ . Similarly, we have  $\mathbf{M}_{tc.p}$ ,  $\mathbf{M}_{p.oc}$ ,  $\mathbf{M}_{p.tc}$ . Let  $\mathbf{c}$  denotes confidence vector of candidates so  $\mathbf{c}_{oc}^t$ ,  $\mathbf{c}_{tc}^t$  and  $\mathbf{c}_p^t$  are confidence vectors for opinion word/target/pattern candidates after walking  $t$  steps. Initially  $\mathbf{c}_{oc}^0$  is uniformly distributed on a few domain-independent opinion word seeds, then the following formula are updated iteratively until  $\mathbf{c}_{tc}^t$  and  $\mathbf{c}_{oc}^t$  converge:

$$\mathbf{c}_p^{t+1} = \mathbf{M}_{oc.p}^T \times \mathbf{c}_{oc}^t + \mathbf{M}_{tc.p}^T \times \mathbf{c}_{tc}^t \quad (1)$$

$$\mathbf{c}_{oc}^{t+1} = (1 - \lambda)\mathbf{M}_{p.oc}^T \times \mathbf{c}_p^t + \lambda\mathbf{c}_{oc}^0 \quad (2)$$

$$\mathbf{c}_{tc}^{t+1} = \mathbf{M}_{p.tc}^T \times \mathbf{c}_p^t \quad (3)$$

where  $\mathbf{M}^T$  is the transpose of matrix  $\mathbf{M}$  and  $\lambda$  is a small probability of teleporting back to the seed vertices which prevents us from walking too far away from the seeds. In the experiments below,  $\lambda$  is set 0.1 empirically.

#### 4 The Second Stage: Refining Extracted Results Using Self-Learning

At the end of the first stage, we obtain a ranked list of opinion words and opinion targets, in which higher ranked terms are more likely to be correct. Nevertheless, there are still some issues needed to be addressed:

- 1) In the target candidate list, some high-frequency frivolous general nouns such as “thing” and “people” are also highly ranked. This is because there exist many opinion expressions containing non-target terms such as “good thing”, “nice people”, etc. in reviews. Due to the lack of ground-truth knowledge for opinion targets, the false opinion target problem still remains unsolved.
- 2) In another aspect, long-tail opinion targets may have low degree in Sentiment Graph. Hence their confidence will be low although they may be extracted by some high quality patterns. Therefore, the first stage is incapable of dealing with the long-tail opinion target problem.
- 3) Furthermore, the first stage also extracts some high-frequency false opinion words such as “every”, “many”, etc. Many terms of this kind are introduced by high-frequency false opinion targets, for there are large

amounts of phrases like “every time” and “many people”. So this issue is a side effect of the false opinion target problem.

To address these issues, we exploit a self-learning strategy. For opinion targets, we use a semi-supervised binary classifier called *target refining classifier* to refine target candidates. For opinion words, we use the classified list of opinion targets to further refine the extracted opinion word candidates.

#### 4.1 Opinion Targets Refinement

There are two keys for opinion target refinement: (i) How to generate the initial labeled data for target refining classifier. (ii) How to properly represent a long-tail opinion target candidate other than comparing frequency between different targets.

For the first key, it is clearly improper to select high-confidence targets as positive examples and choose low-confidence targets as negative examples<sup>2</sup>, for there are noise with high confidence and long-tail targets with low confidence. Fortunately, a large proportion of general noun noises are the most frequent words in common texts. Therefore, we can generate a small domain-independent general noun (GN) corpus from large web corpora to cover some most frequently used general noun examples. Then labeled examples can be drawn from the target candidate list and the GN corpus.

For the second key, we utilize opinion words and opinion patterns with their confidence scores to represent an opinion target. By this means, a long-tail opinion target can be determined by its own contexts, whose weights are learnt from contexts of frequent opinion targets. Thus, if a long-tail opinion target candidate has high contextual support, it will have higher probability to be found out in despite of its low frequency.

**Creation of General Noun Corpora.** 1000 most frequent nouns in Google-1-gram<sup>3</sup> were selected as general noun candidates. On the other hand, we added all nouns in the top three levels of hyponyms in four WordNet (Miller, 1995) synsets “object”, “person”, “group” and “measure” into the GN corpus. Our idea was based on the fact that a term is more general when it sits in higher level in the WordNet hierarchy. Then inapplicable candidates were discarded and a 3071-word English

<sup>2</sup>Note that the “positive” and “negative” here denote opinion targets and non-target terms respectively and they do not indicate sentiment polarities.

<sup>3</sup><http://books.google.com/ngrams>.

GN corpus was created. Another Chinese GN corpus with 3493 words was generated in the similar way from HowNet (Gan and Wong, 2000).

**Generation of Labeled Examples.** Let  $\mathcal{T} = \{\mathcal{Y}_{+1}, \mathcal{Y}_{-1}\}$  denotes the initial labeled set, where  $N$  most highly confident target candidates but not in our GN corpora are regarded as the positive example set  $\mathcal{Y}_{+1}$ , other  $N$  terms from GN corpora which are also top ranked in the target list are selected as the negative example set  $\mathcal{Y}_{-1}$ . The remainder unlabeled candidates are denoted by  $\mathcal{T}^*$ .

**Feature Representation for Classifier.** Given  $\mathcal{T}$  and  $\mathcal{T}^*$  in the form of  $\{(\mathbf{x}_i, y_i)\}$ . For a target candidate  $t_i$ ,  $\mathbf{x}_i = (o_1, \dots, o_n, p_1, \dots, p_m)^T$  represents its feature vector, where  $o_j$  is the opinion word feature and  $p_k$  is the opinion pattern feature. The value of feature is defined as follows,

$$x(o_j) = \text{conf}(o_j) \times \frac{\sum_{p_k} \text{freq}(t_i, o_j, p_k)}{\text{freq}(o_j)} \quad (4)$$

$$x(p_k) = \text{conf}(p_k) \times \frac{\sum_{o_j} \text{freq}(t_i, o_j, p_k)}{\text{freq}(p_k)} \quad (5)$$

where  $\text{conf}(\cdot)$  denotes confidence score estimated by RWR,  $\text{freq}(\cdot)$  has the same meaning as in Section 3.2. Particularly,  $\text{freq}(t_i, o_j, p_k)$  represents the frequency of pattern  $p_k$  extracting opinion target  $t_i$  and opinion word  $o_j$ .

**Target Refinement Classifier:** We use support vector machine as the binary classifier. Hence, the classification problem can be formulated as to find a hyperplane  $\langle \mathbf{w}, b \rangle$  that separates both labeled set  $\mathcal{T}$  and unlabeled set  $\mathcal{T}^*$  with maximum margin. The optimization goal is to minimize over  $(\mathcal{T}, \mathcal{T}^*, \mathbf{w}, b, \xi_1, \dots, \xi_n, \xi_1^*, \dots, \xi_k^*)$ :

$$\frac{1}{2} \|\mathbf{w}\|^2 + C \sum_{i=0}^n \xi_i + C^* \sum_{j=0}^k \xi_j^*$$

$$\text{subject to : } \forall_{i=1}^n : y_i [\mathbf{w} \cdot \mathbf{x}_i + b] \geq 1 - \xi_i$$

$$\forall_{j=1}^k : y_j^* [\mathbf{w} \cdot \mathbf{x}_j^* + b] \geq 1 - \xi_j^*$$

$$\forall_{i=1}^n : \xi_i > 0$$

$$\forall_{j=1}^k : \xi_j^* > 0$$

where  $y_i, y_j^* \in \{+1, -1\}$ ,  $\mathbf{x}_i$  and  $\mathbf{x}_j^*$  represent feature vectors,  $C$  and  $C^*$  are parameters set by user. This optimization problem can be implemented by a typical Transductive Support Vector Machine (TSVM) (Joachims, 1999).

