## Abstract

Natural language parsing has typically been done with small sets of discrete categories such as NP and VP, but this representation does not capture the full syntactic nor semantic richness of linguistic phrases, and attempts to improve on this by lexicalizing phrases or splitting categories only partly address the problem at the cost of huge feature spaces and sparseness. Instead, we introduce a Compositional Vector Grammar (CVG), which combines PCFGs with a syntactically untied recursive neural network that learns syntactico-semantic, compositional vector representations. The CVG improves the PCFG of the Stanford Parser by 3.8% to obtain an F1 score of 90.4%. It is fast to train and implemented approximately as an efficient reranker it is about 20% faster than the current Stanford factored parser. The CVG learns a soft notion of head words and improves performance on the types of ambiguities that require semantic information such as PP attachments.

## 1 Introduction

Syntactic parsing is a central task in natural language processing because of its importance in mediating between linguistic expression and meaning. For example, much work has shown the usefulness of syntactic representations for subsequent tasks such as relation extraction, semantic role labeling (Gildea and Palmer, 2002) and paraphrase detection (Callison-Burch, 2008).

Syntactic descriptions standardly use coarse discrete categories such as NP for noun phrases or PP for prepositional phrases. However, recent work has shown that parsing results can be greatly improved by defining more fine-grained syntactic

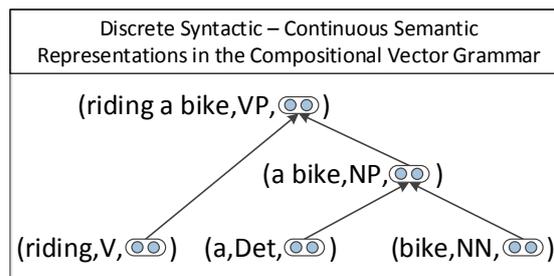

Figure 1: Example of a CVG tree with (category,vector) representations at each node. The vectors for nonterminals are computed via a new type of recursive neural network which is conditioned on syntactic categories from a PCFG.

categories, which better capture phrases with similar behavior, whether through manual feature engineering (Klein and Manning, 2003a) or automatic learning (Petrov et al., 2006). However, subdividing a category like NP into 30 or 60 subcategories can only provide a very limited representation of phrase meaning and semantic similarity. Two strands of work therefore attempt to go further. First, recent work in discriminative parsing has shown gains from careful engineering of features (Taskar et al., 2004; Finkel et al., 2008). Features in such parsers can be seen as defining effective dimensions of similarity between categories. Second, lexicalized parsers (Collins, 2003; Charniak, 2000) associate each category with a lexical item. This gives a fine-grained notion of semantic similarity, which is useful for tackling problems like ambiguous attachment decisions. However, this approach necessitates complex shrinkage estimation schemes to deal with the sparsity of observations of the lexicalized categories.

In many natural language systems, single words and  $n$ -grams are usefully described by their distributional similarities (Brown et al., 1992), among many others. But, even with large corpora, many

$n$ -grams will never be seen during training, especially when  $n$  is large. In these cases, one cannot simply use distributional similarities to represent unseen phrases. In this work, we present a new solution to learn features and phrase representations even for very long, unseen  $n$ -grams.

We introduce a Compositional Vector Grammar Parser (CVG) for structure prediction. Like the above work on parsing, the model addresses the problem of representing phrases and categories. Unlike them, it jointly learns how to parse and how to represent phrases as both discrete categories and continuous vectors as illustrated in Fig. 1. CVGs combine the advantages of standard probabilistic context free grammars (PCFG) with those of recursive neural networks (RNNs). The former can capture the discrete categorization of phrases into NP or PP while the latter can capture fine-grained syntactic and compositional-semantic information on phrases and words. This information can help in cases where syntactic ambiguity can only be resolved with semantic information, such as in the PP attachment of the two sentences: *They ate udon with forks.* vs. *They ate udon with chicken.*

Previous RNN-based parsers used the same (tied) weights at all nodes to compute the vector representing a constituent (Socher et al., 2011b). This requires the composition function to be extremely powerful, since it has to combine phrases with different syntactic head words, and it is hard to optimize since the parameters form a very deep neural network. We generalize the fully tied RNN to one with syntactically untied weights. The weights at each node are conditionally dependent on the categories of the child constituents. This allows different composition functions when combining different types of phrases and is shown to result in a large improvement in parsing accuracy.

Our compositional distributed representation allows a CVG parser to make accurate parsing decisions and capture similarities between phrases and sentences. Any PCFG-based parser can be improved with an RNN. We use a simplified version of the Stanford Parser (Klein and Manning, 2003a) as the base PCFG and improve its accuracy from 86.56 to 90.44% labeled F1 on all sentences of the WSJ section 23. The code of our parser is available at [nlp.stanford.edu](http://nlp.stanford.edu).

## 2 Related Work

The CVG is inspired by two lines of research: Enriching PCFG parsers through more diverse

sets of discrete states and recursive deep learning models that jointly learn classifiers and continuous feature representations for variable-sized inputs.

### Improving Discrete Syntactic Representations

As mentioned in the introduction, there are several approaches to improving discrete representations for parsing. Klein and Manning (2003a) use manual feature engineering, while Petrov et al. (2006) use a learning algorithm that splits and merges the syntactic categories in order to maximize likelihood on the treebank. Their approach splits categories into several dozen subcategories. Another approach is lexicalized parsers (Collins, 2003; Charniak, 2000) that describe each category with a lexical item, usually the head word. More recently, Hall and Klein (2012) combine several such annotation schemes in a factored parser. We extend the above ideas from discrete representations to richer continuous ones. The CVG can be seen as factoring discrete and continuous parsing in one model. Another different approach to the above generative models is to learn discriminative parsers using many well designed features (Taskar et al., 2004; Finkel et al., 2008). We also borrow ideas from this line of research in that our parser combines the generative PCFG model with discriminatively learned RNNs.

### Deep Learning and Recursive Deep Learning

Early attempts at using neural networks to describe phrases include Elman (1991), who used recurrent neural networks to create representations of sentences from a simple toy grammar and to analyze the linguistic expressiveness of the resulting representations. Words were represented as one-on vectors, which was feasible since the grammar only included a handful of words. Collobert and Weston (2008) showed that neural networks can perform well on sequence labeling language processing tasks while also learning appropriate features. However, their model is lacking in that it cannot represent the recursive structure inherent in natural language. They partially circumvent this problem by using either independent window-based classifiers or a convolutional layer. RNN-specific training was introduced by Goller and Küchler (1996) to learn distributed representations of given, structured objects such as logical terms. In contrast, our model both predicts the structure and its representation.

Henderson (2003) was the first to show that neural networks can be successfully used for large scale parsing. He introduced a left-corner parser to estimate the probabilities of parsing decisions conditioned on the parsing history. The input to Henderson’s model consists of pairs of frequent words and their part-of-speech (POS) tags. Both the original parsing system and its probabilistic interpretation (Titov and Henderson, 2007) learn features that represent the *parsing history* and do not provide a principled linguistic representation like our phrase representations. Other related work includes (Henderson, 2004), who discriminatively trains a parser based on synchrony networks and (Titov and Henderson, 2006), who use an SVM to adapt a generative parser to different domains.

Costa et al. (2003) apply recursive neural networks to re-rank possible phrase attachments in an incremental parser. Their work is the first to show that RNNs can capture enough information to make correct parsing decisions, but they only test on a subset of 2000 sentences. Menchetti et al. (2005) use RNNs to re-rank different parses. For their results on full sentence parsing, they re-rank candidate trees created by the Collins parser (Collins, 2003). Similar to their work, we use the idea of letting discrete categories reduce the search space during inference. We compare to fully tied RNNs in which the same weights are used at every node. Our syntactically untied RNNs outperform them by a significant margin. The idea of untying has also been successfully used in deep learning applied to vision (Le et al., 2010).

This paper uses several ideas of (Socher et al., 2011b). The main differences are (i) the dual representation of nodes as discrete categories and vectors, (ii) the combination with a PCFG, and (iii) the syntactic untying of weights based on child categories. We directly compare models with fully tied and untied weights. Another work that represents phrases with a dual discrete-continuous representation is (Kartsaklis et al., 2012).

### 3 Compositional Vector Grammars

This section introduces Compositional Vector Grammars (CVGs), a model to jointly find syntactic structure and capture compositional semantic information.

CVGs build on two observations. Firstly, that a lot of the structure and regularity in languages can be captured by well-designed syntactic patterns.

Hence, the CVG builds on top of a standard PCFG parser. However, many parsing decisions show fine-grained semantic factors at work. Therefore we combine syntactic and semantic information by giving the parser access to rich syntactico-semantic information in the form of distributional word vectors and compute compositional semantic vector representations for longer phrases (Costa et al., 2003; Menchetti et al., 2005; Socher et al., 2011b). The CVG model merges ideas from both generative models that assume discrete syntactic categories and discriminative models that are trained using continuous vectors.

We will first briefly introduce single word vector representations and then describe the CVG objective function, tree scoring and inference.

#### 3.1 Word Vector Representations

In most systems that use a vector representation for words, such vectors are based on co-occurrence statistics of each word and its context (Turney and Pantel, 2010). Another line of research to learn distributional word vectors is based on neural language models (Bengio et al., 2003) which jointly learn an embedding of words into an  $n$ -dimensional feature space and use these embeddings to predict how suitable a word is in its context. These vector representations capture interesting linear relationships (up to some accuracy), such as  $king - man + woman \approx queen$  (Mikolov et al., 2013).

Collobert and Weston (2008) introduced a new model to compute such an embedding. The idea is to construct a neural network that outputs high scores for windows that occur in a large unlabeled corpus and low scores for windows where one word is replaced by a random word. When such a network is optimized via gradient ascent the derivatives backpropagate into the word embedding matrix  $X$ . In order to predict correct scores the vectors in the matrix capture co-occurrence statistics.

For further details and evaluations of these embeddings, see (Turian et al., 2010; Huang et al., 2012). The resulting  $X$  matrix is used as follows. Assume we are given a sentence as an ordered list of  $m$  words. Each word  $w$  has an index  $[w] = i$  into the columns of the embedding matrix. This index is used to retrieve the word’s vector representation  $a_w$  using a simple multiplication with a binary vector  $e$ , which is zero everywhere, except

at the  $i$ th index. So  $a_w = Le_i \in \mathbb{R}^n$ . Henceforth, after mapping each word to its vector, we represent a sentence  $S$  as an ordered list of (word,vector) pairs:  $x = ((w_1, a_{w_1}), \dots, (w_m, a_{w_m}))$ .

Now that we have discrete and continuous representations for all words, we can continue with the approach for computing tree structures and vectors for nonterminal nodes.

### 3.2 Max-Margin Training Objective for CVGs

The goal of supervised parsing is to learn a function  $g : \mathcal{X} \rightarrow \mathcal{Y}$ , where  $\mathcal{X}$  is the set of sentences and  $\mathcal{Y}$  is the set of all possible labeled binary parse trees. The set of all possible trees for a given sentence  $x_i$  is defined as  $Y(x_i)$  and the correct tree for a sentence is  $y_i$ .

We first define a structured margin loss  $\Delta(y_i, \hat{y})$  for predicting a tree  $\hat{y}$  for a given correct tree. The loss increases the more incorrect the proposed parse tree is (Goodman, 1998). The discrepancy between trees is measured by counting the number of nodes  $N(y)$  with an incorrect span (or label) in the proposed tree:

$$\Delta(y_i, \hat{y}) = \sum_{d \in N(\hat{y})} \kappa \mathbf{1}\{d \notin N(y_i)\}. \quad (1)$$

We set  $\kappa = 0.1$  in all experiments. For a given set of training instances  $(x_i, y_i)$ , we search for the function  $g_\theta$ , parameterized by  $\theta$ , with the smallest expected loss on a new sentence. It has the following form:

$$g_\theta(x) = \arg \max_{\hat{y} \in Y(x)} s(\text{CVG}(\theta, x, \hat{y})), \quad (2)$$

where the tree is found by the Compositional Vector Grammar (CVG) introduced below and then scored via the function  $s$ . The higher the score of a tree the more confident the algorithm is that its structure is correct. This max-margin, structure-prediction objective (Taskar et al., 2004; Ratliff et al., 2007; Socher et al., 2011b) trains the CVG so that the highest scoring tree will be the correct tree:  $g_\theta(x_i) = y_i$  and its score will be larger up to a margin to other possible trees  $\hat{y} \in \mathcal{Y}(x_i)$ :

$$s(\text{CVG}(\theta, x_i, y_i)) \geq s(\text{CVG}(\theta, x_i, \hat{y})) + \Delta(y_i, \hat{y}).$$

This leads to the regularized risk function for  $m$

training examples:

$$J(\theta) = \frac{1}{m} \sum_{i=1}^m r_i(\theta) + \frac{\lambda}{2} \|\theta\|_2^2, \text{ where}$$

$$r_i(\theta) = \max_{\hat{y} \in Y(x_i)} (s(\text{CVG}(x_i, \hat{y})) + \Delta(y_i, \hat{y})) - s(\text{CVG}(x_i, y_i)) \quad (3)$$

Intuitively, to minimize this objective, the score of the correct tree  $y_i$  is increased and the score of the highest scoring incorrect tree  $\hat{y}$  is decreased.

### 3.3 Scoring Trees with CVGs

For ease of exposition, we first describe how to score an existing fully labeled tree with a standard RNN and then with a CVG. The subsequent section will then describe a bottom-up beam search and its approximation for finding the optimal tree.

Assume, for now, we are given a labeled parse tree as shown in Fig. 2. We define the word representations as (vector, POS) pairs:  $((a, A), (b, B), (c, C))$ , where the vectors are defined as in Sec. 3.1 and the POS tags come from a PCFG. The standard RNN essentially ignores all POS tags and syntactic categories and each non-terminal node is associated with the same neural network (i.e., the weights across nodes are fully tied). We can represent the binary tree in Fig. 2 in the form of branching triplets  $(p \rightarrow c_1 c_2)$ . Each such triplet denotes that a parent node  $p$  has two children and each  $c_k$  can be either a word vector or a non-terminal node in the tree. For the example in Fig. 2, we would get the triples  $((p^1 \rightarrow bc), (p^2 \rightarrow ap^1))$ . Note that in order to replicate the neural network and compute node representations in a bottom up fashion, the parent must have the same dimensionality as the children:  $p \in \mathbb{R}^n$ .

Given this tree structure, we can now compute activations for each node from the bottom up. We begin by computing the activation for  $p^1$  using the children's word vectors. We first concatenate the children's representations  $b, c \in \mathbb{R}^{n \times 1}$  into a vector  $\begin{bmatrix} b \\ c \end{bmatrix} \in \mathbb{R}^{2n \times 1}$ . Then the composition function multiplies this vector by the parameter weights of the RNN  $W \in \mathbb{R}^{n \times 2n}$  and applies an element-wise nonlinearity function  $f = \tanh$  to the output vector. The resulting output  $p^{(1)}$  is then given as input to compute  $p^{(2)}$ .

$$p^{(1)} = f \left( W \begin{bmatrix} b \\ c \end{bmatrix} \right), p^{(2)} = f \left( W \begin{bmatrix} a \\ p^{(1)} \end{bmatrix} \right)$$

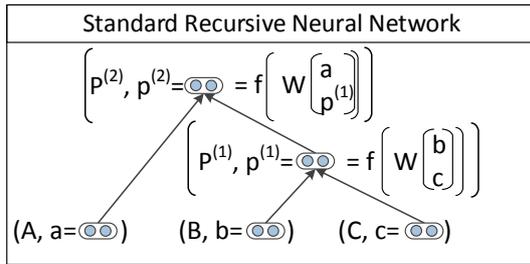

Figure 2: An example tree with a simple Recursive Neural Network: The same weight matrix is replicated and used to compute all non-terminal node representations. Leaf nodes are  $n$ -dimensional vector representations of words.

In order to compute a score of how plausible of a syntactic constituent a parent is the RNN uses a single-unit linear layer for all  $i$ :

$$s(p^{(i)}) = v^T p^{(i)},$$

where  $v \in \mathbb{R}^n$  is a vector of parameters that need to be trained. This score will be used to find the highest scoring tree. For more details on how standard RNNs can be used for parsing, see Socher et al. (2011b).

The standard RNN requires a single composition function to capture all types of compositions: adjectives and nouns, verbs and nouns, adverbs and adjectives, etc. Even though this function is a powerful one, we find a single neural network weight matrix cannot fully capture the richness of compositionality. Several extensions are possible: A two-layered RNN would provide more expressive power, however, it is much harder to train because the resulting neural network becomes very deep and suffers from vanishing gradient problems. Socher et al. (2012) proposed to give every single word a matrix and a vector. The matrix is then applied to the sibling node’s vector during the composition. While this results in a powerful composition function that essentially depends on the words being combined, the number of model parameters explodes and the composition functions do not capture the syntactic commonalities between similar POS tags or syntactic categories.

Based on the above considerations, we propose the Compositional Vector Grammar (CVG) that conditions the composition function at each node on discrete syntactic categories extracted from a

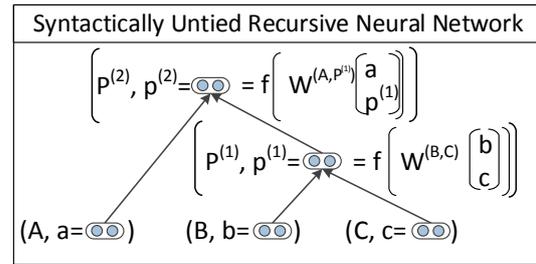

Figure 3: Example of a syntactically untied RNN in which the function to compute a parent vector depends on the syntactic categories of its children which we assume are given for now.

PCFG. Hence, CVGs combine discrete, syntactic rule probabilities and continuous vector compositions. The idea is that the syntactic categories of the children determine what composition function to use for computing the vector of their parents. While not perfect, a dedicated composition function for each rule RHS can well capture common composition processes such as adjective or adverb modification versus noun or clausal complementation. For instance, it could learn that an NP should be similar to its head noun and little influenced by a determiner, whereas in an adjective modification both words considerably determine the meaning of a phrase. The original RNN is parameterized by a single weight matrix  $W$ . In contrast, the CVG uses a syntactically untied RNN (SU-RNN) which has a set of such weights. The size of this set depends on the number of sibling category combinations in the PCFG.

Fig. 3 shows an example SU-RNN that computes parent vectors with syntactically untied weights. The CVG computes the first parent vector via the SU-RNN:

$$p^{(1)} = f \left( W^{(B,C)} \begin{bmatrix} b \\ c \end{bmatrix} \right),$$

where  $W^{(B,C)} \in \mathbb{R}^{n \times 2n}$  is now a matrix that depends on the categories of the two children. In this bottom up procedure, the score for each node consists of summing two elements: First, a single linear unit that scores the parent vector and second, the log probability of the PCFG for the rule that combines these two children:

$$s(p^{(1)}) = (v^{(B,C)})^T p^{(1)} + \log P(P_1 \rightarrow B C), \quad (4)$$

where  $P(P_1 \rightarrow B C)$  comes from the PCFG. This can be interpreted as the log probability of a discrete-continuous rule application with the following factorization:

$$\begin{aligned} P((P_1, p_1) \rightarrow (B, b)(C, c)) \\ = P(p_1 \rightarrow b \mid P_1 \rightarrow B C)P(P_1 \rightarrow B C), \end{aligned} \quad (5)$$

Note, however, that due to the continuous nature of the word vectors, the probability of such a CVG rule application is not comparable to probabilities provided by a PCFG since the latter sum to 1 for all children.

Assuming that node  $p_1$  has syntactic category  $P_1$ , we compute the second parent vector via:

$$p^{(2)} = f \left( W^{(A, P_1)} \begin{bmatrix} a \\ p^{(1)} \end{bmatrix} \right).$$

The score of the last parent in this trigram is computed via:

$$s(p^{(2)}) = (v^{(A, P_1)})^T p^{(2)} + \log P(P_2 \rightarrow A P_1).$$

### 3.4 Parsing with CVGs

The above scores (Eq. 4) are used in the search for the correct tree for a sentence. The goodness of a tree is measured in terms of its score and the CVG score of a complete tree is the sum of the scores at each node:

$$s(\text{CVG}(\theta, x, \hat{y})) = \sum_{d \in N(\hat{y})} s(p^d). \quad (6)$$

The main objective function in Eq. 3 includes a maximization over all possible trees  $\max_{\hat{y} \in Y(x)}$ . Finding the global maximum, however, cannot be done efficiently for longer sentences nor can we use dynamic programming. This is due to the fact that the vectors break the independence assumptions of the base PCFG. A (category, vector) node representation is dependent on all the words in its span and hence to find the true global optimum, we would have to compute the scores for all binary trees. For a sentence of length  $n$ , there are  $\text{Catalan}(n)$  many possible binary trees which is very large even for moderately long sentences.

One could use a bottom-up beam search, keeping a  $k$ -best list at every cell of the chart, possibly for each syntactic category. This beam search inference procedure is still considerably slower than using only the simplified base PCFG, especially since it has a small state space (see next section for

details). Since each probability look-up is cheap but computing SU-RNN scores requires a matrix product, we would like to reduce the number of SU-RNN score computations to only those trees that require semantic information. We note that labeled F1 of the Stanford PCFG parser on the test set is 86.17%. However, if one used an oracle to select the best tree from the top 200 trees that it produces, one could get an F1 of 95.46%.

We use this knowledge to speed up inference via two bottom-up passes through the parsing chart. During the first one, we use only the base PCFG to run CKY dynamic programming through the tree. The  $k = 200$ -best parses at the top cell of the chart are calculated using the efficient algorithm of (Huang and Chiang, 2005). Then, the second pass is a beam search with the full CVG model (including the more expensive matrix multiplications of the SU-RNN). This beam search only considers phrases that appear in the top 200 parses. This is similar to a re-ranking setup but with one main difference: the SU-RNN rule score computation at each node still only has access to its child vectors, not the whole tree or other global features. This allows the second pass to be very fast. We use this setup in our experiments below.

### 3.5 Training SU-RNNs

The full CVG model is trained in two stages. First the base PCFG is trained and its top trees are cached and then used for training the SU-RNN conditioned on the PCFG. The SU-RNN is trained using the objective in Eq. 3 and the scores as exemplified by Eq. 6. For each sentence, we use the method described above to efficiently find an approximation for the optimal tree.

To minimize the objective we want to increase the scores of the correct tree’s constituents and decrease the score of those in the highest scoring incorrect tree. Derivatives are computed via backpropagation through structure (BTS) (Goller and Küchler, 1996). The derivative of tree  $i$  has to be taken with respect to all parameter matrices  $W^{(AB)}$  that appear in it. The main difference between backpropagation in standard RNNs and SU-RNNs is that the derivatives at each node only add to the overall derivative of the specific matrix at that node. For more details on backpropagation through RNNs, see Socher et al. (2010)

### 3.6 Subgradient Methods and AdaGrad

The objective function is not differentiable due to the hinge loss. Therefore, we generalize gradient ascent via the subgradient method (Ratliff et al., 2007) which computes a gradient-like direction. Let  $\theta = (X, W^{(\cdot)}, v^{(\cdot)}) \in \mathbb{R}^M$  be a vector of all  $M$  model parameters, where we denote  $W^{(\cdot)}$  as the set of matrices that appear in the training set. The subgradient of Eq. 3 becomes:

$$\frac{\partial J}{\partial \theta} = \sum_i \frac{\partial s(x_i, \hat{y}_{\max})}{\partial \theta} - \frac{\partial s(x_i, y_i)}{\partial \theta} + \theta,$$

where  $\hat{y}_{\max}$  is the tree with the highest score. To minimize the objective, we use the diagonal variant of AdaGrad (Duchi et al., 2011) with minibatches. For our parameter updates, we first define  $g_\tau \in \mathbb{R}^{M \times 1}$  to be the subgradient at time step  $\tau$  and  $G_t = \sum_{\tau=1}^t g_\tau g_\tau^T$ . The parameter update at time step  $t$  then becomes:

$$\theta_t = \theta_{t-1} - \alpha (\text{diag}(G_t))^{-1/2} g_t, \quad (7)$$

where  $\alpha$  is the learning rate. Since we use the diagonal of  $G_t$ , we only have to store  $M$  values and the update becomes fast to compute: At time step  $t$ , the update for the  $i$ 'th parameter  $\theta_{t,i}$  is:

$$\theta_{t,i} = \theta_{t-1,i} - \frac{\alpha}{\sqrt{\sum_{\tau=1}^t g_{\tau,i}^2}} g_{t,i}. \quad (8)$$

Hence, the learning rate is adapting differently for each parameter and rare parameters get larger updates than frequently occurring parameters. This is helpful in our setting since some  $W$  matrices appear in only a few training trees. This procedure found much better optima (by  $\approx 3\%$  labeled F1 on the dev set), and converged more quickly than L-BFGS which we used previously in RNN training (Socher et al., 2011a). Training time is roughly 4 hours on a single machine.

### 3.7 Initialization of Weight Matrices

In the absence of any knowledge on how to combine two categories, our prior for combining two vectors is to average them instead of performing a completely random projection. Hence, we initialize the binary  $W$  matrices with:

$$W^{(\cdot)} = 0.5[I_{n \times n} I_{n \times n} 0_{n \times 1}] + \epsilon,$$

where we include the bias in the last column and the random variable is uniformly distributed:  $\epsilon \sim$

$\mathcal{U}[-0.001, 0.001]$ . The first block is multiplied by the left child and the second by the right child:

$$\begin{aligned} W^{(AB)} \begin{bmatrix} a \\ b \\ 1 \end{bmatrix} &= \begin{bmatrix} W^{(A)} W^{(B)} \text{bias} \end{bmatrix} \begin{bmatrix} a \\ b \\ 1 \end{bmatrix} \\ &= W^{(A)} a + W^{(B)} b + \text{bias}. \end{aligned}$$

## 4 Experiments

We evaluate the CVG in two ways: First, by a standard parsing evaluation on Penn Treebank WSJ and then by analyzing the model errors in detail.

### 4.1 Cross-validating Hyperparameters

We used the first 20 files of WSJ section 22 to cross-validate several model and optimization choices. The base PCFG uses simplified categories of the Stanford PCFG Parser (Klein and Manning, 2003a). We decreased the state splitting of the PCFG grammar (which helps both by making it less sparse and by reducing the number of parameters in the SU-RNN) by adding the following options to training: ‘noRightRec -dominatesV 0 -baseNP 0’. This reduces the number of states from 15,276 to 12,061 states and 602 POS tags. These include split categories, such as parent annotation categories like  $VP \hat{S}$ . Furthermore, we ignore all category splits for the SU-RNN weights, resulting in 66 unary and 882 binary child pairs. Hence, the SU-RNN has 66+882 transformation matrices and scoring vectors. Note that any PCFG, including latent annotation PCFGs (Matsuzaki et al., 2005) could be used. However, since the vectors will capture lexical and semantic information, even simple base PCFGs can be substantially improved. Since the computational complexity of PCFGs depends on the number of states, a base PCFG with fewer states is much faster.

Testing on the full WSJ section 22 dev set (1700 sentences) takes roughly 470 seconds with the simple base PCFG, 1320 seconds with our new CVG and 1600 seconds with the currently published Stanford factored parser. Hence, increased performance comes also with a speed improvement of approximately 20%.

We fix the same regularization of  $\lambda = 10^{-4}$  for all parameters. The minibatch size was set to 20. We also cross-validated on AdaGrad’s learning rate which was eventually set to  $\alpha = 0.1$  and word vector size. The 25-dimensional vectors provided by Turian et al. (2010) provided the best

Parser	dev (all)	test $\leq$ 40	test (all)
Stanford PCFG	85.8	86.2	85.5
Stanford Factored	87.4	87.2	86.6
Factored PCFGs	89.7	90.1	89.4
Collins			87.7
SSN (Henderson)			89.4
Berkeley Parser			90.1
CVG (RNN)	85.7	85.1	85.0
CVG (SU-RNN)	91.2	91.1	90.4
Charniak-SelfTrain			91.0
Charniak-RS			92.1

Table 1: Comparison of parsers with richer state representations on the WSJ. The last line is the self-trained re-ranked Charniak parser.

performance and were faster than 50-, 100- or 200-dimensional ones. We hypothesize that the larger word vector sizes, while capturing more semantic knowledge, result in too many SU-RNN matrix parameters to train and hence perform worse.

## 4.2 Results on WSJ

The dev set accuracy of the best model is 90.93% labeled F1 on all sentences. This model resulted in 90.44% on the final test set (WSJ section 23). Table 1 compares our results to the two Stanford parser variants (the unlexicalized PCFG (Klein and Manning, 2003a) and the factored parser (Klein and Manning, 2003b)) and other parsers that use richer state representations: the Berkeley parser (Petrov and Klein, 2007), Collins parser (Collins, 1997), SSN: a statistical neural network parser (Henderson, 2004), Factored PCFGs (Hall and Klein, 2012), Charniak-SelfTrain: the self-training approach of McClosky et al. (2006), which bootstraps and parses additional large corpora multiple times, Charniak-RS: the state of the art self-trained and discriminatively re-ranked Charniak-Johnson parser combining (Charniak, 2000; McClosky et al., 2006; Charniak and Johnson, 2005). See Kummerfeld et al. (2012) for more comparisons. We compare also to a standard RNN ‘CVG (RNN)’ and to the proposed CVG with SU-RNNs.

## 4.3 Model Analysis

**Analysis of Error Types.** Table 2 shows a detailed comparison of different errors. We use the code provided by Kummerfeld et al. (2012) and compare to the previous version of the Stanford factored parser as well as to the Berkeley and Charniak-reranked-self-trained parsers (defined above). See Kummerfeld et al. (2012) for details and comparisons to other parsers. One of

Error Type	Stanford	CVG	Berkeley	Char-RS
PP Attach	1.02	0.79	0.82	0.60
Clause Attach	0.64	0.43	0.50	0.38
Diff Label	0.40	0.29	0.29	0.31
Mod Attach	0.37	0.27	0.27	0.25
NP Attach	0.44	0.31	0.27	0.25
Co-ord	0.39	0.32	0.38	0.23
1-Word Span	0.48	0.31	0.28	0.20
Unary	0.35	0.22	0.24	0.14
NP Int	0.28	0.19	0.18	0.14
Other	0.62	0.41	0.41	0.50

Table 2: Detailed comparison of different parsers.

the largest sources of improved performance over the original Stanford factored parser is in the correct placement of PP phrases. When measuring only the F1 of parse nodes that include at least one PP child, the CVG improves the Stanford parser by 6.2% to an F1 of 77.54%. This is a 0.23 reduction in the average number of bracket errors per sentence. The ‘Other’ category includes VP, PRN and other attachments, appositives and internal structures of modifiers and QPs.

**Analysis of Composition Matrices.** An analysis of the norms of the binary matrices reveals that the model learns a soft vectorized notion of head words: Head words are given larger weights and importance when computing the parent vector: For the matrices combining siblings with categories VP:PP, VP:NP and VP:PRT, the weights in the part of the matrix which is multiplied with the VP child vector dominates. Similarly NPs dominate DTs. Fig. 5 shows example matrices. The two strong diagonals are due to the initialization described in Sec. 3.7.

**Semantic Transfer for PP Attachments.** In this small model analysis, we use two pairs of sentences that the original Stanford parser and the CVG did not parse correctly after training on the WSJ. We then continue to train both parsers on two similar sentences and then analyze if the parsers correctly transferred the knowledge. The training sentences are *He eats spaghetti with a fork.* and *She eats spaghetti with pork.* The very similar test sentences are *He eats spaghetti with a spoon.* and *He eats spaghetti with meat.* Initially, both parsers incorrectly attach the PP to the verb in both test sentences. After training, the CVG parses both correctly, while the factored Stanford parser incorrectly attaches both PPs to *spaghetti*. The CVG’s ability to transfer the correct PP attachments is due to the semantic word vector similarity between the words in the sentences. Fig. 4 shows the outputs of the two parsers.

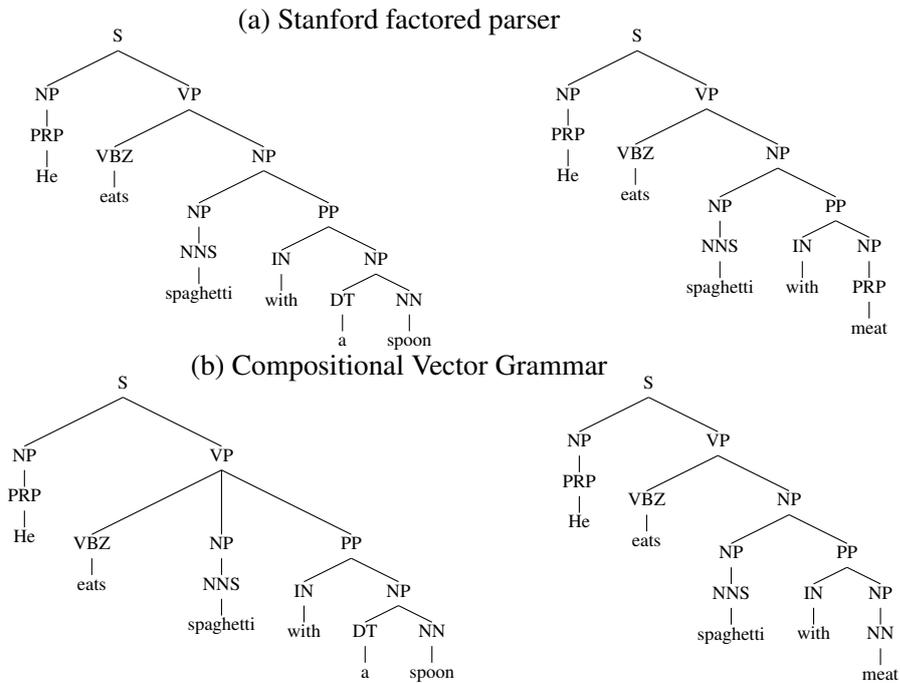

Figure 4: Test sentences of semantic transfer for PP attachments. The CVG was able to transfer semantic word knowledge from two related training sentences. In contrast, the Stanford parser could not distinguish the PP attachments based on the word semantics.

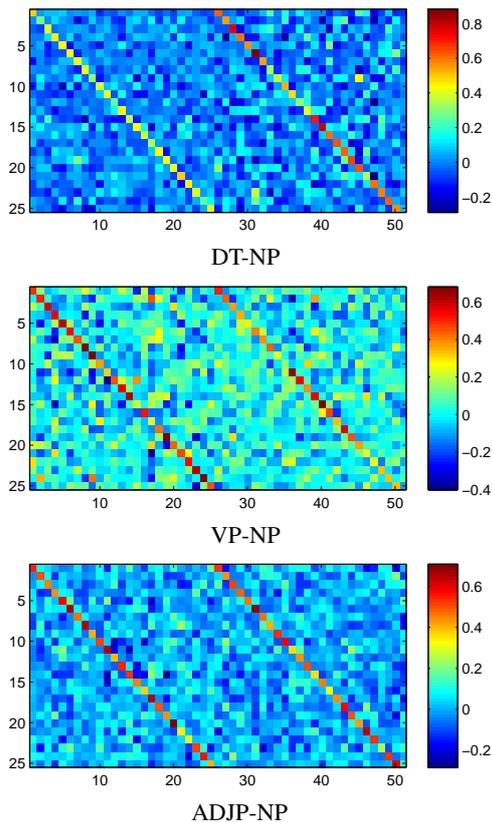

Figure 5: Three binary composition matrices showing that head words dominate the composition. The model learns to not give determiners much importance. The two diagonals show clearly the two blocks that are multiplied with the left and right children, respectively.

## 5 Conclusion

We introduced Compositional Vector Grammars (CVGs), a parsing model that combines the speed of small-state PCFGs with the semantic richness of neural word representations and compositional phrase vectors. The compositional vectors are learned with a new syntactically untied recursive neural network. This model is linguistically more plausible since it chooses different composition functions for a parent node based on the syntactic categories of its children. The CVG obtains 90.44% labeled F1 on the full WSJ test set and is 20% faster than the previous Stanford parser.

## Abstract

In spoken dialog systems, statistical *state tracking* aims to improve robustness to speech recognition errors by tracking a posterior distribution over hidden dialog states. Current approaches based on generative or discriminative models have different but important shortcomings that limit their accuracy. In this paper we discuss these limitations and introduce a new approach for discriminative state tracking that overcomes them by leveraging the problem structure. An offline evaluation with dialog data collected from real users shows improvements in both state tracking accuracy and the quality of the posterior probabilities. Features that encode speech recognition error patterns are particularly helpful, and training requires relatively few dialogs.

## 1 Introduction

Spoken dialog systems interact with users via natural language to help them achieve a goal. As the interaction progresses, the dialog manager maintains a representation of the state of the dialog in a process called *dialog state tracking*. For example, in a bus schedule information system, the dialog state might indicate the user's desired bus route, origin, and destination. Dialog state tracking is difficult because automatic speech recognition (ASR) and spoken language understanding (SLU) errors are common, and can cause the system to misunderstand the user's needs. At the same time, state tracking is crucial because the system relies on the estimated dialog state to choose actions – for example, which bus schedule

information to present to the user.

The dialog state tracking problem can be formalized as follows (Figure 1). Each system turn in the dialog is one datapoint. For each datapoint, the input consists of three items: a set of  $K$  features that describes the current dialog context,  $G$  dialog state hypotheses, and for each dialog state hypothesis,  $M$  features that describe that dialog state hypothesis. The task is to assign a probability distribution over the  $G$  dialog state hypotheses, plus a meta-hypothesis which indicates that none of the  $G$  hypotheses is correct.

Note that  $G$  varies across turns (datapoints) – for example, in the first turn of Figure 1,  $G = 3$ , and in the second and third turns  $G = 5$ . Also note that the dialog state tracker is *not* predicting the contents of the dialog state hypotheses; the dialog state hypotheses contents are given by some external process, and the task is to predict a probability distribution over them, where the probability assigned to a hypothesis indicates the probability that it is correct. It is a requirement that the  $G$  hypotheses are disjoint; with the special “everything else” meta-hypothesis, exactly one hypothesis is correct by construction. After the dialog state tracker has output its distribution, this distribution is passed to a separate, downstream process that chooses what action to take next (e.g., how to respond to the user).

Dialog state tracking can be seen an analogous to assigning a probability distribution over items on an ASR N-best list given speech input and the recognition output, including the contents of the N-best list. In this task, the general features describe the recognition overall (such as length of utterance), and the hypothesis-specific features describe each N-best entry (such as decoder cost).

\* Work done while at Microsoft Research

Another analogous task is assigning a probability distribution over a set of URLs given a search query and the URLs. Here, general features describe the whole set of results, e.g., number of words in the query, and hypothesis-specific features describe each URL, e.g., the fraction of query words contained in page.

For dialog state tracking, most commercial systems use hand-crafted heuristics, selecting the SLU result with the highest confidence score, and discarding alternatives. In contrast, statistical approaches compute a posterior *distribution* over many *hypotheses* for the dialog state. The key insight is that dialog is a temporal process in which correlations between turns can be harnessed to overcome SLU errors. Statistical state tracking has been shown to improve task completion in end-to-end spoken dialog systems (Bohus and Rudnicky (2006); Young et al. (2010); Thomson and Young (2010)).

Two types of statistical state tracking approaches have been proposed. *Generative* approaches (Horvitz and Paek (1999); Williams and Young (2007); Young et al. (2010); Thomson and Young (2010)) use generative models that capture how the SLU results are generated from hidden dialog states. These models can be used to track an arbitrary number of state hypotheses, but cannot easily incorporate large sets of potentially informative features (e.g. from ASR, SLU, dialog history), resulting in poor probability estimates. As an illustration, in Figure 1, a generative model might fail to assign the highest score to the correct hypothesis (61C) after the second turn. In contrast, *discriminative* approaches use conditional models, trained in a discriminative fashion (Bohus and Rudnicky (2006)) to directly estimate the distribution over a set of state hypotheses based on a large set of informative features. They generally produce more accurate distributions, but in their current form they can only track a handful of state hypotheses. As a result, the correct hypothesis may be discarded: for instance, in Figure 1, a discriminative model might consider only the top 2 SLU results, and thus fail to consider the correct 61C hypothesis at all.

The main contribution of this paper is to develop a new discriminative model for dialog state tracking that can operate over an arbitrary number of hypotheses *and* still compute accurate probability estimates. We also explore the relative im-

portance of different feature sets for this task, and measure the amount of data required to reliably train our model.

## 2 Data and experimental design

We use data from the public deployment of two systems in the Spoken Dialog Challenge (Black et al. (2010)) which provide bus schedule information for Pittsburgh, USA. The systems, DS1 and DS2, were fielded by AT&T, and are described in Williams et al. (2010) and Williams (2012). Both systems followed a highly directed flow, separately collecting 5 *slots*. All users were asked for their bus route, origin, and destination; then, they were optionally prompted for a date and time. Each slot was explicitly or implicitly confirmed before collecting the next. At the end, bus times were presented. The two systems differed in acoustic models, confidence scoring model, state tracking method and parameters, number of supported routes (8 vs 40, for DS1 and DS2 respectively), presence of minor bugs, and user population. These differences yield distinctions in the distributions in the two corpora (Williams (2012)).

In both systems, a dialog state hypothesis consists of a value of the user’s goal for a certain slot: for example, a state hypothesis for the origin slot might be “carnegie mellon university”. The number  $G$  of state hypotheses (e.g. slot values) observed so far depends on the dialog, and turn within that dialog. For instance, in Fig. 1,  $G$  progressively takes values 3, 5 and 5. Dialog state hypotheses with identical contents (e.g., the same bus route) are merged. The correctness of the SLU results was manually labeled by professional annotators.

### 2.1 Experimental setup

To perform a comparative analysis of various state tracking algorithms, we test them *offline*, i.e., by re-running state tracking against the SLU results from deployment. However, care must be taken: when the improved state-tracker is installed into a dialog system and used to drive action selection, the distribution of the resulting dialog data (which is an input for the state tracker) will change. In other words, it is known *a priori* that the train and test distributions will be *mismatched*. Hence, when conducting offline experiments, if train and test data were drawn from the same *matched* distribution, this may overstate performance.

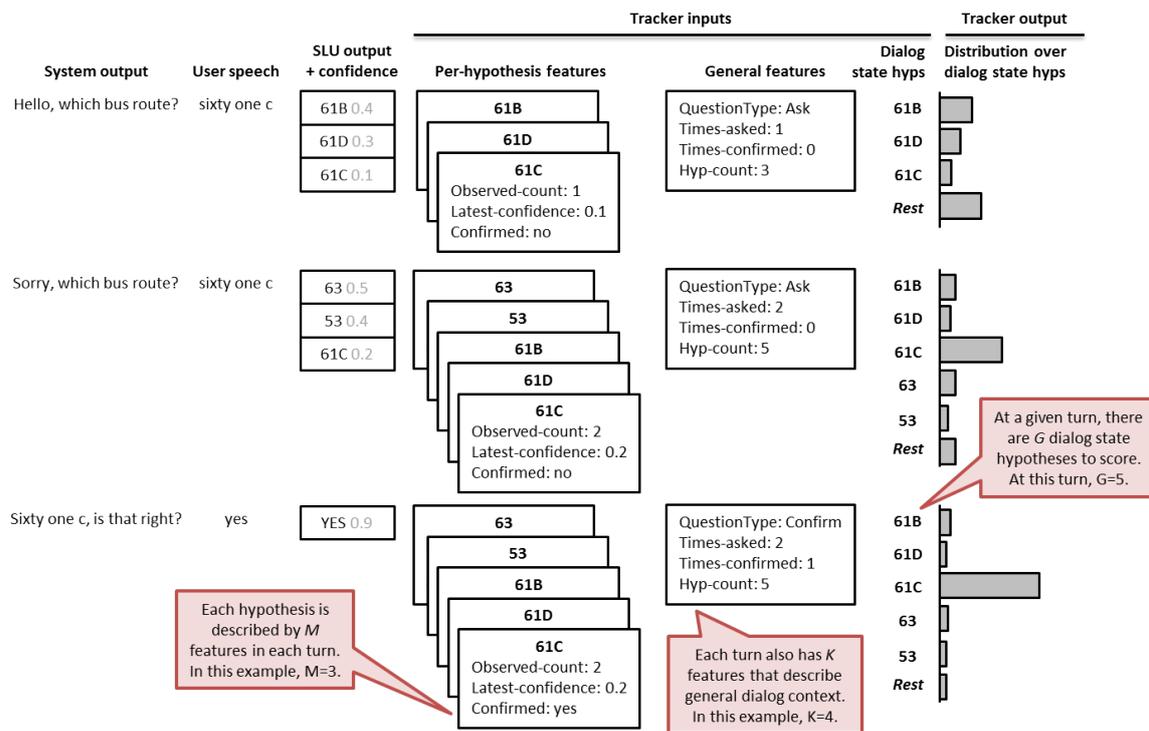

Figure 1: Overview of dialog state tracking. In this example, the dialog state contains the user’s desired bus route. At each turn, the system produces a spoken output. The user’s spoken response is processed to extract a set of spoken language understanding (SLU) results, each with a *local* confidence score. A set of  $G$  dialog state hypotheses is formed by considering all SLU results observed so far, including the current turn and all previous turns. For each state hypothesis, a feature extractor produces a set of  $M$  hypothesis-specific features, plus a single set of  $K$  general features that describes the current dialog context. The dialog state tracker uses these features to produce a distribution over the  $G$  state hypotheses, plus a meta-hypothesis *rest* which accounts for the possibility that none of the  $G$  hypotheses are correct.

dataset	train set	test set
MATCH1	half calls from DS2	remaining calls in DS2
MATCH2	half calls from DS1, half from DS2	remaining calls from DS1 and DS2
MISMATCH	all calls from DS1	all calls from DS2

Table 1: Train-test data splits

To account for this effect, we explicitly study train/test mismatch through three partitions of data from DS1 and DS2 (see Table 1): MATCH1 contains matched train/test data from the DS2 dataset; MATCH2 contains matched train/test data from both datasets; finally, MISMATCH contains mismatched train/test data. While the MISMATCH condition may not identically replicate the mismatch observed from deploying a new state tracker *online* (since online characteristics depend on user behavior) training on DS1 and testing on DS2 at least ensures the presence of some real-world mismatch.

We assess performance via two metrics: *accuracy* and *L2 norm*. Accuracy indicates whether the state hypothesis with the highest assigned probability is correct, where *rest* is correct iff none of the SLU results prior to the current turn include the user’s goal. High accuracy is important as a dialog system must ultimately commit to a single interpretation of the user’s needs – e.g., it must commit to a route in order to provide bus timetable information. In addition, the L2 norm (or Brier score, Murphy (1973)) also captures how well calibrated the output probabilities are, which is crucial to decision theoretic methods for action selection. The L2 norm is computed between the output posterior and the ground-truth vector, which has 1 in the position of the correct item and 0 elsewhere. Both metrics are computed for each slot in each turn, and reported by averaging across all turns and slots.