## 4.2 Opinion Words Refinement

We use the classified opinion target results to refine opinion words by the following equation,

$$s(o_j) = \sum_{t_i \in T} \sum_{p_k} \frac{s(t_i) \text{conf}(p_k) \text{freq}(t_i, o_j, p_k)}{\text{freq}(t_i)}$$

where  $T$  is the opinion target set in which each element is classified as positive during opinion target refinement,  $s(t_i)$  denotes confidence score exported by the target refining classifier. Particularly,  $\text{freq}(t_i) = \sum_{o_j} \sum_{p_k} \text{freq}(t_i, o_j, p_k)$ . A higher score of  $s(o_j)$  means that candidate  $o_j$  is more likely to be an opinion word.

## 5 Experiments

### 5.1 Datasets and Evaluation Metrics

**Datasets:** We select three real world datasets to evaluate our approach. The first one is called *Customer Review Dataset (CRD)* (Hu and Liu, 2004) which contains reviews on five different products (represented by D1 to D5) in English. The second dataset is pre-annotated and published in *COAE08*<sup>4</sup>, where two domains of Chinese reviews are selected. At last, we employ a benchmark dataset in (Wang et al., 2011) and named it as *Large*. We manually annotated opinion words and opinion targets as the gold standard. Three annotators were involved. Firstly, two annotators were required to annotate out opinion words and opinion targets in sentences. When conflicts happened, the third annotator would make the final judgment. The average Kappa-values of the two domains were 0.71 for opinion words and 0.66 for opinion targets. Detailed information of our datasets is shown in Table 1.

Dataset	Domain	#Sentences	#OW	#OT
Large (English)	Hotel	10,000	434	1,015
	MP3	10,000	559	1,158
COAE08 (Chinese)	Camera	2,075	351	892
	Car	4,783	622	1,179

Table 1: The detailed information of datasets. OW stands for opinion words and OT stands for targets.

**Pre-processing:** Firstly, HTML tags are removed from texts. Then Minipar (Lin, 1998) is used to parse English corpora, and Stanford Parser (Chang et al., 2009) is used for Chinese

corpora. Stemming and fuzzy matching are also performed following previous work (Hu and Liu, 2004).

**Evaluation Metrics:** We evaluate our method by precision(P), recall(R) and F-measure(F).

## 5.2 Our Method vs. the State-of-the-art

Three state-of-the-art unsupervised methods are used as competitors to compare with our method.

*Hu* extracts opinion words/targets by using adjacency rules (Hu and Liu, 2004).

*DP* uses a bootstrapping algorithm named as *Double Propagation* (Qiu et al., 2009).

*Zhang* is an enhanced version of *DP* and employs HITS algorithm (Kleinberg, 1999) to rank opinion targets (Zhang et al., 2010).

*Ours-Full* is the full implementation of our method. We employ SVM<sup>light</sup> (Joachims, 1999) as the target refining classifier. Default parameters are used except the bias item is set 0.

*Ours-Stage1* only uses *Sentiment Graph Walking* algorithm which doesn't have opinion word and opinion target refinement.

All of the above approaches use same five common opinion word seeds. The choice of opinion seeds seems reasonable, as most people can easily come up with 5 opinion words such as "good", "bad", etc. The performance on five products of *CRD* dataset is shown in Table 2 and Table 3. *Zhang* does not extract opinion words so their results for opinion words are not taken into account. We can see that *Ours-Stage1* achieves superior recall but has some loss in precision compared with *DP* and *Zhang*. This may be because the *CRD* dataset is too small and our statistic-based method may suffer from data sparseness.

In spite of this, *Ours-Full* achieves comparable F-measure with *DP*, which is a well-designed rule-based method.

The results on two larger datasets are shown in Table 4 and Table 5, from which we can have the following observation: (i) All syntax-based-methods outperform *Hu*, showing the importance of syntactic information in opinion relation identification. (ii) *Ours-Full* outperforms the three competitors on all domains provided. (iii) *Ours-Stage1* outperforms *Zhang*, especially in terms of recall. We believe it benefits from our automatical pattern learning algorithm. Moreover, *Ours-Stage1* do not loss much in precision compared with *Zhang*, which indicates the applicability to estimate pattern confidence in Sentiment Graph. (iv) *Ours-Full* achieves 4-9% improvement in precision over the most accurate method, which shows the effectiveness of our second stage.

## 5.3 Detailed Discussions

This section gives several variants of our method to have a more detailed analysis.

*Ours-Bigraph* constructs a bi-graph between opinion words and targets, so opinion patterns are not included in the graph. Then RWR algorithm is used to only assign confidence to opinion word/target candidates.

*Ours-Stage2* only contains the second stage, which doesn't apply *Sentiment Graph Walking* algorithm. Hence the confidence score  $conf(\cdot)$  in Equations (4) and (5) have no values and they are set to 1. The initial labeled examples are exactly the same as *Ours-Full*. Due to the limitation of space, we only give analysis on opinion target extraction results in Figure 3.

### 5.3.1 The Effect of Sentiment Graph Walking

We can see that our graph-based methods (*Ours-Bigraph* and *Ours-Stage1*) achieve higher recall than *Zhang*. By learning patterns automatically, our method captures opinion relations more efficiently. Also, *Ours-Stage1* outperforms *Ours-Bigraph*, especially in precision. We believe it is because *Ours-Stage1* estimated confidence of patterns so false opinion relations are reduced. Therefore, the consideration of pattern confidence is beneficial as expected, which alleviates the false opinion relation problem. On another hand, we find that *Ours-Stage2* has much worse perfor-

mance than *Ours-Full*. This shows the effectiveness of *Sentiment Graph Walking* algorithm since the confidence scores estimated in the first stage are indispensable and indeed key to the learning of the second stage.

### 5.3.2 The Effect of Self-Learning

Figure 4 shows the average Precision@N curve of four domains on opinion target extraction. *Ours-GN-Only* is implemented by only removing 50 initial negative examples found by our GN corpora. We can see that the GN corpora work quite well, which find out most top-ranked false opinion targets. At the same time, *Ours-Full* has much better performance than *Ours-GN-Only* which indicates that *Ours-Full* can filter out more noises other than the initial negative examples. Therefore, our self-learning strategy alleviates the shortcoming of false opinion target problem. Moreover, Table 5 shows that the performance of opinion word extraction is also improved based on the classified results of opinion targets.

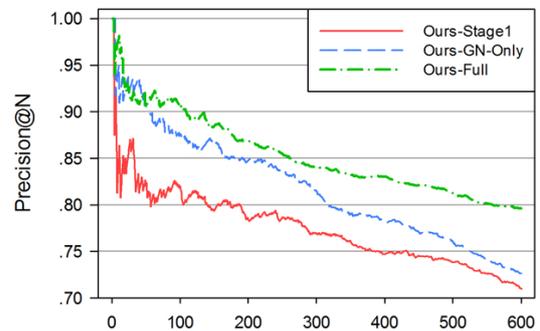

Figure 4: The average precision@N curve of the four domains on opinion target extraction.