## 2.2 Hand-crafted baseline state tracker

As a baseline, we construct a hand-crafted state tracking rule that follows a strategy common in commercial systems: it returns the SLU result with the maximum confidence score, ignoring all other hypotheses. Although this is very a simple rule, it is very often effective. For example, if the user says “no” to an explicit confirmation or “go back” to an implicit confirmation, they are asked the same question again, which gives an opportunity for a higher confidence score. Of the  $G$  possible hypotheses for a slot, we denote the number actually assigned a score by a model as  $\tilde{G}$ , so in this heuristic baseline  $\tilde{G} = 1$ .

The performance of this baseline (BASELINE in Table 3) is relatively strong because the top SLU result is by far most likely to be correct, and because the confidence score was already trained with slot-specific speech data (Williams and Balakrishnan (2009), Williams (2012)). However, this simple rule can’t make use of SLU results on the N-best list, or statistical priors; these limitations motivate the use of statistical state trackers, introduced next.

## 3 Generative state tracking

Generative state tracking approaches leverage models that describe how SLU results are *generated* from a hidden dialog state, denoted  $g$ . The user’s true (unobserved) action  $u$  is conditioned on  $g$  and the system action  $a$  via a user action model  $P(u|g, a)$ , and also on the observed SLU result  $\tilde{u}$  via a model of how SLU results are generated  $P(\tilde{u}|u)$ . Given a prior distribution  $b(g)$  and a result  $\tilde{u}$ , an updated distribution  $b'(g)$  can be computed by summing over all hidden user actions  $u$ :

$$b'(g) = \eta \sum_u P(\tilde{u}|u) \cdot P(u|g, a) b(g) \quad (1)$$

where  $\eta$  is a normalizing constant (Williams and Young (2007)). Generative approaches model the posterior over *all* possible dialog state hypotheses, including those not observed in the SLU N-best lists. In general this is computationally intractable because the number of states is too large. One approach to scaling up is to group  $g$  into a few *partitions*, and to track only states suggested by observed SLU results (Young et al. (2010); Williams (2010); Gašić and Young (2011)). Another approach is to *factor* the components of a dialog

state, make assumptions about conditional independence between the components, and apply approximate inference techniques such as loopy belief propagation (Thomson and Young (2010)).

In deployment, DS1 and DS2 used the AT&T Statistical Dialog Toolkit (ASDT) for dialog state tracking (Williams (2010); AT&T Statistical Dialog Toolkit). ASDT implements a generative update of the form of Eq 1, and uses partitions to maintain tractability. Component models were learned from dialog data from a different dialog system. A maximum of  $\tilde{G} = 20$  state hypotheses were tracked for each slot. The performance (GENONLINE in Table 3), was worse than BASELINE: an in-depth analysis attributed this to the mismatch between train and test data in the component models, and to the underlying flawed assumption of eq. 1 that observations at different turns are independent conditioned on the dialog state – in practice, confusions made by speech recognition are highly correlated (Williams (2012)).

For all datasets, we re-estimated the models on the train set and re-ran generative tracking with an unlimited number of partitions (i.e.,  $\tilde{G} = G$ ); see GENOFFLINE in Table 3. The re-estimated tracker improved accuracy in MATCH conditions, but degraded accuracy in the MISMATCH condition. This can be partly attributed to the difficulty in estimating accurate initial priors  $b(g)$  for MISMATCH, where the bus route, origin, and destination slot values in train and test systems differed significantly.

## 4 Discriminative State Tracking: Preliminaries and existing work

In contrast to generative models, discriminative approaches to dialog state tracking directly predict the correct state hypothesis by leveraging discriminatively trained conditional models of the form  $b(g) = P(g|f)$ , where  $f$  are features extracted from various sources, e.g. ASR, SLU, dialog history, etc. In this work we will use maximum entropy models. We begin by briefly introducing these models in the next subsection. We then describe the features used, and finally review existing discriminative approaches for state tracking which serve as a starting point for the new approach we introduce in Section 5.

## 4.1 Maximum entropy models

The maximum entropy framework (Berger et al. (1996)) models the conditional probability distribution of the label  $y$  given features  $\mathbf{x}$ ,  $p(y|\mathbf{x})$  via an exponential model of the form:

$$P(y|\mathbf{x}, \lambda) = \frac{\exp(\sum_{i \in I} \lambda_i \phi_i(\mathbf{x}, y))}{\sum_{y \in Y} \exp(\sum_{i \in I} \lambda_i \phi_i(\mathbf{x}, y))} \quad (2)$$

where  $\phi_i(\mathbf{x}, y)$  are feature functions jointly defined on features and labels, and  $\lambda_i$  are the model parameters. The training procedure optimizes the parameters  $\lambda_i$  to maximize the likelihood over the data instances subject to regularization penalties. In this work, we optimize the L1 penalty using a cross-validation process on the train set, and we use a fixed L2 penalty based on heuristic based on the dataset size. The same optimization is used for all models.

## 4.2 Features

Discriminative approaches for state tracking rely on informative features to predict the correct dialog state. In this work we designed a set of *hypothesis-specific* features that convey information about the correctness of a particular state hypothesis, and a set of *general* features that convey information about the correctness of the *rest* meta-hypothesis.

*Hypothesis-specific* features can be grouped into 3 categories: *base*, *history* and *confusion* features. *Base* features consider information about the *current* turn, including rank of the current SLU result (current hypothesis), the SLU result confidence score(s) in the current N-best list, the difference between the current hypothesis score and the best hypothesis score in the current N-best list, etc. *History* features contain additional useful information about past turns. Those include the number of times an SLU result has been observed before, the number of times an SLU result has been observed before at a specific rank such as rank 1, the sum and average of confidence scores of SLU results across all past recognitions, the number of possible past user negations or confirmations of the current SLU result etc.

*Confusion* features provide information about likely ASR errors and confusability. Some recognition results are more likely to be incorrect than others – background noise tends to trigger certain results, especially short bus routes like “p”. Moreover, similar sounding phrases are more likely to

be confused. The confusion features were computed on a subset of the training data. For each SLU result we computed the fraction of the time that the result was correct, and the binomial 95% confidence interval for that estimate. Those two statistics were pre-computed for all SLU results in the training data subset, and were stored in a lookup table. At runtime, when an SLU hypothesis is recognized, its statistics from this lookup table are used as features. Similar statistics were computed for prior probability of an SLU result appearing on an N-best list, and prior probability of SLU result appearance at specific rank positions of an N-best list, prior probability of confusion between pairs of SLU results, and others.

*General* features provide aggregate information about dialog history and SLU results, and are shared across different SLU results of an N-best list. For example, from the current turn, we use the number of distinct SLU results, the entropy of the confidence scores, the best path score of the word confusion network, etc. We also include features that contain aggregate information about the sequence of all N-best lists up to the current turn, such as the mean and variance of N-best list lengths, the number of distinct SLU results observed so far, the entropy of their corresponding confidence scores, and others.

We denote the number of *hypothesis-specific* features as  $M$ , and the number of *general* features as  $K$ .  $K$  and  $M$  are each in the range of 100–200, although  $M$  varies depending on whether *history* and *confusion* features are included. For a given dialog turn with  $G$  state hypotheses, there are a total of  $G * M + K$  distinct features.

## 4.3 Fixed-length discriminative state tracking

In past work, Bohus and Rudnicky (2006) introduced discriminative state tracking, casting the problem as standard multiclass classification. In this setup, each turn constitutes one data instance. Since in dialog state tracking the number of state hypotheses varies across turns, Bohus and Rudnicky (2006) chose a *subset* of  $\tilde{G}$  state hypotheses to score. In this work we used a similar setup, where we considered the top  $G_1$  SLU results from the current N-best list at turn  $t$ , and the top  $G_2$  and  $G_3$  SLU results from the previous N-best lists at turns  $t - 1$  and  $t - 2$ . The problem can then be formulated as multiclass classification

over  $\tilde{G} + 1 = G_1 + G_2 + G_3 + 1$  classes, where the correct class indicates which of these hypotheses (or *rest*) is correct. We experimented with different values and found that  $G_1 = 3$ ,  $G_2 = 2$ , and  $G_3 = 1$  ( $\tilde{G} = 6$ ) yielded the best performance.

Feature functions are defined in the standard way, with one feature function  $\phi$  and weight  $\lambda$  for each (feature,class) pair. Formally,  $\phi$  of eq. 2 is defined as  $\phi_{i,j}(x, y) = x_i \delta(y, j)$ , where  $\delta(y, j) = 1$  if  $y = j$  and 0 otherwise.  $i$  indexes over the  $\tilde{G}M + K$  features and  $j$  over the  $\tilde{G} + 1$  classes.<sup>1</sup> The two-dimensional subscript  $i, j$  if used for clarity of notation, but is otherwise identical in role to the one-dimension subscript  $i$  in Eq 2. Figure 2 illustrates the relationship between hypotheses and weights.

Results are reported as DISCFIXED in Table 3. In the MATCH conditions, performance is generally higher than the other baselines, particularly when confusion features are included. In the MIS-MATCH condition, performance is worse than the BASELINE.

A strength of this approach is that it enables features from every hypothesis to independently affect every class. However, the total number of feature functions (hence weights to learn) is  $(\tilde{G} + 1) \times (\tilde{G}M + K)$ , which increases quadratically with the number of hypotheses considered  $\tilde{G}$ . Although regularization can help avoid overfitting *per se*, it becomes a more challenging task with more features. Learning weights for each (feature,class) pair has the drawback that the effect of hypothesis-specific features such as confidence have to be learned separately for every hypothesis. Also, although we know in advance that posteriors for a dialog state hypothesis are most dependent on the features corresponding to that hypothesis, in this approach the features from *all* hypotheses are pooled together and the model is left to discover these correspondences via learning. Furthermore, items lower down on the SLU N-best list are much less likely to be correct: an item at a very deep position (say 19) might never be correct in the training data – when this occurs, it is unreasonable to expect posteriors to be estimated accurately.

As a result of these issues, in practice  $\tilde{G}$  is limited to being a small number – here we found that increasing  $\tilde{G} > 6$  degraded performance. Yet with

<sup>1</sup>Although in practice, maximum entropy model constraints render weights for one class redundant.

$\tilde{G} = 6$ , we found that in 10% of turns, the correct state hypothesis was present but was being discarded by the model, which substantially reduces the upper-bound on tracker performance. In the next section, we introduce a novel discriminative state tracking approach that addresses the above limitations, and enables jointly considering an arbitrary number of state hypotheses, by exploiting the structure inherent in the dialog state tracking problem.

## 5 Dynamic discriminative state tracking

The key idea in the proposed approach is to use feature functions that *link* hypothesis-specific features to their corresponding dialog state hypothesis. This approach makes it straightforward to model relationships such as “higher confidence for an SLU result increases the probability of its corresponding state hypothesis being correct”. This formulation also decouples the number of model parameters (i.e. weights to learn) from the number of hypotheses considered, allowing an arbitrary number of dialog states hypotheses to be scored.

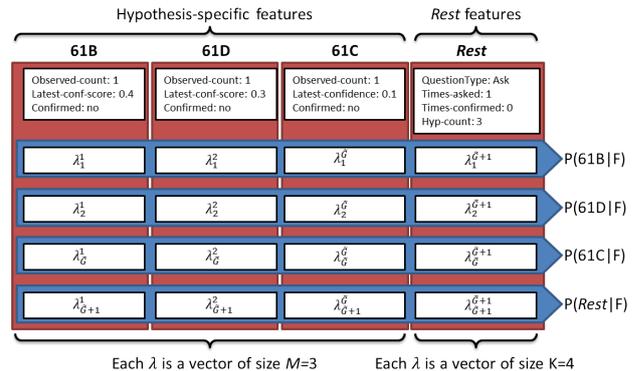

Figure 2: The DISCFIXED model is a traditional maximum entropy model for classification. Every feature in every hypothesis is linked to every hypothesis, requiring  $(\tilde{G} + 1)(\tilde{G}M + K)$  weights.

We begin by re-stating how features are indexed. Recall each dialog state hypothesis has  $M$  hypothesis-specific features; for each hypothesis, we concatenate these  $M$  features with the  $K$  general features, which are identical for all hypotheses. For the meta-hypothesis *rest*, we again concatenate  $M+K$  features, where the  $M$  hypothesis-specific features take special undefined values. We write  $x_i^g$  to refer to the  $i$ th feature of hypothesis  $g$ , where  $i$  ranges from 1 to  $M + K$  and  $g$  from 1 to  $G + 1$ .

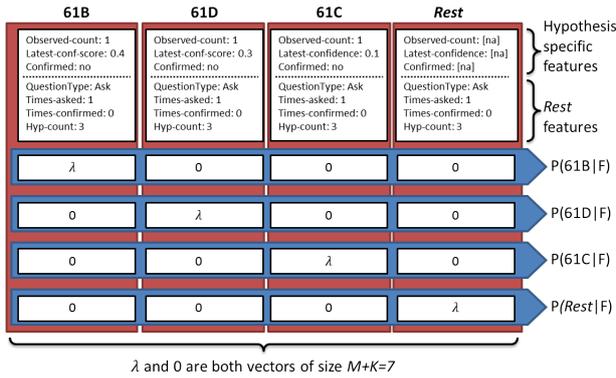

Figure 3: The DISCDYN model presented in this paper exploits the structure of the state tracking problem. Features are linked to only their own hypothesis, and weights are shared across all hypotheses, requiring  $M + K$  weights.

Table 2: Description of the various implemented state tracking algorithms

The model is based on  $M + K$  feature functions. However, unlike in traditional maximum entropy models such as the fixed-position model above, these features functions are *dynamically defined* when presented with each turn. Specifically, for a turn with  $G$  hypotheses, we define  $\phi_i(\mathbf{x}, y = g) = x_i^g$ , where  $y$  ranges over the set of possible dialog states  $G + 1$  (and as above  $i \in 1 \dots M + K$ ). The feature function  $\phi_i$  is dynamic in that the domain of  $y$  – i.e., the number of dialog state hypotheses to score – varies from turn to turn. With feature functions defined this way, standard maximum entropy optimization is then applied to learn the corresponding set of  $M + K$  weights, denoted  $\lambda_i$ . Fig. 3 shows the relationship of hypotheses and weights.

In practice, this formulation – in which *general* features are duplicated across every dialog state hypothesis – may require some additional feature engineering: for every hypothesis  $g$  and *general* feature  $i$ , the value of that general feature  $x_i^g$  will

be multiplied by the same weight  $\lambda_i$ . The result is that any setting of  $\lambda_i$  affects all scores identically, with no net change to the resulting posterior. Nonetheless, *general* features do contain useful information for state tracking; to make use of them, we add conjunctions (combinations) of *general* and *hypothesis-specific* features.

We use 3 different feature variants. In DISCDYN1, we use the original feature set, ignoring the problem described above (so that the *general* features contribute no information), resulting in  $M + K$  weights. DISCDYN2 adds indicator encodings of the ordinal-valued *hypothesis-specific* features. For example, rank is encoded as a vector of boolean indicators, where the first indicator is nonzero if  $rank = 1$ , the second is nonzero if  $rank = 2$ , and the third if  $rank \geq 3$ . This provides a more detailed encoding of the ordinal-valued *hypothesis-specific* features, although it still ignores information from the *general* features. This encoding increases the number of weights to learn to about  $2(M + K)$ .

Finally, DISCDYN3 extends DISCDYN2 by including conjunctions of the ordinal-valued *general* features with ordinal-valued *hypothesis-specific* features. For example, if the 3-way *hypothesis-specific* indicator feature for rank described above were conjoined with a 4-way *general* indicator feature for dialog state, the result would be an indicator of dimension  $3 \times 4 = 12$ . This expansion results in approximately  $10(M + K)$  weights to learn in DISCDYN3.<sup>2</sup>

For comparison, we also estimated a simpler alternative model, called DISCIND. This model consists of 2 binary classifiers: the first one scores each hypothesis in isolation, using the  $M$  *hypothesis-specific* features for that hypothesis + the  $K$  *general* features for that turn, and outputs a (single) probability that the hypothesis is correct. For this classifier, each hypothesis (not each turn) defines a data instance. The second binary classifier takes the  $K$  *general* features, and outputs a probability that the *rest* meta-hypothesis is correct. For this second classifier, each turn defines one data instance. The output of these two models is then calibrated with isotonic regression (Zadrozny and Elkan (2002)) and normalized to generate the posterior over all hypotheses.

<sup>2</sup>We explored adding all possible conjunctions, including real-valued features, but this increased memory and computational requirements dramatically without performance gains.

## 6 Results and discussion

The implemented state tracking methods are summarized in Table 2, and our results are presented in Table 3. These results suggest several conclusions. First, discriminative approaches for state tracking broadly outperform generative methods. Since discriminative methods incorporate many features and are trained directly to optimize performance, this is perhaps unsurprising for the MATCH conditions. It is interesting that discriminative methods are also superior in the more realistic MISMATCH setting, albeit with smaller gains. This result suggests that discriminative methods have good promise when deployed into real systems, where mismatch between training and test distributions is expected.

Second, the dynamic discriminative DISCDYN models also outperformed the fixed-length discriminative methods. This shows the benefit of a model which can score every dialog state hypotheses, rather than a fixed subset. Third, the three variants of the DISCDYN model, which progressively contain more detailed feature encoding and conjunctions, perform similarly. This suggests that a relatively simple encoding is sufficient to achieve good performance, as the feature indicators and conjunctions present in DISCDYN2 and DISCDYN3 give only a small additional increase.

Among the discriminative models, the jointly-optimized DISCDYN versions also slightly outperform the simpler, independently-optimized DISCIND version. This is to be expected, for two reasons: first, DISCIND is trained on a per-hypothesis basis, while the DISCDYN models are trained on a *per-turn* basis, which is the true performance metric. For example, some turns have 1 hypothesis and others have 100, but DISCIND training counts

all hypotheses equally. Second, model parameters in DISCIND are trained independently of competing hypotheses. However, they should rather be adjusted specifically so that the correct item receives a larger score than incorrect items – not merely to increase scores for correct items and decrease scores for incorrect items in isolation – and this is what is done in the DISCDYN models.

The analysis of various feature sets indicates that the ASR/SLU error correlation (*confusion*) features yield the largest improvement – c.f. feature set *bc* compared to *b* in Table 3. The improvement is smallest for MISMATCH, which underscores the challenges of mismatched train and test conditions during a realistic runtime scenario. Note, however, that we have constructed a highly mismatched case where we train on DS1 (that supports just 8 routes) and test on DS2 (that supports 40 routes). Therefore, many route, origin and destination slot values in the test data do not appear in the training data. Hence, it is unsurprising that the positive effect of confusion features would decrease.

While Table 3 shows performance measures averaged across all turns, Table 4 breaks down performance measures *by slot*, using the full feature set *bch* and the realistic MISMATCH dataset. Results here show a large variation in performance across the different slots. For the date and time slots, there is an order of magnitude less data than for the other slots; however performance for dates is quite good, whereas times is rather poor. We believe this is because the SLU confusion features can be estimated well for slots with small cardinalities (there are 7 possible values for the day), and less well for slots with large cardinalities (there are  $24 \times 60 = 1440$  possible time values). This sug-

Table 4: Performance per slot on dataset MIS-MATCH using the full feature set *bch*.

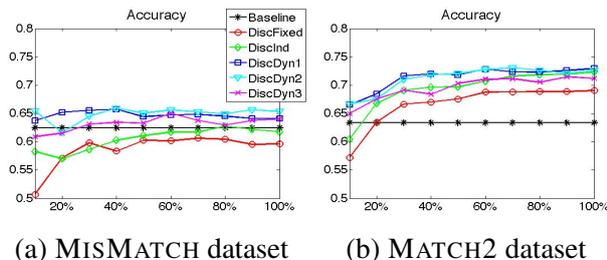

Figure 4: Accuracy vs. amount of training data

gests that the amount of data required to estimate a good model may depend on the cardinality of slot values.

Finally, in Figure 4 we show how performance varies with different amounts of training data for the MATCH2 and MISMATCH datasets, where the full training set size is approximately 5600 and 4400 turns, respectively. In both cases asymptotic performance is reached after about 2000 turns, or about 150 dialogs. This is particularly encouraging, as it suggests models could be learned or adapted online with relatively little data, or could even be individually tailored to particular users.

## 7 Conclusion and Future Work

Dialog state tracking is crucial to the successful operation of spoken dialog systems. Recently developed statistical approaches are promising as they fully utilize the dialog history, and can incorporate priors from past usage data. However,

existing methodologies are either limited in their accuracy or their coverage, both of which hamper performance.

In this paper, we have introduced a new model for discriminative state tracking. The key idea is to exploit the structure of the problem, in which each dialog state hypothesis has features drawn from the same set. In contrast to past approaches to discriminative state tracking which required a number of parameters quadratic in the number of state hypotheses, our approach uses a constant number of parameters, invariant to the number of state hypotheses. This is a crucial property that enables generalization and dealing with an unlimited number of hypotheses, overcoming a key limitation in previous models.

We evaluated the proposed method and compared it to existing generative and discriminative approaches on a corpus of real-world human-computer dialogs chosen to include a mismatch between training and test, as this will be found in deployments. Results show that the proposed model exceeds both the accuracy and probability quality of all baselines when using the richest feature set, which includes information about common ASR confusions and dialog history. The model can be trained efficiently, i.e. only about 150 training dialogs are necessary.

The next step is to incorporate this approach into a deployed dialog system, and use the estimated posterior over dialog states as input to the action selection process. In future, we also hope to explore unsupervised online adaptation, where the trained model can be updated as test data is processed.

## Acknowledgments

We thank Patrick Nguyen for helpful discussions regarding maximum entropy modeling and feature functions for handling structured and dynamic output classification problems.

## Abstract

To overcome the shortage of labeled data for implicit discourse relation recognition, previous works attempted to automatically generate training data by removing explicit discourse connectives from sentences and then built models on these synthetic implicit examples. However, a previous study (Sporleder and Lascarides, 2008) showed that models trained on these synthetic data do not generalize very well to natural (i.e. *genuine*) implicit discourse data. In this work we revisit this issue and present a multi-task learning based system which can effectively use synthetic data for implicit discourse relation recognition. Results on PDTB data show that under the multi-task learning framework our models with the use of the prediction of explicit discourse connectives as auxiliary learning tasks, can achieve an averaged  $F_1$  improvement of 5.86% over baseline models.

## 1 Introduction

The task of implicit discourse relation recognition is to identify the type of discourse relation (a.k.a. *rhetorical relation*) hold between two spans of text, where there is no discourse connective (a.k.a. *discourse marker*, e.g., *but*, *and*) in context to explicitly mark their discourse relation (e.g., *Contrast* or *Explanation*). It can be of great benefit to many downstream NLP applications, such as question answering (QA) (Verberne et al., 2007), information extraction (IE) (Cimiano et al., 2005), and machine translation (MT), etc. This task is quite challenging due to two reasons. First, without discourse connective in text, the task is quite difficult in itself. Second, implicit discourse relation is quite frequent in text. For example, almost half the sentences in the British National Corpus

held implicit discourse relations (Sporleder and Lascarides, 2008). Therefore, the task of implicit discourse relation recognition is the key to improving end-to-end discourse parser performance.

To overcome the shortage of manually annotated training data, (Marcu and Echihiabi, 2002) proposed a pattern-based approach to automatically generate training data from raw corpora. This line of research was followed by (Sporleder and Lascarides, 2008) and (Blair-Goldensohn, 2007). In these works, sentences containing certain words or phrases (e.g. *but*, *although*) were selected out from raw corpora using a pattern-based approach and then these words or phrases were removed from these sentences. Thus the resulting sentences were used as synthetic training examples for implicit discourse relation recognition. Since there is ambiguity of a word or phrase serving for discourse connective (i.e., the ambiguity between discourse and non-discourse usage or the ambiguity between two or more discourse relations if the word or phrase is used as a discourse connective), the synthetic implicit data would contain a lot of noises. Later, with the release of manually annotated corpus, such as Penn Discourse Treebank 2.0 (PDTB) (Prasad et al., 2008), recent studies performed implicit discourse relation recognition on natural (i.e., *genuine*) implicit discourse data (Pitler et al., 2009) (Lin et al., 2009) (Wang et al., 2010) with the use of linguistically informed features and machine learning algorithms.

(Sporleder and Lascarides, 2008) conducted a study of the pattern-based approach presented by (Marcu and Echihiabi, 2002) and showed that the model built on synthetic implicit data has not generalize well on natural implicit data. They found some evidence that this behavior is largely independent of the classifiers used and seems to lie in the data itself (e.g., marked and unmarked examples may be too dissimilar linguistically and

removing unambiguous markers in the automatic labelling process may lead to a meaning shift in the examples). We state that in some cases it is true while in other cases it may not always be so. A simple example is given here:

- (E1) a. We can't win.  
b. [*but*] We must keep trying.

We may find that in this example whether the insertion or the removal of connective *but* would not lead to a redundant or missing information between the above two sentences. That is, discourse connectives can be inserted between or removed from two sentences without changing the semantic relations between them in some cases. Another similar observation is in the annotation procedure of PDTB. To label implicit discourse relation, annotators inserted connective which can best express the relation between sentences without any redundancy<sup>1</sup>. We see that there should be some linguistic similarities between explicit and implicit discourse examples. Therefore, the first question arises: can we exploit this kind of linguistic similarity between explicit and implicit discourse examples to improve implicit discourse relation recognition?

In this paper, we propose a multi-task learning based method to improve the performance of implicit discourse relation recognition (as main task) with the help of relevant auxiliary tasks. Specifically, the main task is to recognize the implicit discourse relations based on genuine implicit discourse data and the auxiliary task is to recognize the implicit discourse relations based on synthetic implicit discourse data. According to the principle of multi-task learning, the learning model can be optimized by the shared part of the main task and the auxiliary tasks without bring unnecessary noise. That means, the model can learn from synthetic implicit data while it would not bring unnecessary noise from synthetic implicit data.

Although (Sporleder and Lascarides, 2008) did not mention, we speculate that another possible reason for the reported worse performance may result from noises in synthetic implicit discourse data. These synthetic data can be generated from two sources: (1) raw corpora with the use of pattern-based approach in (Marcu and Echihiabi,

<sup>1</sup>According to the PDTB Annotation Manual (PDTB-Group, 2008), if the insertion of connective leads to "redundancy", the relation is annotated as Alternative lexicalizations (AltLex), not implicit.

2002) and (Sporleder and Lascarides, 2008), and (2) manually annotated explicit data with the removal of explicit discourse connectives. Obviously, the data generated from the second source is cleaner and more reliable than that from the first source. Therefore, the second question to address in this work is: whether synthetic implicit discourse data generated from explicit discourse data source (i.e., the second source) can lead to a better performance than that from raw corpora (i.e., the first source)? To answer this question, we will make a comparison of synthetic discourse data generated from two corpora, i.e., the BILLIP corpus and the explicit discourse data annotated in PDTB.

The rest of this paper is organized as follows. Section 2 reviews related work on implicit discourse relation classification and multi-task learning. Section 3 presents our proposed multi-task learning method for implicit discourse relation classification. Section 4 provides the implementation technique details of the proposed multi-task method. Section 5 presents experiments and discusses results. Section 6 concludes this work.

## 2 Related Work

### 2.1 Implicit discourse relation classification

#### 2.1.1 Unsupervised approaches

Due to the lack of benchmark data for implicit discourse relation analysis, earlier work used unlabeled data to generate synthetic implicit discourse data. For example, (Marcu and Echihiabi, 2002) proposed an unsupervised method to recognize four discourse relations, i.e., *Contrast*, *Explanation-evidence*, *Condition* and *Elaboration*. They first used unambiguous pattern to extract explicit discourse examples from raw corpus. Then they generated synthetic implicit discourse data by removing explicit discourse connectives from sentences extracted. In their work, they collected word pairs from synthetic data set as features and used machine learning method to classify implicit discourse relation. Based on this work, several researchers have extended the work to improve the performance of relation classification. For example, (Saito et al., 2006) showed that the use of phrasal patterns as additional features can help a word-pair based system for discourse relation prediction on a Japanese corpus. Furthermore, (Blair-Goldensohn, 2007) improved previous work with the use of parameter optimization,

topic segmentation and syntactic parsing. However, (Sporleder and Lascarides, 2008) showed that the training model built on a synthetic data set, like the work of (Marcu and Echihiabi, 2002), may not be a good strategy since the linguistic dissimilarity between explicit and implicit data may hurt the performance of a model on natural data when being trained on synthetic data.

### 2.1.2 Supervised approaches

This line of research work approaches this relation prediction problem by recasting it as a classification problem. (Soricut and Marcu, 2003) parsed the discourse structures of sentences on RST Bank data set (Carlson et al., 2001) which is annotated based on Rhetorical Structure Theory (Mann and Thompson, 1988). (Wellner et al., 2006) presented a study of discourse relation disambiguation on GraphBank (Wolf et al., 2005). Recently, (Pitler et al., 2009) (Lin et al., 2009) and (Wang et al., 2010) conducted discourse relation study on PDTB (Prasad et al., 2008) which has been widely used in this field.

### 2.1.3 Semi-supervised approaches

Research work in this category exploited both labeled and unlabeled data for discourse relation prediction. (Hernault et al., 2010) presented a semi-supervised method based on the analysis of co-occurring features in labeled and unlabeled data. Very recently, (Hernault et al., 2011) introduced a semi-supervised work using structure learning method for discourse relation classification, which is quite relevant to our work. However, they performed discourse relation classification on both explicit and implicit data. And their work is different from our work in many aspects, such as, feature sets, auxiliary task, auxiliary data, class labels, learning framework, and so on. Furthermore, there is no explicit conclusion or evidence in their work to address the two questions raised in Section 1.

Unlike their previous work, our previous work (Zhou et al., 2010) presented a method to predict the missing connective based on a language model trained on an unannotated corpus. The predicted connective was then used as a feature to classify the implicit relation.

## 2.2 Multi-task learning

Multi-task learning is a kind of machine learning method, which learns a main task together with

other related auxiliary tasks at the same time, using a shared representation. This often leads to a better model for the main task, because it allows the learner to use the commonality among the tasks. Many multi-task learning methods have been proposed in recent years, (Ando and Zhang, 2005a), (Argyriou et al., 2008), (Jebara, 2004), (Bonilla et al., 2008), (Evgeniou and Pontil, 2004), (Baxter, 2000), (Caruana, 1997), (Thrun, 1996). One group uses task relations as regularization terms in the objective function to be optimized. For example, in (Evgeniou and Pontil, 2004) the regularization terms make the parameters of models closer for similar tasks. Another group is proposed to find the common structure from data and then utilize the learned structure for multi-task learning (Argyriou et al., 2008) (Ando and Zhang, 2005b).

## 3 Multi-task Learning for Discourse Relation Prediction

### 3.1 Motivation

The idea of using multi-task learning for implicit discourse relation classification is motivated by the observations that we have made on implicit discourse relation.

On one hand, since building a hand-annotated implicit discourse relation corpus is costly and time consuming, most previous work attempted to use synthetic implicit discourse examples as training data. However, (Sporleder and Lascarides, 2008) found that the model trained on synthetic implicit data has not performed as well as expected in natural implicit data. They stated that the reason is linguistic dissimilarity between explicit and implicit discourse data. This indicates that straightly using synthetic implicit data as training data may not be helpful.

On the other hand, as shown in Section 1, we observe that in some cases explicit discourse relation and implicit discourse relation can express the same meaning with or without a discourse connective. This indicates that in certain degree they must be similar to each other. If it is true, the synthetic implicit relations are expected to be helpful for implicit discourse relation classification. Therefore, what we have to do is to find a way to train a model which has the capabilities to learn from their similarity and to ignore their dissimilarity as well.

To solve it, we propose a multi-task learning method for implicit discourse relation classi-

fication, where the classification model seeks the shared part through jointly learning main task and multiple auxiliary tasks. As a result, the model can be optimized by the similar shared part without bringing noise in the dissimilar part. Specifically, in this work, we use alternating structure optimization (ASO) (Ando and Zhang, 2005a) to construct the multi-task learning framework. ASO has been shown to be useful in a *semi-supervised learning* configuration for several NLP applications, such as, text chunking (Ando and Zhang, 2005b) and text classification (Ando and Zhang, 2005a).

### 3.2 Multi-task learning and ASO

Generally, multi-task learning (MTL) considers  $m$  prediction problems indexed by  $\ell \in \{1, \dots, m\}$ , each with  $n_\ell$  samples  $(X_i^\ell, Y_i^\ell)$  for  $i \in \{1, \dots, n_\ell\}$  ( $X_i$  are input *feature vectors* and  $Y_i$  are corresponding *classification labels*) and assumes that there exists a common predictive structure shared by these  $m$  problems. Generally, the joint linear model for MTL is to predict problem  $\ell$  in the following form:

$$f_\ell(\Theta, X) = w_\ell^T X + v_\ell^T \Theta X, \Theta \Theta^T = I, \quad (1)$$

where  $I$  is the identity matrix,  $w_\ell$  and  $v_\ell$  are weight vectors specific to each problem  $\ell$ , and  $\Theta$  is the structure matrix shared by all the  $m$  predictors. The main goal of MTL is to learn a common good feature map  $\Theta X$  for all the  $m$  problems. Several MTL methods have been presented to learn  $\Theta X$  for all the  $m$  problems. In this work, we adopt the ASO method.

Specifically, the ASO method adopted *singular value decomposition* (SVD) to obtain  $\Theta$  and  $m$  predictors that minimize the empirical risk summed over all the  $m$  problems. Thus, the problem of optimization becomes the minimization of the joint empirical risk written as:

$$\sum_{\ell=1}^m \left( \sum_{i=1}^{n_\ell} \frac{L(f_\ell(\Theta, X_i^\ell), Y_i)}{n_\ell} + \lambda \|W_\ell\|^2 \right) \quad (2)$$

where loss function  $L(\cdot)$  quantifies the difference between the prediction  $f(X_i)$  and the true output  $Y_i$  for each predictor, and  $\lambda$  is a regularization parameter for square regularization to control the model complexity. To minimize the empirical risk, ASO repeats the following alternating optimization procedure until a convergence criterion is met:

- 1) Fix  $(\Theta, V_\ell)$ , and find  $m$  predictors  $f_\ell$  that minimize the above joint empirical risk.
- 2) Fix  $m$  predictors  $f_\ell$ , and find  $(\Theta, V_\ell)$  that minimizes the above joint empirical risk.

### 3.3 Auxiliary tasks

There are two main principles to create auxiliary tasks. First, the auxiliary tasks should be automatically labeled in order to reduce the cost of manual labeling. Second, since the MTL model learns from the shared part of main task and auxiliary tasks, the auxiliary tasks should be quite relevant/similar to the main task. It is generally believed that the more the auxiliary tasks are relevant to the main task, the more the main task can benefit from the auxiliary tasks. Following these two principles, we create the auxiliary tasks by generating automatically labeled data as follows.

Previous work (Marcu and Echiabi, 2002) and (Sporleder and Lascarides, 2008) adopted predefined pattern-based approach to generate synthetic labeled data, where each predefined pattern has one discourse relation label. In contrast, we adopt an automatic approach to generate synthetic labeled data, where each discourse connective between two texts serves as their relation label. The reason lies in the very strong connection between discourse connectives and discourse relations. For example, the connective *but* always indicates a *contrast* relation between two texts. And (Pitler et al., 2008) proved that using only connective itself, the accuracy of explicit discourse relation classification is over 93%.

To build the mapping between discourse connective and discourse relation, for each connective, we count the times it appears in each relation and regard the relation in which it appears most frequently as its most relevant relation. Based on this mapping between connective and relation, we extract the synthetic labeled data containing the connective as training data for auxiliary tasks.

For example, *and* appears 3,000 times in PDTB as a discourse connective. Among them, it is manually annotated as an *Expansion* relation for 2,938 times. So we regard the *Expansion* relation as its most relevant relation and generate a mapping pattern like: “*and*  $\rightarrow$  *Expansion*”. Then we extract all sentences which contain discourse “*and*” and remove this connective “*and*” from sentences to generate synthetic implicit data. The resulting sentences are used in auxiliary task and automatically

marked as *Expansion* relation.

## 4 Implementation Details of Multi-task Learning Method

### 4.1 Data sets for *main* and *auxiliary* tasks

To examine whether there is a difference in synthetic implicit data generated from unannotated and annotated corpus, we use two corpora. One is a hand-annotated explicit discourse corpus, i.e., the explicit discourse relations in PDTB, denoted as *exp*. Another is an unannotated corpus, i.e., BLLIP (David McClosky and Johnson., 2008).

#### 4.1.1 Penn Discourse Treebank

PDTB (Prasad et al., 2008) is the largest hand-annotated corpus of discourse relation so far. It contains 2,312 Wall Street Journal (WSJ) articles. The sense label of discourse relations is hierarchically with three levels, i.e., *class*, *type* and *subtype*. The top level contains four major semantic *classes*: *Comparison* (denoted as *Comp.*), *Contingency* (*Cont.*), *Expansion* (*Exp.*) and *Temporal* (*Temp.*). For each class, a set of *types* is used to refine relation sense. The set of *subtypes* is to further specify the semantic contribution of each argument. In this paper, we focus on the top level (*class*) and the second level (*type*) relations because the *subtype* relations are too fine-grained and only appear in some relations.

Both explicit and implicit discourse relations are labeled in PDTB. In our experiment, the implicit discourse relations are used in the main task and for evaluation. While the explicit discourse relations are used in the auxiliary task. A detailed description of the data sources for different tasks is given below.

**Data set for main task** Following previous work in (Pitler et al., 2009) and (Zhou et al., 2010), the implicit relations in sections 2-20 are used as training data for the main task (denoted as *imp*) and the implicit relations in sections 21-22 are for evaluation. Table 1 shows the distribution of implicit relations. There are too few training instances for six second level relations (indicated by \* in Table 1), so we removed these six relations in our experiments.

**Data set for auxiliary task** All explicit instances in sections 00-24 in PDTB, i.e., 18,459 instances, are used for auxiliary task (denoted as *exp*). Following the method described in Section 3.3, we build the mapping patterns between con-

Top level	Second level	train	test

Table 1: Distribution of implicit discourse relations in the top and second level of PDTB

nectives and relations in PDTB and generate synthetic labeled data by removing the connectives. According to the most relevant relation sense of connective removed, the resulting instances are grouped into different data sets.

#### 4.1.2 BLLIP

BLLIP North American News Text (Complete) is used as unlabeled data source to generate synthetic labeled data. In comparison with the synthetic labeled data generated from the explicit relations in PDTB, the synthetic labeled data from BLLIP contains more noise. This is because the former data is manually annotated whether a word serves as discourse connective or not, while the latter does not manually disambiguate two types of ambiguity, i.e., whether a word serves as discourse connective or not, and the type of discourse relation if it is a discourse connective. Finally, we extract 26,412 instances from BLLIP (denoted as *BLLIP*) and use them for auxiliary task.

### 4.2 Feature representation

For both main task and auxiliary tasks, we adopt the following three feature types. These features are chosen due to their superior performance in previous work (Pitler et al., 2009) and our previous work (Zhou et al., 2010).

**Verbs:** Following (Pitler et al., 2009), we extract the pairs of verbs from both text spans. The number of verb pairs which have the same highest

Levin verb class levels (Levin, 1993) is counted as a feature. Besides, the average length of verb phrases in each argument is included as a feature. In addition, the part of speech tags of the main verbs (e.g., base form, past tense, 3rd person singular present, etc.) in each argument, i.e., MD, VB, VBD, VBG, VBN, VBP, VBZ, are recorded as features, where we simply use the first verb in each argument as the main verb.

**Polarity:** This feature records the number of positive, negated positive, negative and neutral words in both arguments and their cross product as well. For negated positives, we first locate the negated words in text span and then define the closely behind positive word as negated positive. The polarity of each word in arguments is derived from Multi-perspective Question Answering Opinion Corpus (MPQA) (Wilson et al., 2009).

**Modality:** We examine six modal words (i.e., *can*, *may*, *must*, *need*, *shall*, *will*) including their various tenses or abbreviation forms in both arguments. This feature records the presence or absence of modal words in both arguments and their cross product.

### 4.3 Classifiers used multi-task learning

We extract the above linguistically informed features from two synthetic implicit data sets (i.e., *BLLIP* and *exp*) to learn the auxiliary classifier and from the natural implicit data set (i.e., *imp*) to learn the main classifier. Under the ASO-based multi-task learning framework, the model of main task learns from the shared part of main task and auxiliary tasks. Specifically, we adopt multiple binary classification to build model for main task. That is, for each discourse relation, we build a binary classifier.

## 5 Experiments and Results

### 5.1 Experiments

Although previous work has been done on PDTB (Pitler et al., 2009) and (Lin et al., 2009), we cannot make a direct comparison with them because various experimental conditions, such as, different classification strategies (multi-class classification, multiple binary classification), different data preparation (feature extraction and selection), different benchmark data collections (different sections for training and test, different levels of discourse relations), different classifiers with various parameters (MaxEnt, Naïve Bayes, SVM, etc) and

even different evaluation methods ( $F_1$ , accuracy) have been adopted by different researchers.

Therefore, to address the two questions raised in Section 1 and to make the comparison reliable and reasonable, we performed experiments on the top and second level of PDTB using single task learning and multi-task learning, respectively. The systems using single task learning serve as baseline systems. Under the single task learning, various combinations of *exp* and *BLLIP* data are incorporated with *imp* data for the implicit discourse relation classification task.

We hypothesize that synthetic implicit data would contribute to the main task, i.e., the implicit discourse relation classification. Specifically, the natural implicit data (i.e., *imp*) are used to create main task and the synthetic implicit data (*exp* or *BLLIP*) are used to create auxiliary tasks for the purpose of optimizing the objective functions of main task. If the hypothesis is correct, the performance of main task would be improved by auxiliary tasks created from synthetic implicit data. Thus in the experiments of multi-task learning, only natural implicit examples (i.e., *imp*) data are used for main task training while different combinations of synthetic implicit examples (*exp* and *BLLIP*) are used for auxiliary task training.

We adopt precision, recall and their combination  $F_1$  for performance evaluation. We also perform one-tailed t-test to validate if there is significant difference between two methods in terms of  $F_1$  performance analysis.

### 5.2 Results

Table 2 summarizes the experimental results under single and multi-task learning on the top level of four PDTB relations with respect to different combinations of synthetic implicit data. For each relation, the first three rows indicate the results of using different single training data under single task learning and the last three rows indicate the results using different combinations of training data under single task and multi-task learning. The best  $F_1$  for every relation is shown in bold font. From this table, we can find that on four relations, our multi-task learning systems achieved the best performance using the combination of *exp* and *BLLIP* synthetic data.

Table 3 summarizes the best single task and the best multi-task learning results on the second level of PDTB. For four relations, i.e., Synchrony, Con-

cession, Alternative and List, the classifier labels no instances due to the small percentages for these four types.

Table 4 summarizes the one-tailed t-test results on the top level of PDTB between the best single task learning system (i.e., *imp*) and three multi-task learning systems (*imp:exp+BLLIP* indicates that *imp* is used for main task and the combination of *exp* and *BLLIP* are for auxiliary task). The systems with insignificant performance differences are grouped into one set and “>” and “>>” denote better than at significance level 0.01 and

0.001 respectively.

### 5.3 Discussion

From Table 2 to Table 4, several findings can be found as follows.

We can see that the multi-task learning systems perform consistently better than the single task learning systems for the prediction of implicit discourse relations. Our best multi-task learning system achieves an averaged  $F_1$  improvement of 5.86% over the best single task learning system on the top level of PDTB relations. Specifically, for

Class	One-tailed t-test results
Comp.	$(imp:exp+BLLIP, imp:exp, imp:BLLIP) \gg (imp)$
Cont.	$(imp:exp+BLLIP, imp:BLLIP) \gg (imp:exp) > (imp)$
Exp.	$(imp:exp+BLLIP, imp:BLLIP) \gg (imp:exp) > (imp)$
Temp.	$(imp:exp+BLLIP, imp:exp, imp:BLLIP) \gg (imp)$

Table 4: Statistical significance tests results.

the relations *Comp.*, *Cont.*, *Exp.*, *Temp.*, our best multi-task learning system achieve 4.26%, 7.06%, 8.8% and 3.34%  $F_1$  improvements over the best single task learning system. It indicates that using synthetic implicit data as auxiliary task greatly improves the performance of the main task. This is confirmed by the following t-tests in Table 4.

In contrast to the performance of multi-task learning, the performance of the best single task learning system has been achieved on natural implicit discourse data alone. This finding is consistent with (Sporleder and Lascarides, 2008). It indicates that under single task learning, directly adding synthetic implicit data to increase the number of training data cannot be helpful to implicit discourse relation classification. The possible reasons result from (1) the different nature of implicit and explicit discourse data in linguistics and (2) the noise brought from synthetic implicit data.

Based on the above analysis, we state that it is the way of utilizing synthetic implicit data that is important for implicit discourse relation classification.

Although all three multi-task learning systems outperformed single task learning systems, we find that the two synthetic implicit data sets have not been shown a universally consistent performance on four top level PDTB relations. On one hand, for the relations *Comp.* and *Temp.*, the performance of the two synthetic implicit data sets alone and their combination are comparable to each other and there is no significant difference between them. On the other hand, for the relations *Cont.* and *Exp.*, the performance of *exp* data is inferior to that of *BLLIP* and their combination. This is contrary to our original expectation that *exp* data which has been manually annotated for discourse connective disambiguation should outperform *BLLIP* which contains a lot of noise. This finding indicates that under the multi-task learning, it may not be worthy of using manually annotated corpus to generate auxiliary data. It is quite promising since it can provide benefits to reducing

the cost of human efforts on corpus annotation.

## 5.4 Ambiguity Analysis

Although our experiments show that synthetic implicit data can help implicit discourse relation classification under multi-task learning framework, the overall performance is still quite low (44.64% in  $F_1$ ). Therefore, we analyze the types of ambiguity in relations and connectives in order to motivate possible future work.

### 5.4.1 Ambiguity of implicit relation

Without explicit discourse connective, the implicit discourse relation instance can be understood in two or more different ways. Given the example E2 in PDTB, the PDTB annotators explain it as *Contingency* or *Expansion* relation and manually insert corresponding implicit connective *for one thing* or *because* to express its relation.

- (E2) **Arg1:**Now the stage is set for the battle to play out  
**Arg2:**The anti-programmers are getting some helpful thunder from Congress  
**Connective1:**because  
**Sense1:**Contingency.Cause.Reason  
**Connective2:**for one thing  
**Sense2:**Expansion.Instantiation (wsj\_0118)

Thus the ambiguity of implicit discourse relations makes this task difficult in itself.

### 5.4.2 Ambiguity of discourse connectives

As we mentioned before, even given an explicit discourse connective in text, its discourse relation still can be explained in two or more different ways. And for different connectives, the ambiguity of relation senses is quite different. That is, the most frequent sense is not always the only sense that a connective expresses. In example E3, “*since*” is explained by annotators to express *Temporal* or *Contingency* relation.

- (E3) **Arg1:**MiniScribe has been on the rocks  
**Arg2:****since** it disclosed early this year that its earnings reports for 1988 weren’t accurate.

Sense1:Temporal.Asynchronous.Succession

Sense2:Contingency.Cause.Reason

(wsj\_0003)

In PDTB, “since” appears 184 times in explicit discourse relations. It expresses *Temporal* relation for 80 times, *Contingency* relation for 94 times and both *Temporal* and *Contingency* for 10 time (like example E3). Therefore, although we use its most frequent sense, i.e., *Contingency*, to automatically extract sentences and label them, almost less than half of them actually express *Temporal* relation. Thus the ambiguity of discourse connectives is another source which has brought noise to data when we generate synthetical implicit discourse relation.