ID	Pattern	Example	#Ext.	Conf.	PrO	PrT
#1	<OC>{mod}<TC>	it has a <b>clear</b> <i>screen</i>	7344	0.3938	0.59	0.66
#2	<TC>{subj}<OC>	the <i>sound quality</i> is <b>excellent</b>	2791	0.0689	0.62	0.70
#3	<TC>{conj}<TC>	the <i>size</i> and <i>weight</i> make it <b>convenient</b>	3620	0.0208	N/A	0.67
#4	<TC>{subj}<TC>	the <i>button layout</i> is a <b>simplistic</b> <i>plus</i>	1615	0.0096	N/A	0.67
#5	<OC>{pnmod}<TC>	the <i>buttons</i> <b>easier</b> to use	128	0.0014	0.61	0.34
#6	<TC>{subj}(V){s}(VBE){subj}<OC>	<i>software</i> provided is <b>simple</b>	189	0.0015	0.54	0.33
#7	<OC>{mod}(Prep){pcomp-c}(V){obj}<TC>	<b>great</b> for playing <i>audible books</i>	211	0.0013	0.43	0.48

Table 6: Examples of English patterns. #Ext. represent number of terms extracted, Conf. denotes confidence score estimated by RWR and PrO/PrT stand for precisions of extraction on opinion words/targets of a pattern respectively. Opinion words in examples are in bold and opinion targets are in italic.

Figure 5 gives the recall of long-tail opinion targets<sup>5</sup> extracted, where *Ours-Full* is shown to have much better performance than *Ours-Stage1* and the three competitors. This observation proves that our method can improve the limitation of long-tail opinion target problem.

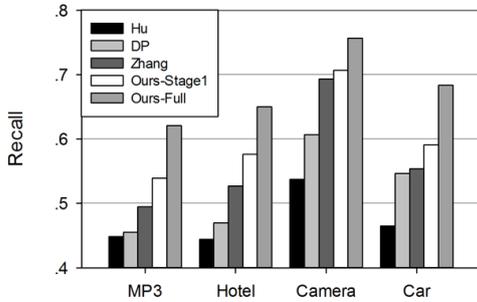

Figure 5: The recall of long-tail opinion targets.

### 5.3.3 Analysis on Opinion Patterns

Table 6 shows some examples of opinion pattern and their extraction accuracy on MP3 reviews in the first stage. Pattern #1 and #2 are the two most high-confidence opinion patterns of “OC-TC” type, and Pattern #3 and #4 demonstrate two typical “TC-TC” patterns. As these patterns extract too many terms, the overall precision is very low. We give Precision@400 of them, which is more meaningful because only top listed terms in the extracted results are regarded as opinion targets. Pattern #5 and #6 have high precision on opinion words but low precision on opinion targets. This observation demonstrates the false opinion target problem. Pattern #7 is a pattern example that extracts many false opinion relations and it has low precision for both opinion words and opinion targets. We can see that Pattern #7 has

<sup>5</sup>Since there is no explicit definition for the notion “long-tail”, we conservatively regard 60% opinion targets with the lowest frequency as the “long-tail” terms.

a lower confidence compared with Pattern #5 and #6 although it extracts more words. It’s because it has a low probability of walking from opinion seeds to this pattern. This further proves that our method can reduce the confidence of low-quality patterns.

### 5.3.4 Sensitivity of Parameters

Finally, we study the sensitivity of parameters when recall is fixed at 0.70. Figure 6 shows the precision curves at different  $N$  initial training examples and  $F$  filtering frequency. We can see that the performance saturates when  $N$  is set to 50 and it does not vary much under different  $F$ , showing the robustness of our method. We thus set  $N$  to 50, and  $F$  to 3 for *CRD*, 5 for *COAE08* and 10 for *Large* accordingly.

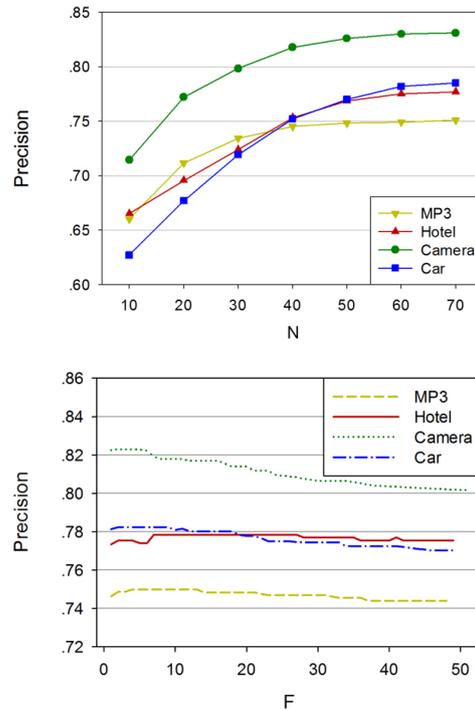

Figure 6: Influence of parameters.

## 6 Conclusion and Future Work

This paper proposes a novel two-stage framework for mining opinion words and opinion targets. In the first stage, we propose a *Sentiment Graph Walking* algorithm, which incorporates syntactic patterns in a Sentiment Graph to improve the extraction performance. In the second stage, we propose a self-learning method to refine the result of first stage. The experimental results show that our method achieves superior performance over state-of-the-art unsupervised methods.

We further notice that opinion words are not limited to adjectives but can also be other type of word such as verbs or nouns. Identifying all kinds of opinion words is a more challenging task. We plan to study this problem in our future work.

## Abstract

Understanding the connotation of words plays an important role in interpreting subtle shades of sentiment beyond denotative or surface meaning of text, as seemingly objective statements often allude nuanced sentiment of the writer, and even purposefully conjure emotion from the readers' minds. The focus of this paper is drawing nuanced, connotative sentiments from even those words that are objective on the surface, such as “*intelligence*”, “*human*”, and “*cheesecake*”. We propose induction algorithms encoding a diverse set of linguistic insights (semantic prosody, distributional similarity, semantic parallelism of coordination) and prior knowledge drawn from lexical resources, resulting in the first *broad-coverage* connotation lexicon.

## 1 Introduction

There has been a substantial body of research in sentiment analysis over the last decade (Pang and Lee, 2008), where a considerable amount of work has focused on recognizing sentiment that is generally explicit and pronounced rather than implied and subdued. However in many real-world texts, even seemingly objective statements can be opinion-laden in that they often allude nuanced sentiment of the writer (Greene and Resnik, 2009), or purposefully conjure emotion from the readers' minds (Mohammad and Turney, 2010). Although some researchers have explored formal and statistical treatments of those implicit and implied sentiments (e.g. Wiebe et al. (2005), Esuli and Sebastiani (2006), Greene and Resnik (2009), Davidov et al. (2010)), automatic analysis of them largely remains as a big challenge.

In this paper, we concentrate on understanding the connotative sentiments of words, as they play an important role in interpreting subtle shades of sentiment beyond denotative or surface meaning of text. For instance, consider the following:

Geothermal replaces oil-heating; it helps reducing greenhouse *emissions*.<sup>1</sup>

Although this sentence could be considered as a factual statement from the general standpoint, the subtle effect of this sentence may not be entirely objective: this sentence is likely to have an influence on readers' minds in regard to their opinion toward “*geothermal*”. In order to sense the subtle overtone of sentiments, one needs to know that the word “*emissions*” has generally negative connotation, which geothermal *reduces*. In fact, depending on the pragmatic contexts, it could be precisely the intention of the author to transfer his opinion into the readers' minds.