## 6 Conclusions

In this paper, we present a multi-task learning method to improve implicit discourse relation classification by leveraging synthetic implicit discourse data. Results on PDTB show that under the framework of multi-task learning, using synthetic discourse data as auxiliary task significantly improves the performance of main task. Our best multi-task learning system achieves an averaged  $F_1$  improvement of 5.86% over the best single task learning system on the top level of PDTB relations. Specifically, for the relations *Comp.*, *Cont.*, *Exp.*, *Temp.*, our best multi-task learning system achieves 4.26%, 7.06%, 8.8%, and 3.34%  $F_1$  improvements over a state of the art baseline system. This indicates that it is the way of utilizing synthetic discourse examples that is important for implicit discourse relation classification.

## Abstract

We propose a novel approach for developing a two-stage document-level discourse parser. Our parser builds a discourse tree by applying an optimal parsing algorithm to probabilities inferred from two Conditional Random Fields: one for intra-sentential parsing and the other for multi-sentential parsing. We present two approaches to combine these two stages of discourse parsing effectively. A set of empirical evaluations over two different datasets demonstrates that our discourse parser significantly outperforms the state-of-the-art, often by a wide margin.

## 1 Introduction

Discourse of any kind is not formed by independent and isolated textual units, but by related and structured units. Discourse analysis seeks to uncover such structures underneath the surface of the text, and has been shown to be beneficial for text summarization (Louis et al., 2010; Marcu, 2000b), sentence compression (Sporleder and Lapata, 2005), text generation (Prasad et al., 2005), sentiment analysis (Somasundaran, 2010) and question answering (Verberne et al., 2007).

Rhetorical Structure Theory (RST) (Mann and Thompson, 1988), one of the most influential theories of discourse, represents texts by labeled hierarchical structures, called Discourse Trees (DTs), as exemplified by a sample DT in Figure 1. The leaves of a DT correspond to contiguous Elementary Discourse Units (EDUs) (six in the example). Adjacent EDUs are connected by rhetorical relations (e.g., *Elaboration*, *Contrast*), forming larger discourse units (represented by internal

nodes), which in turn are also subject to this relation linking. Discourse units linked by a rhetorical relation are further distinguished based on their relative importance in the text: *nucleus* being the central part, whereas *satellite* being the peripheral one. Discourse analysis in RST involves two sub-tasks: *discourse segmentation* is the task of identifying the EDUs, and *discourse parsing* is the task of linking the discourse units into a labeled tree.

While recent advances in automatic discourse segmentation and sentence-level discourse parsing have attained accuracies close to human performance (Fisher and Roark, 2007; Joty et al., 2012), discourse parsing at the document-level still poses significant challenges (Feng and Hirst, 2012) and the performance of the existing document-level parsers (Hernault et al., 2010; Subba and Di-Eugenio, 2009) is still considerably inferior compared to human gold-standard. This paper aims to reduce this performance gap and take discourse parsing one step further. To this end, we address three key limitations of existing parsers as follows.

First, existing discourse parsers typically model the structure and the labels of a DT separately in a *pipeline* fashion, and also do not consider the sequential dependencies between the DT constituents, which has been recently shown to be critical (Feng and Hirst, 2012). To address this limitation, as the first contribution, we propose a novel document-level discourse parser based on probabilistic discriminative parsing models, represented as Conditional Random Fields (CRFs) (Sutton et al., 2007), to infer the probability of all possible DT constituents. The CRF models effectively represent the structure and the label of a DT constituent jointly, and whenever possible, capture the sequential dependencies between the constituents.

Second, existing parsers apply greedy and sub-optimal parsing algorithms to build the DT for a document. To cope with this limitation, our CRF models support a probabilistic bottom-up parsing

---

This work was conducted at the University of British Columbia, Vancouver, Canada.

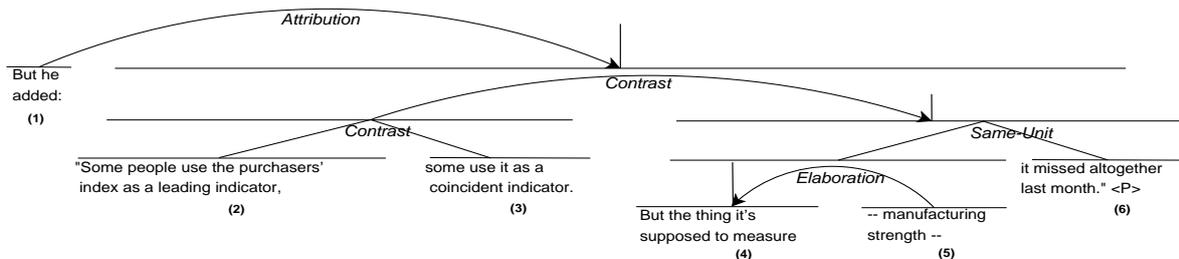

Figure 1: Discourse tree for two sentences in RST-DT. Each of the sentences contains three EDUs. The second sentence has a well-formed discourse tree, but the first sentence does not have one.

algorithm which is non-greedy and optimal.

Third, existing discourse parsers do not discriminate between intra-sentential (i.e., building the DTs for the individual sentences) and multi-sentential parsing (i.e., building the DT for the document). However, we argue that distinguishing between these two conditions can result in more effective parsing. Two separate parsing models could exploit the fact that rhetorical relations are distributed differently intra-sententially vs. multi-sententially. Also, they could independently choose their own informative features. As another key contribution of our work, we devise two different parsing components: one for intra-sentential parsing, the other for multi-sentential parsing. This provides for scalable, modular and flexible solutions, that can exploit the strong correlation observed between the text structure (sentence boundaries) and the structure of the DT.

In order to develop a complete and robust discourse parser, we combine our intra-sentential and multi-sentential parsers in two different ways. Since most sentences have a well-formed discourse sub-tree in the full document-level DT (for example, the second sentence in Figure 1), our first approach constructs a DT for every sentence using our intra-sentential parser, and then runs the multi-sentential parser on the resulting sentence-level DTs. However, this approach would disregard those cases where rhetorical structures violate sentence boundaries. For example, consider the first sentence in Figure 1. It does not have a well-formed sub-tree because the unit containing EDUs 2 and 3 merges with the next sentence and only then is the resulting unit merged with EDU 1. Our second approach, in an attempt of dealing with these cases, builds sentence-level sub-trees by applying the intra-sentential parser on a sliding window covering two adjacent sentences and by then consolidating the results produced by over-

lapping windows. After that, the multi-sentential parser takes all these sentence-level sub-trees and builds a full rhetorical parse for the document.

While previous approaches have been tested on only one corpus, we evaluate our approach on texts from two very different genres: news articles and instructional how-to-do manuals. The results demonstrate that our contributions provide consistent and statistically significant improvements over previous approaches. Our final result compares very favorably to the result of state-of-the-art models in document-level discourse parsing.

In the rest of the paper, after discussing related work in Section 2, we present our discourse parsing framework in Section 3. In Section 4, we describe the intra- and multi-sentential parsing components. Section 5 presents the two approaches to combine the two stages of parsing. The experiments and error analysis, followed by future directions are discussed in Section 6. Finally, we summarize our contributions in Section 7.

## 2 Related work

The idea of staging document-level discourse parsing on top of sentence-level discourse parsing was investigated in (Marcu, 2000a; LeThanh et al., 2004). These approaches mainly rely on discourse markers (or cues), and use hand-coded rules to build DTs for sentences first, then for paragraphs, and so on. However, often rhetorical relations are not explicitly signaled by discourse markers (Marcu and Echihiabi, 2002), and discourse structures do not always correspond to paragraph structures (Sporleder and Lascarides, 2004). Therefore, rather than relying on hand-coded rules based on discourse markers, recent approaches employ supervised machine learning techniques with a large set of informative features.

Hernault et al., (2010) presents the publicly available HILDA parser. Given the EDUs in a doc-

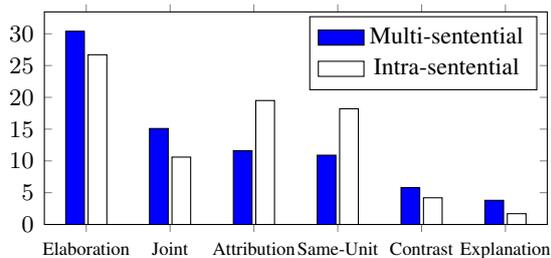

Figure 2: Distributions of six most frequent relations in intra-sentential and multi-sentential parsing scenarios.

ument, HILDA iteratively employs two Support Vector Machine (SVM) classifiers in pipeline to build the DT. In each iteration, a binary classifier first decides which of the adjacent units to merge, then a multi-class classifier connects the selected units with an appropriate relation label. They evaluate their approach on the RST-DT corpus (Carlson et al., 2002) of news articles. On a different genre of instructional texts, Subba and Di-Eugenio (2009) propose a shift-reduce parser that relies on a classifier for relation labeling. Their classifier uses Inductive Logic Programming (ILP) to learn first-order logic rules from a set of features including *compositional semantics*. In this work, we address the limitations of these models (described in Section 1) introducing our novel discourse parser.

### 3 Our Discourse Parsing Framework

Given a document with sentences already segmented into EDUs, the discourse parsing problem is determining which discourse units (EDUs or larger units) to relate (i.e., the structure), and how to relate them (i.e., the labels or the discourse relations) in the resulting DT. Since we already have an accurate sentence-level discourse parser (Joty et al., 2012), a straightforward approach to document-level parsing could be to simply apply this parser to the whole document. However this strategy would be problematic because of scalability and modeling issues. Note that the number of valid trees grows exponentially with the number of EDUs in a document.<sup>1</sup> Therefore, an exhaustive search over the valid trees is often unfeasible, even for relatively small documents.

For modeling, the problem is two-fold. On the one hand, it appears that rhetorical relations are distributed differently intra-sententially vs. multi-sententially. For example, Figure 2 shows a comparison between the two distributions of six most

<sup>1</sup>For  $n + 1$  EDUs, the number of valid discourse trees is actually the *Catalan number*  $C_n$ .

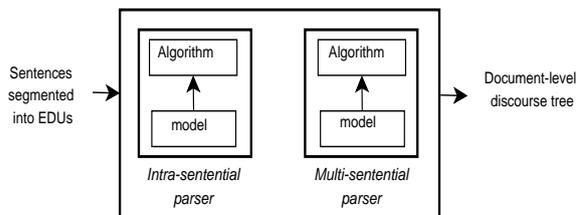

Figure 3: Discourse parsing framework.

frequent relations on a development set containing 20 randomly selected documents from RST-DT. Notice that relations *Attribution* and *Same-Unit* are more frequent than *Joint* in intra-sentential case, whereas *Joint* is more frequent than the other two in multi-sentential case. On the other hand, different kinds of features are applicable and informative for intra-sentential vs. multi-sentential parsing. For example, syntactic features like *dominance sets* (Soricut and Marcu, 2003) are extremely useful for sentence-level parsing, but are not even applicable in multi-sentential case. Likewise, *lexical chain features* (Sporleder and Lascarides, 2004), that are useful for multi-sentential parsing, are not applicable at the sentence level.

Based on these observations, our discourse parsing framework comprises two separate modules: an *intra-sentential parser* and a *multi-sentential parser* (Figure 3). First, the intra-sentential parser produces one or more discourse sub-trees for each sentence. Then, the multi-sentential parser generates a full DT for the document from these sub-trees. Both of our parsers have the same two components: a *parsing model* assigns a probability to every possible DT, and a *parsing algorithm* identifies the most probable DT among the candidate DTs in that scenario. While the two models are rather different, the same parsing algorithm is shared by the two modules. Staging multi-sentential parsing on top of intra-sentential parsing in this way allows us to exploit the strong correlation between the text structure and the DT structure as explained in detail in Section 5. Before describing our parsing models and the parsing algorithm, we introduce some terminology that we will use throughout the paper.

Following (Joty et al., 2012), a DT can be formally represented as a set of constituents of the form  $R[i, m, j]$ , referring to a rhetorical relation  $R$  between the discourse unit containing EDUs  $i$  through  $m$  and the unit containing EDUs  $m+1$  through  $j$ . For example, the DT for the second sentence in Figure 1 can be represented as

$\{Elaboration-NS[4,4,5], Same-Unit-NN[4,5,6]\}$ . Notice that a relation  $R$  also specifies the nuclearity statuses of the discourse units involved, which can be one of *Nucleus-Satellite (NS)*, *Satellite-Nucleus (SN)* and *Nucleus-Nucleus (NN)*.

#### 4 Parsing Models and Parsing Algorithm

The job of our intra-sentential and multi-sentential parsing models is to assign a probability to each of the constituents of all possible DTs at the sentence level and at the document level, respectively. Formally, given the model parameters  $\Theta$ , for each possible constituent  $R[i, m, j]$  in a candidate DT at the sentence or document level, the parsing model estimates  $P(R[i, m, j]|\Theta)$ , which specifies a joint distribution over the label  $R$  and the structure  $[i, m, j]$  of the constituent.

##### 4.1 Intra-Sentential Parsing Model

Recently, we proposed a novel parsing model for sentence-level discourse parsing (Joty et al., 2012), that outperforms previous approaches by effectively modeling sequential dependencies along with structure and labels jointly. Below we briefly describe the parsing model, and show how it is applied to obtain the probabilities of all possible DT constituents at the sentence level.

Figure 4 shows the intra-sentential parsing model expressed as a Dynamic Conditional Random Field (DCRF) (Sutton et al., 2007). The observed nodes  $U_j$  in a sequence represent the discourse units (EDUs or larger units). The first layer of hidden nodes are the structure nodes, where  $S_j \in \{0, 1\}$  denotes whether two adjacent discourse units  $U_{j-1}$  and  $U_j$  should be connected or not. The second layer of hidden nodes are the relation nodes, with  $R_j \in \{1 \dots M\}$  denoting the relation between two adjacent units  $U_{j-1}$  and  $U_j$ , where  $M$  is the total number of relations in the relation set. The connections between adjacent nodes in a hidden layer encode sequential dependencies between the respective hidden nodes, and can enforce constraints such as the fact that a  $S_j = 1$  must not follow a  $S_{j-1} = 1$ . The connections between the two hidden layers model the structure and the relation of a DT (sentence-level) constituent jointly.

To obtain the probability of the constituents of all candidate DTs for a sentence, we apply the parsing model recursively at different levels of the DT and compute the posterior marginals over the relation-structure pairs. To illustrate the

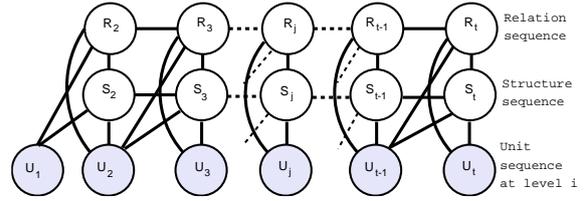

Figure 4: A chain-structured DCRF as our intra-sentential parsing model.

process, let us assume that the sentence contains four EDUs. At the first (bottom) level, when all the units are the EDUs, there is only one possible unit sequence to which we apply our DCRF model (Figure 5(a)). We compute the posterior marginals  $P(R_2, S_2=1|e_1, e_2, e_3, e_4, \Theta)$ ,  $P(R_3, S_3=1|e_1, e_2, e_3, e_4, \Theta)$  and  $P(R_4, S_4=1|e_1, e_2, e_3, e_4, \Theta)$  to obtain the probability of the constituents  $R[1, 1, 2]$ ,  $R[2, 2, 3]$  and  $R[3, 3, 4]$ , respectively. At the second level, there are three possible unit sequences  $(e_{1:2}, e_3, e_4)$ ,  $(e_1, e_{2:3}, e_4)$  and  $(e_1, e_2, e_{3:4})$ . Figure 5(b) shows their corresponding DCRFs. The posterior marginals  $P(R_3, S_3=1|e_{1:2}, e_3, e_4, \Theta)$ ,  $P(R_{2:3}, S_{2:3}=1|e_1, e_{2:3}, e_4, \Theta)$ ,  $P(R_4, S_4=1|e_1, e_{2:3}, e_4, \Theta)$  and  $P(R_{3:4}, S_{3:4}=1|e_1, e_2, e_{3:4}, \Theta)$  computed from the three sequences correspond to the probability of the constituents  $R[1, 2, 3]$ ,  $R[1, 1, 3]$ ,  $R[2, 3, 4]$  and  $R[2, 2, 4]$ , respectively. Similarly, we attain the probability of the constituents  $R[1, 1, 4]$ ,  $R[1, 2, 4]$  and  $R[1, 3, 4]$  by computing their respective posterior marginals from the three possible sequences at the third (top) level.

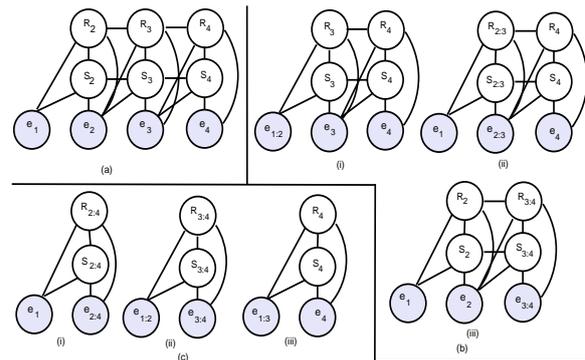

Figure 5: Our parsing model applied to the sequences at different levels of a sentence-level DT. (a) Only possible sequence at the first level, (b) Three possible sequences at the second level, (c) Three possible sequences at the third level.

At this point what is left to be explained is how we generate all possible sequences for a given number of EDUs in a sentence. Algorithm 1 demonstrates how we do that. More specifically, to compute the probabilities of each DT con-

stituent  $R[i, k, j]$ , we need to generate sequences like  $(e_1, \dots, e_{i-1}, e_{i:k}, e_{k+1:j}, e_{j+1}, \dots, e_n)$  for  $1 \leq i \leq k < j \leq n$ . In doing so, we may generate some duplicate sequences. Clearly, the sequence  $(e_1, \dots, e_{i-1}, e_{i:i}, e_{i+1:j}, e_{j+1}, \dots, e_n)$  for  $1 \leq i \leq k < j < n$  is already considered for computing the probability of  $R[i+1, j, j+1]$ . Therefore, it is a duplicate sequence that we exclude from our list of all possible sequences.

```

Input: Sequence of EDUs:  $(e_1, e_2, \dots, e_n)$ 
Output: List of sequences:  $L$ 
for  $i = 1 \rightarrow n - 1$  do
  for  $j = i + 1 \rightarrow n$  do
    if  $j == n$  then
      for  $k = i \rightarrow j - 1$  do
         $L.append$ 
         $((e_1, \dots, e_{i-1}, e_{i:k}, e_{k+1:j}, e_{j+1}, \dots, e_n))$ 
      end
    else
      for  $k = i + 1 \rightarrow j - 1$  do
         $L.append$ 
         $((e_1, \dots, e_{i-1}, e_{i:k}, e_{k+1:j}, e_{j+1}, \dots, e_n))$ 
      end
    end
  end
end

```

**Algorithm 1:** Generating all possible sequences for a sentence with  $n$  EDUs.

Once we obtain the probability of all possible DT constituents, the discourse sub-trees for the sentences are built by applying an optimal probabilistic parsing algorithm (Section 4.4) using one of the methods described in Section 5.

## 4.2 Multi-Sentential Parsing Model

Given the discourse units (sub-trees) for all the sentences of a document, a simple approach to build the rhetorical tree of the document would be to apply a new DCRF model, similar to the one in Figure 4 (with different parameters), to all the possible sequences generated from these units to infer the probability of all possible higher-order constituents. However, the number of possible sequences and their length increase with the number of sentences in a document. For example, assuming that each sentence has a well-formed DT, for a document with  $n$  sentences, Algorithm 1 generates  $O(n^3)$  sequences, where the sequence at the bottom level has  $n$  units, each of the sequences at the second level has  $n-1$  units, and so on. Since the model in Figure 4 has a “fat” chain structure,

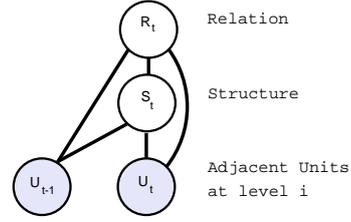

Figure 6: A CRF as a multi-sentential parsing model.

we could use forwards-backwards algorithm for exact inference in this model (Sutton and McCallum, 2012). However, forwards-backwards on a sequence containing  $T$  units costs  $O(TM^2)$  time, where  $M$  is the number of relations in our relation set. This makes the chain-structured DCRF model impractical for multi-sentential parsing of long documents, since learning requires to run inference on every training sequence with an overall time complexity of  $O(TM^2n^3)$  per document.

Our model for multi-sentential parsing is shown in Figure 6. The two observed nodes  $U_{t-1}$  and  $U_t$  are two adjacent discourse units. The (hidden) structure node  $S \in \{0, 1\}$  denotes whether the two units should be connected or not. The hidden node  $R \in \{1 \dots M\}$  represents the relation between the two units. Notice that like the previous model, this is also an undirected graphical model. It becomes a CRF if we directly model the hidden (output) variables by conditioning its clique potential (or factor)  $\phi$  on the observed (input) variables:

$$P(R_t, S_t | \mathbf{x}, \Theta) = \frac{1}{Z(\mathbf{x}, \Theta)} \phi(R_t, S_t | \mathbf{x}, \Theta) \quad (1)$$

where  $\mathbf{x}$  represents input features extracted from the observed variables  $U_{t-1}$  and  $U_t$ , and  $Z(\mathbf{x}, \Theta)$  is the partition function. We use a log-linear representation of the factor:

$$\phi(R_t, S_t | \mathbf{x}, \Theta) = \exp(\Theta^T f(R_t, S_t, \mathbf{x})) \quad (2)$$

where  $f(R_t, S_t, \mathbf{x})$  is a feature vector derived from the input features  $\mathbf{x}$  and the labels  $R_t$  and  $S_t$ , and  $\Theta$  is the corresponding weight vector. Although, this model is similar in spirit to the model in Figure 4, we now break the chain structure, which makes the inference much faster (i.e., complexity of  $O(M^2)$ ). Breaking the chain structure also allows us to balance the data for training (equal number instances with  $S=1$  and  $S=0$ ), which dramatically reduces the learning time of the model.

We apply our model to all possible adjacent units at all levels for the multi-sentential case, and

compute the posterior marginals of the relation-structure pairs  $P(R_t, S_t=1|U_{t-1}, U_t, \Theta)$  to obtain the probability of all possible DT constituents.

### 4.3 Features Used in our Parsing Models

Table 1 summarizes the features used in our parsing models, which are extracted from two adjacent units  $U_{t-1}$  and  $U_t$ . Since most of these features are adopted from previous studies (Joty et al., 2012; Hernault et al., 2010), we briefly describe them.

**Organizational** features include the *length* of the units as the number of EDUs and tokens. It also includes the *distances* of the units from the beginning and end of the sentence (or text in the multi-sentential case). **Text structural** features indirectly capture the correlation between text structure and rhetorical structure by counting the number of *sentence* and *paragraph* boundaries in the units. Discourse markers (e.g., *because*, *although*) carry informative clues for rhetorical relations (Marcu, 2000a). Rather than using a fixed list of discourse markers, we use an empirically learned *lexical N-gram* dictionary following (Joty et al., 2012). This approach has been shown to be more robust and flexible across domains (Biran and Rambow, 2011; Hernault et al., 2010). We also include part-of-speech (*POS*) tags for the beginning and end  $N$  tokens in a unit.

<b>8 Organizational features</b>	<b><i>Intra &amp; Multi-Sentential</i></b>
Number of EDUs in <i>unit 1</i> (or <i>unit 2</i> ).	
Number of tokens in <i>unit 1</i> (or <i>unit 2</i> ).	
Distance of unit 1 in EDUs to the <i>beginning</i> (or to the <i>end</i> ).	
Distance of unit 2 in EDUs to the <i>beginning</i> (or to the <i>end</i> ).	
<b>4 Text structural features</b>	<b><i>Multi-Sentential</i></b>
Number of sentences in <i>unit 1</i> (or <i>unit 2</i> ).	
Number of paragraphs in <i>unit 1</i> (or <i>unit 2</i> ).	
<b>8 N-gram features <math>N \in \{1, 2, 3\}</math></b>	<b><i>Intra &amp; Multi-Sentential</i></b>
<i>Beginning</i> (or <i>end</i> ) lexical N-grams in unit 1.	
<i>Beginning</i> (or <i>end</i> ) lexical N-grams in unit 2.	
<i>Beginning</i> (or <i>end</i> ) POS N-grams in unit 1.	
<i>Beginning</i> (or <i>end</i> ) POS N-grams in unit 2.	
<b>5 Dominance set features</b>	<b><i>Intra-Sentential</i></b>
Syntactic labels of the <i>head</i> node and the <i>attachment</i> node.	
Lexical heads of the <i>head</i> node and the <i>attachment</i> node.	
<i>Dominance relationship</i> between the two units.	
<b>8 Lexical chain features</b>	<b><i>Multi-Sentential</i></b>
Number of chains start in unit 1 and end in unit 2.	
Number of chains <i>start</i> (or <i>end</i> ) in <i>unit 1</i> (or in <i>unit 2</i> ).	
Number of chains skipping both unit 1 and unit 2.	
Number of chains skipping <i>unit 1</i> (or <i>unit 2</i> ).	
<b>2 Contextual features</b>	<b><i>Intra &amp; Multi-Sentential</i></b>
<i>Previous</i> and <i>next</i> feature vectors.	
<b>2 Substructure features</b>	<b><i>Intra &amp; Multi-Sentential</i></b>
Root nodes of the <i>left</i> and <i>right</i> rhetorical sub-trees.	

Table 1: Features used in our parsing models.

Lexico-syntactic features **dominance sets** (Soricut and Marcu, 2003) are very effective for intra-sentential parsing. We include *syntactic labels* and *lexical heads* of head and attachment nodes along with their *dominance relationship* as features. **Lexical chains** (Morris and Hirst, 1991) are sequences of semantically related words that can indicate topic shifts. Features extracted from lexical chains have been shown to be useful for finding paragraph-level discourse structure (Sporleder and Lascarides, 2004). We compute lexical chains for a document following the approach proposed in (Galley and McKeown, 2003), that extracts lexical chains after performing word sense disambiguation. Following (Joty et al., 2012), we also encode *contextual* and *rhetorical sub-structure* features in our models. The rhetorical sub-structure features incorporate hierarchical dependencies between DT constituents.

### 4.4 Parsing Algorithm

Given the probability of all possible DT constituents in the intra-sentential and multi-sentential scenarios, the job of the parsing algorithm is to find the most probable DT for that scenario. Following (Joty et al., 2012), we implement a probabilistic CKY-like bottom-up algorithm for computing the most likely parse using dynamic programming. Specifically, with  $n$  discourse units, we use the upper-triangular portion of the  $n \times n$  dynamic programming table  $D$ . Given  $U_x(0)$  and  $U_x(1)$  are the start and end EDU Ids of unit  $U_x$ :

$$D[i, j] = P(R[U_i(0), U_k(1), U_j(1)]) \quad (3)$$

where,  $k = \operatorname{argmax}_{i \leq p \leq j} P(R[U_i(0), U_p(1), U_j(1)])$ .

Note that, in contrast to previous studies on document-level parsing (Hernault et al., 2010; Subba and Di-Eugenio, 2009; Marcu, 2000b), which use a greedy algorithm, our approach finds a discourse tree that is globally optimal.

## 5 Document-level Parsing Approaches

Now that we have presented our intra-sentential and our multi-sentential parsers, we are ready to describe how they can be effectively combined to perform document-level discourse analysis. Recall that a key motivation for a two-stage parsing is that it allows us to capture the correlation between text structure and discourse structure in a scalable, modular and flexible way. Below we describe two different approaches to model this correlation.

## 5.1 1S-1S (1 Sentence-1 Sub-tree)

A key finding from several previous studies on sentence-level discourse analysis is that most sentences have a well-formed discourse sub-tree in the full document-level DT (Joty et al., 2012; Fisher and Roark, 2007). For example, Figure 7(a) shows 10 EDUs in 3 sentences (see boxes), where the DTs for the sentences obey their respective sentence boundaries. The 1S-1S approach aims to maximally exploit this finding. It first constructs a DT for every sentence using our intra-sentential parser, and then it provides our multi-sentential parser with the sentence-level DTs to build the rhetorical parse for the whole document.

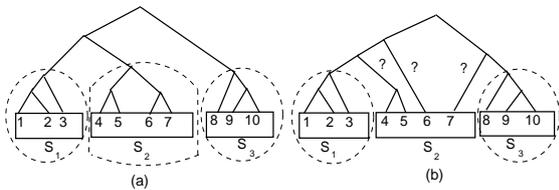

Figure 7: Two possible DTs for three sentences.

## 5.2 Sliding Window

While the assumption made by 1S-1S clearly simplifies the parsing process, it totally ignores the cases where discourse structures violate sentence boundaries. For example, in the DT shown in Figure 7(b), sentence  $S_2$  does not have a well-formed sub-tree because some of its units attach to the left (4-5, 6) and some to the right (7). Vliet and Redeker (2011) call these cases as ‘leaky’ boundaries. Even though less than 5% of the sentences have leaky boundaries in RST-DT, in other corpora this can be true for a larger portion of the sentences. For example, we observe over 12% sentences with leaky boundaries in the Instructional corpus of (Subba and Di-Eugenio, 2009). However, we notice that in most cases where discourse structures violate sentence boundaries, its units are merged with the units of its adjacent sentences, as in Figure 7(b). For example, this is true for 75% cases in our development set containing 20 news articles from RST-DT and for 79% cases in our development set containing 20 how-to-do manuals from the Instructional corpus. Based on this observation, we propose a sliding window approach.

In this approach, our intra-sentential parser works with a window of two consecutive sentences, and builds a DT for the two sentences. For example, given the three sentences in Figure 7, our

intra-sentential parser constructs a DT for  $S_1$ - $S_2$  and a DT for  $S_2$ - $S_3$ . In this process, each sentence in a document except the first and the last will be associated with two DTs: one with the previous sentence (say  $DT_p$ ) and one with the next (say  $DT_n$ ). In other words, for each non-boundary sentence, we will have two decisions: one from  $DT_p$  and one from  $DT_n$ . Our parser consolidates the two decisions and generates one or more sub-trees for each sentence by checking the following three mutually exclusive conditions one after another:

- *Same in both*: If the sentence has the same (in terms of both structure and labels) well-formed sub-tree in both  $DT_p$  and  $DT_n$ , we take this sub-tree for the sentence. For example, in Figure 8(a),  $S_2$  has the same sub-tree in the two DTs, i.e. a DT for  $S_1$ - $S_2$  and a DT for  $S_2$ - $S_3$ . The two decisions agree on the DT for the sentence.
- *Different but no cross*: If the sentence has a well-formed sub-tree in both  $DT_p$  and  $DT_n$ , but the two sub-trees vary either in structure or in labels, we pick the most probable one. For example, consider the DT for  $S_1$ - $S_2$  in Figure 8(a) and the DT for  $S_2$ - $S_3$  in Figure 8(b). In both cases  $S_2$  has a well-formed sub-tree, but they differ in structure. We pick the sub-tree which has the higher probability in the two dynamic programming tables.

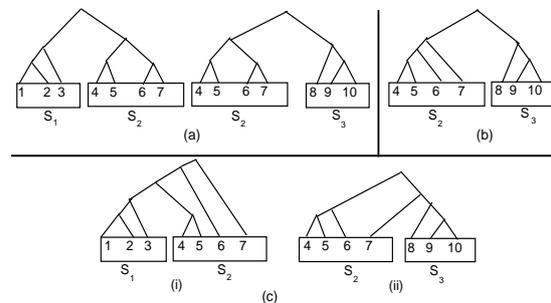

Figure 8: Extracting sub-trees for  $S_2$ .

- *Cross*: If either or both of  $DT_p$  and  $DT_n$  segment the sentence into multiple sub-trees, we pick the one with more sub-trees. For example, consider the two DTs in Figure 8(c). In the DT for  $S_1$ - $S_2$ ,  $S_2$  has three sub-trees (4-5,6,7), whereas in the DT for  $S_2$ - $S_3$ , it has two (4-6,7). So, we extract the three sub-trees for  $S_2$  from the first DT. If the sentence has the same number of sub-trees in both  $DT_p$  and  $DT_n$ , we pick the one with higher probability in the dynamic programming tables.

At the end, the multi-sentential parser takes all these sentence-level sub-trees for a document, and builds a full rhetorical parse for the document.

## 6 Experiments

### 6.1 Corpora

While previous studies on document-level parsing only report their results on a particular corpus, to show the generality of our method, we experiment with texts from two very different genres. Our first corpus is the standard *RST-DT* (Carlson et al., 2002), which consists of 385 Wall Street Journal articles, and is partitioned into a training set of 347 documents and a test set of 38 documents. 53 documents, selected from both sets were annotated by two annotators, based on which we measure human agreement. In *RST-DT*, the original 25 rhetorical relations defined by (Mann and Thompson, 1988) are further divided into a set of 18 coarser relation classes with 78 finer-grained relations. Our second corpus is the *Instructional* corpus prepared by (Subba and Di-Eugenio, 2009), which contains 176 how-to-do manuals on home-repair. The corpus was annotated with 26 informational relations (e.g., *Preparation-Act*, *Act-Goal*).

### 6.2 Experimental Setup

We experiment with our discourse parser on the two datasets using our two different parsing approaches, namely 1S-1S and the sliding window. We compare our approach with *HILDA* (Hernault et al., 2010) on *RST-DT*, and with the *ILP*-based approach of (Subba and Di-Eugenio, 2009) on the *Instructional* corpus, since they are the state-of-the-art on the respective genres. On *RST-DT*, the standard split was used for training and testing purposes. The results for *HILDA* were obtained by running the system with default settings on the same inputs we provided to our system. Since we could not run the *ILP*-based system of (Subba and Di-Eugenio, 2009) (not publicly available) on the *Instructional* corpus, we report the performances presented in their paper. They used 151 documents for training and 25 documents for testing. Since we did not have access to their particular split, we took 5 random samples of 151 documents for training and 25 documents for testing, and report the average performance over the 5 test sets.

To evaluate the parsing performance, we use the standard unlabeled (i.e., hierarchical spans) and labeled (i.e., nuclearity and relation) precision, recall and F-score as described in (Marcu, 2000b). To compare with previous studies, our experiments on *RST-DT* use the 18 coarser relations. After attaching the nuclearity statuses (NS,

SN, NN) to these relations, we get 41 distinct relations. Following (Subba and Di-Eugenio, 2009) on the *Instructional* corpus, we use 26 relations, and treat the reversals of non-commutative relations as separate relations. That is, *Goal-Act* and *Act-Goal* are considered as two different relations. Attaching the nuclearity statuses to these relations gives 76 distinct relations. Analogous to previous studies, we map the *n*-ary relations (e.g., *Joint*) into nested right-branching binary relations.

### 6.3 Results and Error Analysis

Table 2 presents F-score parsing results for our parsers and the existing systems on the two corpora.<sup>2</sup> On both corpora, our parser, namely, 1S-1S (TSP 1-1) and sliding window (TSP SW), outperform existing systems by a wide margin ( $p < 7.1e-05$ ).<sup>3</sup> On *RST-DT*, our parsers achieve absolute F-score improvements of 8%, 9.4% and 11.4% in span, nuclearity and relation, respectively, over *HILDA*. This represents relative error reductions of 32%, 23% and 21% in span, nuclearity and relation, respectively. Our results are also close to the upper bound, i.e. human agreement on this corpus.

On the *Instructional* genre, our parsers deliver absolute F-score improvements of 10.5%, 13.6% and 8.14% in span, nuclearity and relations, respectively, over the *ILP*-based approach. Our parsers, therefore, reduce errors by 36%, 27% and 13% in span, nuclearity and relations, respectively.

If we compare the performance of our parsers on the two corpora, we observe higher results on *RST-DT*. This can be explained in at least two ways. First, the *Instructional* corpus has a smaller amount of data with a larger set of relations (76 when nuclearity attached). Second, some frequent relations are (semantically) very similar (e.g., *Preparation-Act*, *Step1-Step2*), which makes it difficult even for the human annotators to distinguish them (Subba and Di-Eugenio, 2009).

Comparison between our two models reveals that TSP SW significantly outperforms TSP 1-1 only in finding the right structure on both corpora ( $p < 0.01$ ). Not surprisingly, the improvement is higher on the *Instructional* corpus. A likely explanation is that the *Instructional* corpus contains more leaky boundaries (12%), allowing the sliding

<sup>2</sup>Precision, Recall and F-score are the same when manual segmentation is used (see Marcu, (2000b), page 143).

<sup>3</sup>Since we did not have access to the output or to the system of (Subba and Di-Eugenio, 2009), we were not able to perform a significance test on the *Instructional* corpus.

Metrics	RST-DT				Instructional		
	HILDA	TSP 1-1	TSP SW	Human	ILP	TSP 1-1	TSP SW
Span	74.68	<b>82.47*</b>	<b>82.74*†</b>	88.70	70.35	<b>79.67</b>	<b>80.88†</b>
Nuclearity	58.99	<b>68.43*</b>	<b>68.40*</b>	77.72	49.47	<b>63.03</b>	<b>63.10</b>
Relation	44.32	<b>55.73*</b>	<b>55.71*</b>	65.75	35.44	<b>43.52</b>	<b>43.58</b>

Table 2: Parsing results of different models using manual (gold) segmentation. Performances significantly superior to HILDA (with  $p < 7.1e-05$ ) are denoted by \*. Significant differences between TSP 1-1 and TSP SW (with  $p < 0.01$ ) are denoted by †.

Figure 9: Confusion matrix for relation labels on the RST-DT test set. Y-axis represents *true* and X-axis represents *predicted* relations. The relations are Topic-Change (T-C), Topic-Comment (T-CM), Textual Organization (T-O), Manner-Means (M-M), Comparison (CMP), Evaluation (EV), Summary (SU), Condition (CND), Enablement (EN), Cause (CA), Temporal (TE), Explanation (EX), Background (BA), Contrast (CO), Joint (JO), Same-Unit (S-U), Attribution (AT) and Elaboration (EL).

window approach to be more effective in finding those, without inducing much noise for the labels. This clearly demonstrates the potential of TSP SW for datasets with even more leaky boundaries e.g., the Dutch (Vliet and Redeker, 2011) and the German Potsdam (Stede, 2004) corpora.

Error analysis reveals that although TSP SW finds more correct structures, a corresponding improvement in labeling relations is not present because in a few cases, it tends to induce noise from the neighboring sentences for the labels. For example, when parsing was performed on the first sentence in Figure 1 in isolation using 1S-1S, our parser rightly identifies the *Contrast* relation between EDUs 2 and 3. But, when it is considered with its neighboring sentences by the sliding window, the parser labels it as *Elaboration*. A promising strategy to deal with this and similar problems that we plan to explore in future, is to apply both approaches to each sentence and combine them by consolidating three probabilistic decisions, i.e. the one from 1S-1S and the two from sliding window.

To further analyze the errors made by our parser on the hardest task of relation labeling, Figure 9 presents the confusion matrix for TSP 1-1 on the RST-DT test set. The relation labels are ordered according to their frequency in the RST-DT training set. In general, the errors are produced by two different causes acting together: (i) imbalanced distribution of the relations, and (ii) semantic similarity between the relations. The most frequent relation *Elaboration* tends to mislead others especially, the ones which are semantically similar (e.g., *Explanation*, *Background*) and less frequent (e.g., *Summary*, *Evaluation*). The relations which are semantically similar mislead each other (e.g., *Temporal:Background*, *Cause:Explanation*).

These observations suggest two ways to improve our parser. We would like to employ a more robust method (e.g., *ensemble* methods with *bagging*) to deal with the imbalanced distribution of relations, along with taking advantage of a richer semantic knowledge (e.g., compositional semantics) to cope with the errors caused by semantic similarity between the rhetorical relations.

## 7 Conclusion

In this paper, we have presented a novel discourse parser that applies an optimal parsing algorithm to probabilities inferred from two CRF models: one for intra-sentential parsing and the other for multi-sentential parsing. The two models exploit their own informative feature sets and the distributional variations of the relations in the two parsing conditions. We have also presented two novel approaches to combine them effectively. Empirical evaluations on two different genres demonstrate that our approach yields substantial improvement over existing methods in discourse parsing.

## Abstract

This paper proposes a new method for significantly improving the performance of pairwise coreference models. Given a set of indicators, our method learns how to best separate types of mention pairs into equivalence classes for which we construct distinct classification models. In effect, our approach finds an optimal feature space (derived from a base feature set and indicator set) for discriminating coreferential mention pairs. Although our approach explores a very large space of possible feature spaces, it remains tractable by exploiting the structure of the hierarchies built from the indicators. Our experiments on the *CoNLL-2012 Shared Task* English datasets (gold mentions) indicate that our method is robust relative to different clustering strategies and evaluation metrics, showing large and consistent improvements over a single pairwise model using the same base features. Our best system obtains a competitive 67.2 of average F1 over MUC, B<sup>3</sup>, and CEAF which, despite its simplicity, places it above the mean score of other systems on these datasets.

## 1 Introduction

Coreference resolution is the problem of partitioning a sequence of noun phrases (or *mentions*), as they occur in a natural language text, into a set of referential *entities*. A common approach to this problem is to separate it into two modules: on the one hand, one defines a model for evaluating coreference links, in general a discriminative classifier that detects coreferential mention pairs. On

the other hand, one designs a method for grouping the detected links into a coherent global output (i.e. a partition over the set of entity mentions). This second step is typically achieved using greedy heuristics (McCarthy and Lehnert, 1995; Soon et al., 2001; Ng and Cardie, 2002; Bengston and Roth, 2008), although more sophisticated clustering approaches have been used, too, such as cutting graph methods (Nicolae and Nicolae, 2006; Cai and Strube, 2010) and Integer Linear Programming (ILP) formulations (Klenner, 2007; Denis and Baldridge, 2009). Despite its simplicity, this two-step strategy remains competitive even when compared to more complex models utilizing a global loss (Bengston and Roth, 2008).

In this kind of architecture, the performance of the entire coreference system strongly depends on the quality of the local pairwise classifier.<sup>1</sup> Consequently, a lot of research effort on coreference resolution has focused on trying to boost the performance of the pairwise classifier. Numerous studies are concerned with feature extraction, typically trying to enrich the classifier with more linguistic knowledge and/or more world knowledge (Ng and Cardie, 2002; Kehler et al., 2004; Ponzetto and Strube, 2006; Bengston and Roth, 2008; Versley et al., 2008; Uryupina et al., 2011). A second line of work explores the use of distinct local models for different types of mentions, specifically for different types of *anaphoric* mentions based on their grammatical categories (such as pronouns, proper names, definite descriptions) (Morton, 2000; Ng, 2005; Denis and Baldridge, 2008).<sup>2</sup> An important justification for such spe-

<sup>1</sup>There are however no theoretical guarantees that improving pair classification will always result in overall improvements if the two modules are optimized independently.

<sup>2</sup>Sometimes, distinct sample selections are also adopted

cialized models is (psycho-)linguistic and comes from theoretical findings based on salience or accessibility (Ariel, 1988). It is worth noting that, from a machine learning point of view, this is related to feature extraction in that both approaches in effect recast the pairwise classification problem in higher dimensional feature spaces.

In this paper, we claim that mention pairs should not be processed by a single classifier, and instead should be handled through specific models. But we are furthermore interested in *learning* how to construct and select such differential models. Our argument is therefore based on statistical considerations, rather than on purely linguistic ones<sup>3</sup>. The main question we raise is, given a set of indicators (such as grammatical types, distance between two mentions, or named entity types), how to best partition the pool of mention pair examples in order to best discriminate coreferential pairs from non coreferential ones. In effect, we want to learn the “best” subspaces for our different models: that is, subspaces that are neither too coarse (i.e., unlikely to separate the data well) nor too specific (i.e., prone to data sparseness and noise). We will see that this is also equivalent to selecting a single large adequate feature space by using the data.

Our approach generalizes earlier approaches in important ways. For one thing, the definition of the different models is no longer restricted to grammatical typing (our model allows for various other types of indicators) or to the sole typing of the anaphoric mention (our models can also be specific to a particular type antecedent or to the two types of the mention pair). More importantly, we propose an original method for learning the best set of models that can be built from a given set of indicators and a training set. These models are organized in a hierarchy, wherein each leaf corresponds to a mutually disjoint subset of mention pair examples and the classifier that can be trained from it. Our models are trained using the *Online Passive-Aggressive* algorithm or *PA* (Crammer et al., 2006), a large margin version of the perceptron. Our method is exact in that it explores the full space of hierarchies (of size at least  $2^{2^n}$ ) definable on an indicator sequence, while remaining scalable by exploiting the particular structure of these

---

during the training of the distinct local models (Ng and Cardie, 2002; Uryupina, 2004).

<sup>3</sup>However it should be underlined that the statistical viewpoint is complementary to the linguistic work.

hierarchies with dynamic programming. This approach also performs well, and it largely outperforms the single model. As will be shown based on a variety of experiments on the *CoNLL-2012 Shared Task* English datasets, these improvements are consistent across different evaluation metrics and for the most part independent of the clustering decoder that was used.

The rest of this paper is organized as follows. Section 2 discusses the underlying statistical hypotheses of the standard pairwise model and defines a simple alternative framework that uses a simple separation of mention pairs based on grammatical types. Next, in section 3, we generalize the method by introducing indicator hierarchies and explain how to learn the best models associated with them. Section 4 provides a brief system description and Section 5 evaluates the various models on CoNLL-2012 English datasets.

## 2 Modeling pairs

Pairwise models basically employ one local classifier to decide whether two mentions are coreferential or not. When using machine learning techniques, this involves certain assumptions about the statistical behavior of mention pairs.

### 2.1 Statistical assumptions

Let us adopt a probabilistic point of view to describe the prototype of pairwise models. Given a document, the number of mentions is fixed and each pair of mentions follows a certain distribution (that we partly observe in a feature space). The basic idea of pairwise models is to consider mention pairs independently from each other (that is why a decoder is necessary to enforce transitivity).

If we use a single classifier to process all pairs, then they are supposed to be identically distributed. We claim that pairs should not be processed by a single classifier because they are not identically distributed (or at least the distribution is too complex for the classifier); rather, we should separate different “types” on pairs and create a specific model for each of them.

Separating different kinds of pairs and handling them with different specific models can lead to more accurate global models. For instance, some coreference resolution systems process different kinds of anaphors separately, which suggests for example that pairs containing an anaphoric pronoun behave differently from pairs with non-

pronominal anaphors. One could rely on a rich set of features to capture complex distributions, but here we actually have a rather limited set of elementary features (see section 4) and, for instance, using products of features must be done carefully to avoid introducing noise in the model. Instead of imposing heuristic product of features, we will show that a clever separation of instances leads to significant improvements of the pairwise model.

## 2.2 Feature spaces

### 2.2.1 Definitions

We first introduce the problem more formally. Every pair of mentions  $m_i$  and  $m_j$  is modeled by a random variable:

$$\begin{aligned} P_{ij} : \Omega &\rightarrow \mathcal{X} \times \mathcal{Y} \\ \omega &\mapsto (x_{ij}(\omega), y_{ij}(\omega)) \end{aligned}$$

where  $\Omega$  classically represents randomness,  $\mathcal{X}$  is the space of objects (“mention pairs”) that is not directly observable and  $y_{ij}(\omega) \in \mathcal{Y} = \{+1, -1\}$  are the labels indicating whether  $m_i$  and  $m_j$  are coreferential or not. To lighten the notations, we will not always write the index  $ij$ . Now we define a mapping:

$$\begin{aligned} \phi_{\mathcal{F}} : \mathcal{X} &\rightarrow \mathcal{F} \\ x &\mapsto \mathbf{x} \end{aligned}$$

that casts pairs into a feature space  $\mathcal{F}$  through which we observe them. For us,  $\mathcal{F}$  is simply a vector space over  $\mathbb{R}$  (in our case many features are Boolean; they are cast into  $\mathbb{R}$  as 0 and 1).

For technical coherence, we assume that  $\phi_{\mathcal{F}_1}(x(\omega))$  and  $\phi_{\mathcal{F}_2}(x(\omega))$  have the same values when projected on the feature space  $\mathcal{F}_1 \cap \mathcal{F}_2$ : it means that common features from two feature spaces have the same values.

From this formal point of view, the task of coreference resolution consists in fixing  $\phi_{\mathcal{F}}$ , observing labeled samples  $\{(\phi_{\mathcal{F}}(x), y)_t\}_{t \in TrainSet}$  and, given partially observed new variables  $\{(\phi_{\mathcal{F}}(x))_t\}_{t \in TestSet}$ , recovering the corresponding values of  $y$ .

### 2.2.2 Formalizing the statistical assumptions

We claimed before that all mention pairs seemed not to be identically distributed since, for example, pronouns do not behave like nominals. We can formulate this more rigorously: since the object space  $\mathcal{X}$  is not directly observable, we do not

know its complexity. In particular, when using a mapping to a too small feature space, the classifier cannot capture the distribution very well: the data is too noisy.

Now if we say that pronominal anaphora do not behave like other anaphora, we distinguish two kinds of pair i.e. we state that the distribution of pairs in  $\mathcal{X}$  is a mixture of two distributions, and we deterministically separate pairs to their specific distribution part. In this way, we may separate positive and negative pairs more easily if we cast each kind of pair into a specific feature space. Let us call these feature spaces  $\mathcal{F}_1$  and  $\mathcal{F}_2$ . We can either create two independent classifiers on  $\mathcal{F}_1$  and  $\mathcal{F}_2$  to process each kind of pair or define a single model on a larger feature space  $\mathcal{F} = \mathcal{F}_1 \oplus \mathcal{F}_2$ . If the model is linear (which is our case), these approaches happen to be equivalent.

So we can actually assume that the random variables  $P_{ij}$  are identically distributed, but drawn from a complex mixture. A new issue arises: we need to find a mapping  $\phi_{\mathcal{F}}$  that renders the best view on the distribution of the data.

From a theoretical viewpoint, the higher the dimension of the feature space (imagine taking the direct sum of all feature spaces), the more we get details on the distribution of mention pairs and the more we can expect to separate positives and negatives accurately. In practice, we have to cope with data sparsity: there will not be enough data to properly train a linear model on such a space. Finally, we seek a feature space situated between the two extremes of a space that is too big (sparseness) or too small (noisy data). The core of this work is to define a general method for choosing the most adequate space  $\mathcal{F}$  among a huge number of possibilities when we do not know *a priori* which is the best.

### 2.2.3 Linear models

In this work, we try to linearly separate positive and negative instances in the large space  $\mathcal{F}$  with the *Online Passive-Aggressive* (PA) algorithm (Crammer et al., 2006): the model learns a parameter vector  $\mathbf{w}$  that defines a hyperplane that cuts the space into two parts. The predicted class of a pair  $x$  with feature vector  $\phi_{\mathcal{F}}(x)$  is given by:

$$C_{\mathcal{F}}(x) := \text{sign}(\mathbf{w}^T \cdot \phi_{\mathcal{F}}(x))$$

Linearity implies an equivalence between: (i) separating instances of two types,  $t_1$  and  $t_2$ , in two

independent models with respective feature spaces  $\mathcal{F}_1$  and  $\mathcal{F}_2$  and parameters  $\mathbf{w}^1$  and  $\mathbf{w}^2$ , and (ii) a single model on  $\mathcal{F}_1 \oplus \mathcal{F}_2$ . To see why, let us define the map:

$$\phi_{\mathcal{F}_1 \oplus \mathcal{F}_2}(x) := \begin{cases} \begin{pmatrix} \phi_{\mathcal{F}_1}(x)^T & 0 \end{pmatrix}^T & \text{if } x \text{ typed } t_1 \\ \begin{pmatrix} 0 & \phi_{\mathcal{F}_2}(x)^T \end{pmatrix}^T & \text{if } x \text{ typed } t_2 \end{cases}$$

and the parameter vector  $\mathbf{w} = \begin{pmatrix} \mathbf{w}^1 \\ \mathbf{w}^2 \end{pmatrix} \in \mathcal{F}_1 \oplus \mathcal{F}_2$ . Then we have:

$$C_{\mathcal{F}_1 \oplus \mathcal{F}_2}(x) = \begin{cases} C_{\mathcal{F}_1}(x) & \text{if } x \text{ typed } t_1 \\ C_{\mathcal{F}_2}(x) & \text{if } x \text{ typed } t_2 \end{cases}$$

Now we check that the same property applies when the PA fits its parameter  $\mathbf{w}$ . For each new instance of the training set, the weight is updated according to the following rule<sup>4</sup>:

$$\mathbf{w}_{t+1} = \arg \min_{\mathbf{w} \in \mathcal{F}} \frac{1}{2} \|\mathbf{w} - \mathbf{w}_t\|^2 \text{ s.t. } l(\mathbf{w}; (x_t, y_t)) = 0$$

where  $l(\mathbf{w}; (x_t, y_t)) = \min(0, 1 - y_t(\mathbf{w} \cdot \phi_{\mathcal{F}}(x_t)))$ , so that when  $\mathcal{F} = \mathcal{F}_1 \oplus \mathcal{F}_2$ , the minimum if  $x$  is typed  $t_1$  is  $\mathbf{w}_{t+1} = \begin{pmatrix} \mathbf{w}_{t+1}^1 \\ \mathbf{w}_t^2 \end{pmatrix}$  and if  $x$  is typed  $t_2$  is  $\mathbf{w}_{t+1} = \begin{pmatrix} \mathbf{w}_t^1 \\ \mathbf{w}_{t+1}^2 \end{pmatrix}$  where the  $\mathbf{w}_{t+1}^i$  correspond to the updates in space  $\mathcal{F}_i$  independently from the rest. This result can be extended easily to the case of  $n$  feature spaces. Thus, with a deterministic separation of the data, a large model can be learned using smaller independent models.

### 2.3 An example: separation by *gramtype*

To motivate our approach, we first introduce a simple separation of mention pairs which creates 9 models obtained by considering all possible pairs of grammatical types  $\{\textit{nominal}, \textit{name}, \textit{pronoun}\}$  for *both* mentions in the pair (a similar fine-grained separation can be found in (Chen et al., 2011)). This is equivalent to using 9 different feature spaces  $\mathcal{F}_1, \dots, \mathcal{F}_9$  to capture the global distribution of pairs. With the PA, this is also a single model with feature space  $\mathcal{F} = \mathcal{F}_1 \oplus \dots \oplus \mathcal{F}_9$ . We will call it the GRAMTYPE model.

As we will see in Section 5, these separated models significantly outperform a single model

<sup>4</sup>The parameter is updated to obtain a margin of a least 1. It does not change if the instance is already correctly classified with such margin.

that uses the same base feature set. But we would like to define a method that adapts a feature space to the data by choosing the most adequate separation of pairs.

## 3 Hierarchizing feature spaces

In this section, we have to keep in mind that separating the pairs in different models is the same as building a large feature space in which the parameter  $\mathbf{w}$  can be learned by parts in independent subspaces.

### 3.1 Indicators on pairs

For establishing a structure on feature spaces, we use *indicators* which are deterministic functions on mention pairs with a small number of outputs. Indicators classify pairs in predefined categories in one-to-one correspondence with independent feature spaces. We can reuse some features of the system as indicators, e.g. the grammatical or named entity types. We can also employ functions that are not used as features, e.g. the approximate position of one of the mentions in the text.

The small number of outputs of an indicator is required for practical reasons: if a category of pairs is too refined, the associated feature space will suffer from data sparsity. Accordingly, distance-based indicators must be approximated by coarse histograms. In our experiments the outputs never exceeded a dozen values. One way to reduce the output span of an indicator is to binarize it like binarizing a tree (many possible binarizations). This operation produces a hierarchy of indicators which is exactly the structure we exploit in what follows.

### 3.2 Hierarchies for separating pairs

We define hierarchies as combinations of indicators creating finer categories of mention pairs: given a finite sequence of indicators, a mention pair is classified by applying the indicators successively, each time refining a category into sub-categories, just like in a decision tree (each node having the same number of children as the number of outputs of its indicator). We allow the classification to stop before applying the last indicator, but the behavior must be the same for all the instances. So a hierarchy is basically a sub-tree of the complete decision tree that contains copies of the same indicator at each level.

If all the leaves of the decision tree have the

same depth, this corresponds to taking the Cartesian product of outputs of all indicators for indexing the categories. In that case, we refer to *product-hierarchies*. The GRAMTYPE model can be seen as a two level product-hierarchy (figure 1).

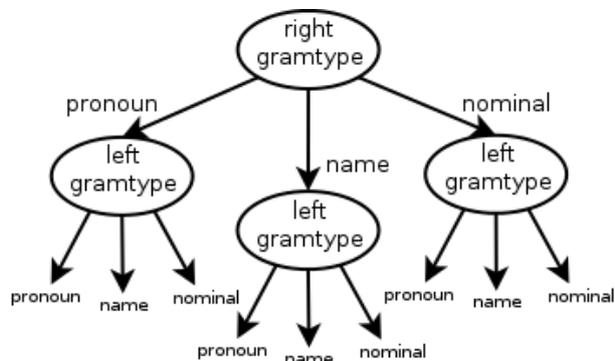

Figure 1: GRAMTYPE seen as a product-hierarchy

Product-hierarchies will be the starting point of our method to find a feature space that fits the data.

Now choosing a relevant sequence of indicators should be achieved through linguistic intuitions and theoretical work (*gramtype* separation is one of them). The system will find by itself the best usage of the indicators when optimizing the hierarchy. The sequence is a parameter of the model.

### 3.3 Relation with feature spaces

Like we did for the GRAMTYPE model, we associate a feature space  $\mathcal{F}_i$  to each leaf of a hierarchy. Likewise, the sum  $\mathcal{F} = \bigoplus_i \mathcal{F}_i$  defines a large feature space. The corresponding parameter  $w$  of the model can be obtained by learning the  $w_i$  in  $\mathcal{F}_i$ .

Given a sequence of indicators, the number of different hierarchies we can define is equal to the number of sub-trees of the complete decision tree (each non-leaf node having all its children). The minimal case is when all indicators are Boolean. The number of full binary trees of height at most  $n$  can be computed by the following recursion:  $T(1) = 1$  and  $T(n + 1) = 1 + T(n)^2$ . So  $T(n) \geq 2^{2^n}$ : even with small values of  $n$ , the number of different hierarchies (or large feature spaces) definable with a sequence of indicators is gigantic (e.g.  $T(10) \approx 3.8 \cdot 10^{90}$ ).

Among all the possibilities for a large feature space, many are irrelevant because for them the data is too sparse or too noisy in some subspaces. We need a general method for finding an adequate space without enumerating and testing each of them.

### 3.4 Optimizing hierarchies

Let us assume now that the sequence of indicators is fixed, and let  $n$  be its length. To find the best feature space among a very high number of possibilities, we need a criterion we can apply without too much additional computation. For that we only evaluate the feature space locally on pairs, i.e. without applying a decoder on the output. We employ 3 measures on pairwise classification results: precision, recall and F1-score. Now selecting the best space for one of these measures can be achieved by using dynamic programming techniques. In the rest of the paper, we will optimize the F1-score.

**Training the hierarchy** Starting from the product-hierarchy, we associate a classifier and its proper feature space to each node of the tree<sup>5</sup>. The classifiers are then trained as follows: for each instance there is a unique path from the root to a leaf of the complete tree. Each classifier situated on the path is updated with this instance. The number of iterations of the Passive-Aggressive is fixed.

**Computing scores** After training, we test all the classifiers on another set of pairs<sup>6</sup>. Again, a classifier is tested on an instance only if it is situated on the path from the root to the leaf associated with the instance. We obtain TP/FP/FN numbers<sup>7</sup> on pair classifications that are sufficient to compute the F1-score. As for training, the data on which a classifier at a given node is evaluated is the same as the union of all data used to evaluate the classifiers corresponding to the children of this node. Thus we are able to compare the scores obtained at a node to the “union of the scores” obtained at its children.

**Cutting down the hierarchy** For the moment we have a complete tree with a classifier at each node. We use a dynamic programming technique to compute the best hierarchy by cutting this tree and only keeping classifiers situated at the leaf. The algorithm assembles the best local models (or feature spaces) together to create larger models. It goes from the leaves to the root and cuts the subtree starting at a node whenever it does not pro-

<sup>5</sup>In the experiments, the classifiers use a copy of a same feature space, but not the same data, which corresponds to crossing the features with the categories of the decision tree.

<sup>6</sup>The training set is cut into two parts, for training and testing the hierarchy. We used 10-fold cross-validation in our experiments.

<sup>7</sup>True positives, false positives and false negatives.

vide a better score than the node itself, or on the contrary propagates the score of the sub-tree when there is an improvement. The details are given in algorithm 1.

```

1 list  $\leftarrow$  list of nodes given by a breadth-first
  search for node in reversed list do
2   if node.children  $\neq \emptyset$  then
3     if sum-score(node.children) >
      node.score then
4       node.TP/FP/FN  $\leftarrow$ 
        sum-num(node.children)
5     else
6       node.children  $\leftarrow \emptyset$ 
7     end
8   end
9 end

```

**Algorithm 1:** Cutting down a hierarchy

Let us briefly discuss the correctness and complexity of the algorithm. Each node is seen two times so the time complexity is linear in the number of nodes which is at least  $\mathcal{O}(2^n)$ . However, only nodes that have encountered at least one training instance are useful and there are  $\mathcal{O}(n \times k)$  such nodes (where  $k$  the size of the training set). So we can optimize the algorithm to run in time  $\mathcal{O}(n \times k)^8$ . If we scan the list obtained by breadth-first search backwards, we are ensured that every node will be processed after its children. (*node.children*) is the set of children of *node*, and (*node.score*) its score. *sum-num* provides TP/FP/FN by simply adding those of the children and *sum-score* computes the score based on these new TP/FP/FN numbers. (line 6) cuts the children of a node when they are not used in the best score. The algorithm thus propagates the best scores from the leaves to the root which finally gives a single score corresponding to the best hierarchy. Only the leaves used to compute the best score are kept, and they define the best hierarchy.

**Relation between cutting and the global feature space** We can see the operation of cutting as replacing a group of subspaces by a single subspace in the sum (see figure 2). So cutting down the product-hierarchy amounts to reducing the global initial feature space in an optimal way.

<sup>8</sup>In our experiments, cutting down the hierarchy was achieved very quickly, and the total training time was about five times longer than with a single model.

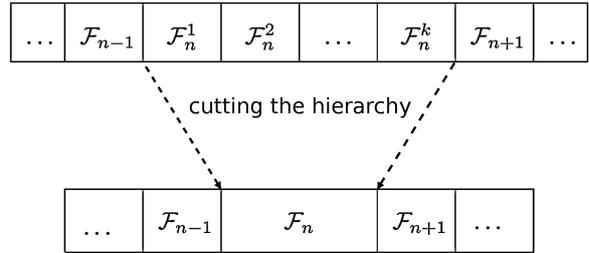

Figure 2: Cutting down the hierarchy reduces the feature space

To sum up, the whole procedure is equivalent to training more than  $\mathcal{O}(2^n)$  perceptrons simultaneously and selecting the best performing.

## 4 System description

Our system consists in the pairwise model obtained by cutting a hierarchy (the PA with selected feature space) and using a greedy decoder to create clusters from the output. It is parametrized by the choice of the initial sequence of indicators.

### 4.1 The base features

We used classical features that can be found in details in (Bengston and Roth, 2008) and (Rahman and Ng, 2011): grammatical type and sub-type of mentions, string match and substring, apposition and copula, distance (number of separating mentions/sentences/words), gender/number match, synonymy/hypernym and animacy (using WordNet), family name (based on lists), named entity types, syntactic features (gold parse) and anaphoricity detection.

### 4.2 Indicators

As indicators we used: left and right grammatical types and subtypes, entity types, a boolean indicating if the mentions are in the same sentence, and a very coarse histogram of distance in terms of sentences. We systematically included right gramtype and left gramtype in the sequences and added other indicators, producing sequences of different lengths. The parameter was optimized by document categories using a development set *after* decoding the output of the pairwise model.

### 4.3 Decoders

We tested 3 classical greedy link selection strategies that form clusters from the classifier decision: Closest-First (merge mentions with their closest coreferent mention on the left) (Soon et al., 2001),

Best-first (merge mentions with the mention on the left having the highest positive score) (Ng and Cardie, 2002; Bengtson and Roth, 2008), and Aggressive-Merge (transitive closure on positive pairs) (McCarthy and Lehnert, 1995). Each of these decoders is typically (although not always) used in tandem with a specific sampling selection at training. Thus, Closest-First for instance is used in combination with a sample selection that generates training instances only for the mentions that occur between the closest antecedent and the anaphor (Soon et al., 2001).

	P	R	F1

Table 1: Pairwise scores on CoNLL-2012 test.

## 5 Experiments

### 5.1 Data

We evaluated the system on the English part of the corpus provided in the *CoNLL-2012 Shared Task* (Pradhan et al., 2012), referred to as CoNLL-2012 here. The corpus contains 7 categories of documents (over 2K documents, 1.3M words). We used the official train/dev/test data sets. We evaluated our system in the *closed mode* which requires that only provided data is used.

### 5.2 Settings

Our baselines are a SINGLE MODEL, the GRAM-TYPE model (section 2) and a RIGHT-TYPE model, defined as the first level of the *gramtype* product hierarchy (i.e. grammatical type of the anaphora (Morton, 2000)), with each greedy decoder and also the original sampling with a single model associated with those decoders.

The hierarchies were trained with 10-fold cross-validation on the training set (the hierarchies are cut after cumulating the scores obtained by cross-validation) and their parameters are optimized *by document category* on the development set: the sequence of indicators obtaining the best average score *after* decoding was selected as parameter for the category. The obtained hierarchy is referred to as the BEST HIERARCHY in the results. We fixed the number of iterations for the PA for all models.

In our experiments, we consider only the *gold mentions*. This is a rather idealized setting but our focus is on comparing various pairwise local models rather than on building a full coreference resolution system. Also, we wanted to avoid having to consider too many parameters in our experiments.

### 5.3 Evaluation metrics

We use the three metrics that are most commonly used<sup>9</sup>, namely:

**MUC** (Vilain et al., 1995) computes for each true entity cluster the number of system clusters that are needed to cover it. Precision is this quantity divided by the true cluster size minus one. Recall is obtained by reversing true and predicated clusters. F1 is the harmonic mean.

**B<sup>3</sup>** (Bagga and Baldwin, 1998) computes recall and precision scores for each mention, based on the intersection between the system/true clusters for that mention. Precision is the ratio of the intersection and the true cluster sizes, while recall is the ratio of the intersection to the system cluster sizes. Global recall, precision, and F1 scores are obtained by averaging over the mention scores.

**CEAF** (Luo, 2005) scores are obtained by computing the best one-to-one mapping between the system/true partitions, which is equivalent to finding the best optimal alignment in the bipartite graph formed out of these partitions. We use the  $\phi_4$  similarity function from (Luo, 2005).

These metrics were recently used in the *CoNLL-2011* and *-2012 Shared Tasks*. In addition, these campaigns use an unweighted average over the F1 scores given by the three metrics. Following common practice, we use micro-averaging when reporting our scores for entire datasets.

### 5.4 Results

The results obtained by the system are reported in table 2. The original sampling for the single model associated to Closest-First and Best-First decoder are referred to as SOON and NGCARDIE.

The P/R/F1 pairwise scores before decoding are given in table 1. BEST HIERARCHY obtains a strong improvement in F1 (+15), a better precision and a less significant diminution of recall compared to GRAMTYPE and RIGHT-TYPE.

<sup>9</sup>BLANC metric (Recasens and Hovy, 2011) results are not reported since they are not used to compute the CoNLL-2012 global score. However we can mention that in our experiments, using hierarchies had a positive effect similar to what was observed on B<sup>3</sup> and CEAF.

Table 2: CoNLL-2012 test (gold mentions): Closest-First, Best-First and Aggressive-Merge decoders.

Despite the use of greedy decoders, we observe a large positive effect of pair separation in the pairwise models on the outputs. On the mean score, the use of distinct models versus a single model yields F1 increases from 6.4 up to 8.3 depending on the decoder. Irrespective of the decoder being used, GRAMTYPE always outperforms RIGHT-TYPE and single model and is always outperformed by BEST HIERARCHY model.

Interestingly, we see that the increment in pairwise and global score are not proportional: for instance, the strong improvement of F1 between RIGHT-TYPE and GRAMTYPE results in a small amelioration of the global score.

Depending on the document category, we found some variations as to which hierarchy was learned in each setting, but we noticed that parameters starting with right and left gramtypes often produced quite good hierarchies: for instance right gramtype  $\rightarrow$  left gramtype  $\rightarrow$  same sentence  $\rightarrow$  right named entity type.

We observed that product-hierarchies did not performed well without cutting (especially when using longer sequences of indicators, because of data sparsity) and could obtain scores lower than the single model. Hopefully, after cutting them the

results always became better as the resulting hierarchy was more balanced.

Looking at the different metrics, we notice that overall, pair separation improves B<sup>3</sup> and CEAF (but not always MUC) after decoding the output: GRAMTYPE provides a better mean score than the single model, and BEST HIERARCHY gives the highest B<sup>3</sup>, CEAF and mean score.

The best classifier-decoder combination reaches a score of 67.19, which would place it above the mean score (66.41) of the systems that took part in the *CoNLL-2012 Shared Task* (gold mentions track). Except for the first at 77.22, the best performing systems have a score around 68-69. Considering the simple decoding strategy we employed, our current system sets up a strong baseline.

## 6 Conclusion and perspectives

In this paper, we described a method for selecting a feature space among a very large number of choices by using linearity and by combining indicators to separate the instances. We employed dynamic programming on hierarchies of indicators to compute the feature space providing the best pairwise classifications efficiently. We applied this

method to optimize the pairwise model of a coreference resolution system. Using different kinds of greedy decoders, we showed a significant improvement of the system.

Our approach is flexible in that we can use a variety of indicators. In the future we will apply the hierarchies on finer feature spaces to make more accurate optimizations. Observing that the general method of cutting down hierarchies is not restricted to modeling mention pairs, but can be applied to problems having Boolean aspects, we aim at employing hierarchies to address other tasks in computational linguistics (e.g. anaphoricity detection or discourse and temporal relation classification wherein position information may help separating the data).

In this work, we have only considered standard, heuristic linking strategies like Closest-First. So, a natural extension of this work is to combine our method for learning pairwise models with more sophisticated decoding strategies (like *Bestcut* or using ILP). Then we can test the impact of hierarchies with more realistic settings.

Finally, the method for cutting hierarchies should be compared to more general but similar methods, for instance polynomial kernels for SVM and tree-based methods (Hastie et al., 2001). We also plan to extend our method by breaking the symmetry of our hierarchies. Instead of cutting product-hierarchies, we will employ usual techniques to build decision trees<sup>10</sup> and apply our cutting method on their structure. The objective is twofold: first, we will get rid of the sequence of indicators as parameter. Second, we will avoid fragmentation or overfitting (which can arise with classification trees) by deriving an optimal large margin linear model from the tree structure.

## Abstract

Techniques that compare short text segments using dependency paths (or simply, paths) appear in a wide range of automated language processing applications including question answering (QA). However, few models in ad hoc information retrieval (IR) use paths for document ranking due to the prohibitive cost of parsing a retrieval collection. In this paper, we introduce a flexible notion of paths that describe chains of words on a dependency path. These chains, or *catenae*, are readily applied in standard IR models. Informative *catenae* are selected using supervised machine learning with linguistically informed features and compared to both non-linguistic terms and *catenae* selected heuristically with filters derived from work on paths. Automatically selected *catenae* of 1-2 words deliver significant performance gains on three TREC collections.

## 1 Introduction

In the past decade, an increasing number of techniques have used complex and effective syntactic and semantic features to determine the similarity, entailment or alignment between short texts. These approaches are motivated by the idea that sentence meaning can be flexibly captured by the syntactic and semantic relations between words, and encoded in dependency parse tree fragments. Dependency paths (or simply, paths) are compared using techniques such as tree edit distance (Punyakonok et al., 2004; Heilman and Smith, 2010), relation probability (Gao et al., 2004) and parse tree alignment (Wang et al., 2007; Park et al., 2011).

Much work on sentence similarity using dependency paths focuses on question answering (QA) where textual inference requires attention to linguistic detail. Dependency-based techniques can also be highly effective for ad hoc information

retrieval (IR) (Park et al., 2011). However, few path-based methods have been explored for ad hoc IR, largely because parsing large document collections is computationally prohibitive.

In this paper, we explore a flexible application of dependency paths that overcomes this difficulty. We reduce paths to chains of words called *catenae* (Osborne and Groß, 2012) that capture salient semantic content in an underspecified manner. *Catenae* can be used as lexical units in a reformulated query to explicitly indicate important word relationships while retaining efficient and flexible proximity matching. Crucially, this does not require parsing documents. Moreover, *catenae* are compatible with a variety of existing IR models.

We hypothesize that *catenae* identify most units of salient knowledge in text. This is because they are a condition for ellipsis, in which salient knowledge can be successfully omitted from text (Osborne and Groß, 2012). To our knowledge, this paper is the first time that *catenae* are proposed as a means for term selection in IR, and where ellipsis is considered as a means for identification of semantic units.

We also extend previous work with development of a linguistically informed, supervised machine learning technique for selection of informative *catenae*. Previous heuristic filters for dependency paths (Lin and Pantel, 2001; Shen et al., 2005; Cui et al., 2005) can exclude informative relations. Alternatively, treating all paths as equally informative (Punyakonok et al., 2004; Park et al., 2011; Moschitti, 2008) can generate noisy word relations and is computationally intensive.

The challenge of path selection is that no explicit information in text indicates which paths are relevant. Consider the *catenae* captured by heuristic filters for the TREC<sup>1</sup> query, ‘*What role does blood-alcohol level play in automobile accident fatalities*’ (#358, Table 1). It may appear obvious that the component words of ‘*role play*’

<sup>1</sup>Text REtrieval Conference, see <http://trec.nist.gov/>

Query: What role does blood-alcohol level play in automobile* accident fatalities*? (*abbreviated to `auto`, `fatal`)				
Catenaes	Governor-dependent	Predicate-argument	Nominal end slots	Sequential dependence
blood alcohol level play auto accident accident fatal role play play fatal blood alcohol play play accident fatal auto accident fatal level play fatal role play fatal role level play	blood alcohol level play auto accident accident fatal role play play fatal	auto accident accident fatal  play fatal  play accident fatal auto accident fatal	auto accident accident fatal   auto accident fatal level play fatal role play fatal	blood alcohol level play auto accident accident fatal       role blood alcohol level play auto

Table 1: Catenaes derived from dependency paths, as selected by heuristic methods. Selections are compared to sequential bigrams that use no linguistic knowledge.

and ‘*level play*’ do not have an important semantic relationship relative to the query, yet these catenae are described by parent-child relations that are commonly used to filter paths in text processing applications. Alternative filters that avoid such trivial word combinations also omit descriptions of key entities such as ‘*blood alcohol*’, and identify longer catenae that may be overly restrictive. These shortcomings suggest that an optimized selection process may improve performance of techniques that use dependency paths in ad hoc IR.

We identify three previously proposed selection methods, and compare them on the task of catenae selection for ad hoc IR. Selections are tested using three TREC collections: Robust04, WT10G, and GOV2. This provides a diverse platform for experiments. We also develop a linguistically informed machine learning technique for catenae selection that captures both key aspects of heuristic filters, and novel characteristics of catenae and paths. The basic idea is that selection, or weighting, of catenae can be improved by features that are *specific to paths*, rather than *generic for all terms*.

Results show that our selection method is more effective in identifying key catenae compared to previously proposed filters. Integration of the identified catenae in queries also improves IR effectiveness compared to a highly effective baseline that uses sequential bigrams with no linguistic knowledge. This model represents the obvious alternative to catenae for term selection in IR.

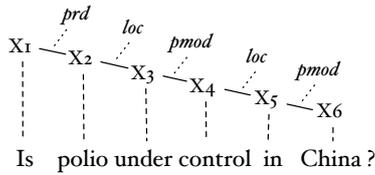

The rest of this paper is organised as follows. §2 reviews related work, §3 describes catenae and their linguistic motivation and §4 describes our selection method. §5 evaluates classification experiments using the supervised filter. §6 presents the results of experiments in ad hoc IR. Finally, §7 concludes the paper.

## 2 Related work

Techniques that compare short text segments using dependency paths are applied to a wide range of automated language processing tasks, including paraphrasing, summarization, entailment detection, QA, machine translation and the evaluation of word, phrase and sentence similarity. A generic approach uses a matching function to compare a dependency path between any two stemmed terms  $x$  and  $y$  in a sentence  $A$  with any dependency path between  $x$  and  $y$  in sentence  $B$ . The match score for  $A$  and  $B$  is computed over all dependency paths in  $A$ .

In QA this approach improves question representation, answer selection and answer ranking compared to methods that use bag-of-words and ngram features (Surdeanu et al., 2011). For example, Lin and Pantel (2001) present a method to derive paraphrasing rules for QA using analysis of paths that connect two nouns; Echihabi and Marcu (2003) align all paths in questions with trees for heuristically pruned answers; Cui et al. (2005) score answers using a variation of the IBM translation model 1; Wang et al. (2007) use quasi-synchronous translation to map all parent-child paths in a question to any path in an answer; and Moschitti (2008) explores syntactic and semantic kernels for QA classification.

In ad hoc IR, most models of term dependence use word co-occurrence and proximity (Song and Croft, 1999; Metzler and Croft, 2005; Srikanth and Srihari, 2002; van Rijsbergen, 1993). Syntactic language models for IR are a significant departure from this trend (Gao et al., 2004; Lee et al., 2006; Cai et al., 2007; Maisonnasse et al., 2007) that use dependency paths to address long-distance dependencies and normalize spurious differences in surface text. Paths are constrained in both

Catena (stoplisted)	Dependency paths
polio	<i>loc</i> <i>pmod</i>
polio control	polio → under → control
control	<i>loc</i> <i>pmod</i>
control China	control → in → China
China	<i>loc</i> <i>pmod</i> <i>loc</i> <i>pmod</i>
polio control China	polio → under → control → in → China

Figure 1: Catenae are an economical and intuitive representation of dependency paths.

queries and documents to parent-child relations. In contrast, (Park et al., 2011) present a quasi-synchronous translation model for IR that does not limit paths. This is based on the observation that semantically related words have a variety of direct and indirect relations. All of these models require parsing of an entire document collection.

Techniques using dependency paths in both QA and ad hoc IR show promising results, but there is no clear understanding of which path constraints result in the greatest IR effectiveness. We directly compare selections of catenae as a simplified representation of paths.

In addition, a vast number of methods have been presented for term weighting and selection in ad hoc IR. Our supervised selection extends the successful method presented by Bendersky and Croft (2008) for selection and weighting of query noun phrases (NPs). It also extends work for determining the variability of governor-dependent pairs (Song et al., 2008). In contrast to this work, we apply linguistic features that are specific to catenae and dependency paths, and select among units containing more than two content-bearing words.

### 3 Catenae as semantic units

Catenae (Latin for ‘chain’, singular *catena*) are dependency-based syntactic units. This section outlines their unique semantic properties.

A catena is defined on a dependency graph that has lexical nodes (or words) linked by binary asymmetrical relations called dependencies. Dependencies hold between a *governor* and a *dependent* and may be syntactic or semantic in nature (Nivre, 2005). A dependency graph is usually acyclic such that each node has only one governor, and one root node of the tree does not depend on any other node.

A catena is a word, or sequence of words that are continuous with respect to a walk on a dependency

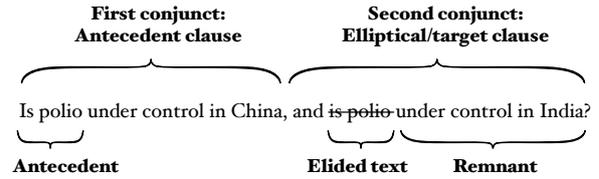

Figure 2: Ellipsis in a coordinated construct.

graph. For example, Fig. 1 shows a dependency parse that generates 21 catenae in total: (using  $i$  for  $X_i$ ) 1, 2, 3, 4, 5, 6, 12, 23, 34, 45, 56, 123, 234, 345, 456, 1234, 2345, 3456, 12345, 23456, 123456. We process catenae to remove stop words on the INQUERY stoplist (Allan et al., 2000) and lexical units containing 18 TREC description stop words such as ‘describe’. This results in a reduced set of catenae as shown in Fig. 1.

A dependency path is ordered and includes both word tokens and the relations between them. In contrast, a catena is a set of word types that may be ordered or partially ordered. A catena is an economical, intuitive lexical unit that corresponds to a dependency path and is argued to play an important role in syntax (Osborne et al., 2012).

In this paper, we explore catenae instead of paths for ad hoc IR due to their suitability for efficient IR models and flexible representation of language semantics. Specifically, we note that catenae identify words that can be omitted in elliptical constructions (Osborne et al., 2012). They thus represent *salient semantic information* in text. To clarify this insight, we briefly review catenae in ellipsis.

#### 3.1 Semantic units in ellipsis

Fig. 2 shows terminology for the phenomenon of ellipsis. The omitted words are called *elided* text, and words that could be omitted, but are not, we call *elliptical candidates*.

Ellipsis relies on the logical structure of a coordinated construction in which two or more elements, such as sentences, are joined by a conjunctive word or phrase such as ‘and’ or ‘more than’. A coordinated structure is required because the omitted words are ‘filled in’ by assuming a parallel relation  $p$  between the first and second conjunct. In ellipsis,  $p$  is omitted and its arguments are retained in text. In order for ellipsis to be successful and grammatically correct,  $p$  must be salient shared knowledge at the time of communication (Prince, 1986; Steedman, 1990). If  $p$  is salient then the omitted text can be inferred. If  $p$  is not salient then the omission of words merely results in ungrammatical, or incoherent, sentences.

This framework is practically illustrated in Fig.

Nugues, 2008) to generate the dependency parse. This enables us to explore semantic classification features and is highly accurate. However, any dependency parser may be applied instead. For comparison, catenae extracted from 500 queries using the Stanford dependency parser (de Marneffe et al., 2006) overlap with 77% of catenae extracted from the same queries using the applied parser.

#### 4.1 Feature Classes

Four feature classes are presented in Table 2:

**Ellipsis candidates:** The ellipsis hypothesis suggests that informative catenae are elliptical candidates. However, queries are not in the coordinated structures required for ellipsis. To enable extraction of characteristic features we (a) construct a *coordinated query* by adding the query to itself; and (b) elide catenae from the second conjunct. For example, for the query, *Is polio under control in China?* we have:

- (a) Is polio under control in China, and is polio under control in China?
- (b) Is polio under control in China, and is polio in China?

We refer to the words in (b) as the *query remainder* and use this to identify features detailed in Table 2.

**Dependency path features:** Part-of-speech tags and semantic roles have been used to filter dependency paths. We identify several features that use these characteristics from prior work (Table 2).

In addition, variability in the separation distance in documents observed for words that have governor-dependent relations in queries has been proposed for identification of promising paths (Song et al., 2008). We also observe that due to the phenomenon of rising, words that form catenae can be discontinuous in text, and the ability of catenae to match similar word combinations is limited by variability of how they appear in documents. Thus, we propose features for separation distance, but use efficient collection statistics rather than summing statistics for every document in a collection.

**Co-occurrence features:** A governor  $w_1$  tends to subcategorize for its dependents  $w_n$ . This means that  $w_1$  often determines the choice of  $w_n$ . We conclude that co-occurrence is an important feature of dependency relations (Mel'čuk, 2003). In addition, term frequencies and inverse document frequencies calculated using word co-occurrence measures are commonly used in IR. We use features previously proposed for filtering terms in IR (Bendersky and Croft, 2008) with two methods

to normalize co-occurrence counts for catenae of different lengths: a factor  $|c|^{-|c|}$ , where  $|c|$  is the number of words in catena  $c$  (Hagen et al., 2011), and the average score for a feature type over all pairwise word combinations in  $c$ .

**IR performance predictors:** Catenae take the same form as typical IR search terms. For this reason, we also use predictors of IR effectiveness previously applied to IR terms.

In general, path and co-occurrence features are similar to those applied by Surdeanu et al. (2011) but we do not parse documents. Path features are also similar to Song et al. (2008), but more efficient and suited to units of variable length. Ellipsis features have not been used before.

## 5 Experimental setup

### 5.1 Classification

Catenae selection is framed as a supervised classification problem trained on binary human judgments of *informativeness*: how well catenae represent a query and discriminate between relevant and non-relevant documents in a collection. Kappa for two annotators on catenae in 100 sample queries was 0.63, and test-retest reliability for individual judges was similar  $(0.62)^3$ . Although this is low, human annotations produced consistently better classification accuracy than other labelling methods explored.

We use the Weka (Hall et al., 2009) Adaboost.M1 meta-classifier (Freund and Schapire, 1996) with unpruned C4.5 decision trees as base learners to classify catenae as informative or not. Adaboost.M1 boosts decisions over  $T$  weak learners for  $T$  features using weighted majority voting. At each round, predictions of a new learner are focused on incorrectly classified examples from the previous round. Adaboost.M1 was selected in preference to other algorithms because it performed better in preliminary experiments, leverages many weak features to advantage, and usually does not overfit (Schapire et al., 1997).

Predictions are made using 10-fold cross-validation. There are roughly three times the number of uninformative catenae compared to informative catenae. In addition, the number of training examples is small (1295 to 5163 per collection). To improve classifier accuracy, the training data for each collection is supplemented and balanced by generating examples from queries for

<sup>3</sup>Catenae, judgments and annotation details available at [ciir.cs.umass.edu/~tmaxwell](http://ciir.cs.umass.edu/~tmaxwell)

Ellipsis candidate features (E)	
<i>R_ppl1</i>	Minimum perplexity of ngrams with length 2, 3, and 4 in a window of up to a 3 words around the site of catenae omission. This is the area where ungrammaticality may be introduced. For the remainder R='ABCDE&ABE' we compute ppl1 for {&ABE, &AB, ABE, &A, AB, BE}.
<i>R_strict</i>	Compliance with strict hand-coded rules for grammaticality of a remainder. Rules include unlikely orderings of punctuation and part-of-speech (POS) tags (e.g. ,, ), poor placement of determiners and punctuation, and orphaned words, such as adjectives without the nouns they modify.
<i>R_relax</i>	A relaxed version of hand-coded rules for <i>R_strict</i> . Some rules were observed to be overly aggressive in detection of ungrammatical remainders.
<i>NP_split</i>	Unsuccessful ellipsis often results if elided words only partly describe a base NP. Boolean feature for presence of a partial NP in the remainder. NPs (and PPs) are identified using the MontyLingua toolkit.
<i>PP_split</i>	As for <i>NP_split</i> , defined for prepositional phrases (PP).
<i>F_split</i>	As for <i>NP_split</i> , defined for finite clauses.
Dependency path features (D)	
<i>c_ppl1</i>	Dependency paths traverse nodes including stopwords and may be filtered based on POS tags. We use perplexity for the sequence of POS tags in catenae before removing stopwords. This is computed using a POS language model built on ukWaC parsed wikipedia data (Baroni et al., 2009).
<i>phClass</i>	Phrasal class for a catena, with options <i>NP</i> , <i>VP</i> and <i>Other</i> . A catena has a NP or VP class if it is, or is entirely contained by, an NP or VP (Song et al., 2008).
<i>semRole</i>	Boolean feature indicating whether a catena describes all, or part of, a predicate-argument structure (PAS). Previous work approximated PAS by using paths between head nouns and verbs, and all paths excluding those within base chunks.
<i>nomEnd</i>	Boolean indicating whether the words at each end of the catena are nouns (or the catena is a single noun).
<i>sepMode</i>	Most frequent separation distance of words in catena <i>c</i> in the retrieval collection, with possible values $S = \{1, 2, 3, long\}$ . 1 means that all words are adjacent, 2 means separation by 0-1 words, and <i>long</i> means containment in a window of size $4 *  c $ .
<i>H_c</i>	Entropy for separation distance <i>s</i> of words in catena <i>c</i> in the retrieval collection. $f_s$ is the frequency of <i>c</i> in window size <i>s</i> , and $f_S$ is the frequency of <i>c</i> in a window of size $4 *  c $ . All $f$ are normalized for catena length using $ c ^{ c }$ (Hagen et al., 2011). $H_c = \sum_{s \in S} \frac{f_s + 0.5}{f_S + 0.5} \log_2 \frac{f_s + 0.5}{f_S + 0.5}$

Dependency path features (D) (continued)	
<i>sepRatio</i>	Where $f_s$ and $f_S$ are defined as for <i>H_c</i> : $sepRatio_c = \frac{f_{s>2} + 0.5}{f_S + 0.5}$
<i>wRatio</i>	For words <i>w</i> in catena <i>c</i> ; $f_S$ is defined as for <i>H_c</i> . $wRatio_c = \frac{0.5 + \frac{1}{ c } \sum_{w \in c} f_w}{f_S + 0.5}$
Co-occurrence features (C)	
<i>isSeq</i>	Boolean indicating if catena words are sequential in stoplisted surface text.
<i>cf_ow</i>	Frequency of a catena in the retrieval collection, words appearing ordered in a window the length of the catena.
<i>cf_uw</i>	As for <i>cf_ow</i> , but words may appear unordered.
<i>cf_uw8</i>	As for <i>cf_uw</i> , but the window has a length of 8 words.
<i>idf_ow</i>	Inverse document frequency ( <i>idf</i> ) where document frequency ( <i>df</i> ) of a catena is calculated using <i>cf_ow</i> windows. Let <i>N</i> be the number of documents in the retrieval collection, then: $idf(C_i) = \log_2 \frac{N}{df(C_i)}$ and $idf(C_i) = N$ if $df(C_i) = 0$ .
<i>idf_uw</i>	As for <i>idf_ow</i> , but words may appear unordered.
<i>idf_uw8</i>	As for <i>idf_uw</i> , but the window has a length of 8 words.
<i>gf</i>	Google ngrams frequency (Brants and Franz, 2006) from a web crawl of approximately one trillion English word tokens. Counts from a large collection are expected to be more reliable than those from smaller test collections.
<i>qf_in</i>	Frequency of appearance in queries from the Live Search 2006 search query log (approximately 15 million queries). Query log frequencies are a measure of the likelihood that a catena will appear in any query.
<i>wf_in</i>	As for <i>qf_in</i> , but using frequency counts in Wikipedia titles instead of queries.
IR performance prediction features (I)	
<i>c_len</i>	Length of a stopped catenae. Longer terms tend to reduce IR recall.
<i>WIG</i>	Normalized Weighted Information Gain (WIG) is the change in information over top ranked documents between a random ranked list and an actual ranked list retrieved with a catena <i>c</i> (Zhou and Croft, 2007). $wig(c) = \frac{\frac{1}{k} \sum_{d \in D_k(c)} \log p(c d) - \log p(c C)}{-\log p(c C)}$ where $D_k$ are the top $k=50$ documents retrieved with catena <i>c</i> from collection <i>C</i> , and $p(c \cdot)$ are maximum likelihood estimates. A second feature uses the average WIG score for all pairwise word combinations in <i>c</i> .

Table 2: Classifier features.

	Feature Classes							
	E-D-CI		E-D		E-CI		D-CI	
	Pr	R	Pr	R	Pr	R	Pr	R
ROB04	86.2	72.8	83.5	67.5	86.2	71.7	86.2	72.0
WT10G	79.3	67.1	76.9	59.7	77.2	65.6	79.6	66.1
GOV2	77.0	68.0	70.9	61.8	72.8	63.9	75.5	67.2

Table 3: Average classifier precision (Pr) and recall (R) over 10 folds. Pr is % positive predictions that are correct. R is % positive labeled instances predicted as positive. A combination of all classes marginally performs best.

other collections used in this paper, plus TREC8-QA. For example, training data for Robust04 includes data from WT10G, GOV2 and TREC8-QA. Any examples that replicate catenae in the test collection are excluded. For Robust04, WT10G and GOV2 respectively, 30%, 82% and 69% of the training data is derived from other collections.

## 5.2 Classification results

Average classification precision and recall is shown in Table 3. Co-occurrence and IR effectiveness prediction features (CI) was the most influential class, and accounted for 70% of all features in the model. Performance is marginally better using all features (E-D-CI) with a moderate improvement over human agreement on the annotation task. The E-D-CI filter is used in subsequent experiments.

Catenae were predicted for all queries. Predictions were more accurate for Robust04 than the other two collections. One potential explanation is that Robust04 queries are longer on average (up to 32 content words per query, compared to up to 16 words) so they generate a more diverse set of catenae that are more easily distinguished with respect to informativeness. The proportion of training data specific to the retrieval collection may also be a factor. Longer queries produce a greater number of catenae, so less training data from other collections is required.

## 6 Evaluation framework

### 6.1 Baseline IR models

Baselines are a unigram query likelihood (QL) model (bag of words) and a highly effective sequential dependence (SD) variant of the Markov random field (MRF) model (Metzler and Croft, 2005). SD uses a linear combination of three cliques of terms, where each clique is prioritized by a weight  $\lambda_c$ . The first clique contains individual words (query likelihood  $QL$ ),  $\lambda_1 = 0.85$ . The second clique contains query bigrams that match

document bigrams in 2-word ordered windows ( $\#l^1$ ),  $\lambda_2 = 0.1$ . The third clique uses the same bigrams as clique 2 with an 8-word unordered window ( $\#uw8^8$ ),  $\lambda_3 = 0.05$ . For example, the query *new york city* in Indri<sup>4</sup> query language is:

```
#weight(
 $\lambda_1$  #combine(new york city)
 $\lambda_2$  #combine(#1(new york) #1(york city))
 $\lambda_3$  #combine(#uw8(new york) #uw8(york city)))
```

SD is a competitive baseline in IR (Bendersky and Croft, 2008; Park et al., 2011; Xue et al., 2010). Our reformulated model uses the same query format as SD, but the second and third cliques contain filtered catenae instead of query bigrams. In addition, because catenae may be multi-word units, we adjust the unordered window size to  $4 * |c|$ . So, if two catenae ‘*york*’ and ‘*new york city*’ are selected, the last clique has the form:

```
 $\lambda_3$  #combine( york #uw12(new york city))
```

This query representation enables word relations to be explicitly indicated while maintaining efficient and flexible matching of catenae in documents. Moreover, it does not use dependency relations between words during retrieval, so there is no need to parse a collection.