The main contribution of this paper is a *broad-coverage* connotation lexicon that determines the connotative polarity of even those words with ever so subtle connotation beneath their surface meaning, such as “*Literature*”, “*Mediterranean*”, and “*wine*”. Although there has been a number of previous work that constructed sentiment lexicons (e.g., Esuli and Sebastiani (2006), Wilson et al. (2005a), Kaji and Kitsuregawa (2007), Qiu et al. (2009)), which seem to be increasingly and inevitably expanding over words with (strongly) connotative sentiments rather than explicit sentiments alone (e.g., “*gun*”), little prior work has directly tackled this problem of learning connotation,<sup>2</sup> and much of the subtle connotation of many seemingly objective words is yet to be determined.

<sup>1</sup>Our learned lexicon correctly assigns negative polarity to *emission*.

<sup>2</sup>A notable exception would be the work of Feng et al.

POSITIVE	NEGATIVE
FEMA, Mandela, Intel, Google, Python, Sony, Pulitzer, Harvard, Duke, Einstein, Shakespeare, Elizabeth, Clooney, Hoover, Goldman, Swarovski, Hawaii, Yellowstone	Katrina, Monsanto, Halliburton, Enron, Teflon, Hiroshima, Holocaust, Afghanistan, Mugabe, Hutu, Saddam, Osama, Qaeda, Kosovo, Helicobacter, HIV

Table 1: Example Named Entities (Proper Nouns) with Polar Connotation.

A central premise to our approach is that it is collocational statistics of words that affect and shape the polarity of connotation. Indeed, the etymology of “*connotation*” is from the Latin “*com-*” (“together or with”) and “*notare*” (“to mark”). It is important to clarify, however, that we do not simply assume that words that collocate share the same polarity of connotation. Although such an assumption played a key role in previous work for the analogous task of learning sentiment lexicon (Velikovich et al., 2010), we expect that the same assumption would be less reliable in drawing subtle connotative sentiments of words. As one example, the predicate “cure”, which has a positive connotation typically takes arguments with negative connotation, e.g., “disease”, when used as the “relieve” sense.<sup>3</sup>

Therefore, in order to attain a broad coverage lexicon while maintaining good precision, we guide the induction algorithm with multiple, carefully selected linguistic insights: [1] distributional similarity, [2] semantic parallelism of coordination, [3] selectional preference, and [4] semantic prosody (e.g., Sinclair (1991), Louw (1993), Stubbs (1995), Stefanowitsch and Gries (2003)), and also exploit existing lexical resources as an additional inductive bias.

We cast the connotation lexicon induction task as a collective inference problem, and consider approaches based on three distinct types of algorithmic framework that have been shown successful for conventional sentiment lexicon induction:

*Random walk based on HITS/PageRank* (e.g.,

Kleinberg (1999), Page et al. (1999), Feng et al. (2011) Heerschop et al. (2011), Montejo-Ráez et al. (2012))

*Label/Graph propagation* (e.g., Zhu and Ghahra-

(2011) but with practical limitations. See §3 for detailed discussion.

<sup>3</sup>Note that when “cure” is used as the “preserve” sense, it expects objects with non-negative connotation. Hence word-sense-disambiguation (WSD) presents a challenge, though not unexpectedly. In this work, we assume the general connotation of each word over statistically prevailing senses, leaving a more cautious handling of WSD as future work.

mani (2002), Velikovich et al. (2010))

*Constraint optimization* (e.g., Roth and Yih (2004), Choi and Cardie (2009), Lu et al. (2011)).

We provide comparative empirical results over several variants of these approaches with comprehensive evaluations including lexicon-based, human judgments, and extrinsic evaluations.

It is worthwhile to note that not all words have connotative meanings that are distinct from denotational meanings, and in some cases, it can be difficult to determine whether the overall sentiment is drawn from denotational or connotative meanings exclusively, or both. Therefore, we encompass any sentiment from either type of meanings into the lexicon, where non-neutral polarity prevails over neutral one if some meanings lead to neutral while others to non-neutral.<sup>4</sup>

Our work results in the first broad-coverage connotation lexicon,<sup>5</sup> significantly improving both the coverage and the precision of Feng et al. (2011). As an interesting by-product, our algorithm can be also used as a proxy to measure the general connotation of real-world named entities based on their collocational statistics. Table 1 highlights some example proper nouns included in the final lexicon.

The rest of the paper is structured as follows. In §2 we describe three types of induction algorithms followed by evaluation in §3. Then we revisit the induction algorithms based on constraint optimization in §4 to enhance quality and scalability. §5 presents comprehensive evaluation with human judges and extrinsic evaluations. Related work and conclusion are in §6 and §7.

<sup>4</sup>In general, polysemous words do not seem to have conflicting non-neutral polarities over different senses, though there are many exceptions, e.g., “heat”, or “fine”. We treat each word in each part-of-speech as a separate word to reduce such cases, otherwise aim to learn the most prevalent polarity in the corpus with respect to each part-of-speech of each word.

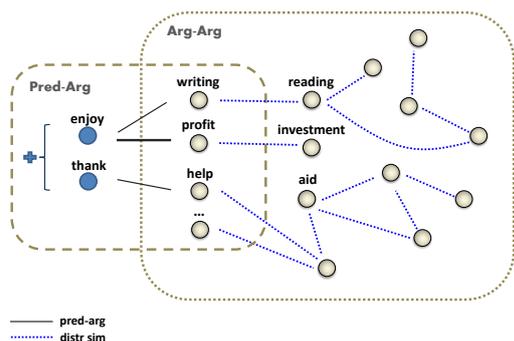

Figure 1: Graph for Graph Propagation (§2.2).

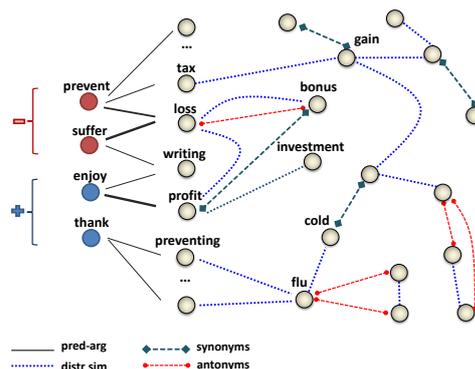

Figure 2: Graph for ILP/LP (§2.3, §4.2).

## 2 Connotation Induction Algorithms

We develop induction algorithms based on three distinct types of algorithmic framework that have been shown successful for the analogous task of sentiment lexicon induction: HITS & PageRank (§2.1), Label/Graph Propagation (§2.2), and Constraint Optimization via Integer Linear Programming (§2.3). As will be shown, each of these approaches will incorporate additional, more diverse linguistic insights.

### 2.1 HITS & PageRank

The work of Feng et al. (2011) explored the use of HITS (Kleinberg, 1999) and PageRank (Page et al., 1999) to induce the general connotation of words hinging on the linguistic phenomena of selectional preference and semantic prosody, i.e., *connotative predicates* influencing the connotation of their arguments. For example, the object of a negative connotative predicate “cure” is likely to have negative connotation, e.g., “disease” or “cancer”. The bipartite graph structure for this approach corresponds to the left-most box (labeled as “pred-arg”) in Figure 1.

### 2.2 Label Propagation

With the goal of obtaining a broad-coverage lexicon in mind, we find that relying only on the structure of semantic prosody is limiting, due to relatively small sets of connotative predicates available.<sup>6</sup> Therefore, we extend the graph structure as an *overlay of two sub-graphs* (Figure 1) as described below:

<sup>6</sup>For connotative predicates, we use the seed predicate set of Feng et al. (2011), which comprises of 20 positive and 20 negative predicates.