### 6.2 Baseline catenae selection

We explore four filters for catenae. Three are based on previous work and describe heuristic features of promising catenae. The fourth is our novel supervised classifier.

**NomEnd:** Catenae starting and ending with nouns, or containing only one word that is a noun. Paths between nouns are used by Lin and Pantel (2001).

**SemRol:** Catenae in which all component words are either predicates or argument heads. This is based on work that uses paths between head nouns and verbs (Shen et al., 2005), semantic roles (Moschitti, 2008), and all dependency paths except those that occur between words in the same base chunk (e.g. noun / verb phrase) (Cui et al., 2005).

**GovDep:** Catenae containing words with a governor-dependent relation. Many IR models use this form of path filtering e.g. (Gao et al., 2004; Wang et al., 2007). Relations are ‘collapsed’ by removing stopwords to reduce the distance between content nodes in a dependency graph.

Table 5: Results with supervised selection of catenae with specified length (SF-12, SF-123) are more effective than combinations of SFeat with heuristic NomEnd (SF-NE) or GovDep (SF-GD).

### 6.3 Experiments

Experiments compare queries reformulated using catenae selected by baseline filters and our supervised selection method (SFeat) to SD and a bag-of-words model (QL). We also compare IR effectiveness of all catenae filtered using SFeat with approaches that combine SFeat with baseline filters. All models are implemented using the Indri retrieval engine version 4.12.

### 6.4 Results

Results in Table 4 show significant improvement in mean average precision (MAP) of queries using catenae compared to QL. Consistent improvements over SD are also demonstrated for supervised selection applied to all catenae (SFeat) and catenae with only 1-2 words (SF-12) across all collections (Table 5). Overall, changes are small and fairly robust, with one half to two thirds of all queries showing less than 10% change in MAP.

Unlike sFeat, other filters tend to decrease performance compared to SD. Governor-dependent relations for WT10G are an exception and we speculate that this is due to a negative influence of 3-word catenae for this collection. Manual inspection suggests that WT10G queries are short and have relatively simple syntactic structure (e.g. few PP attachment ambiguities). This means that 3-word catenae (in all models except GovDep) tend to include uninformative words, such as ‘*reasons*’ in ‘*fasting religious reasons*’. In contrast, 3-word cate-

nae in other collections tend to identify query sub-concepts or phrases, such as ‘*science plants water*’.

Classification results for catenae separated by length, such that the classifier for catenae with a specific length are trained on examples of catenae with the same length, confirm this intuition. The rejection rate for 3-word catenae is twice as high for WT10G as for other collections. It is also more difficult to distinguish informative 3-word catenae compared to catenae with 1-2 words. To assess the impact of classification accuracy on IR effectiveness, Table 5 shows results with oracle knowledge of annotator judgments.

The SF-12 model combines catenae predicted for lengths 1 and 2. Its strong performance across all collections suggests that most of the benefit derived from catenae in IR is found in governor-dependent and single word units, where single words are important (GovDep uses only 2-word catenae). Another major observation (Table 5) is that mixing baseline heuristic filters with a supervised approach is not as successful as supervised selection alone. In particular, performance decreases for filtered governor-dependent pairs. This suggests that some important word relations in GovDep and NomEnd are captured by triangulation.

Finally, we review selected catenae for queries that perform significantly better or worse than SD ( $> 75\%$  change in MAP). The best IR effectiveness occurs when selected catenae clearly focus on the most important aspect of a query. Poor perfor-

mance is caused by a lack of focus in a catenae set, even though selected catenae are reasonable, or an emphasis on words that are not central to the query. The latter can occur when words that are not essential to query semantics appear in many catenae due to their position in the dependency graph.

## 7 Conclusion

We presented a flexible implementation of dependency paths for long queries in ad hoc IR that does not require dependency parsing a collection. Our supervised selection technique for catenae addresses the need to balance a representation of language expressiveness with effective, efficient statistical methods. This is a core challenge in computational linguistics.

It is not possible to directly compare performance of our approach with ad hoc techniques in IR that parse a retrieval collection. However, we note that a recent result using query translation based on dependency paths (Park et al., 2011) reports 14% improvement over query likelihood (QL). Our approach achieves 7% improvement over QL on the same collection. We conclude that catenae do not replace path-based techniques, but may offer some insight into their application, and have particular value when it is not practical to parse target documents to determine text similarity.

## Abstract

Paratactic syntactic structures are notoriously difficult to represent in dependency formalisms. This has painful consequences such as high frequency of parsing errors related to coordination. In other words, coordination is a pending problem in dependency analysis of natural languages. This paper tries to shed some light on this area by bringing a systematizing view of various formal means developed for encoding coordination structures. We introduce a novel taxonomy of such approaches and apply it to treebanks across a typologically diverse range of 26 languages. In addition, empirical observations on convertibility between selected styles of representations are shown too.

## 1 Introduction

In the last decade, dependency parsing has gradually been receiving visible attention. One of the reasons is the increased availability of dependency treebanks, be they results of genuine dependency annotation projects or converted automatically from previously existing phrase-structure treebanks.

In both cases, a number of decisions have to be made during the construction or conversion of a dependency treebank. The traditional notion of dependency does not always provide unambiguous solutions, e.g. when it comes to attaching functional words. Worse, dependency representation is at a loss when it comes to representing paratactic linguistic phenomena such as coordination, whose nature is symmetric (two or more conjuncts play the same role), as opposed to the head-modifier asymmetry of dependencies.<sup>1</sup>

<sup>1</sup>We use the term *modifier* (or *child*) for all types of dependent nodes including *arguments*.

The dominating solution in treebank design is to introduce artificial rules for the encoding of coordination structures within dependency trees using the same means that express dependencies, i.e., by using edges and by labeling of nodes or edges. Obviously, any tree-shaped representation of a coordination structure (CS) must be perceived only as a “shortcut” since relations present in coordination structures form an undirected cycle, as illustrated already by Tesnière (1959). For example, if a noun is modified by two coordinated adjectives, there is a (symmetric) coordination relation between the two conjuncts and two (asymmetric) dependency relations between the conjuncts and the noun.

However, as there is no obvious linguistic intuition telling us which tree-shaped CS encoding is better and since the degree of freedom has several dimensions, one can find a number of distinct conventions introduced in particular dependency treebanks. Variations exist both in topology (tree shape) and labeling. The main goal of this paper is to give a systematic survey of the solutions adopted in these treebanks.

Naturally, the interplay of dependency and coordination links in a single tree leads to serious parsing issues.<sup>2</sup> The present study does not try to decide which coordination style is the best from the parsing point of view.<sup>3</sup> However, we believe that our survey will substantially facilitate experiments in this direction in the future, at least by exploring and describing the space of possible candidates.

<sup>2</sup>CSs have been reported to be one of the most frequent sources of parsing errors (Green and Žabokrtský, 2012; McDonald and Nivre, 2007; Kübler et al., 2009; Collins, 2003). Their impact on quality of dependency-based machine translation can also be substantial; as documented on an English-to-Czech dependency-based translation system (Popel and Žabokrtský, 2009), 39% of serious translation errors which are caused by wrong parsing have to do with coordination.

<sup>3</sup>There might be no such answer, as different CS conventions might serve best for different applications or for different parser architectures.

The rest of the paper is structured as follows. Section 2 describes some known problems related to CS. Section 3 shows possible “styles” for representing CS. Section 4 lists treebanks whose CS conventions we studied. Section 5 presents empirical observations on CS convertibility. Section 6 concludes the paper.

## 2 Related work

Let us first recall the basic well-known characteristics of CSs.

In the simplest case of a CS, a coordinating conjunction joins two (usually syntactically and semantically compatible) words or phrases called conjuncts. Even this simplest case is difficult to represent within a dependency tree because, in the words of Lombardo and Lesmo (1998): *Dependency paradigms exhibit obvious difficulties with coordination because, differently from most linguistic structures, it is not possible to characterize the coordination construct with a general schema involving a head and some modifiers of it.*

Proper formal representation of CSs is further complicated by the following facts:

- CSs with more than two conjuncts (multi-conjunct CSs) exist and are frequent.
- Besides “private” modifiers of individual conjuncts, there are modifiers shared by all conjuncts, such as in “*Mary came and cried*”. Shared modifiers may appear alongside with private modifiers of particular conjuncts.
- Shared modifiers can be coordinated, too: “*big and cheap apples and oranges*”.
- Nested (embedded) coordinations are possible: “*John and Mary or Sam and Lisa*”.
- Punctuation (commas, semicolons, three dots) is frequently used in CSs, mostly with multi-conjunct coordinations or juxtapositions which can be interpreted as CSs without conjunctions (e.g. “*Don’t worry, be happy!*”).
- In many languages, comma or other punctuation mark may play the role of the main coordinating conjunction.
- The coordinating conjunction may be a multiword expression (“*as well as*”).
- Deficient CSs with a single conjunct exist.
- Abbreviations like “*etc.*” comprise both the

conjunction and the last conjunct.

- Coordination may form very intricate structures when combined with ellipsis. For example, a conjunct can be elided while its arguments remain in the sentence, such as in the following traditional example: “*I gave the books to Mary and the records to Sue.*”
- The border between paratactic and hypotactic surface means of expressing coordination relations is fuzzy. Some languages can use enclitics instead of conjunctions/prepositions, e.g. Latin “*Senatus Populusque Romanus*”. Purely hypotactic surface means such as the preposition in “*John with Mary*” occur too.<sup>4</sup>
- Careful semantic analysis of CSs discloses additional complications: if a node is modified by a CS, it might happen that it is the node itself (and not its modifiers) what should be semantically considered as a conjunct. Note the difference between “*red and white wine*” (which is synonymous to “*red wine and white wine*”) and “*red and white flag of Poland*”. Similarly, “*five dogs and cats*” has a different meaning than “*five dogs and five cats*”.

Some of these issues were recognized already by Tesnière (1959). In his solution, conjuncts are connected by vertical edges directly to the head and by horizontal edges to the conjunction (which constitutes a cycle in every CS). Many different models have been proposed since, out of which the following are the most frequently used ones:

- MS = Mel’čuk style used in the Meaning-Text Theory (MTT): the first conjunct is the head of the CS, with the second conjunct attached as a dependent of the first one, third conjunct under the second one, etc. Coordinating conjunction is attached under the penultimate conjunct, and the last conjunct is attached under the conjunction (Mel’čuk, 1988),
- PS = Prague Dependency Treebank (PDT) style: all conjuncts are attached under the coordinating conjunction (along with shared modifiers, which are distinguished by a special attribute) (Hajič et al., 2006),

<sup>4</sup>As discussed by Stassen (2000), all languages seem to have some strategy for expressing coordination. Some of them lack the paratactic surface means (the so called WITH-languages), but the hypotactic surface means are present almost always.

- SS = Stanford parser style:<sup>5</sup> the first conjunct is the head and the remaining conjuncts (as well as conjunctions) are attached under it.

One can find various arguments supporting the particular choices. MTT possesses a complex set of linguistic criteria for identifying the governor of a relation (see Mazziotta (2011) for an overview), which lead to MS. MS is preferred in a rule-based dependency parsing system of Lombardo and Lesmo (1998). PS is advocated by Štěpánek (2006) who claims that it can represent shared modifiers using a single additional binary attribute, while MS would require a more complex co-indexing attribute. An argumentation of Tratz and Hovy (2011) follows a similar direction: *We would like to change our [MS] handling of coordinating conjunctions to treat the coordinating conjunction as the head [PS] because this has fewer ambiguities than [MS]. . .*

We conclude that the influence of the choice of coordination style is a well-known problem in dependency syntax. Nevertheless, published works usually focus only on a narrow ad-hoc selection of few coordination styles, without giving any systematic perspective.

Choosing a file format presents a different problem. Despite various efforts to standardize linguistic annotation,<sup>6</sup> no commonly accepted standard exists. The primitive format used for CoNLL shared tasks is widely used in dependency parsing, but its weaknesses have already been pointed out (cf. Straňák and Štěpánek (2010)). Moreover, particular treebanks vary in their contents even more than in their format, i.e. each treebank has its own way of representing prepositions or different granularity of syntactic labels.

### 3 Variations in representing coordination structures

Our analysis of variations in representing coordination structures is based on observations from a set of dependency treebanks for 26 languages.<sup>7</sup>

<sup>5</sup>We use the already established MS-PS-SS distinction to facilitate literature overview; as shown in Section 3, the space of possible coordination styles is much richer.

<sup>6</sup>For example, TEI (TEI Consortium, 2013), PML (Hana and Štěpánek, 2012), SynAF (ISO 24615, 2010).

<sup>7</sup>The primary data sources are the following: *Ancient Greek*: Ancient Greek Dependency Treebank (Bamman and Crane, 2011), *Arabic*: Prague Arabic Dependency Treebank 1.0 (Smrž et al., 2008), *Basque*: Basque Dependency Treebank (larger version than CoNLL 2007 generously pro-

In accordance with the usual conventions, we assume that each sentence is represented by one dependency tree, in which each node corresponds to one token (word or punctuation mark). Apart from that, we deliberately limit ourselves to CS representations that have shapes of connected subgraphs of dependency trees.

We limit our inventory of means of expressing CSs within dependency trees to (i) tree topology (presence or absence of a directed edge between two nodes, Section 3.1), and (ii) node labeling (additional attributes stored inside nodes, Section 3.2).<sup>8</sup> Further, we expect that the set of possible variations can be structured along several dimensions, each of which corresponds to a certain simple characteristic (such as choosing the leftmost conjunct as the CS head, or attaching shared modifiers below the nearest conjunct). Even if it does not make sense to create the full Cartesian product of all dimensions because some values cannot be combined, it allows to explore the space of possible CS styles systematically.<sup>9</sup>

#### 3.1 Topological variations

We distinguish the following dimensions of topological variations of CS styles (see Figure 1):

**Family – configuration of conjuncts.** We divide the topological variations into three main groups, labeled as Prague (fP), Moscow (fM), and

vided by IXA Group) (Aduriz and others, 2003), *Bulgarian*: BulTreeBank (Simov and Osenova, 2005), *Czech*: Prague Dependency Treebank 2.0 (Hajič et al., 2006), *Danish*: Danish Dependency Treebank (Kromann et al., 2004), *Dutch*: Alpino Treebank (van der Beek and others, 2002), *English*: Penn TreeBank 3 (Marcus et al., 1993), *Finnish*: Turku Dependency Treebank (Haverinen et al., 2010), *German*: Tiger Treebank (Brants et al., 2002), *Greek (modern)*: Greek Dependency Treebank (Prokopidis et al., 2005), *Hindi, Bengali and Telugu*: Hyderabad Dependency Treebank (Husain et al., 2010), *Hungarian*: Szeged Treebank (Csendes et al., 2005), *Italian*: Italian Syntactic-Semantic Treebank (Montemagni and others, 2003), *Latin*: Latin Dependency Treebank (Bamman and Crane, 2011), *Persian*: Persian Dependency Treebank (Rasooli et al., 2011), *Portuguese*: Floresta sintá(c)tica (Afonso et al., 2002), *Romanian*: Romanian Dependency Treebank (Călăcean, 2008), *Russian*: Syntagrus (Boguslavsky et al., 2000), *Slovene*: Slovene Dependency Treebank (Džeroski et al., 2006), *Spanish*: AnCora (Taulé et al., 2008), *Swedish*: Talbanken05 (Nilsson et al., 2005), *Tamil*: TamilTB (Ramasamy and Žabokrtský, 2012), *Turkish*: METU-Sabancı Turkish Treebank (Atalay et al., 2003).

<sup>8</sup>Edge labeling can be trivially converted to node labeling in tree structures.

<sup>9</sup>The full Cartesian product of variants in Figure 1 would result in topological 216 variants, but only 126 are applicable (the inapplicable combinations are marked with “—” in Figure 1). Those 126 topological variants can be further combined with labeling variants defined in Section 3.2.

Main family	Prague family (code fP) [14 treebanks]	Moscow family (code fM) [5 treebanks]	Stanford family (code fS) [6 treebanks]
<b>Choice of head</b>			
Head on left (code hL) [10 treebanks]			
Head on right (code hR) [14 treebanks]			
Mixed head (code hM) [1 treebank]	A mixture of hL and hR		
<b>Attachment of shared modifiers</b>			
Shared modifier below the nearest conjunct (code sN) [15 treebanks]			
Shared modifier below head (code sH) [11 treebanks]			
<b>Attachment of coordinating conjunction</b>			
Coordinating conjunction below previous conjunct (code cP) [2 treebanks]	—		
Coordinating conjunction below following conjunct (code cF) [1 treebank]	—		
Coordinating conjunction between two conjuncts (code cB) [8 treebanks]	—		
Coordinating conjunction as the head (code cH) is the only applicable style for the Prague family [14 treebanks]	—	—	—
<b>Placement of punctuation</b>			
values pP [7 treebanks], pF [1 treebank] and pB [15 treebanks] are analogous to cP, cF and cB (but applicable also to the Prague family)			

Figure 1: Different coordination styles, variations in tree topology. Example phrase: “(lazy) dogs, cats and rats”. Style codes are described in Section 3.1.

Stanford (fS) families.<sup>10</sup> This first dimension distinguishes the configuration of conjuncts: in the Prague family, all the conjuncts are siblings governed by one of the conjunctions (or a punctuation fulfilling its role); in the Moscow family, the conjuncts form a chain where each node in the chain depends on the previous (or following) node; in the Stanford family, the conjuncts are siblings except for the first (or last) conjunct, which is the

<sup>10</sup>Names are chosen purely as a mnemonic device, so that Prague Dependency Treebank belongs to the Prague family, Mel’čuk style belongs to the Moscow family, and Stanford parser style belongs to the Stanford family.

head.<sup>11</sup>

**Choice of head – leftmost or rightmost.** In the Prague family, the head can be either the leftmost<sup>12</sup> (hL) or the rightmost (hR) conjunction or punctuation. Similarly, in the Moscow and Stanford families, the head can be either the leftmost (hL) or the rightmost (hR) conjunct. A third op-

<sup>11</sup>Note that for CSs with just two conjuncts, fM and fS may look exactly the same (depending on the attachment of conjunctions and punctuation as described below).

<sup>12</sup>For simplicity, we use the terms left and right even if their meaning is reversed for languages with right-to-left writing systems such as Arabic or Persian.

tion (hM) is to mix hL and hR based on some criterion, e.g. the Persian treebank uses hR for coordination of verbs and hL otherwise. For the experiments in Section 5, we choose the head which is closer to the parent of the whole CS, with the motivation to make the edge between CS head and its parent shorter, which may improve parser training.

**Attachment of shared modifiers.** Shared modifiers may appear before the first conjunct or after the last one. Therefore, it seems reasonable to attach shared modifiers either to the CS head (SH), or to the nearest (i.e. first or last) conjunct (SN).

**Attachment of coordinating conjunctions.** In the Moscow family, conjunctions may be either part of the chain of conjuncts (cB), or they may be put outside of the chain and attached to the previous (cP) or following (cF) conjunct. In the Stanford family, conjunctions may be either attached to the CS head (and therefore *between* conjuncts) (cB), or they may be attached to the previous (cP) or the following (cF) conjunct. The cB option in both Moscow and Stanford families, treats conjunctions in the same way as conjuncts (with respect to topology only). In the Prague family, there is just one option available (cH) – one of the conjunctions is the CS head while the others are attached to it.

**Attachment of punctuation.** Punctuation tokens separating conjuncts (commas, semicolons etc.) could be treated the same way as conjunctions. However, in most treebanks it is treated differently, so we consider it as well. The values pP, pF and pB are analogous to cP, cF and cB except that punctuation may be also attached to the conjunction in case of pP and pF (otherwise, a comma before the conjunction would be non-projectively attached to the member following the conjunction).

The three established styles mentioned in Section 2 can be defined in terms of the newly introduced abbreviations: PS = fPhRsHcHpB, MS = fMhLsNcBp?, and SS = fShLsNcBp?.<sup>13</sup>

### 3.2 Labeling variations

Most state-of-the-art dependency parsers can produce labeled edges. However, the parsers produce only one label per edge. To fully capture CSs, we need more than one label, because there are several aspects involved (see the initial assump-

<sup>13</sup>The question marks indicate that the original Mel'čuk and Stanford parser styles ignore punctuation.

tions in Section 3): We need to identify the coordinating conjunction (its POS tag might not be enough), conjuncts, shared modifiers, and punctuation that separates conjuncts. Besides that, there should be a label classifying the dependency relation between the CS and its parent.

Some of the information can be retrieved from the topology of the tree and the “main label” of each node, but not everything. The additional information can be attached to the main label, but such approach obscures the logical structure.

In the **Prague family**, there are two possible ways to label a conjunction and conjuncts:

Code dU (“dependency labeled at the upper level of the CS”). The dependency relation of the whole CS to its parent is represented by the label of the conjunction, while the conjuncts are marked with a special label for conjuncts (e.g. ccof in the Hyderabad Dependency Treebank).

Code dL (“lower level”). The CS is represented by a coordinating conjunction (or punctuation if there is no conjunction) with a special label (e.g. Coord in PDT). Subsequently, each conjunct has its own label that reflects the dependency relation towards the parent of the whole CS, therefore, conjuncts of the same CS can have different labels, e.g. “Who[*SUBJ*] and why[*ADV*] did it?”

Most Prague family treebanks use SH, i.e. shared modifiers are attached to the head (coordinating conjunction). Each child of the head has to belong to one of three sets: conjuncts, shared modifiers, and punctuation or additional conjunctions. In PDT, conjuncts, punctuation and additional conjunctions are recognized by specific labels. Any other children of the head are shared modifiers.

In the **Stanford and Moscow families**, one of the conjuncts is the head. In practice, it is never labeled as a conjunct explicitly, because the fact that it is a conjunct can be deduced from the presence of conjuncts among its children. Usually, the other conjuncts are labeled as conjuncts; conjunctions and punctuation also have a special label. This type of labeling corresponds to the dU type.

Alternatively (as found in the Turkish treebank, dL), all conjuncts in the Moscow chain have their own dependency labels and the fact that they are conjuncts follows from the COORDINATION labels of the conjunction and punctuation nodes between them.

To represent shared modifiers in the Stan-

ford and Moscow families, an additional label is needed again to distinguish between private and shared modifiers since they cannot be distinguished topologically. Moreover, if nested CSs are allowed, a binary label is not sufficient (i.e. “shared” versus “private”) because it also has to indicate which conjuncts the shared modifier belongs to.<sup>14</sup>

We use the following binary flag codes for capturing which CS participants are distinguished in the annotation: m01 = shared modifiers annotated; m10 = conjuncts annotated; m11 = both annotated; m00 = neither annotated.

#### 4 Coordination Structures in Treebanks

In this section, we identify the CS styles defined in the previous section as used in the primary treebank data sources; statistical observations (such as the amount of annotated shared modifiers) presented here, as well as experiments on CS-style convertibility presented in Section 5.2, are based on the normalized shapes of the treebanks as contained in the HamleDT 1.0 treebank collection (Zeman et al., 2012).<sup>15</sup>

Some of the treebanks were downloaded individually from the web, but most of them came from previously published collections for dependency parsing campaigns: six languages from CoNLL-2006 (Buchholz and Marsi, 2006), seven languages from CoNLL-2007 (Nivre et al., 2007), two languages from CoNLL-2009 (Hajič and others, 2009), three languages from ICON-2010 (Husain et al., 2010). Obviously, there is a certain risk that the CS-related information contained in the source treebanks was slightly biased by the properties of the CoNLL format upon conversion. In addition, many of the treebanks were natively dependency-based (cf. the 2nd column of Table 1), but some were originally based on constituents and thus specific converters to the CoNLL format had to be created (for instance, the Spanish phrase-structure trees were converted to dependencies using a procedure described by Civit et al. (2006); similarly, treebank-specific converters have been used for other languages). Again,

<sup>14</sup>This is not needed in Prague family where shared modifiers are attached to the conjunction provided that each shared modifier is shared by conjuncts that form a full subtree together with their coordinating conjunctions; no exceptions were found during the annotation process of the PDT.

<sup>15</sup>A subset of the treebanks whose license terms permit redistribution is available directly at <http://ufal.mff.cuni.cz/hamledt/>.

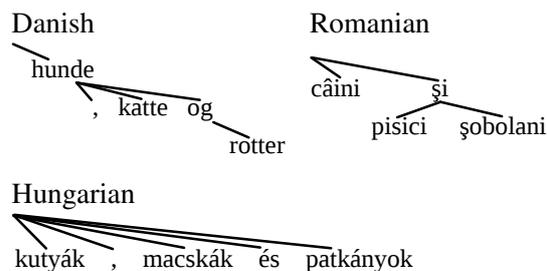

Figure 2: Annotation styles of a few treebanks do not fit well into the multidimensional space defined in Section 3.1.

there is some risk that the CS-related information contained in treebanks resulting from such conversions is slightly different from what was intended in the very primary annotation.

There are several other languages (e.g. Estonian or Chinese) which are not included in our study, despite of the fact that constituency treebanks do exist for them. The reason is that the choice of their CS style would be biased, because no independent converters exist – we would have to convert them to dependencies ourselves. We also know about several more dependency treebanks that we have not processed yet.

Table 1 shows 26 languages whose treebanks we have studied from the viewpoint of their CS styles. It gives the basic quantitative properties of the treebanks, their CS style in terms of the taxonomy introduced in Section 3, as well as statistics related to CSs: the average number of CSs per 100 tokens, the average number of conjuncts per one CS, the average number of shared modifiers per one CS,<sup>16</sup> and the percentage of nested CSs among all CSs. The reader can return to Figure 1 to see the basic statistics on the “popularity” of individual design decisions among the developers of dependency treebanks or constituency treebank converters.

CS styles of most treebanks are easily classifiable using the codes introduced in Section 3, plus a few additional codes:

- p0 = punctuation was removed from the treebank.

<sup>16</sup>All non-Prague family treebanks are marked sN and m00 or m10, (i.e. shared modifiers not marked in the original annotation, but attached to the head conjunct) because we found no counterexamples (modifiers attached to a conjunct, but not the nearest one). The HamleDT normalization procedure contains a few heuristics to detect shared modifiers, but it cannot recover the missing distinction reliably, so the numbers in the “SMs/CJ” column are mostly underestimated.

Language	Orig. type	Data set	Sents.	Tokens	Original CS style code	CSs / 100 tok.	CJs / CS	SMs / CS	Nested CS[%]	RT UAS

Table 1: Overview of analyzed treebanks. prim. = primary source; C06–C09 = CoNLL 2006–2009; I10 = ICON 2010; SM = shared modifier; CJ = conjunct; Nested CS = portion of CSs participating in nested CSs (both as the inner and outer CS); RT UAS = unlabeled attachment score of the roundtrip experiment described in Section 5. Style codes are defined in Sections 3 and 4.

- fM\* = Persian treebank uses a mix of fM and fS: fS for coordination of verbs and fM otherwise.

Figure 2 shows three other anomalies:

- fS\* = Danish treebank employs a mixture of fS and fM, where the last conjunct is attached indirectly via the conjunction.
- fP\* = Romanian treebank omits punctuation tokens and multi-conjunct coordinations get split.
- fT = Hungarian Szeged treebank uses “Tesnière family” – disconnected graphs for CSs where conjuncts (and conjunction and punctuation) are attached directly to the parent of CS, and so the other style dimensions are not applicable (hX, cX, pX).

## 5 Empirical Observations on Convertibility of Coordination Styles

The various styles cannot represent the CS-related information to the same extent. For example,

it is not possible to represent nested CSs in the Moscow and Stanford families without significantly changing the number of possible labels.<sup>17</sup> The dL style (which is most easily applicable to the Prague family) can represent coordination of different dependency relations. This is again not possible in the other styles without adding e.g. a special “prefix” denoting the relations.

We can see that the Prague family has a greater expressive power than the other two families: it can represent complex CSs using just one additional binary label, distinguishing between shared modifiers and conjuncts. A similar additional label is needed in the other styles to distinguish between shared and private modifiers.

Because of the different expressive power, converting a CS from one style to another may lead to a loss of information. For example, as

<sup>17</sup>Mel’čuk uses “grouping” to nest CSs – cf. related solutions involving coindexing or bubble trees (Kahane, 1997). However, these approaches were not used in any of the researched treebanks. To combine grouping with shared modifiers, each group in a tree should have a different identifier.

there is no way of representing shared modifiers in the Moscow family without an additional attribute, converting a CS with shared modifiers from Prague to Moscow family makes the modifiers private. When converting back, one can use certain heuristics to handle the most obvious cases, but sometimes the modifiers will stay private (very often, the nature of a modifier depends on context or is debatable even for humans, e.g. “*Young boys and girls*”).

### 5.1 Transformation algorithm

We developed an algorithm to transform one CS style to another. Two subtasks must be solved by the algorithm: identification of individual CSs and their participants, and transforming of the individual CSs.

Obviously, the individual CSs cannot be transformed independently because of coordination nesting. For instance, when transforming a nested coordination from the Prague style to the Moscow style (e.g. to fMhL), the leftmost conjunct in the inner (lower) coordination must climb up to become the head of the inner CS, but then it must climb up once again to become the head of the outer (upper) CS too. This shows that inner CSs must be transformed first.

We tackle this problem by a depth-first recursion. When going down the tree, we only recognize all the participants of the CSs, classify them and gather them in a separate data structure (one for each visited CS). The following four types of CS participants are distinguished: coordinating conjunctions, conjuncts, shared modifiers, and punctuations that separate conjuncts.<sup>18</sup> No change of the tree is performed during these descent steps.

When returning back from the recursion (i.e., when climbing from a node back up to its parent), we test whether the abandoned node is the topmost node of some CS. If so, then this CS is transformed, which means that its participants are rehanged and relabelled according to the target CS style.

This procedure naturally guarantees that the in-

<sup>18</sup>Conjuncts are explicitly marked in most styles. Coordinating conjunctions can be usually identified with the help of dependency labels and POS tags. Punctuation separating conjuncts can be detected with high accuracy using simple rules. If shared modifiers are not annotated (code m00 or m10), one can imagine rule-based heuristics or special classifiers trained to distinguish shared modifiers. For the experiments in this section, we use the HamleDT gold annotation attribute `is_shared_modifier`.

ner CSs are transformed first and that all CSs are transformed when the recursions returns to the root.

### 5.2 Roundtrip experiment

The number of possible conversion directions obviously grows quadratically with the number of styles. So far, we limited ourselves only to conversions from/to the style of the HamleDT treebank collection, which contains all the treebanks under our study already converted into a common scheme. The common scheme is based on the conventions of PDT, whose CS style is fPhRsHcHpB.<sup>19</sup>

We selected nine styles (3 families times 3 head choices) and transformed all the HamleDT scheme treebanks to these nine styles and back, which we call a *roundtrip*. Resulting averaged unlabeled attachment scores (UAS, evaluated against the HamleDT scheme) in the last column of Table 1 indicate that the percentage of transformation errors (i.e. tokens attached to a different parent after the roundtrip) is lower than 1% for 20 out of the 26 languages.<sup>20</sup> A manual inspection revealed two main error sources. First, as noted above, the Stanford and Moscow families have lower expressive power than the Prague family, so naturally, the inverse transformation was ambiguous and the transformation heuristics were not capable of identifying the correct variant every time. Second, we also encountered inconsistencies in the original treebanks (which we were not trying to fix in HamleDT for now).

## 6 Conclusions and Future Work

We described a (theoretically very large) space of possible representations of CSs within the dependency framework. We pointed out a range of details that make CSs a really complex phenomenon; anyone dealing with CSs in treebanking should take these observations into account.

We proposed a taxonomy of those approaches

<sup>19</sup>As documented in Zeman et al. (2012), the normalization procedures used in HamleDT embrace many other phenomena as well (not only those related to coordination), and involve both structural transformation and dependency relation labeling.

<sup>20</sup>Table 1 shows that Latin and Ancient Greek treebanks have on average more than 6 CSs per 100 tokens, more than 2 conjuncts per CS, and Latin has also the highest number of shared modifiers per CS. Therefore the percentage of nodes affected by the roundtrip is the highest for these languages and the lower roundtrip UAS is not surprising.

that have been argued for in literature or employed in real treebanks.

We studied 26 existing treebanks of different languages. For each value of each dimension in Figure 1, we found at least one treebank where the value is used; even so, several treebanks take their own unique path that cannot be clearly classified under the taxonomy (the taxonomy could indeed be extended, for the price of being less clearly arranged).

We discussed the convertibility between the various styles and implemented a universal tool that transforms between any two styles of the taxonomy. The tool achieves a roundtrip accuracy close to 100%. This is important because it opens the door to easily switching coordination styles for parsing experiments, phrase-to-dependency conversion etc.

While the focus of this paper is to explore and describe the expressive power of various annotation styles, we did not address the learnability of the styles by parsers. That will be a complementary point of view, and thus a natural direction of future work for us.

## Acknowledgments

We thank the providers of the primary data resources. The work on this project was supported by the Czech Science Foundation grants no. P406/11/1499 and P406/2010/0875, and by research resources of the Charles University in Prague (PRVOUK). This work has been using language resources developed and/or stored and/or distributed by the LINDAT-Clarin project of the Ministry of Education of the Czech Republic (project LM2010013). Further, we would like to thank Jan Hajič, Ondřej Dušek and four anonymous reviewers for many useful comments on the manuscript of this paper.

# GlossBoot: Bootstrapping Multilingual Domain Glossaries from the Web

Flavio De Benedictis, Stefano Faralli and Roberto Navigli

Dipartimento di Informatica

Sapienza Università di Roma

flavio.debene@gmail.com, {faralli, navigli}@di.uniroma1.it

## Abstract

We present GlossBoot, an effective minimally-supervised approach to acquiring wide-coverage domain glossaries for many languages. For each language of interest, given a small number of hypernymy relation seeds concerning a target domain, we bootstrap a glossary from the Web for that domain by means of iteratively acquired term/gloss extraction patterns. Our experiments show high performance in the acquisition of domain terminologies and glossaries for three different languages.

## 1 Introduction

Much textual content, such as that available on the Web, contains a great deal of information focused on specific areas of knowledge. However, it is not infrequent that, when reading a domain-specific text, we humans do not know the meaning of one or more terms. To help the human understanding of specialized texts, repositories of textual definitions for technical terms, called glossaries, are compiled as reference resources within each domain of interest. Interestingly, electronic glossaries have been shown to be key resources not only for humans, but also in Natural Language Processing (NLP) tasks such as Question Answering (Cui et al., 2007), Word Sense Disambiguation (Duan and Yates, 2010; Faralli and Navigli, 2012) and ontology learning (Navigli et al., 2011; Velardi et al., 2013).

Today large numbers of glossaries are available on the Web. However most such glossaries are small-scale, being made up of just some hundreds of definitions. Consequently, individual glossaries typically provide a partial view of a given domain. Moreover, there is no easy way of retrieving the subset of Web glossaries which appertains to a domain of interest. Although online services such

as Google Define allow the user to retrieve definitions for an input term, such definitions are extracted from Web glossaries and put together for the given term regardless of their domain. As a result, gathering a large-scale, full-fledged domain glossary is not a speedy operation.

Collaborative efforts are currently producing large-scale encyclopedias, such as Wikipedia, which are proving very useful in NLP (Hovy et al., 2013). Interestingly, wikipedias also include manually compiled glossaries. However, such glossaries still suffer from the same above-mentioned problems, i.e., being incomplete or over-specific,<sup>1</sup> and hard to customize according to a user's needs.

To automatically obtain large domain glossaries, over recent years computational approaches have been developed which extract textual definitions from corpora (Navigli and Velardi, 2010; Reiplinger et al., 2012) or the Web (Fujii and Ishikawa, 2000). The former methods start from a given set of terms (possibly automatically extracted from a domain corpus) and then harvest textual definitions for these terms from the input corpus using a supervised system. Web-based methods, instead, extract text snippets from Web pages which match pre-defined lexical patterns, such as “X is a Y”, along the lines of Hearst (1992). These approaches typically perform with high precision and low recall, because they fall short of detecting the high variability of the syntactic structure of textual definitions. To address the low-recall issue, recurring cue terms occurring within dictionary and encyclopedic resources can be automatically extracted and incorporated into lexical patterns (Saggion, 2004). However, this approach is term-specific and does not scale to arbitrary terminologies and domains.

In this paper we propose GlossBoot, a novel approach which reduces human intervention to a bare minimum and exploits the Web to learn a

<sup>1</sup><http://en.wikipedia.org/wiki/Portal:Contents/Glossaries>

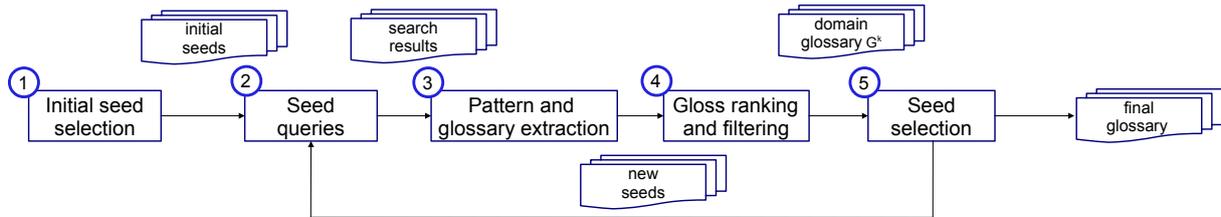

Figure 1: The GlossBoot bootstrapping process for glossary learning.

full-fledged domain glossary. Given a domain and a language of interest, we bootstrap the glossary learning process with just a few hypernymy relations (such as *computer is-a device*), with the only condition that the (term, hypernym) pairs must be specific enough to implicitly identify the domain in the target language. Hence we drop the requirement of a large domain corpus, and also avoid the use of training data or a manually defined set of lexical patterns. To the best of our knowledge, this is the first approach which jointly acquires large amounts of terms and glosses from the Web with minimal supervision for any target domain and language.

## 2 GlossBoot

Our objective is to harvest a domain glossary  $G$  containing pairs of terms/glosses in a given language. To this end, we automatically populate a set of HTML patterns  $P$  which we use to extract definitions from Web glossaries. Initially, both  $P := \emptyset$  and  $G := \emptyset$ . We incrementally populate the two sets by means of an initial seed selection step and four iterative steps (cf. Figure 1):

**Step 1. Initial seed selection:** first, we manually select a set of  $K$  hypernymy relation seeds  $S = \{(t_1, h_1), \dots, (t_K, h_K)\}$ , where the pair  $(t_i, h_i)$  contains a term  $t_i$  and its generalization  $h_i$  (e.g., (*firewall*, *security system*)). This is the only human input to the entire glossary learning process. The selection of the input seeds plays a key role in the bootstrapping process, in that the pattern and gloss extraction process will be driven by these seeds. The chosen hypernymy relations thus have to be as topical and representative as possible for the domain of interest (e.g., (*compiler*, *computer program*) is an appropriate pair for computer science, while (*byte*, *unit of measurement*) is not, as it might cause the extraction of several glossaries of units and measures).

We now set the iteration counter  $k$  to 1 and start the first iteration of the glossary bootstrapping pro-

cess (steps 2-5). After each iteration  $k$ , we keep track of the set of glosses  $G^k$ , acquired during iteration  $k$ .

**Step 2. Seed queries:** for each seed pair  $(t_i, h_i)$ , we submit the following query to a Web search engine: “ $t_i$ ” “ $h_i$ ” `glossaryKeyword`<sup>2</sup> (where `glossaryKeyword` is the term in the target language referring to *glossary* (i.e., *glossary* for English, *glossaire* for French etc.)) and collect the top-ranking results for each query.<sup>3</sup> Each resulting page is a candidate glossary for the domain implicitly identified by our relation seeds  $S$ .

**Step 3. Pattern and glossary extraction:** we initialize the glossary for iteration  $k$  as follows:  $G^k := \emptyset$ . Next, from each resulting page, we harvest all the text snippets  $s$  starting with  $t_i$  and ending with  $h_i$  (e.g., “*firewall*</b> – a <i>*security system*” where  $t_i = \textit{firewall}$  and  $h_i = \textit{security system}$ ), i.e.,  $s = t_i \dots h_i$ . For each such text snippet  $s$ , we perform the following substeps:

**(a) extraction of the term/gloss separator:** we start from  $t_i$  and move right until we extract the longest sequence  $p_M$  of HTML tags and non-alphanumeric characters, which we call the *term/gloss separator*, between  $t_i$  and the glossary definition (e.g., “</b> –” between “*firewall*” and “*a*” in the above example).

**(b) gloss extraction:** we expand the snippet  $s$  to the right of  $h_i$  in search of the entire gloss of  $t_i$ , i.e., until we reach a block element (e.g., <span>, <p>, <div>), while ignoring formatting elements such as <b>, <i> and <a> which are typically included within a definition sentence. As a result, we obtain the sequence  $t_i p_M gloss_s(t_i) p_R$ , where  $gloss_s(t_i)$  is our gloss for seed term  $t_i$  in snippet  $s$  (which includes  $h_i$  by construction) and  $p_R$  is the HTML block element

<sup>2</sup>In what follows we use the `typewriter` font for keywords and term/gloss separators.

<sup>3</sup>We use the Google Ajax APIs, which return the 64 top-ranking search results.

Generalized pattern	HTML text snippet
$\langle \text{strong} \rangle * \langle / \text{strong} \rangle - * \langle / \text{span} \rangle$	$\langle \text{strong} \rangle$ Interrupt $\langle / \text{strong} \rangle$ - The suspension of normal program execution to perform a higher priority service routine as requested by a peripheral device. $\langle / \text{span} \rangle$

$\langle \text{span} \rangle * \langle / \text{span} \rangle : * \langle \text{span} \rangle$	$\langle \text{span} \rangle$ Blog $\langle / \text{span} \rangle$ : Short for “web log”, a blog is an online journal. $\langle \text{span} \rangle$

Table 1: Examples of generalized patterns together with matching HTML text snippets.

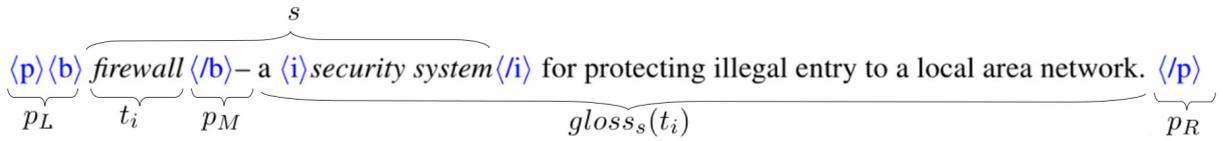

Figure 2: An example of decomposition during pattern extraction for a snippet matching the seed pair (*firewall*, *security system*).

to the right of the extracted gloss. In Figure 2 we show the decomposition of our example snippet matching the seed (*firewall*, *security system*).

**(c) pattern instance extraction:** we extract the following pattern instance:

$$p_L t_i p_M gloss_s(t_i) p_R,$$

where  $p_L$  is the longest sequence of HTML tags and non-alphanumeric characters obtained when moving to the left of  $t_i$  (see Figure 2).

**(d) pattern extraction:** we generalize the above pattern instance to the following pattern:

$$p_L * p_M * p_R,$$

i.e., we replace  $t_i$  and  $gloss_s(t_i)$  with  $*$ . For the above example, we obtain the following pattern:

$$\langle \text{p} \rangle \langle \text{b} \rangle * \langle / \text{b} \rangle - * \langle / \text{p} \rangle.$$

Finally, we add the generalized pattern to the set of patterns  $P$ , i.e.,  $P := P \cup \{p_L * p_M * p_R\}$ . We also add the first sentence of the retrieved gloss  $gloss_s(t_i)$  to our glossary  $G^k$ , i.e.,  $G^k := G^k \cup \{(t_i, first(gloss_s(t_i)))\}$ , where  $first(g)$  returns the first sentence of gloss  $g$ .

**(e) pattern matching:** finally, we look for additional pairs of terms/glosses in the Web page containing the snippet  $s$  by matching the page against the generalized pattern  $p_L * p_M * p_R$ . We then

add to  $G^k$  the new (term, gloss) pairs matching the generalized pattern. In Table 1 we show some non-trivial generalized patterns together with matching HTML text snippets.

As a result of step 3, we obtain a glossary  $G^k$  for the terms discovered at iteration  $k$ .

**Step 4. Gloss ranking and filtering:** importantly, not all the extracted definitions pertain to the domain of interest. In order to rank the glosses obtained at iteration  $k$  by domain pertinence, we assume that the terms acquired at previous iterations belong to the target domain, i.e., they are domain terms at iteration  $k$ . Formally, we define the terminology  $T_1^{k-1}$  of the domain terms accumulated up until iteration  $k - 1$  as follows:  $T_1^{k-1} := \bigcup_{i=1}^{k-1} T^i$ , where  $T^i := \{t : \exists(t, g) \in G^i\}$ . For the base step  $k = 1$ , we define  $T_1^0 := \{t : \exists(t, g) \in G^1\}$ , i.e., we use the first-iteration terminology itself.

To rank the glosses, we first transform each acquired gloss  $g$  to its bag-of-words representation  $Bag(g)$ , which contains all the single- and multi-word expressions in  $g$ . We use the lexicon of the target language’s Wikipedia together with  $T_1^{k-1}$  in order to obtain the bag of content words.<sup>4</sup> Then we

<sup>4</sup>In fact Wikipedia is only utilized in the multi-word identification phase. We do not use Wikipedia for discovering new terms.

Term	Gloss	Hypernym	# Seeds	Score
dynamic packet filter	A <b>firewall</b> <i>facility</i> that can monitor the <i>state</i> of active <u>connections</u> and use this <u>information</u> to determine which <u>network</u> packets to allow through the <b>firewall</b>	firewall	2	0.75
die	An integrated <i>circuit</i> <b>chip</b> <u>cut</u> from a finished <u>wafer</u> .	integrated circuit	1	0.75
constructor	a <u>method</u> used to help create a new <u>object</u> and initialise its <u>data</u>	method	0	1.00

Table 2: Examples of extracted terms, glosses and hypernyms (seeds are in bold, domain terms, i.e., in  $T_1^{k-1}$ , are underlined, non-domain terms in italics).

calculate the domain score of a gloss  $g$  as follows:

$$score(g) = \frac{|Bag(g) \cap T_1^{k-1}|}{|Bag(g)|}. \quad (1)$$

Finally, we use a threshold  $\theta$  (whose tuning is described in the experimental section) to remove from  $G^k$  those glosses  $g$  whose  $score(g) < \theta$ .

In Table 2 we show some glosses in the computer science domain (second column, domain terms are underlined) together with their scores (last column).

**Step 5. Seed selection for next iteration:** we now aim at selecting the new set of hypernymy relation seeds to be used to start the next iteration. We perform three substeps:

**(a) Hypernym extraction:** for each newly-acquired term/gloss pair  $(t, g) \in G^k$ , we automatically extract a candidate hypernym  $h$  from the textual gloss  $g$ . To do this we use a simple unsupervised heuristic which just selects the first term in the gloss.<sup>5</sup> We show an example of hypernym extraction for some terms in Table 2 (we report the term in column 1, the gloss in column 2 and the hypernyms extracted by the first term hypernym extraction heuristic in column 3).

**(b) (Term, Hypernym)-ranking:** we sort all the glosses in  $G^k$  by the number of seed terms found in each gloss. In the case of ties (i.e., glosses with the same number of seed terms), we further sort the glosses by the score given in Formula 1. We show an example of rank for some glosses in Table 2, where seed terms are in bold, domain terms (i.e., in  $T_1^{k-1}$ ) are underlined, and non-domain terms are shown in italics.

<sup>5</sup>While more complex strategies could be used, such as supervised classifiers (Navigli and Velardi, 2010), we found that this heuristic works well because, even when it is not a hypernym, the first term plays the role of a cue word for the defined term.

**(c) New seed selection:** we select the (term, hypernym) pairs corresponding to the  $K$  top-ranking glosses.

Finally, if  $k$  equals the maximum number of iterations, we stop. Else, we increment the iteration counter (i.e.,  $k := k + 1$ ) and jump to step (2) of our glossary bootstrapping algorithm after replacing  $S$  with the new set of seeds.

The output of glossary bootstrapping is a domain glossary  $G := \bigcup_{i=1, \dots, max} G^i$ , which includes a domain terminology  $T := \{t : \exists(t, g) \in G\}$  (i.e.,  $T := T_1^{max}$ ) and a set of glosses  $glosses(t)$  for each term  $t \in T$  (i.e.,  $glosses(t) := \{g : \exists(t, g) \in G\}$ ).

## 3 Experimental Setup

### 3.1 Domains and Gold Standards

For our experiments we focused on four different domains, namely, Computing, Botany, Environment, and Finance, and on three languages, namely, English, French and Italian. Note that not all the four domains are clear-cut. For instance, the Environment domain is quite interdisciplinary, including terms from fields such as Chemistry, Biology, Law, Politics, etc.

For each domain and language we selected as gold standards well-reputed glossaries on the Web, such as: the Utah computing glossary,<sup>6</sup> the Wikipedia glossary of botanical terms,<sup>7</sup> a set of Wikipedia glossaries about environment,<sup>8</sup> and the Reuters glossary for Finance<sup>9</sup> (full list at <http://lcl.uniroma1.it/glossboot/>). We report the size of the four gold-standard datasets in Table 4.

<sup>6</sup><http://www.math.utah.edu/~wisnia/glossary.html>

firewall	security system	flower	reproductive organ	global warming	temperature	derivative	financial product

Table 3: Hypernymy relation seeds used to bootstrap glossary learning in the four domains for the English language.

### 3.2 Seed Selection

For each domain and language we manually selected five seed hypernymy relations, shown for the English language in Table 3. The seeds were selected by the authors on the basis of just two conditions: i) the seeds should cover different aspects of the domain and should, indeed, identify the domain implicitly, ii) at least 10,000 results should be returned by the search engine when querying it with the seeds plus the `glossaryKeyword` (see step (2) of GlossBoot). The seed selection was not fine-tuned (i.e., it was not adjusted to improve performance), so it might well be that better seeds would provide better results (see, e.g., (Kozareva and Hovy, 2010b)). However, this type of consideration is beyond the scope of this paper.

#### 3.2.1 Evaluation measures

We performed experiments to evaluate the quality of both terms and glosses, as jointly extracted by GlossBoot.

**Terms.** For each domain and language we calculated coverage, extra-coverage and precision of the acquired terms  $T$ . Coverage is the ratio of extracted terms in  $T$  also contained in the gold standard  $\hat{T}$  to the size of  $\hat{T}$ . Extra-coverage is calculated as the ratio of the additional extracted terms in  $T \setminus \hat{T}$  over the number of gold standard terms  $\hat{T}$ . Finally, precision is the ratio of extracted terms in  $T$  deemed to be within the domain. To calculate precision we randomly sampled 5% of the retrieved terms and asked two human annotators to manually tag their domain pertinence (with adjudication in case of disagreement;  $\kappa = .62$ , indicating substantial agreement). Note that by sampling on the entire set  $T$ , we calculate the precision of both terms in  $T \cap \hat{T}$ , i.e., in the gold standard, and terms in  $T \setminus \hat{T}$ , i.e., not in the gold standard, which are not necessarily outside the domain.

**Glosses.** We calculated the precision of the extracted glosses as the ratio of glosses which were both well-formed textual definitions and specific

			Botany	Comput.	Environ.	Finance

Table 4: Size of the gold-standard and automatically-acquired glossaries for the four domains in the three languages of interest.

to the target domain. Precision was determined on a random sample of 5% of the acquired glosses for each domain and language. The annotation was made by two annotators, with  $\kappa = .675$ , indicating substantial agreement.

### 3.3 Parameter tuning

We tuned the minimum and maximum length of both  $p_L$  and  $p_R$  (see step (3) of GlossBoot) and the threshold  $\theta$  that we use to filter out non-domain glosses (see step (4) of GlossBoot) using an extra domain, i.e., the Arts domain. To do this, we created a development dataset made up of the full set of 394 terms from the Tate Gallery glossary,<sup>10</sup> and bootstrapped our glossary extraction method with just one seed, i.e., (*fresco, painting*). We chose an optimal value of  $\theta = 0.1$  on the basis of a harmonic mean of coverage and precision. Note that, since precision also concerns terms not in the gold standard, we had to manually validate a sample of the extracted terms for each of the 21 tested values of  $\theta \in \{0, 0.05, 0.1, \dots, 1.0\}$ .

## 4 Results and Discussion

### 4.1 Terms

The size of the extracted terminologies for the four domains after five iterations are reported in Table 4. In Table 5 we show examples of the possible scenarios for terms: in-domain extracted terms

<sup>10</sup><http://www.tate.org.uk/collections/glossary/>

	In-domain (in gold std, $\in \hat{T} \cap T$ )	In-domain (not in gold std, $\in T \setminus \hat{T}$ )	Out-of-domain (not in gold std, $\in T \setminus \hat{T}$ )	In-domain (missed, $\in \hat{T} \setminus T$ )
Computing	software, inheritance, microprocessor	clipboard, even parity, sudoer	gs1-128 label, grayscale, quantum dots	openwindows, sun microsystems, hardwired
Botany	pollinium, stigma, spore	vegetation, dichogamous, fertilisation	ion, free radicals, mana-mana	nomenclature, endemism, insectivorous
Environment	carcinogen, footprint, solar power	frigid soil, biosafety, fire simulator	epidermis, science park, alum	g8, best practice, polystyrene
Finance	cash, bond, portfolio	truster, naked option, market price	precedent, immigration, heavy industry	co-location, petrodollars, euronext

Table 5: Examples of extracted (and missed) terms.

		Botany	Comput.	Environ.	Finance

	Extra-coverage	425%	1219%	1646%	1350%
IT	Precision	89%	98%	76%	99%
	Coverage	42%	27%	11%	73%
	Extra-coverage	511%	1349%	356%	746%

Table 6: Precision, coverage and extra-coverage of the term extraction phase after 5 iterations.

which are also found in the gold standard (column 2), in-domain extracted terms but not in the gold standard (column 3), out-of-domain extracted terms (column 4), and domain terms in the gold standard but not extracted by our approach (column 5).

A quantitative evaluation is provided in Table 6, which shows the percentage results in terms of precision, coverage, and extra-coverage after 5 iterations of GlossBoot. For the English language we observe good coverage (between 32% and 40% on three domains, with a high peak of 85% coverage on Botany) and generally very high precision values. Moreover for the French and the Italian languages we observe a peak in the Botany and Finance domains respectively, while the lowest performances in terms of precision and coverage are observed for Environment, i.e., the most interdisciplinary domain.

In all three languages GlossBoot provides very high extra coverage of domain terms, i.e., additional terms which are not in the gold standard but are returned by our system. The figures, shown in Table 6, range between 266% (4726/1777) for the English Finance domain and 1646% (1926/117) for the French Environment domain. These results, together with the generally high precision values, indicate the larger extent of our bootstrapped glossaries compared to our gold standards.

Botany		Computing		Environm.		Finance	
Min	Max	Min	Max	Min	Max	Min	Max
26%	68%	8%	39%	5%	33%	14%	30%

Table 7: Coverage ranges for single-seed term extraction for the English language.

**Number of seeds.** Although the choice of selecting five hypernymy relation seeds is quite arbitrary, it shows that we can acquire a reliable terminology with minimal human intervention. Now, an obvious question arises: what if we bootstrapped GlossBoot with fewer hypernym seeds, e.g., just one seed? To answer this question we replicated our English experiments on each single (term, hypernym) pair in our seed set. In Table 7 we show the coverage ranges – i.e., the minimum and maximum coverage values – for the five seeds on each domain. We observe that the maximum coverage can attain values very close to those obtained with five seeds. However, the minimum coverage values are much lower. So, if we adopt a 1-seed bootstrapping policy there is a high risk of acquiring a poorer terminology unless we select the single seed very carefully, whereas we have shown that just a few seeds can cope with domain variability. Similar considerations can be made regarding different seed set sizes (we also tried 2, 3 and 4). So five is not a magic number, just one which can guarantee an adequate coverage of the domain.

**Number of iterations.** In order to study the coverage trend over iterations we selected 5 seeds for our tuning domain (i.e., Arts, see Section 3.3). Figure 3 shows the size (left graph), coverage, extra-coverage and precision (middle graph) of the acquired glossary after each iteration, from 1 to 20. As expected, (extra-)coverage grows over iterations, while precision drops. Stopping at iteration 5, as we do, is optimal in terms of the harmonic mean of precision and coverage (right graph in Figure 3).

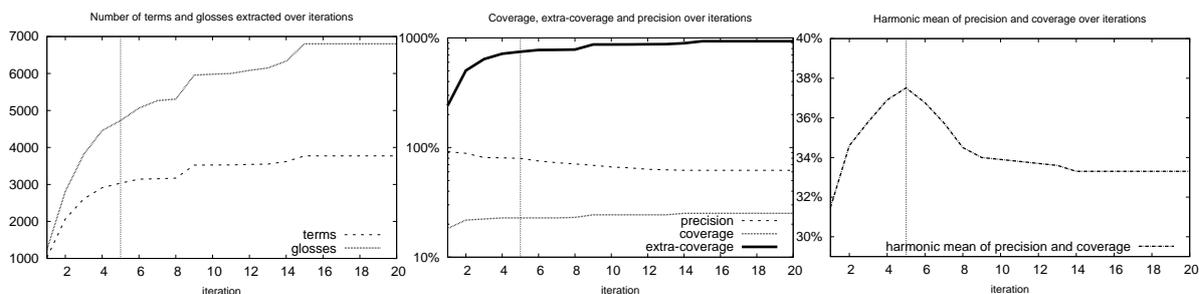

Figure 3: Size, coverage and precision trends for Arts (tuning domain) over 20 iterations for English.

	Botany	Comput.	Environm.	Finance
EN	96%	94%	97%	97%
FR	88%	89%	88%	95%
IT	94%	98%	83%	99%

Table 8: Precision of the glosses for the four domains and for the three languages.

## 4.2 Glosses

We show the results of gloss evaluation in Table 8. Precision ranges between 83% and 99%, with three domains performing above 92% on average across languages, and the Environment domain performing relatively worse because of its highly interdisciplinary nature (89% on average). We observe that these results are strongly correlated with the precision of the extracted terms (cf. Table 6), because the retrieved glosses of domain terms are usually in-domain too, and follow a definitional style because they come from glossaries. Note, however, that the gloss precision can also be higher than term precision, because many pertinent glosses might be extracted for the same term, cf. Table 4.

## 5 Comparative Evaluation

### 5.1 Comparison with Google Define

We performed a comparison with Google Define,<sup>11</sup> a state-of-the-art definition search service. This service inputs a term query and outputs a list of glosses. First, we randomly sampled 100 terms from our gold standard for each domain and each of the three languages. Next, for each domain and language, we manually calculated the fraction of terms for which an in-domain definition was provided by Google Define and GlossBoot. Table 9 shows the coverage results.

Google Define outperforms our system on all four domains (with a few exceptions). However

<sup>11</sup> Accessible from Google search by means of the `define: keyword`.

		Botany	Comput.	Environm.	Finance
EN	Google Define	90%	87%	84%	82%
	GlossBoot	77%	47%	44%	51%
FR	Google Define	40%	48%	36%	82%
	GlossBoot	88%	42%	22%	32%
IT	Google Define	52%	74%	78%	80%
	GlossBoot	64%	38%	44%	92%

Table 9: Number of domain glosses (from a random sample of 100 gold standard terms per domain) retrieved using Google Define and GlossBoot.

we note that Google Define: i) requires knowing the domain term to be defined in advance, whereas we jointly acquire thousands of terms and glosses starting from just a few seeds; ii) does not discriminate between glosses pertaining to the target domain and glosses concerning other fields or senses, whereas we extract domain-specific glosses.

### 5.2 Comparison with TaxoLearn

We also compared GlossBoot with a recent approach to glossary learning embedded into a framework for graph-based taxonomy learning from scratch, called TaxoLearn (Navigli et al., 2011). Since this approach requires the manual selection of a domain corpus to automatically extract terms and glosses, we decided to keep a level playing field and experimented with the same domain used by the authors, i.e., Artificial Intelligence (AI). TaxoLearn was applied to the entire set of IJCAI 2009 proceedings, resulting in the extraction of 427 terms and 834 glosses.<sup>12</sup> As regards GlossBoot, we selected 10 seeds to cover all the fields of AI, obtaining 5827 terms and 6716 glosses after 5 iterations, one order of magnitude greater than TaxoLearn.

As for the precision of the extracted terms, we randomly sampled 50% of them for each system. We show in Table 10 (first row) the estimated term

<sup>12</sup> Available at: <http://lcl.uniroma1.it/taxolearn>

	GlossBoot	TaxoLearn
Term Precision	82.3% (2398/2913)	77.0% (164/213)
Gloss Precision	82.8% (2780/3358)	78.9% (329/417)

Table 10: Estimated term and gloss precision of GlossBoot and TaxoLearn for the Artificial Intelligence domain.

precision for GlossBoot and TaxoLearn. The precision value for GlossBoot is lower than the precision values of the four domains in Table 6, due to the AI domain being highly interdisciplinary. TaxoLearn obtained a lower precision because it acquires a full-fledged taxonomy for the domain, thus also including higher-level concepts which do not necessarily pertain to the domain.

We performed a similar evaluation for the precision of the acquired glosses, by randomly sampling 50% of them for each system. We show in Table 10 (second row) the estimated gloss precision of GlossBoot and TaxoLearn. Again, GlossBoot outperforms TaxoLearn, retrieving a larger amount of glosses (6716 vs. 834) with higher precision. We remark, however, that in TaxoLearn glossary extraction is a by-product of the taxonomy learning process.

Finally, we note that we cannot compare with approaches based on lexical patterns (such as (Kozareva and Hovy, 2010a)), because they are not aimed at learning glossaries, but just at retrieving sentence snippets which contain pairs of terms/hypernyms (e.g., “*supervised systems* such as *decision trees*”).

## 6 Related Work

There are several techniques in the literature for the automated acquisition of definitional knowledge. Fujii and Ishikawa (2000) use an n-gram model to determine the definitional nature of text fragments, whereas Klavans and Muresan (2001) apply pattern matching techniques at the lexical level guided by cue phrases such as “is called” and “is defined as”. Cafarella et al. (2005) developed a Web search engine which handles more general and complex patterns like “*cities* such as *ProperNoun(Head(NP))*” in which it is possible to constrain the results with syntactic properties. More recently, a domain-independent supervised approach was presented which learns Word-Class Lattices (WCLs), i.e. lattice-based definition classifiers that are applied to candidate sentences containing the input terms (Navigli and Velardi, 2010). WCLs have been shown to perform with

high precision in several domains (Velardi et al., 2013).

To avoid the burden of manually creating a training dataset, definitional patterns can be extracted automatically. Reiplinger et al. (2012) experimented with two different approaches for the acquisition of lexical-syntactic patterns. The first approach involves bootstrapping patterns from a domain corpus, and then manually refining the acquired patterns. The second approach, instead, involves automatically acquiring definitional sentences by using a more sophisticated syntactic and semantic processing. The results shows high precision in both cases.

However, these approaches to glossary learning extract unrestricted textual definitions from open text. In order to filter out non-domain definitions, Velardi et al. (2008) automatically extract a domain terminology from an input corpus which they later use for assigning a domain score to each harvested definition and filtering out non-domain candidates. The extraction of domain terms from corpora can be performed either by means of statistical measures such as specificity and cohesion (Park et al., 2002), or just TF\*IDF (Kim et al., 2009).

To avoid the use of a large domain corpus, terminologies can be obtained from the Web by using Doubly-Anchored Patterns (DAPs) which, given a (term, hypernym) pair, harvest sentences matching manually-defined patterns like “<hypernym> such as <term>, and \*” (Kozareva et al., 2008). Kozareva and Hovy (2010a) further extend this term extraction process by harvesting new hypernyms using the corresponding inverse patterns (called  $DAP^{-1}$ ) like “\* such as <term<sub>1</sub>>, and <term<sub>2</sub>>”. Similarly to our approach, they drop the requirement of a domain corpus and start from a small number of (term, hypernym) seeds. However, while Doubly-Anchored Patterns have proven useful in the induction of domain taxonomies (Kozareva and Hovy, 2010a), they cannot be applied to the glossary learning task, because the extracted sentences are not formal definitions.

In contrast, GlossBoot performs the novel task of multilingual glossary learning from the Web by bootstrapping the extraction process with a few (term, hypernym) seeds. Bootstrapping techniques (Brin, 1998; Agichtein and Gravano, 2000; Paşca et al., 2006) have been successfully applied to several tasks, including high-precision semantic lexicon extraction from large corpora (Riloff and Jones, 1999; Thelen and Riloff, 2002; McIntosh

	Domain	Term	Gloss

and Curran, 2008; McIntosh and Curran, 2009), learning semantic relations (Pantel and Pennacchiotti, 2006), extracting surface text patterns for open-domain question answering (Ravichandran and Hovy, 2002), semantic tagging (Huang and Riloff, 2010) and unsupervised Word Sense Disambiguation (Yarowsky, 1995). By exploiting the (term, hypernym) seeds to bootstrap the iterative acquisition of extraction patterns from Web glossary pages, we can cover the high variability of textual definitions, including both sentences matching the above-mentioned lexico-syntactic patterns (e.g., “a corpus is a collection of documents”) and glossary-style definitions (e.g., “corpus: a collection of document”) independently of the target domain and language.

## 7 Conclusions

In this paper we have presented GlossBoot, a new, minimally-supervised approach to multilingual glossary learning. Starting from a few hypernymy relation seeds which implicitly identify the domain of interest, we apply a bootstrapping approach which iteratively obtains HTML patterns from Web glossaries and then applies them to the extraction of term/gloss pairs. To our knowledge, GlossBoot is the first approach to large-scale glossary learning which jointly acquires thousands of terms and glosses for a target domain and language with minimal supervision.

The gist of GlossBoot is our glossary bootstrapping approach, thanks to which we can drop the requirements of existing techniques such as the availability of domain text corpora, which often do not contain enough definitions, and the man-

ual specification of lexical patterns, which typically extract sentence snippets, instead of formal glosses.

GlossBoot will be made available to the research community as open-source software. Beyond the immediate usability of its output and its effective use for domain Word Sense Disambiguation (Faralli and Navigli, 2012), we wish to show the benefit of GlossBoot in gloss-driven approaches to ontology learning (Navigli et al., 2011; Velardi et al., 2013) and semantic network enrichment (Navigli and Ponzetto, 2012). In Table 11 we show an excerpt of the acquired glossaries. All the glossaries and gold standards created for our experiments are available from the authors' Web site <http://lcl.uniroma1.it/glossboot/>.

We remark that the terminologies covered with GlossBoot are not only precise, but also one order of magnitude greater than those covered in individual online glossaries. As future work we plan to study the ability of GlossBoot to acquire domain glossaries at different levels of specificity (i.e., domains vs. subdomains). We also plan to exploit the acquired HTML patterns for implementing an open-source glossary crawler, along the lines of Google Define.

# Collective Annotation of Linguistic Resources: Basic Principles and a Formal Model

Ulle Endriss and Raquel Fernández

Institute for Logic, Language & Computation

University of Amsterdam

{ulle.endriss|raquel.fernandez}@uva.nl

## Abstract

Crowdsourcing, which offers new ways of cheaply and quickly gathering large amounts of information contributed by volunteers online, has revolutionised the collection of labelled data. Yet, to create annotated linguistic resources from this data, we face the challenge of having to combine the judgements of a potentially large group of annotators. In this paper we investigate how to aggregate individual annotations into a single collective annotation, taking inspiration from the field of social choice theory. We formulate a general formal model for collective annotation and propose several aggregation methods that go beyond the commonly used majority rule. We test some of our methods on data from a crowdsourcing experiment on textual entailment annotation.

## 1 Introduction

In recent years, the possibility to undertake large-scale annotation projects with hundreds or thousands of annotators has become a reality thanks to online crowdsourcing methods such as Amazon's *Mechanical Turk* and *Games with a Purpose*. Although these techniques open the door to a true revolution for the creation of annotated corpora, within the computational linguistics community there so far is no clear understanding of how the so-called "wisdom of the crowds" could or should be used to develop useful annotated linguistic resources. Those who have looked into this increasingly important issue have mostly concentrated on validating the quality of multiple non-expert annotations in terms of how they compare to expert gold standards; but they have only used simple aggregation methods based on majority voting to combine the judgments of individual annotators (Snow et al., 2008; Venhuizen et al., 2013).

In this paper, we take a different perspective and instead focus on investigating different aggregation methods for deriving a single *collective annotation* from a diverse set of judgments. For this we draw inspiration from the field of *social choice theory*, a theoretical framework for combining the preferences or choices of several individuals into a collective decision (Arrow et al., 2002). Our aim is to explore the parallels between the task of aggregating the preferences of the citizens participating in an election and the task of combining the expertise of speakers taking part in an annotation project. Our contribution consists in the formulation of a general formal model for collective annotation and, in particular, the introduction of several families of aggregation methods that go beyond the commonly used majority rule.

The remainder of this paper is organised as follows. In Section 2 we introduce some basic terminology and argue that there are four natural forms of collective annotation. We then focus on one of them and present a formal model for it in Section 3. We also formulate some basic principles of aggregation within this model in the same section. Section 4 introduces three families of aggregation methods: bias-correcting majority rules, greedy methods for identifying (near-)consensual coalitions of annotators, and distance-based aggregators. We test the former two families of aggregators, as well as the simple majority rule commonly used in similar studies, in a case study on data extracted from a crowdsourcing experiment on textual entailment in Section 5. Section 6 discusses related work and Section 7 concludes.

## 2 Four Types of Collective Annotation

An annotation task consists of a set of *items*, each of which is associated with a set of possible *categories* (Artstein and Poesio, 2008). The categories may be the same for all items or they may be item-specific. For instance, dialogue act annotation

(Allen and Core, 1997; Carletta et al., 1997) and word similarity rating (Miller and Charles, 1991; Finkelstein et al., 2002) involve choosing from amongst a set of categories—acts in a dialogue act taxonomy or values on a scale, respectively—which remains fixed for all items in the annotation task. In contrast, in tasks such as word sense labelling (Kilgarriff and Palmer, 2000; Palmer et al., 2007; Venhuizen et al., 2013) and PP-attachment annotation (Rosenthal et al., 2010; Jha et al., 2010) coders need to choose a category amongst a set of options specific to each item—the possible senses of each word or the possible attachment points in each sentence with a prepositional phrase.

In either case (one set of categories for all items vs. item-specific sets of categories), annotators are typically asked to identify, for each item, the category they consider the best match. In addition, they may be given the opportunity to indicate that they cannot judge (the “don’t know” or “unclear” category). For large-scale annotation projects run over the Internet it is furthermore very likely that an annotator will not be confronted with every single item, and it makes sense to distinguish items not seen by the annotator from items labelled as “don’t know”. We refer to this form of annotation, i.e., an annotation task where coders have the option to (i) label items with one of the available categories, to (ii) choose “don’t know”, or to (iii) not label an item at all, as *plain annotation*.

Plain annotation is the most common form of annotation and it is the one we shall focus on in this paper. However, other, more complex, forms of annotation are also possible and of interest. For instance, we may ask coders to *rank* the available categories (resulting in, say, a weak or partial order over the categories); we may ask them to provide a *qualitative ratings* of the available categories for each item (e.g., *excellent match*, *good match*, etc.); or we may ask for *quantitative ratings* (e.g., numbers from 1 to 100).<sup>1</sup> We refer to these forms of annotation as *complex annotation*.

We want to investigate how to aggregate the information available for each item once annotations by multiple annotators have been collected. In line with the terminology used in social choice theory and particularly judgment aggregation (Ar-

row, 1963; List and Pettit, 2002), let us call an aggregation method *independent* if the outcome regarding a given item  $j$  only depends on the categories provided by the annotators regarding  $j$  itself (but not on, say, the categories assigned to a different item  $j'$ ). Independent aggregation methods are attractive due to their simplicity. They also have some conceptual appeal: when deciding on  $j$  maybe we *should* only concern ourselves with what people have to say regarding  $j$ ? On the other hand, insisting on independence prevents us from exploiting potentially useful information that cuts across items. For instance, if a particular annotator almost always chooses category  $c$ , then we should maybe give less weight to her selecting  $c$  for the item  $j$  at hand than when some other annotator chooses  $c$  for  $j$ . This would call for methods that do not respect independence, which we shall refer to as *general* aggregation. Note that when studying independent aggregation methods, without loss of generality, we may assume that each annotation task consists of just a single item.

In view of our discussion above, there are four classes of approaches to collective annotation:

- (1) *Independent aggregation of plain annotations*. This is the simplest case, resulting in a fairly limited design space. When, for a given item, each annotator has to choose between  $k$  categories (or abstain) and we do not permit ourselves to use any other information, then the only reasonable choice is to implement the *plurality rule* (Taylor, 2005), under which the winning category is the category chosen by the largest number of annotators. In case there are exactly two categories available, the plurality rule is also called the *majority rule*. The only additional consideration to make here (besides how to deal with ties) is whether or not we may want to declare no winner at all in case the plurality winner does not win by a sufficiently significant margin or does not make a particular quota. This is the most common approach in the literature (see, e.g., Venhuizen et al., 2013).
- (2) *Independent aggregation of complex annotations*. This is a natural generalisation of the first approach, resulting in a wider range of possible methods. We shall not explore it here, but only point out that in case annotators provide *linear orders* over categories, there is a close resemblance to classical voting the-

<sup>1</sup>Some authors have combined qualitative and quantitative ratings; e.g., for the Graded Word Sense dataset of Erk et al. (2009) coders were asked to classify each relevant WordNet sense for a given item on a 5-point scale: 1 *completely different*, 2 *mostly different*, 3 *similar*, 4 *very similar*, 5 *identical*.

ory (Taylor, 2005); in case only *partial orders* can be elicited, recent work in computational social choice on the generalisation of classical voting rules may prove helpful (Pini et al., 2009; Endriss et al., 2009); and in case annotators rate categories using qualitative expressions such as *excellent match*, the method of *majority judgment* of Balinski and Laraki (2011) should be considered.

- (3) *General aggregation of plain annotations.* This is the approach we shall discuss below. It is related to *voting in combinatorial domains* studied in computational social choice (Chevaleyre et al., 2008), and to both *binary aggregation* (Dokow and Holzman, 2010; Grandi and Endriss, 2011) and *judgment aggregation* (List and Pettit, 2002).
- (4) *General aggregation of complex annotations.* While appealing due to its great level of generality, this approach can only be tackled successfully once approaches (2) and (3) are sufficiently well understood.

### 3 Formal Model

Next we present our model for general aggregation of plain annotations into a collective annotation.

#### 3.1 Terminology and Notation

An *annotation task* is defined in terms of  $m$  items, with each item  $j \in \{1, \dots, m\}$  being associated with a finite set of possible *categories*  $\mathcal{C}_j$ . Annotators are asked to provide an answer for each of the items of the annotation task. In the context of plain annotations, a valid *answer* for item  $j$  is an element of the set  $\mathcal{A}_j = \mathcal{C}_j \cup \{?, \perp\}$ .<sup>2</sup> Here  $?$  represents the answer “don’t know” and we use  $\perp$  to indicate that the annotator has not answered (or even seen) the item at all. An *annotation* is a vector of answers by one annotator, one answer for each item of the annotation task at hand, i.e., an annotation is an element of the Cartesian product  $\mathcal{A} = \mathcal{A}_1 \times \mathcal{A}_2 \times \dots \times \mathcal{A}_m$ . A typical element of  $\mathcal{A}$  will be denoted as  $A = (a_1, \dots, a_m)$ .

Let  $\mathcal{N} = \{1, \dots, n\}$  be a finite set of  $n$  *annotators* (or *coders*). A *profile*  $\mathbf{A} = (A_1, \dots, A_n) \in \mathcal{A}^n$ , for a given annotation task, is a vector of annotations, one for each annotator. That is,  $\mathbf{A}$  is an

<sup>2</sup>As discussed earlier, in the context of *complex annotations*, an answer could also be, say, a partial order on  $\mathcal{C}_j$  or a function associating elements of  $\mathcal{C}_j$  with numerical ratings.

	Item 1	Item 2	Item 3
Annotator 1	B	A	A
Annotator 2	B	B	B
Annotator 3	A	B	A
Majority	B	B	A

Table 1: A profile with a collective annotation.

$n \times m$ -matrix; e.g.,  $a_{3,7}$  is the answer that the 3rd annotator provides for the 7th item.

We want to aggregate the information provided by the annotators into a (single) collective annotation. For the sake of simplicity, we use  $\mathcal{A}$  also as the domain of possible collective annotations (even though the distinction between  $?$  and  $\perp$  may not be strictly needed here; they both indicate that we do not want to commit to any particular category). An *aggregator* is a function  $F : \mathcal{A}^n \rightarrow \mathcal{A}$ , mapping any given profile into a collective annotation, i.e., a labelling of the items in the annotation task with corresponding categories (or  $?$  or  $\perp$ ). An example is the *plurality rule* (also known as the *majority rule* for binary tasks with  $|\mathcal{C}_j| = 2$  for all items  $j$ ), which annotates each item with the category chosen most often.

Note that the collective annotation need not coincide with any of the individual annotations. Take, for example, a binary annotation task in which three coders label three items with category A or B as shown in Table 1. Here using the majority rule to aggregate the annotations would result in a collective annotation that does not fully match any annotation by an individual coder.

#### 3.2 Basic Properties

A typical task in social choice theory is to formulate *axioms* that formalise specific desirable properties of an aggregator  $F$  (Arrow et al., 2002). Below we adapt three of the most basic axioms that have been considered in the social choice literature to our setting and we briefly discuss their relevance to collective annotation tasks.

We will require some additional notation: for any profile  $\mathbf{A}$ , item  $j$ , and possible answer  $a \in \mathcal{A}_j$ , let  $N_{j:a}^{\mathbf{A}}$  denote the set of annotators who chose answer  $a$  for item  $j$  under profile  $\mathbf{A}$ .

- $F$  is *anonymous* if it treats coders symmetrically, i.e., if for every permutation  $\pi : \mathcal{N} \rightarrow \mathcal{N}$ ,  $F(A_1, \dots, A_n) = F(A_{\pi(1)}, \dots, A_{\pi(n)})$ . In social choice theory, this is a fairness constraint. For us, fairness *per se* is not a desideratum,

but when we do not have any *a priori* information regarding the expertise of annotators, then anonymity is a natural axiom to adopt.

- $F$  is *neutral* if it treats all items symmetrically, i.e., if for every two items  $j$  and  $j'$  with the same set of possible categories (i.e., with  $C_j = C_{j'}$ ) and for every profile  $\mathbf{A}$ , it is the case that whenever  $N_{j:a}^{\mathbf{A}} = N_{j':a}^{\mathbf{A}}$  for all answers  $a \in \mathcal{A}_j = \mathcal{A}_{j'}$ , then  $F(\mathbf{A})_j = F(\mathbf{A})_{j'}$ . That is, if the patterns of individual annotations of  $j$  and  $j'$  are the same, then also their collective annotation should coincide. In social choice theory, neutrality is also considered a basic fairness requirement (avoiding preferential treatment one candidate in an election). In the context of collective annotation there may be good reasons to violate neutrality: e.g., we may use an aggregator that assigns different default categories to different items and that can override such a default decision only in the presence of a significant majority (note that this is different from anonymity: we will often not have any information on our annotators, but we may have tangible information on items).<sup>3</sup>
- $F$  is *independent* if the collective annotation of any given item  $j$  only depends on the individual annotations of  $j$ . Formally,  $F$  is independent if, for every item  $j$  and every two profiles  $\mathbf{A}$  and  $\mathbf{A}'$ , it is the case that whenever  $N_{j:a}^{\mathbf{A}} = N_{j:a}^{\mathbf{A}'}$  for all answers  $a \in \mathcal{A}_j$ , then  $F(\mathbf{A})_j = F(\mathbf{A}')_j$ . In social choice theory, independence is often seen as a desirable albeit hard (or even impossible) to achieve property (Arrow, 1963). For collective annotation, we strongly believe that it is *not* a desirable property: by considering how annotators label other items we can learn about their biases and we should try to exploit this information to obtain the best possible annotation for the item at hand.

Note that the plurality/majority rule is independent. All of the methods we shall propose in Section 4 are both anonymous and neutral—except to the extent to which we have to violate basic symmetry requirements in order to break ties between categories chosen equally often for a given item. None of our aggregators is independent.

<sup>3</sup>It would also be of interest to formulate a neutrality axiom w.r.t. categories (rather than items). For two categories, this idea has been discussed under the name of *domain-neutrality* in the literature (Grandi and Endriss, 2011), but for larger sets of categories it has not yet been explored.

Some annotation tasks might be subject to *integrity constraints* that determine the internal consistency of an annotation. For example, if our items are pairs of words and the possible categories include *synonymous* and *antonymous*, then if item 1 is about words  $A$  and  $B$ , item 2 about words  $B$  and  $C$ , and item 3 about words  $A$  and  $C$ , then any annotation that labels items 1 and 2 as *synonymous* should not label item 3 as *antonymous*. Thus, a further desirable property that will play a role for some annotation tasks is *collective rationality* (Grandi and Endriss, 2011): if all individual annotations respect a given integrity constraint, then so should the collective annotation.

We can think of integrity constraints as imposing top-down expert knowledge on an annotation. However, for some annotation tasks, no integrity constraints may be known to us in advance, even though we may have reasons to believe that the individual annotators do respect some such constraints. In that case, selecting one of the individual annotations in the profile as the collective annotation is the only way to ensure that these integrity constraints will be satisfied by the collective annotation (Grandi and Endriss, 2011). Of course, to do so we would need to assume that there is at least one annotator who has labelled *all* items (and to be able to design a high-quality aggregator in this way we should have a sufficiently large number of such annotators to choose from), which may not always be possible, particularly in the context of crowdsourcing.

## 4 Three Families of Aggregators

In this section we instantiate our formal model by proposing three families of methods for aggregation. Each of them is inspired, in part, by standard approaches to designing aggregation rules developed in social choice theory and, in part, by the specific needs of collective annotation. Regarding the latter point, we specifically emphasise the fact that not all annotators can be expected to be equally reliable (in general or w.r.t. certain items) and we try to integrate the process of aggregation with a process whereby less reliable annotators are either given less weight or are excluded altogether.

### 4.1 Bias-Correcting Majority Rules

We first want to explore the following idea: If a given annotator annotates *most* items with 0, then we might want to assign less significance to that

choice for any particular item.<sup>4</sup> That is, if an annotator appears to be biased towards a particular category, then we might want to try to correct for this bias during aggregation.

What follows applies only to annotation tasks where every item is associated with the same set of categories. For ease of exposition, let us furthermore assume that there are only two categories, 0 and 1, and that annotators do not make use of the option to annotate with ? (“don’t know”).

For every annotator  $i \in \mathcal{N}$  and every category  $X \in \{0, 1\}$ , fix a *weight*  $w_i^X \in \mathbb{R}$ . The *bias-correcting majority* (BCM) rule for this family of weights is defined as follows. Given profile  $\mathbf{A}$ , the collective category for item  $j$  will be 1 in case  $\sum_{a_{i,j}=1} w_i^1 > \sum_{a_{i,j}=0} w_i^0$ , and 0 otherwise.<sup>5</sup> That is, we compute the overall weight for category 1 by adding up the corresponding weights for those coders that chose 1 for item  $j$ , and we do accordingly for the overall weight for category 0; finally, we choose as collective category that category with the larger overall weight. Note that for  $w_i^X \equiv 1$  we obtain the simple majority rule.

Below we define three intuitively appealing families of weights, and thereby three BCM rules. However, before we do so, we first require some additional notation. Fix a profile of annotations. For  $X \in \{0, 1\}$ , let  $\text{Freq}_i(X)$  denote the relative frequency with which annotator  $i$  has chosen category  $X$ . For instance, if  $i$  has annotated 20 items and has chosen 1 in five cases, then  $\text{Freq}_i(1) = 0.25$ . Similarly, let  $\text{Freq}(X)$  denote the frequency of  $X$  across the entire profile.

Here are three ways of making the intuitive idea of bias correction concrete:

- (1) The *complement-based* BCM rule (ComBCM) is defined by weights  $w_i^X = \text{Freq}_i(1-X)$ . That is, the weight of annotator  $i$  for category  $X$  is equal to her relative frequency of having chosen the other category  $1-X$ . For example, if you annotate two items with 1 and eight with 0, then each of your 1-annotations will have weight 0.8, while each of your 0-annotations will only have weight 0.2.
- (2) The *difference-based* BCM rule (DiffBCM) is defined by weights  $w_i^X = 1 + \text{Freq}_i(X) -$

<sup>4</sup>A similar idea is at the heart of *cumulative voting*, which requires a voter to distribute a fixed number of points amongst the candidates (Glasser, 1959; Brams and Fishburn, 2002).

<sup>5</sup>For the sake of simplicity, our description here presupposes that ties are always broken in favour of 0. Other tie-breaking rules (e.g., random tie-breaking) are possible.

$\text{Freq}_i(X)$ . Recall that  $\text{Freq}(X)$  is the relative frequency of  $X$  in the entire profile, while  $\text{Freq}_i(X)$  is the relative frequency of  $X$  in the annotation of  $i$ . Hence, if  $i$  assigns category  $X$  less often than the general population, then her weight on  $X$ -choices will be increased by the difference (and *vice versa* in case she assigns  $X$  more often than the population at large). For example, if you assign 1 in two out of ten cases, while in general category 1 appears in exactly 50% of all annotations, then your weight for a choice of 1 will be  $1 + 0.5 - 0.2 = 1.3$ , while your weight for a choice of 0 will only be 0.7.

- (3) The *relative* BCM rule (RelBCM) is defined by weights  $w_i^X = \frac{\text{Freq}_i(X)}{\text{Freq}(X)}$ . The idea is very similar to the DiffBCM rule. For the example given above, your weight for a choice of 1 would be  $0.5/0.2 = 2.5$ , while your weight for a choice of 0 would be  $0.5/0.8 = 0.625$ .

The main difference between the ComBCM rule and the other two rules is that the former only takes into account the possible bias of individual annotators, while the latter two factor in as well the possible skewness of the data (as reflected by the labelling behaviour of the full set of annotators).

In addition, while ComBCM is specific to the case of two categories, DiffBCM and RelBCM immediately generalise to any number of categories. In this case, we add up the category-specific weights as before and then choose the category with maximal support (i.e., we generalise the majority rule underlying the family of BCM rules to the plurality rule).

We stress that our bias-correcting majority rules do *not* violate anonymity (nor neutrality for that matter). If we were to give less weight to a given annotator based on, say, her name, this would constitute a violation of anonymity; if we do so due to properties of the profile at hand and if we do so in a symmetric manner, then it does not.

## 4.2 Greedy Consensus Rules

Now consider the following idea: If for a given item there is almost complete consensus amongst those coders that annotated it with a proper category (i.e., those who did not choose ? or  $\perp$ ), then we should probably adopt their choice for the collective annotation. Indeed, most aggregators will make this recommendation. Furthermore, the fact that there is almost full consensus for one item

may cast doubts on the reliability of coders who disagree with this near-consensus choice and we might want to disregard their views not only w.r.t. that item but also as far as the annotation of other items is concerned. Next we propose a family of aggregators that implement this idea.

For simplicity, suppose that the only proper categories available are 0 and 1 and that annotators do not make use of ? (but it is easy to generalise to arbitrary numbers of categories and scenarios where different items are associated with different categories). Fix a *tolerance value*  $t \in \{0, \dots, m\}$ . The *greedy consensus rule* GreedyCR<sup>t</sup> works as follows. First, initialise the set  $\mathcal{N}^*$  with the full population of annotators  $\mathcal{N}$ . Then iterate the following two steps:

- (1) Find the item with the strongest majority for either 0 or 1 amongst coders in  $\mathcal{N}^*$  and lock in that value for the collective annotation.
- (2) Eliminate all coders from  $\mathcal{N}^*$  who disagree on more than  $t$  items with the values locked in for the collective annotation so far.

Repeat this process until the categories for all  $m$  items have been settled.<sup>6</sup> We may think of this as a “greedy” way of identifying a coalition  $\mathcal{N}^*$  with high inter-annotator agreement and then applying the majority rule to this coalition to obtain the collective annotation.

To be precise, the above is a description of an entire *family* of aggregators: Whenever there is more than one item with a majority of maximal strength, we could choose to lock in any one of them. Also, when there is a split majority between annotators in  $\mathcal{N}^*$  voting 0 and those voting 1, we have to use a tie-breaking rule to make a decision. Additional heuristics may be used to make these local decisions, or they may be left to chance.

Note that in case  $t = m$ , GreedyCR<sup>t</sup> is simply the majority rule (as no annotator will ever get eliminated). In case  $t = 0$ , we end up with a coalition of annotators that unanimously agree with all of the categories chosen for the collective annotation. However, this coalition of perfectly aligned

<sup>6</sup>There are some similarities to Tideman’s *Ranked Pairs* method for preference aggregation (Tideman, 1987), which works by fixing the relative rankings of pairs of alternatives in order of the strength of the supporting majorities. In preference aggregation (unlike here), the population of voters is *not* reduced in the process; instead, decisions against the majority are taken whenever this is necessary to guarantee the transitivity of the resulting collective preference order.

annotators need not be the largest such coalition (due to the greedy nature of our rule).

Note that greedy consensus rules, as defined here, are both anonymous and neutral. Specifically, it is important not to confuse possible skewness of the data with a violation of neutrality of the aggregator.

### 4.3 Distance-based Aggregation

Our third approach is based on the notion of *distance*. We first define a metric on choices to be able to say how distant two choices are. This induces an aggregator that, for a given profile, returns a collective choice that minimises the sum of distances to the individual choices in the profile.<sup>7</sup> This opens up a wide range of possibilities; we only sketch some of them here.

A natural choice is the *adjusted Hamming distance*  $H : \mathcal{A} \times \mathcal{A} \rightarrow \mathbb{R}_{\geq 0}$ , which counts how many items two annotations differ on:

$$H(A, A') = \sum_{j=1}^m \delta(a_j, a'_j)$$

Here  $\delta$  is the *adjusted discrete distance* defined as  $\delta(x, y) = 0$  if  $x = y$  or  $x \in \{?, \perp\}$  or  $y \in \{?, \perp\}$ , and as  $\delta(x, y) = 1$  in all other cases.<sup>8</sup>

Once we have fixed a distance  $d$  on  $\mathcal{A}$  (such as  $H$ ), this induces an aggregator  $F_d$ :

$$F_d(\mathbf{A}) = \operatorname{argmin}_{A \in \mathcal{A}} \sum_{i=1}^n d(A, A_i)$$

To be precise,  $F_d$  is an *irresolute* aggregator that might return a *set* of best annotations with minimal distance to the profile.

Note that  $F_H$  is simply the plurality rule. This is so because every element of the Cartesian product is a possible annotation. In the presence of integrity constraints excluding some combinations, however, a distance-based rule allows for more sophisticated forms of aggregation (by choosing the optimal annotation w.r.t. all feasible annotations).

We may also try to restrict the computation of distances to a subset of “reliable” annotators. Consider the following idea: If a group of annotators is (fairly) reliable, then they should have a

<sup>7</sup>This idea has been used in voting (Kemeny, 1959), belief merging (Konieczny and Pino Pérez, 2002), and judgment aggregation (Miller and Osherson, 2009).

<sup>8</sup>This  $\delta$ , divided by  $m$ , is the same thing as what Artstein and Poesio (2008) call the agreement value  $\operatorname{agr}_j$  for item  $j$ .

(fairly) high inter-annotator agreement. By this reasoning, we should choose a group of annotators  $\text{ANN} \subseteq \mathcal{N}$  that maximises inter-annotator agreement in ANN and work with the aggregator  $\text{argmin}_{A \in \mathcal{A}} \sum_{i \in \text{ANN}} d(A, A_i)$ . But this is too simplistic: any singleton  $\text{ANN} = \{i\}$  will result in perfect agreement. That is, while we can easily maximise agreement, doing so in a naïve way means ignoring most of the information collected. In other words, we face the following dilemma:

- On the one hand, we should choose a *small* set ANN (i.e., select *few* annotators to base our collective annotation on), as that will allow us to increase the (average) reliability of the annotators taken into account.
- On the other hand, we should choose a *large* set ANN (i.e., select *many* annotators to base our collective annotation on), as that will increase the amount of information exploited.

One pragmatic approach is to fix a minimum quality threshold regarding one of the two dimensions and optimise in view of the other.<sup>9</sup>

## 5 A Case Study

In this section, we report on a case study in which we have tested our bias-correcting majority and greedy consensus rules.<sup>10</sup> We have used the dataset created by Snow et al. (2008) for the task of recognising textual entailment, originally proposed by Dagan et al. (2006) in the PASCAL Recognizing Textual Entailment (RTE) Challenge. RTE is a binary classification task consisting in judging whether the meaning of a piece of text (the so-called hypothesis) can be inferred from another piece of text (the entailing text). The original RTE1 Challenge testset consists of 800 text-hypothesis pairs (such as  $T$ : “*Chrétien visited Peugeot’s newly renovated car factory*”,  $H$ : “*Peugeot manufactures cars*”) with a gold standard annotation that classifies each item as either *true* (1)—in case  $H$  can be inferred from  $T$ —or *false* (0). Exactly 400 items are annotated as 0 and exactly 400 as 1. Bos and Markert (2006) performed an independent expert annotation of

<sup>9</sup>GreedyCR<sup>*t*</sup> is a greedy (rather than optimal) implementation of this basic idea, with the tolerance value  $t$  fixing a threshold on (a particular form of) inter-annotator agreement.

<sup>10</sup>Since the annotation task and dataset used for our case study do not involve any interesting integrity constraints, we have not tested any distance-based aggregation rules.

this testset, obtaining 95% agreement between the RTE1 gold standard and their own annotation.