### Sub-graph #1: Predicate–Argument Graph

This sub-graph is the bipartite graph that encodes the selectional preference of connotative predicates over their arguments. In this graph, connotative predicates  $p$  reside on one side of the graph and their co-occurring arguments  $a$  reside on the other side of the graph based on Google Web 1T corpus.<sup>7</sup> The weight on the edges between the predicates  $p$  and arguments  $a$  are defined using Point-wise Mutual Information (PMI) as follows:

$$w(p \rightarrow a) := PMI(p, a) = \log_2 \frac{P(p, a)}{P(p)P(a)}$$

PMI scores have been widely used in previous studies to measure association between words (e.g., Turney (2001), Church and Hanks (1990)).

### Sub-graph #2: Argument–Argument Graph

The second sub-graph is based on the distributional similarities among the arguments. One possible way of constructing such a graph is simply connecting all nodes and assign edge weights proportionate to the word association scores, such as PMI, or distributional similarity. However, such a completely connected graph can be susceptible to propagating noise, and does not scale well over a very large set of vocabulary.

We therefore reduce the graph connectivity by exploiting *semantic parallelism of coordination* (Bock (1986), Hatzivassiloglou and McKeown

<sup>7</sup>We restrict predicate-argument pairs to verb-object pairs in this study. Note that Google Web 1T dataset consists of  $n$ -grams upto  $n = 5$ . Since  $n$ -gram sequences are too short to apply a parser, we extract verb-object pairs approximately by matching part-of-speech tags. Empirically, when overlaid with the second sub-graph, we found that it is better to keep the connectivity of this sub-graph as uni-directional. That is, we only allow edges to go from a predicate to an argument.

	POSITIVE	NEGATIVE	NEUTRAL
n.	avatar, adrenaline, keynote, debut, stakeholder, sunshine, cooperation	unbeliever, delay, shortfall, gunshot, misdemeanor, mutiny, rigor	header, mark, clothing, outline, grid, gasoline, course, preview
v.	handcraft, volunteer, party, accredit, personalize, nurse, google	sentence, cough, trap, scratch, debunk, rip, misspell, overcharge	state, edit, send, put, arrive, type, drill, name, stay, echo, register
a.	floral, vegetarian, prepared, ageless, funded, contemporary	debilitating, impaired, swollen, intentional, jarring, unearned	same, cerebral, west, uncut, automatic, hydrated, unheated, routine

Table 2: Example Words with Learned Connotation: Nouns(n), Verbs(v), Adjectives(a).

(1997), Pickering and Branigan (1998)). In particular, we consider an undirected edge between a pair of arguments  $a_1$  and  $a_2$  only if they occurred together in the “ $a_1$  and  $a_2$ ” or “ $a_2$  and  $a_1$ ” coordination, and assign edge weights as:

$$w(a_1 - a_2) = \text{CosineSim}(\vec{a}_1, \vec{a}_2) = \frac{\vec{a}_1 \cdot \vec{a}_2}{\|\vec{a}_1\| \|\vec{a}_2\|}$$

where  $\vec{a}_1$  and  $\vec{a}_2$  are co-occurrence vectors for  $a_1$  and  $a_2$  respectively. The co-occurrence vector for each word is computed using PMI scores with respect to the top  $n$  co-occurring words.<sup>8</sup>  $n$  (=50) is selected empirically. The edge weights in two sub-graphs are normalized so that they are in the comparable range.<sup>9</sup>

### Limitations of Graph-based Algorithms

Although graph-based algorithms (§2.1, §2.2) provide an intuitive framework to incorporate various lexical relations, limitations include:

1. They allow only *non-negative* edge weights. Therefore, we can encode only positive (supportive) relations among words (e.g., distributionally similar words will endorse each other with the same polarity), while missing on exploiting negative relations (e.g., antonyms may drive each other into the opposite polarity).
2. They induce positive and negative polarities in isolation via separate graphs. However, we expect that a more effective algorithm should induce both polarities simultaneously.
3. The framework does not readily allow incorporating a diverse set of *soft* and *hard* constraints.

<sup>8</sup>We discard edges with cosine similarity  $\leq 0$ , as those indicate either independence or the opposite of similarity.

<sup>9</sup>Note that cosine similarity does not make sense for the first sub-graph as there is no reason why a predicate and an argument should be distributionally similar. We experimented with many different variations on the graph structure and edge weights, including ones that include any word pairs that occurred frequently enough together. For brevity, we present the version that achieved the best results here.

### 2.3 Constraint Optimization

Addressing limitations of graph-based algorithms (§2.2), we propose an induction algorithm based on Integer Linear Programming (ILP). Figure 2 provides the pictorial overview. In comparison to Figure 1, two new components are: (1) dictionary-driven relations targeting enhanced *precision*, and (2) dictionary-driven words (i.e., unseen words with respect to those relations explored in Figure 1) targeting enhanced *coverage*. We formulate insights in Figure 2 using ILP as follows:

#### Definition of sets of words:

1.  $\mathcal{P}^+$ : the set of positive seed predicates.  
 $\mathcal{P}^-$ : the set of negative seed predicates.
2.  $\mathcal{S}$ : the set of seed sentiment words.
3.  $\mathcal{R}^{syn}$ : word pairs in synonyms relation.  
 $\mathcal{R}^{ant}$ : word pairs in antonyms relation.  
 $\mathcal{R}^{coord}$ : word pairs in coordination relation.  
 $\mathcal{R}^{pred}$ : word pairs in pred-arg relation.  
 $\mathcal{R}^{pred^{+(-)}}$ :  $\mathcal{R}^{pred}$  based on  $\mathcal{P}^+$  ( $\mathcal{P}^-$ ).

**Definition of variables:** For each word  $i$ , we define binary variables  $x_i, y_i, z_i \in \{0, 1\}$ , where  $x_i = 1$  ( $y_i = 1, z_i = 1$ ) if and only if  $i$  has a positive (negative, neutral) connotation respectively. For every pair of word  $i$  and  $j$ , we define binary variables  $d_{ij}^{pq}$  where  $p, q \in \{+, -, 0\}$  and  $d_{ij}^{pq} = 1$  if and only if the polarity of  $i$  and  $j$  are  $p$  and  $q$  respectively.

**Objective function:** We aim to maximize:

$$F = \Phi^{prosody} + \Phi^{coord} + \Phi^{neu}$$

where  $\Phi^{prosody}$  is the scores based on semantic prosody,  $\Phi^{coord}$  captures the distributional similarity over coordination, and  $\Phi^{neu}$  controls the sensitivity of connotation detection between positive (negative) and neutral. In particular,

$$\begin{aligned} \Phi^{prosody} &= \sum_{i,j}^{\mathcal{R}^{pred}} w_{i,j}^{pred} (d_{i,j}^{++} + d_{i,j}^{--} - d_{i,j}^{+-} - d_{i,j}^{-+}) \\ \Phi^{coord} &= \sum_{i,j}^{\mathcal{R}^{coord}} w_{i,j}^{coord} (d_{i,j}^{++} + d_{i,j}^{--} + d_{i,j}^{00}) \end{aligned}$$

$$\Phi^{neu} = \alpha \sum_{i,j}^{\mathcal{R}^{pred}} w_{i,j}^{pred} \cdot z_j$$

**Soft constraints (edge weights):** The weights in the objective function are set as follows:

$$w^{pred}(p, a) = \frac{freq(p, a)}{\sum_{(p,x) \in \mathcal{R}^{pred}} freq(p, x)}$$

$$w^{coord}(a_1, a_2) = CosSim(\vec{a}_1, \vec{a}_2) = \frac{\vec{a}_1 \cdot \vec{a}_2}{\|\vec{a}_1\| \|\vec{a}_2\|}$$

Note that the same  $w^{coord}(a_1, a_2)$  has been used in graph propagation described in Section 2.2.  $\alpha$  controls the sensitivity of connotation detection such that higher value of  $\alpha$  will promote neutral connotation over polar ones.

**Hard constrains for variable consistency:**

1. Each word  $i$  has one of  $\{+, -, \emptyset\}$  as polarity:  
 $\forall i, x_i + y_i + z_i = 1$
2. Variable consistency between  $d_{ij}^{pq}$  and  $x_i, y_i, z_i$ :

$$x_i + x_j - 1 \leq 2d_{i,j}^{++} \leq x_i + x_j$$

$$y_i + y_j - 1 \leq 2d_{i,j}^{--} \leq y_i + y_j$$

$$z_i + z_j - 1 \leq 2d_{i,j}^{00} \leq z_i + z_j$$

$$x_i + y_j - 1 \leq 2d_{i,j}^{+-} \leq x_i + y_j$$

$$y_i + x_j - 1 \leq 2d_{i,j}^{-+} \leq y_i + x_j$$

**Hard constrains for WordNet relations:**

1.  $\mathcal{C}^{ant}$ : Antonym pairs will not have the same positive or negative polarity:

$$\forall (i, j) \in \mathcal{R}^{ant}, x_i + x_j \leq 1, y_i + y_j \leq 1$$

For this constraint, we only consider antonym pairs that share the same root, e.g., “sufficient” and “insufficient”, as those pairs are more likely to have the opposite polarities than pairs without sharing the same root, e.g., “east” and “west”.

2.  $\mathcal{C}^{syn}$ : Synonym pairs will not have the opposite polarity:

$$\forall (i, j) \in \mathcal{R}^{syn}, x_i + y_j \leq 1, x_j + y_i \leq 1$$

### 3 Experimental Result I

We provide comprehensive comparisons over variants of three types of algorithms proposed in §2. We use the Google Web 1T data (Brants and Franz (2006)), and POS-tagged ngrams using Stanford POS Tagger (Toutanova and Manning (2000)). We filter out the ngrams with punctuations and other special characters to reduce the noise.

### 3.1 Comparison against Conventional Sentiment Lexicon

Note that we consider the connotation lexicon to be inclusive of a sentiment lexicon for two practical reasons: first, it is highly unlikely that any word with non-neutral sentiment (i.e., positive or negative) would carry connotation of the opposite, i.e., conflicting<sup>10</sup> polarity. Second, for some words with distinct sentiment or strong connotation, it can be difficult or even unnatural to draw a precise distinction between connotation and sentiment, e.g., “efficient”. Therefore, sentiment lexicons can serve as a surrogate to measure a subset of connotation words induced by the algorithms, as shown in Table 3 with respect to General Inquirer (Stone and Hunt (1963)) and MPQA (Wilson et al. (2005b)).<sup>11</sup>

**Discussion** Table 3 shows the agreement statistics with respect to two conventional sentiment lexicons. We find that the use of label propagation alone [PRED-ARG (CP)] improves the performance substantially over the comparable graph construction with different graph analysis algorithms, in particular, HITS and PageRank approaches of Feng et al. (2011). The two completely connected variants of the graph propagation on the Pred-Arg graph, [ $\otimes$  PRED-ARG (PMI)] and [ $\otimes$  PRED-ARG (CP)], do not necessarily improve the performance over the simpler and computationally lighter alternative, [PRED-ARG (CP)]. The [OVERLAY], which is based on both Pred-Arg and Arg-Arg subgraphs (§2.2), achieves the best performance among graph-based algorithms, significantly improving the precision over all other baselines. This result suggests:

- 1 The sub-graph #2, based on the semantic parallelism of coordination, is simple and yet very powerful as an inductive bias.
- 2 The performance of graph propagation varies significantly depending on the graph topology and the corresponding edge weights.

Note that a direct comparison against ILP for top N words is tricky, as ILP does not *rank* results. Only for comparison purposes however, we assign

<sup>10</sup>We consider “positive” and “negative” polarities conflict, but “neutral” polarity does *not* conflict with any.

<sup>11</sup>In the case of General Inquirer, we use words in POSITIV and NEGATIV sets as words with positive and negative labels respectively.

	GENINQ EVAL					MPQA EVAL

Table 3: Evaluation of Induction Algorithms (§2) with respect to Sentiment Lexicons (precision%).

ranks based on the frequency of words for ILP. Because of this issue, the performance of top  $\sim 1k$  words of ILP should be considered only as a conservative measure. Importantly, when evaluated over more than top 5k words, ILP is overall the top performer considering both precision (shown in Table 3) and coverage (omitted for brevity).<sup>12</sup>

#### 4 Precision, Coverage, and Efficiency

In this section, we address three important aspects of an ideal induction algorithm: *precision*, *coverage*, and *efficiency*. For brevity, the remainder of the paper will focus on the algorithms based on constraint optimization, as it turned out to be the most effective one from the empirical results in §3.

**Precision** In order to see the effectiveness of the induction algorithms more sharply, we had used a limited set of seed words in §3. However to build a lexicon with substantially enhanced precision, we will use as a large seed set as possible, e.g., entire sentiment lexicons<sup>13</sup>.

**Broad coverage** Although statistics in Google 1T corpus represent a very large amount of text, words that appear in pred-arg and coordination relations are still limited. To substantially increase the coverage, we will leverage dictionary words (that are not in the corpus) as described in §2.3 and Figure 2.

**Efficiency** One practical problem with ILP is efficiency and scalability. In particular, we found that it becomes nearly impractical to run the ILP formulation including all words in WordNet plus all words in the argument position in Google Web 1T. We therefore explore an alternative approach based on Linear Programming in what follows.

<sup>12</sup>In fact, the performance of PRED-ARG variants for top 10K w.r.t. GENINQ is not meaningful as no additional word was matched beyond top 5k words.

<sup>13</sup>Note that doing so will prevent us from evaluating against the same sentiment lexicon used as a seed set.

#### 4.1 Induction using Linear Programming

One straightforward option for Linear Programming formulation may seem like using the same Integer Linear Programming formulation introduced in §2.3, only changing the variable definitions to be real values  $\in [0, 1]$  rather than integers. However, because the hard constraints in §2.3 are defined based on the assumption that all the variables are binary integers, those constraints are not as meaningful when considered for real numbers. Therefore we revise those hard constraints to encode various semantic relations (WordNet and semantic coordination) more directly.

**Definition of variables:** For each word  $i$ , we define variables  $x_i, y_i, z_i \in [0, 1]$ .  $i$  has a positive (negative) connotation if and only if the  $x_i$  ( $y_i$ ) is assigned the greatest value among the three variables; otherwise,  $i$  is neutral.