The dataset of Snow et al. (2008) includes 10 non-expert annotations for each of the 800 items in the RTE1 testset, collected with Amazon’s *Mechanical Turk*. A quick examination of the dataset shows that there are a total of 164 annotators who have annotated between 20 items (124 annotators) and 800 items each (only one annotator). Non-expert annotations with category 1 (rather than 0) are slightly more frequent ( $\text{Freq}(1) \approx 0.57$ ).

We have applied our aggregators to this data and compared the outcomes with each other and to the gold standard. The results are summarised in Table 2 and discussed in the sequel. For each pair we report the *observed agreement*  $A_o$  (proportion of items on which two annotations agree) and, in brackets, Cohen’s *kappa*  $\kappa = \frac{A_o - A_e}{1 - A_e}$ , with  $A_e$  being the expected agreement for independent annotators (Cohen, 1960; Artstein and Poesio, 2008).

Note that there are several variants of the majority rule, depending on how we break ties. In Table 2,  $\text{Maj}^{1>0}$  is the majority rule that chooses 1 in case the number of annotators choosing 1 is equal to the number of annotators choosing 0 (and accordingly for  $\text{Maj}^{0>1}$ ). For 65 out of the 800 items there has been a tie (i.e., five annotators choose 0 and another five choose 1). This means that the tie-breaking rule used can have a significant impact on results. Snow et al. (2008) work with a majority rule where ties are broken uniformly at random and report an observed agreement (accuracy) between the majority rule and the gold standard of 89.7%. This is confirmed by our results: 89.7% is the mean of 87.5% (our result for  $\text{Maj}^{1>0}$ ) and 91.9% (our result for  $\text{Maj}^{0>1}$ ). If we break ties in the optimal way (in view of approximating the gold standard (which of course would not actually be possible without having access to that gold standard), then we obtain an observed agreement of 93.8%, but if we are unlucky and ties happen to get broken in the worst possible way, we obtain an observed agreement of only 85.6%.

For none of our bias-correcting majority rules did we encounter any ties. Hence, for these aggregators the somewhat arbitrary choices we have to make when breaking ties are of no significance, which is an important point in their favour. Observe that all of the bias-correcting majority rules approximate the gold standard better than the majority rule with uniformly random tie-breaking.

Annotation	Maj <sup>1&gt;0</sup>	Maj <sup>0&gt;1</sup>	ComBCM	DiffBCM	RelBCM	GreedyCR <sup>0</sup>	GreedyCR <sup>15</sup>
Gold Standard	87.5% (.75)	91.9% (.84)	91.1% (.80)	91.5% (.81)	90.8% (.80)	86.6% (.73)	92.5% (.85)
Maj <sup>1&gt;0</sup>		91.9% (.84)	88.9% (.76)	94.3% (.87)	94.0% (.87)	87.6% (.75)	91.5% (.83)
Maj <sup>0&gt;1</sup>			96.0% (.91)	97.6% (.95)	96.9% (.93)	89.0% (.78)	96.1% (.92)
ComBCM				94.6% (.86)		88.8% (.75)	93.9% (.86)
DiffBCM					98.8% (.97)	88.6% (.75)	94.8% (.88)
RelBCM						88.4% (.74)	93.8% (.86)
GreedyCR <sup>0</sup>							90.6% (.81)

Table 2: Observed agreement (and  $\kappa$ ) between collective annotations and the gold standard.

Recall that the greedy consensus rule is in fact a family of aggregators: whenever there is more than one item with a maximal majority, we may lock in any one of them. Furthermore, when there is a split majority, then ties may be broken either way. The results reported here refer to an implementation that always chooses the lexicographically first item amongst all those with a maximal majority and that breaks ties in favour of 1. These parameters yield neither the best or the worst approximations of the gold standard. We tested a range of tolerance values. As an example, Table 2 includes results for tolerance values 0 and 15. The coalition found for tolerance 0 consists of 46 annotators who all completely agree with the collective annotation; the coalition found for tolerance 15 consists of 156 annotators who all disagree with the collective annotation on at most 15 items. While GreedyCR<sup>0</sup> appears to perform rather poorly, GreedyCR<sup>15</sup> approximates the gold standard particularly well. This is surprising and suggests, on the one hand, that eliminating only the most extreme outlier annotators is a useful strategy, and on the other hand, that a high-quality collective annotation can be obtained from a group of annotators that disagree substantially.<sup>11</sup>

## 6 Related Work

There is an increasing number of projects using crowdsourcing methods for labelling data. Online *Games with a Purpose*, originally conceived by von Ahn and Dabbish (2004) to annotate images, have been used for a variety of linguistic tasks: Lafourcade (2007) created JeuxDeMots to develop a semantic network by asking players to label words with semantically related words; Phrase Detectives (Chamberlain et al., 2008) has been used to gather annotations on anaphoric coreference; and more recently Basile et al. (2012)

<sup>11</sup>Recall that 124 out of 164 coders only annotated 20 items each; a tolerance value of 15 thus is fairly lenient.

have developed the Wordrobe set of games for annotating named entities, word senses, homographs, and pronouns. Similarly, crowdsourcing via microworking sites like Amazon’s *Mechanical Turk* has been used in several annotation experiments related to tasks such as affect analysis, event annotation, sense definition and word sense disambiguation (Snow et al., 2008; Rumshisky, 2011; Rumshisky et al., 2012), amongst others.<sup>12</sup>

All these efforts face the problem of how to aggregate the information provided by a group of volunteers into a collective annotation. However, by and large, the emphasis so far has been on issues such as experiment design, data quality, and costs, with little attention being paid to the aggregation methods used, which are typically limited to some form of majority vote (or taking averages if the categories are numeric). In contrast, our focus has been on investigating different aggregation methods for arriving at a collective annotation.

Our work has connections with the literature on inter-annotator agreement. Agreement scores such as *kappa* are used to assess the quality of an annotation but do not play a direct role in constructing one single annotation from the labellings of several coders.<sup>13</sup> The methods we have proposed, in contrast, do precisely that. Still, agreement plays a prominent role in some of these methods. In our discussion of distance-based aggregation, we suggested how agreement can be used to select a subset of annotators whose individual annotations are minimally distant from the resulting collective annotation. Our greedy consensus rule also makes use of agreement to ensure a minimum level of consensus. In both cases, the aggregators have the effect of disregarding some outlier annotators.

<sup>12</sup>See also the papers presented at the NAACL 2010 Workshop on Creating Speech and Language Data with Amazon’s *Mechanical Turk* ([tinyurl.com/amtworkshop2010](http://tinyurl.com/amtworkshop2010)).

<sup>13</sup>Creating a gold standard often involves adjudication of disagreements by experts, or even the removal of cases with disagreement from the dataset. See, e.g., the papers cited by Beigman Klebanov and Beigman (2009).

Other researchers have explored ways to directly identify “low-quality” annotators. For instance, Snow et al. (2008) and Raykar et al. (2010) propose Bayesian methods for identifying and correcting annotators’ biases, while Ipeirotis et al. (2010) propose an algorithm for assigning a quality score to annotators that distinguishes intrinsic error rate from an annotator’s bias. In our approach, we do not directly rate annotators or recalibrate their annotations—rather, some outlier annotators get to play a marginal role in the resulting collective annotation as a side effect of the aggregation methods themselves.

Although in our case study we have tested our aggregators by comparing their outcomes to a gold standard, our approach to collective annotation itself does *not* assume that there is in fact a ground truth. Instead, we view collective annotations as reflecting the views of a community of speakers.<sup>14</sup> This contrasts significantly with, for instance, the machine learning literature, where there is a focus on estimating *the hidden true label* from a set of noisy labels using maximum-likelihood estimators (Dawid and Skene, 1979; Smyth et al., 1995; Raykar et al., 2010).

In application domains where it is reasonable to assume the existence of a ground truth and where we are able to model the manner in which individual judgments are being distorted relative to this ground truth, social choice theory provides tools (using again maximum-likelihood estimators) for the design of aggregators that maximise chances of recovering the ground truth for a given model of distortion (Young, 1995; Conitzer and Sandholm, 2005). In recent work, Mao et al. (2013) have discussed the use of these methods in the context of crowdsourcing. Specifically, they have designed an experiment in which the ground truth is defined unambiguously and known to the experiment designer, so as to be able to extract realistic models of distortion from the data collected in a crowdsourcing exercise.

## 7 Conclusions

We have presented a framework for combining the expertise of speakers taking part in large-scale

---

<sup>14</sup>In some domains, such as medical diagnosis, it makes perfect sense to assume that there is a ground truth. However, in tasks related to linguistic knowledge and language use such an assumption seems far less justified. Hence, a collective annotation may be the closest we can get to a representation of the linguistic knowledge/use of a linguistic community.

annotation projects. Such projects are becoming more and more common, due to the availability of online crowdsourcing methods for data annotation. Our work is novel in several respects. We have drawn inspiration from the field of social choice theory to formulate a general formal model for aggregation problems, which we believe sheds light on the kind of issues that arise when trying to build annotated linguistic resources from a potentially large group of annotators; and we have proposed several families of concrete methods for aggregating individual annotations that are more fine-grained than the standard majority rule that so far has been used across the board. We have tested some of our methods on a gold standard testset for the task of recognising textual entailment.

Our aim has been conceptual, namely to point out that it is important for computational linguists to reflect on the methods used when aggregating annotation information. We believe that social choice theory offers an appropriate general methodology for supporting this reflection. Importantly, this does not mean that the concrete aggregation methods developed in social choice theory are immediately applicable or that all the axioms typically studied in social choice theory are necessarily relevant to aggregating linguistic annotations. Rather, what we claim is that it is the *methodology* of social choice theory which is useful: to formally state desirable properties of aggregators as axioms and then to investigate which specific aggregators satisfy them. To put it differently: at the moment, researchers in computational linguistics simply use some given aggregation methods (almost always the majority rule) and judge their quality on how they fare in specific experiments—but there is no principled reflection on the methods themselves. We believe that this should change and hope that the framework outlined here can provide a suitable starting point.

In future work, the framework we have presented here should be tested more extensively, not only against a gold standard but also in terms of the usefulness of the derived collective annotations for training supervised learning systems. On the theoretical side, it would be interesting to study the axiomatic properties of the methods of aggregation we have proposed here in more depth and to define axiomatic properties of aggregators that are specifically tailored to the task of collective annotation of linguistic resources.

## Abstract

This paper discusses the construction of a parallel treebank currently involving ten languages from six language families. The treebank is based on deep LFG (Lexical-Functional Grammar) grammars that were developed within the framework of the ParGram (Parallel Grammar) effort. The grammars produce output that is maximally parallelized across languages and language families. This output forms the basis of a parallel treebank covering a diverse set of phenomena. The treebank is publicly available via the INESS treebanking environment, which also allows for the alignment of language pairs. We thus present a unique, multilayered parallel treebank that represents more and different types of languages than are available in other treebanks, that represents

deep linguistic knowledge and that allows for the alignment of sentences at several levels: dependency structures, constituency structures and POS information.

## 1 Introduction

This paper discusses the construction of a parallel treebank currently involving ten languages that represent several different language families, including non-Indo-European. The treebank is based on the output of individual deep LFG (Lexical-Functional Grammar) grammars that were developed independently at different sites but within the overall framework of ParGram (the Parallel Grammar project) (Butt et al., 1999a; Butt et al., 2002). The aim of ParGram is to produce deep, wide coverage grammars for a variety of languages. Deep grammars provide detailed syntactic analysis, encode grammatical functions as well as

other grammatical features such as tense or aspect, and are linguistically well-motivated. The ParGram grammars are couched within the linguistic framework of LFG (Bresnan, 2001; Dalrymple, 2001) and are constructed with a set of grammatical features that have been commonly agreed upon within the ParGram group. ParGram grammars are implemented using XLE, an efficient, industrial-strength grammar development platform that includes a parser, a generator and a transfer system (Crouch et al., 2012). XLE has been developed in close collaboration with the ParGram project. Over the years, ParGram has continuously grown and includes grammars for Arabic, Chinese, English, French, German, Georgian, Hungarian, Indonesian, Irish, Japanese, Malagasy, Murrinh-Patha, Norwegian, Polish, Spanish, Tigrinya, Turkish, Urdu, Welsh and Wolof.

ParGram grammars produce output that has been parallelized maximally across languages according to a set of commonly agreed upon universal proto-type analyses and feature values. This output forms the basis of the ParGramBank parallel treebank discussed here. ParGramBank is constructed using an innovative alignment methodology developed in the XPAR project (Dyvik et al., 2009) in which grammar parallelism is presupposed to propagate alignment across different projections (section 6). This methodology has been implemented with a drag-and-drop interface as part of the LFG Parsebanker in the INESS infrastructure (Rosén et al., 2012; Rosén et al., 2009). ParGramBank has been constructed in INESS and is accessible in this infrastructure, which also offers powerful search and visualization.

In recent years, parallel treebanking<sup>1</sup> has gained in importance within NLP. An obvious application for parallel treebanking is machine translation, where treebank size is a deciding factor for whether a particular treebank can support a particular kind of research project. When conducting in-depth linguistic studies of typological features, other factors such as the number of included languages, the number of covered phenomena, and the depth of linguistic analysis become more important. The treebanking effort reported on in this paper supports work of the latter focus, including efforts at multilingual dependency parsing (Naseem et al., 2012). We have

<sup>1</sup>Throughout this paper ‘treebank’ refers to both phrase-structure resources and their natural extensions to dependency and other deep annotation banks.

created a parallel treebank whose prototype includes ten typologically diverse languages and reflects a diverse set of phenomena. We thus present a unique, multilayered parallel treebank that represents more languages than are currently available in other treebanks, and different types of languages as well. It contains deep linguistic knowledge and allows for the parallel and simultaneous alignment of sentences at several levels. LFG’s f(unctional)-structure encodes dependency structures as well as information that is equivalent to Quasi-Logical Forms (van Genabith and Crouch, 1996). LFG’s c(onstituent)-structure provides information about constituency, hierarchical relations and part-of-speech. Currently, ParGramBank includes structures for the following languages (with the ISO 639-3 code and language family): English (*eng*, Indo-European), Georgian (*kat*, Kartvelian), German (*deu*, Indo-European), Hungarian (*hun*, Uralic), Indonesian (*ind*, Austronesian), Norwegian (Bokmål) (*nob*, Indo-European), Polish (*pol*, Indo-European), Turkish (*tur*, Altaic), Urdu (*urd*, Indo-European) and Wolof (*wol*, Niger-Congo). It is freely available for download under the CC-BY 3.0 license via the INESS treebanking environment and comes in two formats: a Prolog format and an XML format.<sup>2</sup>

This paper is structured as follows. Section 2 discusses related work in parallel treebanking. Section 3 presents ParGram and its approach to parallel treebanking. Section 4 focuses on the treebank design and its construction. Section 5 contains examples from the treebank, focusing on typological aspects and challenges for parallelism. Section 6 elaborates on the mechanisms for parallel alignment of the treebank.

## 2 Related Work

There have been several efforts in parallel treebanking across theories and annotation schemes.

Kuhn and Jellinghaus (2006) take a minimal approach towards multilingual parallel treebanking. They bootstrap phrasal alignments over a sentence-aligned parallel corpus of English, French, German and Spanish and report concrete treebank annotation work on a sample of sentences from the Europarl corpus. Their annotation

<sup>2</sup><http://iness.uib.no>. The treebank is in the public domain (CC-BY 3.0). The use of the INESS platform itself is not subject to any licensing. To access the treebank, click on ‘Treebank selection’ and choose the ParGram collection.

scheme is the “leanest” possible scheme in that it consists solely of a bracketing for a sentence in a language (where only those units that play the role of a semantic argument or modifier in a larger unit are bracketed) and a correspondence relation of the constituents across languages.

Klyueva and Mareček (2010) present a small parallel treebank using data and tools from two existing treebanks. They take a syntactically annotated gold standard text for one language and run an automated annotation on the parallel text for the other language. Manually annotated Russian data are taken from the SynTagRus treebank (Nivre et al., 2008), while tools for parsing the corresponding text in Czech are taken from the TectoMT framework (Popel and Žabokrtský, 2010).

The SMULTRON project is concerned with constructing a parallel treebank of English, German and Swedish. The sentences have been POS-tagged and annotated with phrase structure trees. These trees have been aligned on the sentence, phrase and word level. Additionally, the German and Swedish monolingual treebanks contain lemma information. The treebank is distributed in TIGER-XML format (Volk et al., 2010).

Megyesi et al. (2010) discuss a parallel English-Swedish-Turkish treebank. The sentences in each language are annotated morphologically and syntactically with automatic tools, aligned on the sentence and the word level and partially hand-corrected.<sup>3</sup>

A further parallel treebanking effort is ParTUT, a parallel treebank (Sanguinetti and Bosco, 2011; Bosco et al., 2012) which provides dependency structures for Italian, English and French and which can be converted to a CCG (Combinatory Categorical Grammar) format.

Closest to our work is the ParDeepBank, which is engaged in the creation of a highly parallel treebank of English, Portuguese and Bulgarian. ParDeepBank is couched within the linguistic framework of HPSG (Head-Driven Phrase Structure Grammar) and uses parallel automatic HPSG grammars, employing the same tools and implementation strategies across languages (Flickinger et al., 2012). The parallel treebank is aligned on the sentence, phrase and word level.

In sum, parallel treebanks have so far focused exclusively on Indo-European languages

<sup>3</sup>The paper mentions Hindi as the fourth language, but this is not yet available: <http://stp.lingfil.uu.se/~bea/turkiska/home-en.html>.

(with Turkish providing the one exception) and generally do not extend beyond three or four languages. In contrast, our ParGramBank treebank currently includes ten typologically different languages from six different language families (Altaic, Austronesian, Indo-European, Kartvelian, Niger-Congo, Uralic).

A further point of comparison with ParDeepBank is that it relies on dynamic treebanks, which means that structures are subject to change during the further development of the resource grammars. In ParDeepBank, additional machinery is needed to ensure correct alignment on the phrase and word level (Flickinger et al., 2012, p. 105). ParGramBank contains finalized analyses, structures and features that were designed collaboratively over more than a decade, thus guaranteeing a high degree of stable parallelism. However, with the methodology developed within XPAR, alignments can easily be recomputed from f-structure alignments in case of grammar or feature changes, so that we also have the flexible capability of allowing ParGramBank to include dynamic treebanks.

### 3 ParGram and its Feature Space

The ParGram grammars use the LFG formalism which produces c(onstituent)-structures (trees) and f(unctional)-structures as the syntactic analysis. LFG assumes a version of Chomsky’s Universal Grammar hypothesis, namely that all languages are structured by similar underlying principles (Chomsky, 1988; Chomsky, 1995). Within LFG, f-structures encode a language universal level of syntactic analysis, allowing for crosslinguistic parallelism at this level of abstraction. In contrast, c-structures encode language particular differences in linear word order, surface morphological vs. syntactic structures, and constituency (Dalrymple, 2001). Thus, while the Chomskyan framework is derivational in nature, LFG departs from this view by embracing a strictly representational approach to syntax.

ParGram tests the LFG formalism for its universality and coverage limitations to see how far parallelism can be maintained across languages. Where possible, analyses produced by the grammars for similar constructions in each language are parallel, with the computational advantage that the grammars can be used in similar applications and that machine translation can be simplified.

The ParGram project regulates the features and values used in its grammars. Since its inception in 1996, ParGram has included a “feature committee”, which collaboratively determines norms for the use and definition of a common multilingual feature and analysis space. Adherence to feature committee decisions is supported technically by a routine that checks the grammars for compatibility with a feature declaration (King et al., 2005); the feature space for each grammar is included in ParGramBank. ParGram also conducts regular meetings to discuss constructions, analyses and features.

For example, Figure 1 shows the c-structure of the Urdu sentence in (1) and the c-structure of its English translation. Figure 2 shows the f-structures for the same sentences. The left/upper c- and f-structures show the parse from the English ParGram grammar, the right/lower ones from Urdu ParGram grammar.<sup>4,5</sup> The c-structures encode linear word order and constituency and thus look very different; e.g., the English structure is rather hierarchical while the Urdu structure is flat (Urdu is a free word-order language with no evidence for a VP; Butt (1995)). The f-structures, in contrast, are parallel aside from grammar-specific characteristics such as the absence of grammatical gender marking in English and the absence of articles in Urdu.<sup>6</sup>

- (1) کسان نی اپنا ٹریکٹر بیچا ؟  
 kisAn=nE      apnA  
 farmer.M.Sg=Erg self.M.Sg  
 TrEkTar      bEc-A  
 tractor.M.Sg sell-Perf.M.Sg  
 ‘Did the farmer sell his tractor?’

With parallel analyses and parallel features, maximal parallelism across typologically different languages is maintained. As a result, during the construction of the treebank, post-processing and conversion efforts are kept to a minimum.

<sup>4</sup>The Urdu ParGram grammar makes use of a transliteration scheme that abstracts away from the Arabic-based script; the transliteration scheme is detailed in Malik et al. (2010).

<sup>5</sup>In the c-structures, dotted lines indicate distinct functional domains; e.g., in Figure 1, the NP *the farmer* and the VP *sell his tractor* belong to different f-structures: the former maps onto the SUBJ f-structure, while the latter maps onto the topmost f-structure (Dyvik et al., 2009). Section 6 elaborates on functional domains.

<sup>6</sup>The CASE feature also varies: since English does not distinguish between accusative, dative, and other oblique cases, the OBJ is marked with a more general *obl* CASE.

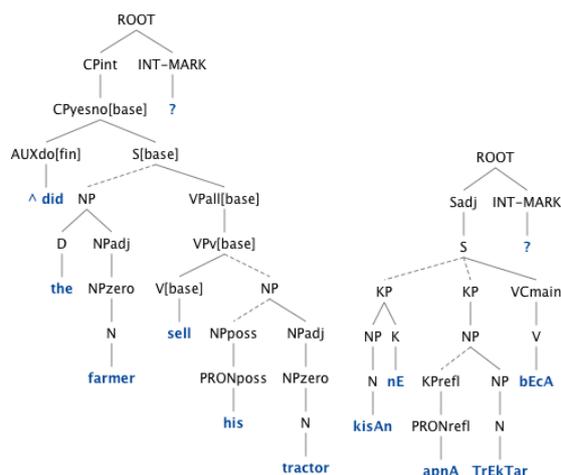

Figure 1: English and Urdu c-structures

We emphasize the fact that ParGramBank is characterized by a maximally reliable, human-controlled and linguistically deep parallelism across aligned sentences. Generally, the result of automatic sentence alignment procedures are parallel corpora where the corresponding sentences normally have the same purported meaning as intended by the translator, but they do not necessarily match in terms of structural expression. In building ParGramBank, conscious attention is paid to maintaining semantic and constructional parallelism as much as possible. This design feature renders our treebank reliable in cases when the constructional parallelism is reduced even at f-structure. For example, typological variation in the presence or absence of finite passive constructions represents a case of potential mismatch. Hungarian, one of the treebank languages, has no productive finite passives. The most common strategy in translation is to use an active construction with a topicalized object, with no overt subject and with 3PL verb agreement:

- (2) A fá-t      ki-vág-t-ák.  
 the tree-ACC out-cut-PAST-3PL  
 ‘The tree was cut down.’

In this case, a topicalized object in Hungarian has to be aligned with a (topical) subject in English. Given that both the sentence level and the phrase level alignments are human-controlled in the treebank (see sections 4 and 6), the greatest possible parallelism is reliably captured even in such cases of relative grammatical divergence.

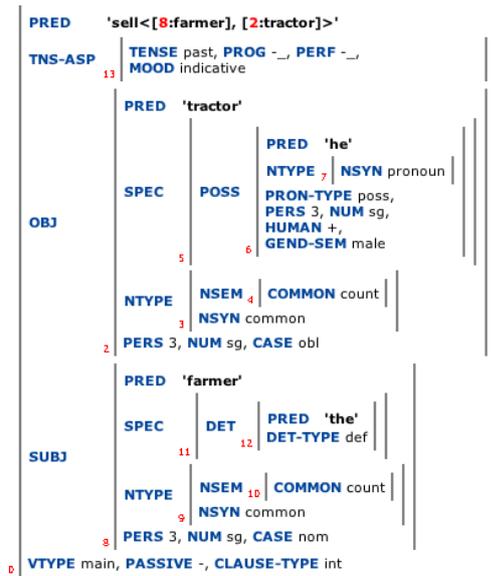

Figure 2: Parallel English and Urdu f-structures

#### 4 Treebank Design and Construction

For the initial seeding of the treebank, we focused on 50 sentences which were constructed manually to cover a diverse range of phenomena (transitivity, voice alternations, interrogatives, embedded clauses, copula constructions, control/raising verbs, etc.). We followed Lehmann et al. (1996) and Bender et al. (2011) in using coverage of grammatical constructions as a key component for grammar development. (3) lists the first 16 sentences of the treebank. An expansion to 100 sentences is scheduled for next year.

- (3) a. Declaratives:
1. The driver starts the tractor.
  2. The tractor is red.

- b. Interrogatives:
  3. What did the farmer see?
  4. Did the farmer sell his tractor?
- c. Imperatives:
  5. Push the button.
  6. Don't push the button.
- d. Transitivity:
  7. The farmer gave his neighbor an old tractor.
  8. The farmer cut the tree down.
  9. The farmer groaned.
- e. Passives and traditional voice:
  10. My neighbor was given an old tractor by the farmer.
  11. The tree was cut down yesterday.
  12. The tree had been cut down.
  13. The tractor starts with a shudder.
- f. Unaccusative:
  14. The tractor appeared.
- g. Subcategorized declaratives:
  15. The boy knows the tractor is red.
  16. The child thinks he started the tractor.

The sentences were translated from English into the other treebank languages. Currently, these languages are: English, Georgian, German, Hungarian, Indonesian, Norwegian (Bokmål), Polish, Turkish, Urdu and Wolof. The translations were done by ParGram grammar developers (i.e., expert linguists and native speakers).

The sentences were automatically parsed with ParGram grammars using XLE. Since the parsing was performed sentence by sentence, our resulting treebank is automatically aligned at the sentence level. The resulting c- and f-structures were banked in a database using the LFG Parsebanker (Rosén et al., 2009). The structures were disambiguated either prior to banking using XLE or during banking with the LFG Parsebanker and its discriminant-based disambiguation technique. The banked analyses can be exported and downloaded in a Prolog format using the LFG Parsebanker interface. Within XLE, we automatically convert the structures to a simple XML format and make these available via ParGramBank as well.

The Prolog format is used with applications which use XLE to manipulate the structures, e.g. for further semantic processing (Crouch and King, 2006) or for sentence condensation (Crouch et al., 2004).

## 5 Challenges for Parallelism

We detail some challenges in maintaining parallelism across typologically distinct languages.

### 5.1 Complex Predicates

Some languages in ParGramBank make extensive use of complex predicates. For example, Urdu uses a combination of predicates to express concepts that in languages like English are expressed with a single verb, e.g., ‘memory do’ = ‘remember’, ‘fear come’ = ‘fear’. In addition, verb+verb combinations are used to express permissive or aspectual relations. The strategy within ParGram is to abstract away from the particular surface morphosyntactic expression and aim at parallelism at the level of f-structure. That is, monoclausal predications are analyzed via a simple f-structure whether they consist of periphrastically formed complex predicates (Urdu, Figure 3), a simple verb (English, Figure 4), or a morphologically derived form (Turkish, Figure 5).

In Urdu and in Turkish, the top-level PRED is complex, indicating a composed predicate. In Urdu, this reflects the noun-verb complex predicate *sTArT kar* ‘start do’, in Turkish it reflects a morphological causative. Despite this morphosyntactic complexity, the overall dependency structure corresponds to that of the English simple verb.

(4) ڈرائیور ٹریکٹر کو سٹارٹ کرتا ہے

DrAIvar            TrEkTar=kO  
driver.M.Sg.Nom tractor.M.Sg=Acc  
sTArT    kartA        hE  
start.M.Sg do.Impf.M.Sg be.Pres.3Sg  
‘The driver starts the tractor.’

(5) sürücü traktör-ü çalış-tır-ıyor  
driver.Nom tractor-Acc work-Caus-Prog.3Sg  
‘The driver starts the tractor.’

The f-structure analysis of complex predicates is thus similar to that of languages which do not use complex predicates, resulting in a strong syntactic parallelism at this level, even across typologically diverse languages.

### 5.2 Negation

Negation also has varying morphosyntactic surface realizations. The languages in ParGramBank differ with respect to their negation strategies. Languages such as English and German use independent negation: they negate using words such as

<b>PRED</b>	'kar<[9:DrAIvar], 'sTArT<[4:TrEkTar]>'>'		
<b>VTYP</b>	13	COMPLEX-PRED-FORM kar, COMPLEX-PRED nv	
<b>TNS-ASP</b>	12	TENSE pres, MOOD indicative, ASPECT impf

<b>VTYP</b>	7	main, PASSIVE -, CLAU-TYPE decl	

Figure 4: Simple predicate: English analysis of (4)

adverbs (English *not*, German *nicht*) or verbs (English *do*-support). Other languages employ non-independent, morphological negation techniques; Turkish, for instance, uses an affix on the verb, as in (6).

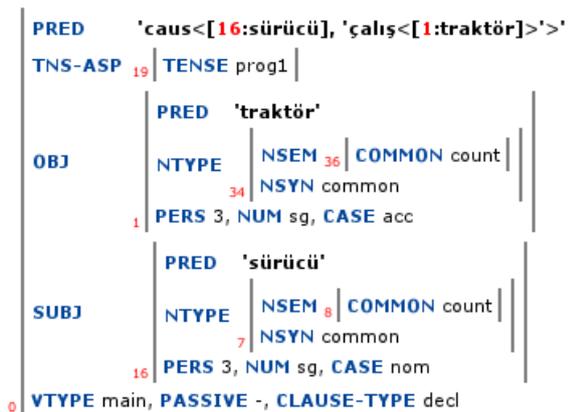

Figure 5: Causative: Turkish analysis of (5)

- (6) düğme-ye bas-ma  
 button-Dat push-Neg.Imp  
 'Don't push the button.'

Within ParGram we have not abstracted away from this surface difference. The English *not* in (6) functions as an adverbial adjunct that modifies the main verb (see top part of Figure 6) and information would be lost if this were not represented at f-structure. However, the same cannot be said of the negative affix in Turkish — the morphological affix is not an adverbial adjunct. We have therefore currently analyzed morphological negation as adding a feature to the f-structure which marks the clause as negative, see bottom half of Figure 6.

### 5.3 Copula Constructions

Another challenge to parallelism comes from copula constructions. An approach advocating a uniform treatment of copulas crosslinguistically was advocated in the early years of ParGram (Butt et al., 1999b), but this analysis could not do justice to the typological variation found with copulas. ParGramBank reflects the typological difference with three different analyses, with each language making a language-specific choice among the three possibilities that have been identified (Dalrymple et al., 2004; Nordlinger and Sadler, 2007; Attia, 2008; Sulger, 2011; Laczkó, 2012).

The possible analyses are demonstrated here with respect to the sentence *The tractor is red*. The English grammar (Figure 7) uses a raising approach that reflects the earliest treatments of copulas in LFG (Bresnan, 1982). The copula takes a non-finite complement whose subject is raised to the matrix clause as a non-thematic subject of the copula. In contrast, in Urdu (Figure 8), the

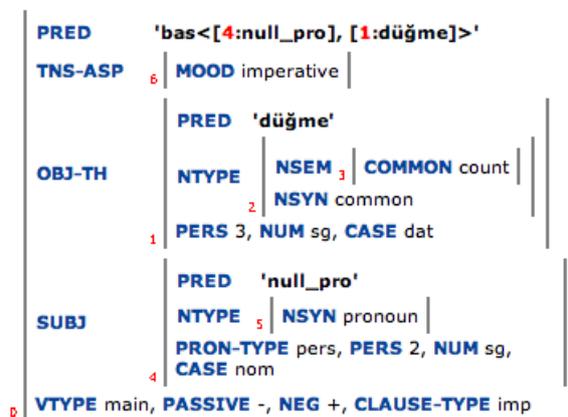

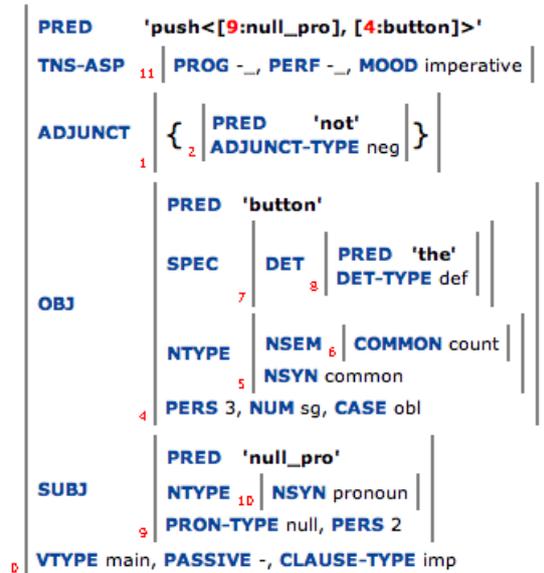

Figure 6: Different f-structural analyses for negation (English vs. Turkish)

copula is a two-place predicate, assigning SUBJ and PREDLINK functions. The PREDLINK function is interpreted as predicating something about the subject. Finally, in languages like Indonesian (Figure 9), there is no overt copula and the adjective is the main predicational element of the clause.

#### 5.4 Summary

This section discussed some challenges for maintaining parallel analyses across typologically diverse languages. Another challenge we face is when no corresponding construction exists in a language, e.g. with impersonals as in the English *It is raining*. In this case, we provide a translation and an analysis of the structure of the corresponding translation, but note that the phenomenon being exemplified does not actually exist in the language. A further extension to the capabilities of the treebank could be the addition of pointers from the alternative structure used in the translation to the parallel aligned set of sentences that correspond to this alternative structure.

### 6 Linguistically Motivated Alignment

The treebank is automatically aligned on the sentence level, the top level of alignment within ParGramBank. For phrase-level alignments, we use the drag-and-drop alignment tool in the LFG Parsebanker (Dyvik et al., 2009). The tool allows the alignment of f-structures by dragging the index of a subsidiary source f-structure onto the index of the corresponding target f-structure. Two f-structures correspond if they have translationally matching predicates, and the arguments of each predicate correspond to an argument or adjunct in the other f-structure. The tool automatically computes the alignment of c-structure nodes on the basis of the manually aligned corresponding f-structures.<sup>7</sup>

<sup>7</sup>Currently we have not measured inter-annotator agreement (IAA) for the f-structure alignments. The f-structure alignments were done by only one person per language pair. We anticipate that multiple annotators will be needed for this

This method is possible because the c-structure to f-structure correspondence (the  $\phi$  relation) is encoded in the ParGramBank structures, allowing the LFG Parsebanker tool to compute which c-structure nodes contributed to a given f-structure via the inverse ( $\phi^{-1}$ ) mapping. A set of nodes mapping to the same f-structure is called a ‘functional domain’. Within a source and a target functional domain, two nodes are automatically aligned only if they dominate corresponding word forms. In Figure 10 the nodes in each functional domain in the trees are connected by whole lines while dotted lines connect different functional domains. Within a functional domain, thick whole lines connect the nodes that share alignment; for simplicity the alignment is only indicated for the top nodes. The automatically computed c-structural alignments are shown by the curved lines. The alignment information is stored as an additional layer and can be used to explore alignments at the string (word), phrase (c-)structure, and functional (f-)structure levels.

We have so far aligned the treebank pairs English-Urdu, English-German, English-Polish and Norwegian-Georgian. As Figure 10 illustrates for (7) in an English-Urdu pairing, the English object *neighbor* is aligned with the Urdu indirect object (OBJ-GO) *hamsAyA* ‘neighbor’, while the English indirect object (OBJ-TH) *tractor* is aligned with the Urdu object *TrEkTar* ‘tractor’. The c-structure correspondences were computed automatically from the f-structure alignments.

- (7) کسان ني اپني همسايي کو پرانا ٹريڪٽر ديا  
 kisAn=nE                    apnE  
 farmer.M.Sg=Erg self.Obl  
 hamsAyE=kO                    purAnA  
 neighbor.M.Sg.Obl=Acc old.M.Sg  
 TrEkTar                    di-yA  
 tractor.M.Sg give-Perf.M.Sg  
 ‘The farmer gave his neighbor an old tractor.’

The INESS platform additionally allows for the highlighting of connected nodes via a mouse-over technique. It thus provides a powerful and flexible tool for the semi-automatic alignment and subse-

task in the future, in which case we will measure IAA for this step.

## 7 Discussion and Future Work

We have discussed the construction of ParGramBank, a parallel treebank for ten typologically different languages. The analyses in ParGramBank are the output of computational LFG ParGram grammars. As a result of ParGram’s centrally agreed upon feature sets and prototypical analyses, the representations are not only deep in nature, but maximally parallel. The representations offer information about dependency relations as well as word order, constituency and part-of-speech.

In future ParGramBank releases, we will provide more theory-neutral dependencies along with the LFG representations. This will take the form of triples (King et al., 2003). We also plan to provide a POS-tagged and a named entity marked up version of the sentences; these will be of use for more general NLP applications and for systems which use such markup as input to deeper processing.

<sup>8</sup>One reviewer inquires about possibilities of linking (semi-)automatically between languages, for example using lexical resources such as WordNets or Panlex. We agree that this would be desirable, but unrealizable, since many of the languages included in ParGramBank do not have a WordNet resource and are not likely to achieve an adequate one soon.

Third, the treebank will be expanded to include 100 more sentences within the next year. We also plan to include more languages as other ParGram groups contribute structures to ParGramBank.

ParGramBank, including its multilingual sentences and all annotations, is made freely available for research and commercial use under the CC-BY 3.0 license via the INESS platform, which supports alignment methodology developed in the XPAR project and provides search and visualization methods for parallel treebanks. We encourage the computational linguistics community to contribute further layers of annotation, including semantic (Crouch and King, 2006), abstract knowledge representational (Bobrow et al., 2007), PropBank (Palmer et al., 2005), or TimeBank (Mani and Pustejovsky, 2004) annotations.

# Identifying Bad Semantic Neighbors for Improving Distributional Thesauri

Olivier Ferret

CEA, LIST, Vision and Content Engineering Laboratory,  
Gif-sur-Yvette, F-91191 France.  
olivier.ferret@cea.fr

## Abstract

Distributional thesauri are now widely used in a large number of Natural Language Processing tasks. However, they are far from containing only interesting semantic relations. As a consequence, improving such thesaurus is an important issue that is mainly tackled indirectly through the improvement of semantic similarity measures. In this article, we propose a more direct approach focusing on the identification of the neighbors of a thesaurus entry that are not semantically linked to this entry. This identification relies on a discriminative classifier trained from unsupervised selected examples for building a distributional model of the entry in texts. Its bad neighbors are found by applying this classifier to a representative set of occurrences of each of these neighbors. We evaluate the interest of this method for a large set of English nouns with various frequencies.

## 1 Introduction

The work we present in this article focuses on the automatic building of a thesaurus from a corpus. As illustrated by Table 1, such thesaurus gives for each of its entries a list of words, called *semantic neighbors*, that are supposed to be semantically linked to the entry. Generally, each neighbor is associated with a weight that characterizes the strength of its link with the entry and all the neighbors of an entry are sorted according to the decreasing order of their weight.

The term *semantic neighbor* is very generic and can have two main interpretations according to the kind of semantic relations it is based on: one relies only on paradigmatic relations, such as hypernymy or synonymy, while the other consid-

ers syntagmatic relations, called collocation relations by (Halliday and Hasan, 1976) in the context of lexical cohesion or “non-classical relations” by (Morris and Hirst, 2004). The distinction between these two interpretations refers to the distinction between the notions of *semantic similarity* and *semantic relatedness* as it was done in (Budanitsky and Hirst, 2006) or in (Zesch and Gurevych, 2010) for instance. However, the limit between these two notions is sometimes hard to find in existing work as terms *semantic similarity* and *semantic relatedness* are often used interchangeably. Moreover, *semantic similarity* is frequently considered as included into *semantic relatedness* and the two problems are often tackled by using the same methods. In the remainder of this article, we will use the term *semantic similarity* with its generic sense and the term *semantic relatedness* for referring more specifically to similarity based on syntagmatic relations.

Following work such as (Grefenstette, 1994), a widespread way to build a thesaurus from a corpus is to use a semantic similarity measure for extracting the semantic neighbors of the entries of the thesaurus. Three main ways of implementing such measures can be distinguished. The first one relies on handcrafted resources in which semantic relations are clearly identified. Work based on WordNet-like lexical networks for building semantic similarity measures such as (Budanitsky and Hirst, 2006) or (Pedersen et al., 2004) falls into this category. These measures typically exploit the hierarchical structure of these networks, based on hypernymy relations. The second approach makes use of a less structured source of knowledge about words such as the definitions of classical dictionaries or the *glosses* of WordNet. WordNet’s *glosses* were used to support Lesk-like measures in (Banerjee and Pedersen, 2003) and more recently, measures were also defined from Wikipedia or Wiktionaries (Gabrilovich and

Markovitch, 2007). The last option is the corpus-based approach, based on the distributional hypothesis (Firth, 1957): each word is characterized by the set of contexts from a corpus in which it appears and the semantic similarity of two words is computed from the contexts they share. This perspective was first adopted by (Grefenstette, 1994) and (Lin, 1998) and then, explored in details in (Curran and Moens, 2002b), (Weeds, 2003) or (Heylen et al., 2008).

The problem of improving the results of the “classical” implementation of the distributional approach as it can be found in (Curran and Moens, 2002a) for instance was already tackled by some work. A part of these proposals focus on the weighting of the elements that are part of the contexts of words such as (Broda et al., 2009), in which the weights of context elements are turned into ranks, or (Zhitomirsky-Geffet and Dagan, 2009), followed and extended by (Yamamoto and Asakura, 2010), that proposes a bootstrapping method for modifying the weights of context elements according to the semantic neighbors found by an initial distributional similarity measure. However, another part of these proposals implies more radical changes. The use of dimensionality reduction techniques, for instance Latent Semantic Analysis in (Padó and Lapata, 2007), the multi-prototype (Reisinger and Mooney, 2010) or exemplar-based models (Erk and Pado, 2010), the Deep Learning approach of (Huang et al., 2012) or the redefinition of the distributional approach in a Bayesian framework (Kazama et al., 2010) can be classified into this second category.

The work we present in this article takes place in the framework defined by (Grefenstette, 1994) for implementing the distributional approach but proposes a new method for improving a thesaurus built in this context based on the identification of its bad semantic neighbors rather than on the adaptation of the weight of their features.

## 2 Principles

Our work shares with (Zhitomirsky-Geffet and Dagan, 2009) the use of a kind of bootstrapping as it starts from a distributional thesaurus and to some extent, exploits it for its improvement. However, it adopts a more indirect approach: instead of selecting the “best” semantic neighbors of an entry in the thesaurus for adapting the weights of distributional context elements, it focuses on the detection

of its bad semantic neighbors, that is to say the neighbors of the entry that are actually not semantically similar to the entry. In Table 1, *waterworks* for the entry *cabdriver* and *hollowness* for the entry *machination* are two examples of such kind of neighbors. By discarding these bad neighbors or at least by downgrading them, the rank of true semantic neighbors is expected to be lower. This makes the thesaurus more interesting to use since the quality of such thesaurus strongly decreases as the rank of the neighbors of its entries increases (see Section 4.1 for an illustration), which means in practice that only the first neighbors of an entry can be generally exploited.

The approach we propose for identifying the bad semantic neighbors of a thesaurus entry relies on the distributional hypothesis, as the method for the initial building of the thesaurus, but implements it in a different way. This hypothesis roughly specifies that from a semantic viewpoint, the meaning of a word can be characterized by the set of contexts in which this word occurs. As a consequence, two words are considered as semantically similar if they occur in a large enough set of shared contexts. In work such as (Curran and Moens, 2002a), this hypothesis is implemented by collecting for each entry the words it co-occurs with in a large corpus. This co-occurrence can be based either on the position of the word in the text in relation to the entry or on the presence of a syntactic relation between the entry and the word. As a result, the distributional representation of a word takes the unstructured form of a bag of words or the more structured form of a set of pairs {syntactic relation, word}. A variant of this approach was proposed in (Kazama et al., 2010) where the distributional representation of a word is modeled as a multinomial distribution with Dirichlet as prior.

However, this approach globally faces a certain lack of diversity and complexity of the features of its models. For instance, features such as ngrams of words or ngrams of parts of speech are not considered whereas they are widely used in tasks such as word sense disambiguation (WSD) for instance, probably because they would lead to very large models and because similarity measures such as the *Cosine* measure are not necessarily suitable for heterogeneous representations (Alexandrescu and Kirchhoff, 2007). Hence, we propose in this article to build a discriminative model for repre-

abnormality	defect [0.30], disorder [0.23], deformity [0.22], mutation [0.21], prolapse [0.21], anomaly [0.21] ...

Table 1: First neighbors of some entries of the distributional thesaurus of section 3.2

senting the contexts of a word since this kind of models are known to integrate easily a wide set of different types of features. This model aims more precisely at discriminating from a semantic viewpoint a word in context, *i.e.* in a sentence, from all other words and more particularly, from those of its neighbors in a distributional thesaurus that are likely to be actually not semantically similar to it. The underlying hypothesis follows the distributional principles: a word and a synonym should appear in the same contexts, which means that they are characterized by the same features. As a consequence, a model based on these features that can identify a word in a sentence is likely to identify also a synonym of this word in a sentence, and by extension, to identify a word that is paradigmatically linked to it. More precisely, we found that such model is specifically effective for discarding the bad neighbors of the entries of a distributional thesaurus.

### 3 Improving a distributional thesaurus

#### 3.1 Overview

The principles presented in the previous section face one major problem compared to the “classical” distributional approach : the semantic similarity of two words can be evaluated directly by computing the similarity of their distributional representations. However, in our case, since this representation is a discriminative model, the similarity of two words can not be evaluated through the direct comparison of their models. These models have to be applied to words in context for being exploited. As a consequence, for deciding whether a neighbor of a thesaurus entry is a bad neighbor or not, the discriminative model of the entry has to be applied to occurrences of this neighbor in texts. Hence, the method we propose for improving a distributional thesaurus applies the following process to each of its entries:

- building of a classifier for determining whether a word in a sentence corresponds or not to the entry;
- selection of a set of examples sentences for each of the neighbors of the entry in the the-

saurus;

- application of the classifier to these sentences;
- identification of bad neighbors according to the results of the classifier;
- reranking of entry’s neighbors according to bad neighbors.

#### 3.2 Building of the initial thesaurus

Before introducing our method for improving distributional thesauri, we first present the way we build such a thesaurus. As in (Lin, 1998) or (Curran and Moens, 2002a), this building is based on the definition of a semantic similarity measure from a corpus. The corpus used for defining this measure was the AQUAINT-2 corpus, a middle-size corpus made of around 380 million words coming from news articles. Although our target language is English, we chose to limit deliberately the level of the tools applied for preprocessing texts to part-of-speech tagging and lemmatization to make possible the transposition of our method to a large set of languages. This seems to be a reasonable compromise between the approach of (Freitag et al., 2005), in which none normalization of words is done, and the more widespread use of syntactic parsers in work such as (Lin, 1998). More precisely, we used *TreeTagger* (Schmid, 1994) for performing the linguistic preprocessing of the AQUAINT-2 corpus.