**Objective function:** We aim to maximize:

$$\begin{aligned}
 F &= \Phi^{prosody} + \Phi^{coord} + \Phi^{syn} + \Phi^{ant} + \Phi^{neu} \\
 \Phi^{prosody} &= \sum_{i,j}^{\mathcal{R}^{pred^+}} w_{i,j}^{pred^+} \cdot x_j + \sum_{i,j}^{\mathcal{R}^{pred^-}} w_{i,j}^{pred^-} \cdot y_j \\
 \Phi^{coord} &= \sum_{i,j}^{\mathcal{R}^{coord}} w_{i,j}^{coord} \cdot (dc_{i,j}^{++} + dc_{i,j}^{--}) \\
 \Phi^{syn} &= W^{syn} \sum_{i,j}^{\mathcal{R}^{syn}} (ds_{i,j}^{++} + ds_{i,j}^{--}) \\
 \Phi^{ant} &= W^{ant} \sum_{i,j}^{\mathcal{R}^{ant}} (da_{i,j}^{++} + da_{i,j}^{--}) \\
 \Phi^{neu} &= \alpha \sum_{i,j}^{\mathcal{R}^{pred}} w_{i,j}^{pred} \cdot z_j
 \end{aligned}$$

**Hard constraints** We add penalties to the objective function if the polarity of a pair of words is not consistent with its corresponding semantic relations. For example, for synonyms  $i$  and  $j$ , we introduce a penalty  $W^{syn}$  (a positive constant) for  $ds_{i,j}^{++}, ds_{i,j}^{--} \in [-1, 0]$ , where we set the upper bound of  $ds_{i,j}^{++}$  ( $ds_{i,j}^{--}$ ) as the signed distance of

	FORMULA	POSITIVE			NEGATIVE			ALL		
		R	P	F	R	P	F	R	P	F
ILP	$\Phi^{prosody} + \mathcal{C}^{syn} + \mathcal{C}^{ant}$	51.4	85.7	64.3	44.7	87.9	59.3	48.0	86.8	61.8

	$\Phi^{prosody} + \Phi^{coord} + \Phi^{syn} + \Phi^{ant} + \Phi^S$	<b>78.6</b>	90.5	<b>84.1</b>	<b>73.3</b>	87.1	<b>79.6</b>	<b>75.9</b>	88.8	<b>81.8</b>

Table 4: ILP/LP Comparison on MQPA' (%).

$x_i$  and  $x_j$  ( $y_i$  and  $y_j$ ) as shown below:

For  $(i, j) \in \mathcal{R}^{syn}$ ,

$$ds_{i,j}^{++} \leq x_i - x_j, \quad ds_{i,j}^{++} \leq x_j - x_i$$

$$ds_{i,j}^{--} \leq y_i - y_j, \quad ds_{i,j}^{--} \leq y_j - y_i$$

Notice that  $ds_{i,j}^{++}, ds_{i,j}^{--}$  satisfying above inequalities will be always of negative values, hence in order to maximize the objective function, the LP solver will try to minimize the absolute values of  $ds_{i,j}^{++}, ds_{i,j}^{--}$ , effectively pushing  $i$  and  $j$  toward the same polarity. Constraints for semantic coordination  $\mathcal{R}^{coord}$  can be defined similarly. Lastly, following constraints encode antonym relations:

For  $(i, j) \in \mathcal{R}^{ant}$ ,

$$da_{i,j}^{++} \leq x_i - (1 - x_j), \quad da_{i,j}^{++} \leq (1 - x_j) - x_i$$

$$da_{i,j}^{--} \leq y_i - (1 - y_j), \quad da_{i,j}^{--} \leq (1 - y_j) - y_i$$

**Interpretation** Unlike ILP, some of the variables result in fractional values. We consider a word has positive or negative polarity only if the assignment indicates 1 for the corresponding polarity and 0 for the rest. In other words, we treat all words with fractional assignments over different polarities as neutral. Because the optimal solutions of LP correspond to extreme points in the convex polytope formed by the constraints, we obtain a large portion of words with non-fractional assignments toward non-neutral polarities. Alternatively, one can round up fractional values.

## 4.2 Empirical Comparisons: ILP v.s. LP

To solve the ILP/LP, we run ILOG CPLEX Optimizer (CPLEX, 2009) on a 3.5GHz 6 core CPU machine with 96GB RAM. Efficiency-wise, LP runs within 10 minutes while ILP takes several hours. Table 4 shows the results evaluated against MPQA for different variations of ILP and LP. We find that LP variants much better recall and F-score, while maintaining comparable precision.

Therefore, we choose the connotation lexicon by LP (C-LP) in the following evaluations in §5.

## 5 Experimental Results II

In this section, we present comprehensive intrinsic §5.1 and extrinsic §5.2 evaluations comparing three representative lexicons from §2 & §4: C-LP, OVERLAY, PRED-ARG (CP), and two popular sentiment lexicons: SentiWordNet (Baccianella et al., 2010) and GI+MPQA.<sup>14</sup> Note that C-LP is the largest among all connotation lexicons, including  $\sim 70,000$  polar words.<sup>15</sup>

### 5.1 Intrinsic Evaluation: Human Judgements

We evaluate 4000 words<sup>16</sup> using Amazon Mechanical Turk (AMT). Because we expect that judging a connotation can be dependent on one's cultural background, personality and value systems, we gather judgements from 5 people for each word, from which we hope to draw a more general judgement of connotative polarity. About 300 unique Turkers participated the evaluation tasks. We gather gold standard only for those words for which more than half of the judges agreed on the same polarity. Otherwise we treat them as ambiguous cases.<sup>17</sup> Figure 3 shows a part of the AMT task, where Turkers are presented with questions that help judges to determine the subtle connotative polarity of each word, then asked to rate the degree of connotation on a scale from -5 (most negative) and 5 (most positive). To draw

<sup>14</sup>GI+MPQA is the union of General Inquirer and MPQA. The GI, we use words in the "Positiv" & "Negativ" set. For SentiWordNet, to retrieve the polarity of a given word, we sum over the polarity scores over all senses, where positive (negative) values correspond to positive (negative) polarity.

<sup>15</sup> $\sim 13k$  adj,  $\sim 6k$  verbs,  $\sim 28k$  nouns,  $\sim 22k$  proper nouns.

<sup>16</sup>We choose words that are not already in GI+MPQA and obtain most frequent 10,000 words based on the unigram frequency in Google-Ngram, then randomly select 4000 words.

<sup>17</sup>We allow Turkers to mark words that can be used with both positive and negative connotation, which results in about 7% of words that are excluded from the gold standard set.

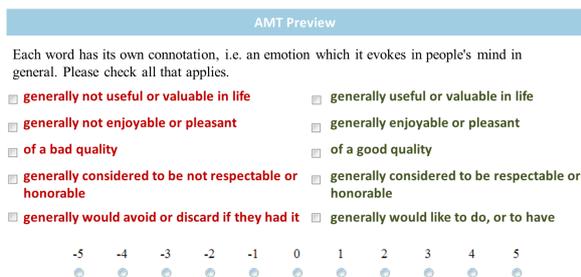

Figure 3: A Part of AMT Task Design.

QUESTION	YES		NO	
	%	Avg	%	Avg
“Enjoyable or pleasant”	43.3	2.9	16.3	-2.4
“Of a good quality”	56.7	2.5	6.1	-2.7
“Respectable / honourable”	21.0	3.3	14.0	-1.1
“Would like to do or have”	52.5	2.8	11.5	-2.4

Table 5: Distribution of Answers from AMT.

the gold standard, we consider two different voting schemes:

- $\Omega^{Vote}$ : The judgement of each Turker is mapped to neutral for  $-1 \leq \text{score} \leq 1$ , positive for  $\text{score} \geq 2$ , negative for  $\text{score} \leq -2$ , then we take the majority vote.
- $\Omega^{Score}$ : Let  $\sigma(i)$  be the sum (weighted vote) of the scores given by 5 judges for word  $i$ . Then we determine the polarity label  $l(i)$  of  $i$  as:

$$l(i) = \begin{cases} \text{positive} & \text{if } \sigma(i) > 1 \\ \text{negative} & \text{if } \sigma(i) < -1 \\ \text{neutral} & \text{if } -1 \leq \sigma(i) \leq 1 \end{cases}$$

The resulting distribution of judgements is shown in Table 5 & 6. Interestingly, we observe that *among the relatively frequently used English words, there are overwhelmingly more positively connotative words than negative ones.*

In Table 7, we show the percentage of words with the same label over the mutual words by the two lexicon. The highest agreement is 77% by C-LP and the gold standard by  $\text{AMT}^{Vote}$ . How good is this? It depends on what is the natural degree of agreement over subtle connotation among people. Therefore, we also report the degree of agreement among human judges in Table 7, where we compute the agreement of one Turker with respect to the gold standard drawn from the rest of the Turkers, and take the average across over all five Turkers<sup>18</sup>. Interestingly, the performance of

<sup>18</sup>In order to draw the gold standard from the 4 remaining Turkers, we consider adjusted versions of  $\Omega^{Vote}$  and  $\Omega^{Score}$  schemes described above.

	POS	NEG	NEU	UNDETERMINED
$\Omega^{Vote}$	50.4	14.6	24.1	10.9
$\Omega^{Score}$	67.9	20.6	11.5	n/a

Table 6: Distribution of Connotative Polarity from AMT.

	C-LP	SENTIWN	HUMAN JUDGES
$\Omega^{Vote}$	77.0	71.5	66.0
$\Omega^{Score}$	73.0	69.0	69.0

Table 7: Agreement (Accuracy) against AMT-driven Gold Standard.

Turkers is not as good as that of C-LP lexicon. We conjecture that this could be due to generally varying perception of different people on the connotative polarity,<sup>19</sup> while the corpus-driven induction algorithms focus on the *general* connotative polarity corresponding to the most prevalent senses of words in the corpus.

## 5.2 Extrinsic Evaluation

We conduct lexicon-based binary sentiment classification on the following two corpora.

**SemEval** From the SemEval task, we obtain a set of news headlines with annotated scores (ranging from -100 to 87). The positive/negative scores indicate the degree of positive/negative polarity orientation. We construct several sets of the positive and negative texts by setting thresholds on the scores as shown in Table 8. “ $\leq n$ ” indicates that the positive set consists of the texts with scores  $\geq n$  and the negative set consists of the texts with scores  $\leq -n$ .

**Emoticon tweets** The sentiment Twitter data<sup>20</sup> consists of tweets containing either a smiley emoticon (positive sentiment) or a frowny emoticon (negative sentiment). We filter out the tweets with question marks or more than 30 words, and keep the ones with at least two words in the union of all polar words in the five lexicons in Table 8, and then randomly select 10000 per class.

We denote the short text (e.g., content of tweets or headline texts from SemEval) by  $t$ .  $w$  represents the word in  $t$ .  $W^+/W^-$  is the set of posi-

<sup>19</sup>Pearson correlation coefficient among turkers is 0.28, which corresponds to a positive small to medium correlation. Note that when the annotation of turkers is aggregated, we observe agreement as high as 77% with respect to the learned connotation lexicon.

<sup>20</sup><http://www.stanford.edu/~alecmgo/cs224n/twitterdata.2009.05.25.c.zip>

LEXICON	DATA				
	TWEET	SEMEVAL			
		≤20	≤40	≤60	≤80
C-LP	<b>70.1</b>	<b>70.8</b>	<b>74.6</b>	<b>80.8</b>	<b>93.5</b>
OVERLAY	68.5	70.0	72.9	76.8	89.6
PRED-ARG (CP)	60.5	64.2	69.3	70.3	79.2
SENTIWN	67.4	61.0	64.5	70.5	79.0
GI+MPQA	65.0	64.5	69.0	74.0	80.5

Table 8: Accuracy on Sentiment Classification (%).

tive/negative words of the lexicon. We define the weight of  $w$  as  $s(w)$ . If  $w$  is adjective,  $s(w) = 2$ ; otherwise  $s(w) = 1$ . Then the polarity of each text is determined as follows:

$$pol(t) = \begin{cases} positive & \text{if } \sum_{w \in t}^{W^+} s(w) \geq \sum_{w \in t}^{W^-} s(w) \\ negative & \text{if } \sum_{w \in t}^{W^+} s(w) < \sum_{w \in t}^{W^-} s(w) \end{cases}$$

As shown in Table 8, C-LP generally performs better than the other lexicons on both corpora. Considering that only very simple classification strategy is applied, the result by the connotation lexicon is quite promising.

Finally, Table 1 highlights interesting examples of proper nouns with connotative polarity, e.g., “Mandela”, “Google”, “Hawaii” with positive connotation, and “Monsanto”, “Halliburton”, “Enron” with negative connotation, suggesting that our algorithms could potentially serve as a proxy to track the general connotation of real world entities. Table 2 shows example common nouns with connotative polarity.

### 5.3 Practical Remarks on WSD and MWEs

In this work we aim to find the polarity of most prevalent senses of each word, in part because it is not easy to perform unsupervised word sense disambiguation (WSD) on a large corpus in a reliable way, especially when the corpus consists primarily of short  $n$ -grams. Although the resulting lexicon loses on some of the polysemous words with potentially opposite polarities, per-word connotation (rather than per-sense connotation) does have a practical value: it provides a convenient option for users who wish to avoid the burden of WSD before utilizing the lexicon. Future work includes handling of WSD and multi-word expressions (MWEs), e.g., “Great Leader” (for Kim Jong-Il), “Inglourious Basterds” (a movie title).<sup>21</sup>

<sup>21</sup>These examples credit to an anonymous reviewer.

## 6 Related Work

A very interesting work of Mohammad and Turney (2010) uses Mechanical Turk in order to build the lexicon of emotions evoked by words. In contrast, we present an automatic approach that infers the general connotation of words. Velikovich et al. (2010) use graph propagation algorithms for constructing a web-scale polarity lexicon for sentiment analysis. Although we employ the same graph propagation algorithm, our graph construction is fundamentally different in that we integrate stronger inductive biases into the graph topology and the corresponding edge weights. As shown in our experimental results, we find that judicious construction of graph structure, exploiting multiple complementing linguistic phenomena can enhance both the performance and the efficiency of the algorithm substantially. Other interesting approaches include one based on min-cut (Dong et al., 2012) or LDA (Xie and Li, 2012). Our proposed approaches are more suitable for encoding a much diverse set of linguistic phenomena however. But our work use a few seed predicates with selectional preference instead of relying on word similarity. Some recent work explored the use of constraint optimization framework for inducing domain-dependent sentiment lexicon (Choi and Cardie (2009), Lu et al. (2011)). Our work differs in that we provide comprehensive insights into different formulations of ILP and LP, aiming to learn the much different task of learning the general connotation of words.

## 7 Conclusion

We presented a broad-coverage connotation lexicon that determines the subtle nuanced sentiment of even those words that are objective on the surface, including the general connotation of real-world named entities. Via a comprehensive evaluation, we provided empirical insights into three different types of induction algorithms, and proposed one with good precision, coverage, and efficiency.

## Acknowledgments

This research was supported in part by the Stony Brook University Office of the Vice President for Research. We thank reviewers for many insightful comments and suggestions, and for providing us with several very inspiring examples to work with.