For the extraction of distributional data and the characteristics of the distributional similarity measure, we adopted the options of (Ferret, 2010), resulting from a kind of grid search procedure performed with the extended TOEFL test proposed in (Freitag et al., 2005) as an optimization objective. More precisely, the following characteristics were taken:

- distributional contexts made of the co-occurrences collected in a 3 word window centered on each occurrence in the corpus of the target word. These co-occurrences were restricted to nouns, verbs and adjectives;
- soft filtering of contexts: removal of co-occurrences with only one occurrence;
- weighting function of co-occurrences in con-

texts = *Pointwise Mutual Information* (PMI) between the target word and the co-occurent;

- similarity measure between contexts, for evaluating the semantic similarity of two words = *Cosine* measure.

The building of our initial thesaurus from the similarity measure above was performed classically by extracting the closest semantic neighbors of each of its entries. More precisely, the selected measure was computed between each entry and its possible neighbors. These neighbors were then ranked in the decreasing order of the values of this measure and the first 100 neighbors were kept as the semantic neighbors of the entry. Both entries and possible neighbors were AQUAINT-2 nouns whose frequency was higher than 10.

### 3.3 Building a discriminative model of words in context

As mentioned in section 3.1, the starting point of our reranking process is the definition of a model for determining to what extent a word in a sentence, which is not supposed to be known in the context of this task, corresponds or not to a reference word  $E$ . This task can also be viewed as a tagging task in which the occurrences of a target word  $T$  are labeled with two tags:  $E$  and  $notE$ . In the context of our global objective, we are not of course interested by this task itself but rather by the fact that such classifier is likely to model the contexts in which  $E$  occurs and as a consequence, is also likely to model its meaning according to the distributional hypothesis.

A step further, such classifier can be viewed as a means for testing whether or not a word has the same meaning as  $E$ . This is a problem close to WSD as it is performed in the context of the pseudo-word disambiguation paradigm (Gale et al., 1992): a pseudo-word is created with two senses,  $E$  and  $notE$ ,  $notE$  corresponding to one or several words that are supposed to be representative of a meaning different from the meaning of  $E$ . The objective is then to build a classifier for distinguishing the pseudo-senses  $E$  and  $notE$ . As a consequence of this view, we adopt the same kind of features as the ones used for WSD for building our classifier. More precisely, we follow (Lee and Ng, 2002), a reference work for WSD, by adopting a Support Vector Machines (SVM) classifier with a linear kernel and three kinds of features for characterizing each considered occur-

rence in a text of the reference word  $E$ :

- neighboring words;
- Part-of-Speech (POS) of neighboring words;
- local collocations.

Only features based on syntactic relations are not taken from (Lee and Ng, 2002) since their use would have not been coherent with the window based approach of the building of our initial thesaurus.

For the *neighboring words* features, we consider all plain words (common and proper nouns, verbs and adjectives) and adverbs that are present in the same sentence of an occurrence of  $E$ . Each neighboring word is represented under its lemma form as a binary feature whose value is equal to 1 when it is present in the same sentence as  $E$ .

For the second type of features, we take more precisely the POS of the three words before  $E$  and those of the three words after  $E$ . Each pair {POS, position} corresponds to a binary feature for the SVM classifier. A special *empty* symbol is used for the POS when the position goes beyond the end or the beginning of the current sentence. Since we analyze texts with *TreeTagger*, the tagset is very close to the set of Penn Treebank tags.

Finally, the *local collocations* features correspond to pairs of words, named collocations, in the neighborhood of  $E$ . A collocation is specified by the notation  $C_{i,j}$ , with  $i$  and  $j$  referring to the position of the first and the second word of the collocation. In our case,  $i$  and  $j$  take their values in the interval  $[-3, +3]$ , similarly to POS. More precisely, the following 11 types of collocations are extracted for each occurrence of  $E$ :  $C_{-1,-1}$ ,  $C_{1,1}$ ,  $C_{-2,-2}$ ,  $C_{2,2}$ ,  $C_{-2,-1}$ ,  $C_{-1,1}$ ,  $C_{1,2}$ ,  $C_{-3,-1}$ ,  $C_{-2,1}$ ,  $C_{-1,2}$  and  $C_{1,3}$ . As for POS, a special empty symbol stands for words beyond the end or the beginning of the sentence and similarly to *neighboring words* features, words in collocations are given under their lemma form. Each instance of the 11 types of collocations is represented by a tuple (lemma1, position1, lemma2, position2) and leads to a binary feature for the SVM classifier.

In accordance with the process of section 3.1, a specific SVM classifier is trained for each entry of our initial thesaurus, which requires the unsupervised selection of a set of positive and negative examples. The case of positive examples is simple: a fixed number of sentences containing at least one occurrence of the target entry are randomly chosen in the corpus used for building our

initial thesaurus and the first occurrence of this entry in the sentence is taken as a positive example. Since we want to characterize words as much as possible from a semantic viewpoint, the selection of negative examples is guided by our initial thesaurus. Choosing a neighbor of the entry with a high rank would guarantee in principle few false negative examples, that is to say words<sup>1</sup> which are semantically similar to the entry, since the number of such neighbors strongly decreases as the rank of neighbors increases as we will illustrate it in section 4.1. In practice, taking neighbors with a rather small rank as negative examples is a better option because these examples are more useful in terms of discrimination as they are close to the transition zone between negative and positive examples. Moreover, in order to limit the risk of selecting only false negative examples, three neighbors are taken as negative examples, at ranks 10, 15 and 20<sup>2</sup>. For each of these negative examples, a fixed number of sentences is selected following the same principles as for positive examples, which means that on average, the number of negative examples is equal to three times the number of positive examples. This ratio reflects the fact that among the neighbors of an entry, the number of those that are semantically similar to the entry is far lower than the number of those that are not.

### 3.4 Identification of bad neighbors and thesaurus reranking

Once a word-in-context classifier was trained for an entry, it is used for identifying the bad neighbors of this entry, that is to say the neighbors that are not semantically similar to it. As this classifier can only be applied to words in context, a fixed number of representative occurrences have to be selected from our reference corpus for each neighbor of the entry. This selection is performed similarly to the selection of positive and negative examples in the previous section. The application of our word-in-context classifier to each of these occurrences determines whether the context of this occurrence is likely to be compatible with the context of an occurrence of the entry.

In practice, the decision of the classifier is rarely

<sup>1</sup>More precisely, an example here is an occurrence of a word in a text but by extension, we also use the term *example* for referring to the word itself.

<sup>2</sup>It should be noted that these ranks come from the evaluation of section 4.1 but their choice is not the result of an optimization process.

positive, which is not surprising: even if two words are semantically equivalent, each one is characterized by specific usages, especially in a given corpus, and some features of our classifier, such as the collocation features, are more likely to capture such specificities than the unigrams of “classical” distributional contexts. As a consequence, we consider that a positive outcome of our classifier is a significant hint about the presence of a word that is semantically similar to the entry and we keep a neighbor as a “good” neighbor if at least a fixed number  $G$  of its occurrences, among those selected as reference, are tagged positively by our word-in-context classifier. Conversely, a neighbor is defined as “bad” if the number of its reference occurrences tagged positively by our classifier is lower or equal to  $G$ .

The neighbors of an entry identified as bad neighbors are not fully discarded. They are rather downgraded to the end of the list of neighbors. Among the downgraded neighbors, their initial order is left unchanged. It should be noted that the word-in-context classifier is not applied to the neighbors whose occurrences are used for its training as it would frequently lead to downgrade these neighbors, which is not necessarily optimum as we chose them with a rather low rank.

## 4 Experiments and evaluation

### 4.1 Initial thesaurus evaluation

Table 2 shows the results of the evaluation of our initial thesaurus, achieved by comparing the selected semantic neighbors with two complementary reference resources: WordNet 3.0 synonyms (Miller, 1990) [W], which characterize a semantic similarity based on paradigmatic relations, and the Moby thesaurus (Ward, 1996) [M], which gathers a larger set of types of relations and is more representative of *semantic relatedness*<sup>3</sup>. The fourth column of Table 2, which gives the average number of synonyms and similar words in our references for the AQUAINT-2 nouns, also illustrates the difference of these two resources in terms of richness. A fusion of the two resources is also considered [WM]. As our objective is to evaluate the extracted semantic neighbors and not the ability to rebuild the reference resources, these re-

<sup>3</sup>The Moby thesaurus includes more precisely both paradigmatic and syntactic relations but we will sometimes use the term *synonym* as a shortcut for referring to all the words associated to one of its entries.

freq.	ref.	#eval. words	#syn. / word	recall	R-prec.	MAP	P@1	P@5	P@10	P@100

Table 2: Evaluation of semantic neighbor extraction

sources were filtered to discard entries and synonyms that are not part of the AQUAINT-2 vocabulary (see the difference between the number of words in the first column and the number of evaluated words of the third column). Since the frequency of words is an important factor in distributional approaches, we give our results globally but also for three ranges of frequencies that split our set of nouns into roughly equal parts: *high* frequency (frequency > 1000), *middle* frequency (100 < frequency ≤ 1000) and *low* frequency (10 < frequency ≤ 100). These results take the form of several measures and start at the fifth column by the proportion of the synonyms and similar words of our references that are found among the first 100 extracted neighbors of each noun. As these neighbors are ranked according to their similarity value with their target word, the evaluation measures are taken from the Information Retrieval field by replacing documents with synonyms and queries with target words (see the four last columns of Table 2). The R-precision (R-prec.) is the precision after the first R neighbors were retrieved, R being the number of reference synonyms; the Mean Average Precision (MAP) is the average of the precision value after a reference synonym is found; precision at different cut-offs is given for the 1, 5, 10 and 100 first neighbors. All these values are given as percentages.

The results of Table 2 lead to three main observations. First, the level of results heavily depends on the frequency range of target words: the best results are obtained for high frequency words while evaluation measures significantly decrease for words whose frequency is low. Sec-

ond, the characteristics of the reference resources have a significant impact on results. WordNet provides a restricted number of synonyms for each noun while the Moby thesaurus contains for each entry a large number of synonyms and similar words. As a consequence, the precisions at different cut-offs have a significantly higher value with Moby as reference than with WordNet as reference. Finally, the results of Table 2 are compatible with those of (Lin, 1998) for instance (R-prec. = 11.6 and MAP = 8.1 with WM as reference for all entries of the thesaurus at <http://webdocs.cs.ualberta.ca/lindek/Downloads/sim.tgz>) if we take into account the fact that the thesaurus of Lin was built from a much larger corpus and with syntactic co-occurrences.

## 4.2 Implementation issues

The implementation of the method we have presented in section 3 raises several issues. One of these concerns the occurrences to select from texts of both the entries of the thesaurus and their neighbors. These occurrences are used both for the training of our word-in-context classifier and for the identification of bad neighbors. In practice, we extract randomly from our reference corpus, *i.e.* the AQUAINT-2 corpus, a fixed number of sentences, equal to 250, for each word of the vocabulary of our initial thesaurus and exploit them for the two tasks. This extraction is performed on the basis of the lemma form of these words. It should be noted that 250 is the upper limit of the number of occurrences by word since the frequency in the corpus of many words is lower than 250. When this limit is not reached, all the available oc-

currences are taken, which may be no more than 11 occurrences for certain low-frequency words. The upper limit of 250 is halfway between the 385 training examples on average for the Lexical Sample Task of Senseval 1 and the 118 training examples on average for the same task of Senseval 2.

The training of our word-in-context classifier is also an important issue. As mentioned before, this classifier is a linear SVM. Hence, only its  $C$  regularization parameter can be optimized. Since we have one specific classifier for each thesaurus entry, such optimization has globally a high cost, even for a linear kernel. Hence, we have first evaluated through a 5-fold cross-validation method the results of these classifiers with a default value of  $C$ , equal to 1. Table 3 gives their average accuracy value along with their standard deviation for all the entries of the thesaurus and for the three frequency ranges of Table 2.

	all	high	middle	low
accuracy	86.2	86.1	86.0	86.5
standard deviation	6.1	4.2	5.7	7.6

Table 3: Results of word-in-context classifiers

This table shows a global high level of result along with similar values for all the frequency ranges of entries<sup>4</sup>. Hence, we have decided not to optimize the  $C$  parameter and to adopt the default value of 1 for all the word-in-context classifiers.

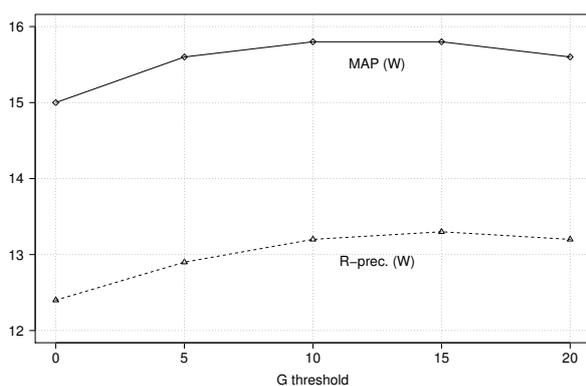

Figure 1: R-precision and MAP for various values of the  $G$  threshold

The last and the most important implementation issue is the setting of the threshold  $G$  for determining whether a neighbor is likely to be a bad

<sup>4</sup>The standard deviation is a little bit higher for the lowest frequencies but it should be noted that the low number of examples for low frequency entries does not seem to have a strong impact on the results of such classifier.

neighbor. For this setting, we have randomly chosen a subset of 859 entries of our initial thesaurus that corresponds to 10% of the entries with at least one true neighbor in any of our references. Figure 1 gives the results of the reranked thesaurus for these entries in terms of R-precision and MAP against reference  $W^5$  for various values of  $G$ . Although the level of these measures does not change a lot for  $G > 5$ , the graph of Figure 1 shows that  $G = 15$  appears to be an optimal value. Hence, this is the value used for the detailed evaluation of the next section.

### 4.3 Evaluation of the reranked thesaurus

Table 4 gives the evaluation of the application of our reranking method to the initial thesaurus according to the same principles as in section 4.1. The value of each measure comes with its difference with the corresponding value for the initial thesaurus. As the recall measure and the precision for the last rank do not change in a reranking process, they are not given again.

The first thing to notice is that at the global scale, all measures for all references are significantly improved<sup>6</sup>, which means that our hypothesis about the possibility for a discriminative classifier to capture the meaning of a word tends to be validated. It is an interesting result since the features upon which this classifier was built were taken from WSD and were not specifically selected for this task. As a consequence, there is probably some room for improvement.

If we go into details, Table 4 clearly shows two main trends. First, the improvement of results is particularly effective for middle frequency entries, then for low frequency and finally, for high frequency entries. Because of their already high level in the initial thesaurus, results for high frequency entries are difficult to improve but it is important to note that our selection of bad neighbors has a very low error rate, which at least preserves these results. This is confirmed by the fact that, with WordNet as reference, only 744 neighbors were found wrongly downgraded, spread over 686 entries, which represents only 5% of all downgraded neighbors. The second main trend of Table 4 con-

<sup>5</sup>The use of  $W$  as reference is justified by the fact that the number of synonyms for an entry in  $W$  is more compatible, especially for R-precision, with the real use of the resulting thesaurus in an application.

<sup>6</sup>The statistical significance of differences with the initial thesaurus was evaluated by a paired Wilcoxon test with  $p$ -value  $< 0.05$  and  $< 0.01$  ( $\dagger$  and  $\ddagger$  for non significance).

freq.	ref.	R-prec.	MAP	P@1	P@5	P@10
all	W	9.1 (0.9)	10.7 (0.9)	12.8 (1.1)	5.6 (0.5)	3.7 (0.3)
	M	7.2 (0.5)	3.5 (0.3)	26.5 (2.4)	17.9 (1.5)	14.0 (1.0)
	WM	8.4 (0.7)	6.1 (0.5)	24.8 (2.3)	15.4 (1.3)	11.7 (0.9)
high	W	11.3 (0.2) †	12.6 (0.1)	17.3 (0.1) ‡	7.8 (0.1) ‡	5.1 (0.0)
	M	10.3 (0.1)	4.9 (0.0)	42.1 (0.8)	28.4 (0.4)	22.1 (0.2)
	WM	11.1 (0.1)	6.6 (0.1)	42.0 (0.7)	27.2 (0.4)	20.9 (0.1)
middle	W	11.8 (1.4)	13.8 (1.3)	15.7 (2.1)	6.5 (0.7)	4.1 (0.4)
	M	7.3 (0.8)	3.6 (0.5)	23.3 (4.6)	16.0 (2.9)	12.4 (2.0)
	WM	10.3 (1.0)	8.1 (0.7)	25.1 (4.2)	14.6 (2.3)	10.9 (1.6)
low	W	3.2 (1.1)	4.6 (1.3)	3.9 (1.3)	1.8 (0.6)	1.3 (0.4)
	M	1.8 (0.6)	0.8 (0.3)	4.4 (1.9)	2.9 (1.4)	2.6 (1.1)
	WM	3.1 (1.0)	3.3 (0.9)	5.1 (1.8)	2.9 (1.2)	2.3 (0.8)

Table 4: Results of the reranking of semantic neighbors

cerns the type of semantic relations: results with Moby as reference are improved in a larger extent than results with WordNet as reference. This suggests that our procedure is more effective for semantically related words than for semantically similar words, which can be considered as a little bit surprising since the notion of context in our discriminative classifier seems *a priori* more strict than in “classical” distributional contexts. However, this point must be investigated further as a significant part of the relations in Moby, even if they do not represent the largest part of them, are paradigmatic relations.

<b>WordNet</b>	respect, admiration, regard
<u>Moby</u>	admiration, appreciation, acceptance, dignity, regard, respect, account, adherence, consideration, estimate, estimation, fame, greatness, reverence + 79 words more
initial	cordiality, gratitude, <b>admiration</b> , comradeship, back-scratching, perplexity, <b>respect</b> , ruination, appreciation, neighbourliness . . .
reranking	gratitude, <b>admiration</b> , <b>respect</b> , appreciation, neighborliness, trust, empathy, goodwill, reciprocity, half-staff, affection, self-esteem, reverence, longing, <b>regard</b> . . .

Table 5: Impact of our reranking for the entry *esteem*

Table 5 illustrates more precisely the impact of our reranking procedure for the middle frequency entry *esteem*. Its **WordNet** row gives all the reference synonyms for this entry in WordNet while its Moby row gives the first reference related words

for this entry in Moby. In our *initial* thesaurus, the first two neighbors of *esteem* that are present in our reference resources are *admiration* (rank 3) and *respect* (rank 7). The reranking produces a thesaurus in which these two words appear as the second and the third neighbors of the entry because neighbors without clear relation with it such as *back-scratching* were downgraded while its third synonym in WordNet is raised from rank 22 to rank 15. Moreover, the number of neighbors among the first 15 ones that are present in Moby increases from 3 to 5.

## 5 Related work

The building of distributional thesaurus is generally viewed as an application or a mode of evaluation of work about semantic similarity or semantic relatedness. As a consequence, the improvement of such thesaurus is generally not directly addressed but is a possible consequence of the improvement of semantic similarity measures. However, the extent of this improvement is rarely evaluated as most of the work about semantic similarity is evaluated on datasets such as the WordSim-353 test collection (Gabrilovich and Markovitch, 2007), which are only partially representative of the results for thesaurus building.

If we consider more specifically the problem of improving semantic similarity, and by the way thesauri, in a given paradigm, (Broda et al., 2009), (Zhitomirsky-Geffet and Dagan, 2009) and (Yamamoto and Asakura, 2010), which all take place in the paradigm defined by (Grefenstette, 1994), are the closest works to ours. (Broda et al., 2009) proposes a new weighting scheme of words in distributional contexts that replaces the weight of

word by a function of its rank in the context, which is a way to be less dependent on the values of a particular weighting function. (Zhitomirsky-Geffet and Dagan, 2009) shares with our work the use of bootstrapping by relying on an initial thesaurus to derive means of improving it. More specifically, (Zhitomirsky-Geffet and Dagan, 2009) assumes that the first neighbors of an entry are more relevant than the others and as a consequence, that their most significant features are also representative of the meaning of the entry. The neighbors of the entry are reranked according to this hypothesis by increasing the weight of these features to favor their influence in the distributional contexts that support the evaluation of the similarity between the entry and its neighbors. (Yamamoto and Asakura, 2010) is a variant of (Zhitomirsky-Geffet and Dagan, 2009) that takes into account a larger number of features for the reranking process. One main difference between all these works and ours is that they assume that the initial thesaurus was built by relying on distributional contexts represented as bags-of-words. Our method does not make this assumption as its reranking is based on a classifier built in an unsupervised way<sup>7</sup> from and applied to the corpus used for building the initial thesaurus. As a consequence, it could even be applied to other paradigms than (Grefenstette, 1994).

If we focus more specifically on the improvement of distributional thesauri, (Ferret, 2012) is the most comparable work to ours, both because it is specifically focused on this task and it is based on the same evaluation framework. (Ferret, 2012) selects in an unsupervised way a set of positive and negative examples of semantically similar words from the initial thesaurus, uses them for training a classifier deciding whether or not a pair of words are semantically similar and finally, applies this classifier to the neighbors of each entry for reranking them. One of the objectives of (Ferret, 2012) was to rebalance the initial thesaurus in favor of low frequency entries. Although this objective was reached, the resulting thesaurus tends to have a lower performance than the initial thesaurus for high frequency entries and for synonyms. The problem with high frequency entries comes from the fact that applying a machine learning classifier to its training examples does not lead to a perfect result. The problem with synonyms

---

<sup>7</sup>It is a supervised classifier but its training set is selected in an unsupervised way.

arises from the imbalance between *semantic similarity* and *semantic relatedness* among training examples: most of selected examples were pairs of words linked by *semantic relatedness* because this kind of relations are more frequent among semantic neighbors than relations based on *semantic similarity*.

In both cases, the method proposed in (Ferret, 2012) faces the problem of relying only on the distributional thesaurus it tries to improve. This is an important difference with the method presented in this article, which mainly exploits the context of the occurrences of words in the corpus used for the building the initial thesaurus. As a consequence, at a global scale, our reranked thesaurus outperforms the final thesaurus of (Ferret, 2012) for nearly all measures. The only exceptions are the P@1 values for M and WM as reference. However, it should be noted that values for both MAP and R-precision, which are more reliable measures than P@1, are identical for the two thesauri and the same references.

## 6 Conclusion and perspectives

In this article, we have presented a new approach for reranking the semantic neighbors of a distributional thesaurus. This approach relies on the unsupervised building of discriminative classifiers dedicated to the identification of its entries in texts, with the objective to characterize their meaning according to the distributional hypothesis. The classifier built for an entry is then applied to a set of occurrences of its neighbors for identifying and downgrading those that are not semantically related to the entry. The proposed method was tested on a large thesaurus of nouns for English and led to a significant improvement of this thesaurus, especially for middle and low frequency entries and for semantic relatedness. We plan to extend this work by taking into account the notion of word sense as it is done in (Reisinger and Mooney, 2010) or (Huang et al., 2012): since we rely on occurrences of words in texts, this extension should be quite straightforward by turning our word-in-context classifiers into true word sense classifiers.

## Abstract

We consider the problem of grounding the meaning of words in the physical world and focus on the visual modality which we represent by *visual attributes*. We create a new large-scale taxonomy of visual attributes covering more than 500 concepts and their corresponding 688K images. We use this dataset to train attribute classifiers and integrate their predictions with text-based distributional models of word meaning. We show that these bimodal models give a better fit to human word association data compared to amodal models and word representations based on hand-crafted norming data.

## 1 Introduction

Recent years have seen increased interest in grounded language acquisition, where the goal is to extract representations of the meaning of natural language tied to the physical world. The *language grounding problem* has assumed several guises in the literature such as semantic parsing (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Kate and Mooney, 2007; Lu et al., 2008; Börschinger et al., 2011), mapping natural language instructions to executable actions (Branavan et al., 2009; Tellex et al., 2011), associating simplified language to perceptual data such as images or video (Siskind, 2001; Roy and Pentland, 2002; Gorniak and Roy, 2004; Yu and Ballard, 2007), and learning the meaning of words based on linguistic and perceptual input (Bruni et al., 2012b; Feng and Lapata, 2010; Johns and Jones, 2012; Andrews et al., 2009; Silberer and Lapata, 2012).

In this paper we are concerned with the latter task, namely constructing perceptually grounded

distributional models. The motivation for models that do not learn exclusively from text is twofold. From a cognitive perspective, there is mounting experimental evidence suggesting that our interaction with the physical world plays an important role in the way we process language (Barsalou, 2008; Bornstein et al., 2004; Landau et al., 1998). From an engineering perspective, the ability to learn representations for multimodal data has many practical applications including image retrieval (Datta et al., 2008) and annotation (Chai and Hung, 2008), text illustration (Joshi et al., 2006), object and scene recognition (Lowe, 1999; Oliva and Torralba, 2007; Fei-Fei and Perona, 2005), and robot navigation (Tellex et al., 2011).

One strand of research uses feature norms as a stand-in for sensorimotor experience (Johns and Jones, 2012; Andrews et al., 2009; Steyvers, 2010; Silberer and Lapata, 2012). Feature norms are obtained by asking native speakers to write down attributes they consider important in describing the meaning of a word. The attributes represent perceived physical and functional properties associated with the referents of words. For example, *apples* are typically green or red, round, shiny, smooth, crunchy, tasty, and so on; *dogs* have four legs and bark, whereas *chairs* are used for sitting. Feature norms are instrumental in revealing which dimensions of meaning are psychologically salient, however, their use as a proxy for people's perceptual representations can itself be problematic (Sloman and Ripps, 1998; Zeigenfuse and Lee, 2010). The number and types of attributes generated can vary substantially as a function of the amount of time devoted to each concept. It is not entirely clear how people generate attributes and whether all of these are important for representing concepts. Finally, multiple participants are required to create a representation for each con-

cept, which limits elicitation studies to a small number of concepts and the scope of any computational model based on feature norms.

Another strand of research focuses exclusively on the visual modality, even though the grounding problem could involve auditory, motor, and haptic modalities as well. This is not entirely surprising. Visual input represents a major source of data from which humans can learn semantic representations of linguistic and non-linguistic communicative actions (Regier, 1996). Furthermore, since images are ubiquitous, visual data can be gathered far easier than some of the other modalities. Distributional models that integrate the visual modality have been learned from texts and images (Feng and Lapata, 2010; Bruni et al., 2012b) or from ImageNet (Deng et al., 2009), e.g., by exploiting the fact that images in this database are hierarchically organized according to WordNet synsets (Leong and Mihalcea, 2011). Images are typically represented on the basis of low-level features such as SIFT (Lowe, 2004), whereas texts are treated as bags of words.

Our work also focuses on images as a way of physically grounding the meaning of words. We, however, represent them by high-level *visual attributes* instead of low-level image features. Attributes are not concept or category specific (e.g., animals have stripes and so do clothing items; balls are round, and so are oranges and coins), and thus allow us to express similarities and differences across concepts more easily. Furthermore, attributes allow us to generalize to unseen objects; it is possible to say something about them even though we cannot identify them (e.g., it has a beak and a long tail). We show that this attribute-centric approach to representing images is beneficial for distributional models of lexical meaning. Our attributes are similar to those provided by participants in norming studies, however, importantly they are *learned* from training data (a database of images and their visual attributes) and thus generalize to new images without additional human involvement.

In the following we describe our efforts to create a new large-scale dataset that consists of 688K images that match the same concrete concepts used in the feature norming study of McRae et al. (2005). We derive a taxonomy of 412 visual attributes and explain how we learn attribute classifiers following recent work in computer vision (Lampert et al., 2009; Farhadi et al., 2009). Next,

we show that this attribute-based image representation can be usefully integrated with textual data to create distributional models that give a better fit to human word association data over models that rely on human generated feature norms.

## 2 Related Work

Grounding semantic representations with visual information is an instance of multimodal learning. In this setting the data consists of multiple input modalities with different representations and the learner’s objective is to extract a unified representation that fuses the modalities together. The literature describes several successful approaches to multimodal learning using different variants of deep networks (Ngiam et al., 2011; Srivastava and Salakhutdinov, 2012) and data sources including text, images, audio, and video.

Special-purpose models that address the fusion of distributional meaning with visual information have been also proposed. Feng and Lapata (2010) represent documents and images by a common multimodal vocabulary consisting of textual words and visual terms which they obtain by quantizing SIFT descriptors (Lowe, 2004). Their model is essentially Latent Dirichlet Allocation (LDA, Blei et al., 2003) trained on a corpus of multimodal documents (i.e., BBC news articles and their associated images). Meaning in this model is represented as a vector whose components correspond to word-topic distributions. A related model has been proposed by Bruni et al. (2012b) who obtain distinct representations for the textual and visual modalities. Specifically, they extract a visual space from images contained in the ESP-Game data set (von Ahn and Dabbish, 2004) and a text-based semantic space from a large corpus collection totaling approximately two billion words. They concatenate the two modalities and subsequently project them to a lower-dimensionality space using Singular Value Decomposition (Golub et al., 1981).

Traditionally, computer vision algorithms describe visual phenomena (e.g., objects, scenes, faces, actions) by giving each instance a categorical label (e.g., cat, beer garden, Brad Pitt, drinking). The ability to describe images by their attributes allows to generalize to new instances for which there are no training examples available. Moreover, attributes can transcend category and task boundaries and thus provide a generic description of visual data.

Initial work (Ferrari and Zisserman, 2007)

focused on simple color and texture attributes (e.g., blue, stripes) and showed that these can be learned in a weakly supervised setting from images returned by a search engine when using the attribute as a query. Farhadi et al. (2009) were among the first to use visual attributes in an object recognition task. Using an inventory of 64 attribute labels, they developed a dataset of approximately 12,000 instances representing 20 objects from the PASCAL Visual Object Classes Challenge 2008 (Everingham et al., 2008). Visual semantic attributes (e.g., hairy, four-legged) were used to identify familiar objects and to describe unfamiliar objects when new images and bounding box annotations were provided. Lampert et al. (2009) showed that attribute-based representations can be used to classify objects when there are no training examples of the target classes available. Their dataset contained over 30,000 images representing 50 animal concepts and used 85 attributes from the norming study of Osherson et al. (1991). Attribute-based representations have also been applied to the tasks of face detection (Kumar et al., 2009), action identification (Liu et al., 2011), and scene recognition (Patterson and Hays, 2012).

The use of visual attributes in models of distributional semantics is novel to our knowledge. We argue that they are advantageous for two reasons. Firstly, they are cognitively plausible; humans employ visual attributes when describing the properties of concept classes. Secondly, they occupy the middle ground between non-linguistic low-level image features and linguistic words. Attributes crucially represent image properties, however by being words themselves, they can be easily integrated in any text-based distributional model thus eschewing known difficulties with rendering images into word-like units.

A key prerequisite in describing images by their attributes is the availability of training data for learning attribute classifiers. Although our database shares many features with previous work (Lampert et al., 2009; Farhadi et al., 2009) it differs in focus and scope. Since our goal is to develop distributional models that are applicable to many words, it contains a considerably larger number of concepts (i.e., more than 500) and attributes (i.e., 412) based on a detailed taxonomy which we argue is cognitively plausible and beneficial for image and natural language processing tasks. Our experiments evaluate a number of models previously proposed in the literature and in

Attribute Categories		Example Attributes
color_patterns	(25)	is_red, has_stripes
diet	(35)	eats_nuts, eats_grass
shape_size	(16)	is_small, is_chubby
parts	(125)	has_legs, has_wheels
botany;anatomy	(25;78)	has_seeds, has_fur
behavior (in)animate	(55)	flies, waddles, pecks
texture_material	(36)	made_of_metal, is_shiny
structure	(3)	2_pieces, has_pleats

Table 1: Attribute categories and examples of attribute instances. Parentheses denote the number of attributes per category.

all cases show that the attribute-based representation brings performance improvements over just using the textual modality. Moreover, we show that automatically computed attributes are comparable and in some cases superior to those provided by humans (e.g., in norming studies).

### 3 The Attribute Dataset

**Concepts and Images** We created a dataset of images and their visual attributes for the nouns contained in McRae et al.’s (2005) feature norms. The norms cover a wide range of concrete concepts including animate and inanimate things (e.g., animals, clothing, vehicles, utensils, fruits, and vegetables) and were collected by presenting participants with words and asking them to list properties of the objects to which the words referred. To avoid confusion, in the remainder of this paper we will use the term *attribute* to refer to properties of concepts and the term *feature* to refer to image features, such as color or edges.

Images for the concepts in McRae et al.’s (2005) production norms were harvested from ImageNet (Deng et al., 2009), an ontology of images based on the nominal hierarchy of WordNet (Fellbaum, 1998). ImageNet has more than 14 million images spanning 21K WordNet synsets. We chose this database due to its high coverage and the high quality of its images (i.e., cleanly labeled and high resolution). McRae et al.’s norms contain 541 concepts out of which 516 appear in ImageNet<sup>1</sup> and are represented by 688K images overall. The average number of images per concept is 1,310 with the most popular being *closet* (2,149 images) and the least popular *prune* (5 images).

<sup>1</sup>Some words had to be modified in order to match the correct synset, e.g., *tank\_(container)* was found as *storage\_tank*.

	behavior diet shape_size anatomy  color_patterns	eats, walks, climbs, swims, runs drinks_water, eats_anything is_tall, is_large has_mouth, has_head, has_nose, has_tail, has_claws, has_jaws, has_neck, has_snout, has_feet, has_tongue is_black, is_brown, is_white
	botany color_patterns shape_size texture_material	has_skin, has_seeds, has_stem, has_leaves, has_pulp purple, white, green, has_green_top is_oval, is_long is_shiny
	behavior parts  texture_material color_patterns	rolls has_step_through_frame, has_fork, has_2_wheels, has_chain, has_pedals has_gears, has_handlebar, has_bell, has_breaks, has_seat, has_spokes made_of_metal different_colors, is_black, is_red, is_grey, is_silver

Table 2: Human-authored attributes for *bear*, *eggplant*, and *bike*.

The images depicting each concept were randomly partitioned into a training, development, and test set. For most concepts the development set contained a maximum of 100 images and the test set a maximum of 200 images. Concepts with less than 800 images in total were split into 1/8 test and development set each, and 3/4 training set. The development set was used for devising and refining our attribute annotation scheme. The training and test sets were used for learning and evaluating, respectively, attribute classifiers (see Section 4).

**Attribute Annotation** Our aim was to develop a set of visual attributes that are both discriminating and cognitively plausible, i.e., humans would generally use them to describe a concrete concept. As a starting point, we thus used the visual attributes from McRae et al.’s (2005) norming study. Attributes capturing other primary sensory information (e.g., smell, sound), functional/motor properties, or encyclopaedic information were not taken into account. For example, *is\_purple* is a valid visual attribute for an *eggplant*, whereas *a\_vegetable* is not, since it cannot be visualized. Collating all the visual attributes in the norms resulted in a total of 673 which we further modified and extended during the annotation process explained below.

The annotation was conducted on a *per-concept* rather than a *per-image* basis (as for example in Farhadi et al. (2009)). For each concept (e.g., *bear* or *eggplant*), we inspected the images in the development set and chose all McRae et al. (2005) visual attributes that applied. If an attribute was generally true for the concept, but the images did not

provide enough evidence, the attribute was nevertheless chosen and labeled with `<no_evidence>`. For example, a *plum* has *a\_pit*, but most images in ImageNet show plums where only the outer part of the fruit is visible. Attributes supported by the image data but missing from the norms were added. For example, *has\_lights* and *has\_bumper* are attributes of *cars* but are not included in the norms. Attributes were grouped in eight general classes shown in Table 1. Annotation proceeded on a category-by-category basis, e.g., first all food-related concepts were annotated, then animals, vehicles, and so on. Two annotators (both co-authors of this paper) developed the set of attributes for each category. One annotator first labeled concepts with their attributes, and the other annotator reviewed the annotations, making changes if needed. Annotations were revised and compared per category in order to ensure consistency across all concepts of that category.

Our methodology is slightly different from Lampert et al. (2009) in that we did not simply transfer the attributes from the norms to the concepts in question but refined and extended them according to the visual data. There are several reasons for this. Firstly, it makes sense to select attributes corroborated by the images. Secondly, by looking at the actual images, we could eliminate errors in McRae et al.’s (2005) norms. For example, eight study participants erroneously thought that a *catfish* has *scales*. Thirdly, during the annotation process, we normalized synonymous attributes (e.g., *has\_pit* and *has\_stone*) and attributes that exhibited negligible variations

has\_2\_pieces, has\_pointed\_end, has\_strap, has\_thumb, has\_buckles, has\_heels  
has\_shoe\_laces, has\_soles, is\_black, is\_brown, is\_white, made\_of\_leather, made\_of\_rubber

climbs, climbs\_trees, crawls, hops, jumps, eats, eats\_nuts, is\_small, has\_bushy\_tail  
has\_4\_legs, has\_head, has\_neck, has\_nose, has\_snout, has\_tail, has\_claws  
has\_eyes, has\_feet, has\_toes,

diff\_colours, has\_2\_legs, has\_2\_wheels, has\_windshield, has\_floorboard, has\_stand, has\_tank  
has\_mudguard, has\_seat, has\_exhaust\_pipe, has\_frame, has\_handlebar, has\_lights, has\_mirror  
has\_step-through\_frame, is\_black, is\_blue, is\_red, is\_white, made\_of\_aluminum, made\_of\_steel

Table 3: Attribute predictions for *sandals*, *squirrel*, and *motorcycle*.

in meaning (e.g., *has\_stem* and *has\_stalk*). Finally, our aim was to collect an exhaustive list of visual attributes for each concept which is consistent across all members of a category. This is unfortunately not the case in McRae et al.’s norms. Participants were asked to list up to 14 different properties that describe a concept. As a result, the attributes of a concept denote the set of properties humans consider most salient. For example, both, *lemons* and *oranges* have *has\_pulp*. But the norms provide this attribute only for the second concept.

On average, each concept was annotated with 19 attributes; approximately 14.5 of these were not part of the semantic representation created by McRae et al.’s (2005) participants for that concept even though they figured in the representations of other concepts. Furthermore, on average two McRae et al. attributes per concept were discarded. Examples of concepts and their attributes from our database<sup>2</sup> are shown in Table 2.

#### 4 Attribute-based Classification

Following previous work (Farhadi et al., 2009; Lampert et al., 2009) we learned one classifier per attribute (i.e., 350 classifiers in total).<sup>3</sup> The training set consisted of 91,980 images (with a maximum of 350 images per concept). We used an L2-regularized L2-loss linear SVM (Fan et al., 2008) to learn the attribute predictions. We adopted the training procedure of Farhadi et al. (2009).<sup>4</sup> To learn a classifier for a particular attribute, we used all images in the training data. Images of concepts annotated with the attribute were used as positive examples, and the rest as negative examples. The

data was randomly split into a training and validation set of equal size in order to find the optimal cost parameter  $C$ . The final SVM for the attribute was trained on the entire training data, i.e., on all positive and negative examples.

The SVM learners used the four different feature types proposed in Farhadi et al. (2009), namely color, texture, visual words, and edges. Texture descriptors were computed for each pixel and quantized to the nearest 256 k-means centers. Visual words were constructed with a HOG spatial pyramid. HOG descriptors were quantized into 1000 k-means centers. Edges were detected using a standard Canny detector and their orientations were quantized into eight bins. Color descriptors were sampled for each pixel and quantized to the nearest 128 k-means centers. Shapes and locations were represented by generating histograms for each feature type for each cell in a grid of three vertical and horizontal blocks. Our classifiers used 9,688 features in total. Table 3 shows their predictions for three test images.

Note that attributes are predicted on an image-by-image basis; our task, however, is to describe a concept  $w$  by its visual attributes. Since concepts are represented by many images we must somehow aggregate their attributes into a single representation. For each image  $i_w \in I_w$  of concept  $w$ , we output an  $F$ -dimensional vector containing prediction scores  $\text{score}_a(i_w)$  for attributes  $a = 1, \dots, F$ . We transform these attribute vectors into a single vector  $\mathbf{p}_w \in [0, 1]^{1 \times F}$ , by computing the centroid of all vectors for concept  $w$ . The vector is normalized to obtain a probability distribution over attributes given  $w$ :

$$\mathbf{p}_w = \frac{(\sum_{i_w \in I_w} \text{score}_a(i_w))_{a=1, \dots, F}}{\sum_{a=1}^F \sum_{i_w \in I_w} \text{score}_a(i_w)} \quad (1)$$

We additionally impose a threshold  $\delta$  on  $\mathbf{p}_w$  by set-

<sup>2</sup>Available from <http://homepages.inf.ed.ac.uk/mlap/index.php?page=resources>.

<sup>3</sup>We only trained classifiers for attributes corroborated by the images and excluded those labeled with `<no_evidence>`.

<sup>4</sup><http://vision.cs.uiuc.edu/attributes/>

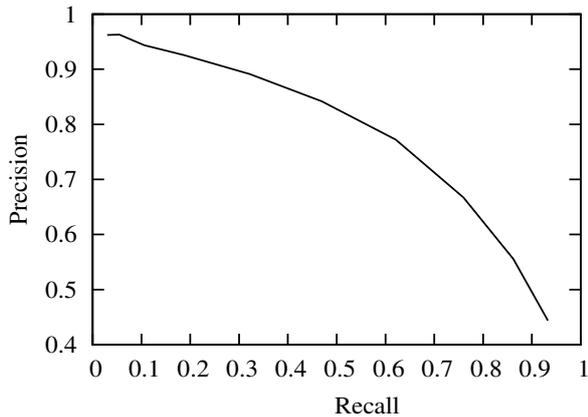

Figure 1: Attribute classifier performance for different thresholds  $\delta$  (test set).

ting each entry less than  $\delta$  to zero.

Figure 1 shows the results of the attribute prediction on the test set on the basis of the computed centroids; specifically, we plot recall against precision based on threshold  $\delta$ .<sup>5</sup> Table 4 shows the 10 nearest neighbors for five example concepts from our dataset. Again, we measure the cosine similarity between a concept and all other concepts in the dataset when these are represented by their visual attribute vector  $\mathbf{p}_w$ .

## 5 Attribute-based Semantic Models

We evaluated the effectiveness of our attribute classifiers by integrating their predictions with traditional text-only models of semantic representation. These models have been previously proposed in the literature and were also described in a recent comparative study (Silberer and Lapata, 2012).

We represent the visual modality by attribute vectors computed as shown in Equation (1). The linguistic environment is approximated by *textual* attributes. We used Strudel (Baroni et al., 2010) to obtain these attributes for the nouns in our dataset. Given a list of target words, Strudel extracts weighted word-attribute pairs from a lemmatized and pos-tagged text corpus (e.g., *eggplant-cook-v*, *eggplant-vegetable-n*). The weight of each word-attribute pair is a log-likelihood ratio score expressing the pair’s strength of association. In our experiments we learned word-attribute pairs from a lemmatized and pos-tagged (2009) dump of the English Wikipedia.<sup>6</sup> In the remainder of this section we will briefly describe the models we

<sup>5</sup>Threshold values ranged from 0 to 0.9 with 0.1 stepsize.

<sup>6</sup>The corpus can be downloaded from <http://wacky.sslmit.unibo.it/doku.php?id=corpora>.

Concept	Nearest Neighbors
boat	ship, sailboat, yacht, submarine, canoe, whale, airplane, jet, helicopter, tank_(army)
rooster	chicken, turkey, owl, pheasant, peacock, stork, pigeon, woodpecker, dove, raven
shirt	blouse, robe, cape, vest, dress, coat, jacket, skirt, camisole, nightgown
spinach	lettuce, parsley, peas, celery, broccoli, cabbage, cucumber, rhubarb, zucchini, asparagus
squirrel	chipmunk, raccoon, groundhog, gopher, porcupine, hare, rabbit, fox, mole, emu

Table 4: Ten most similar concepts computed on the basis of averaged attribute vectors and ordered according to cosine similarity.

used in our study and how the textual and visual modalities were fused to create a joint representation.

**Concatenation Model** Variants of this model were originally proposed in Bruni et al. (2011) and Johns and Jones (2012). Let  $T \in \mathbb{R}^{N \times D}$  denote a term-attribute co-occurrence matrix, where each cell records a weighted co-occurrence score of a word and a textual attribute. Let  $P \in [0, 1]^{N \times F}$  denote a visual matrix, representing a probability distribution over visual attributes for each word. A word’s meaning can be then represented by the concatenation of its normalized textual and visual vectors.

**Canonical Correlation Analysis** The second model uses Canonical Correlation Analysis (CCA, Hardoon et al. (2004)) to learn a joint semantic representation from the textual and visual modalities. Given two random variables  $\mathbf{x}$  and  $\mathbf{y}$  (or two sets of vectors), CCA can be seen as determining two sets of basis vectors in such a way, that the correlation between the projections of the variables onto these bases is mutually maximized (Borga, 2001). In effect, the representation-specific details pertaining to the two views of the same phenomenon are discarded and the underlying hidden factors responsible for the correlation are revealed.

The linguistic and visual views are the same as in the simple concatenation model just explained. We use a kernelized version of CCA (Hardoon et al., 2004) that first projects the data into a higher-dimensional feature space and then performs CCA in this new feature space. The two kernel matrices are  $K_T = TT'$  and  $K_P = PP'$ . After applying CCA we obtain two matrices projected onto  $l$  basis vectors,  $\tilde{T} \in \mathbb{R}^{N \times l}$ , resulting from the projection of the

textual matrix  $T$  onto the new basis and  $\tilde{P} \in \mathbb{R}^{N \times I}$ , resulting from the projection of the corresponding visual attribute matrix. The meaning of a word is then represented by  $\tilde{T}$  or  $\tilde{P}$ .

**Attribute-topic Model** Andrews et al. (2009) present an extension of LDA (Blei et al., 2003) where words in documents and their associated attributes are treated as observed variables that are explained by a generative process. The idea is that each document in a document collection  $\mathcal{D}$  is generated by a mixture of components  $\{x_1, \dots, x_c, \dots, x_C\} \in \mathcal{C}$ , where a component  $x_c$  comprises a latent discourse topic coupled with an attribute cluster. Inducing these attribute-topic components from  $\mathcal{D}$  with the extended LDA model gives two sets of parameters: word probabilities given components  $P_W(w_i|X = x_c)$  for  $w_i$ ,  $i = 1, \dots, n$ , and attribute probabilities given components  $P_A(a_k|X = x_c)$  for  $a_k$ ,  $k = 1, \dots, F$ . For example, most of the probability mass of a component  $x$  would be reserved for the words *shirt*, *coat*, *dress* and the attributes *has\_1\_piece*, *has\_seams*, *made\_of\_material* and so on.

Word meaning in this model is represented by the distribution  $P_{X|W}$  over the learned components. Assuming a uniform distribution over components  $x_c$  in  $\mathcal{D}$ ,  $P_{X|W}$  can be approximated as:

$$P_{X=x_c|W=w_i} = \frac{P(w_i|x_c)P(x_c)}{P(w_i)} \approx \frac{P(w_i|x_c)}{\sum_{l=1}^C P(w_i|x_l)} \quad (2)$$

where  $C$  is the total number of components.

In our work, the training data is a corpus  $\mathcal{D}$  of *textual* attributes (rather than documents). Each attribute is represented as a bag-of-concepts, i.e., words demonstrating the property expressed by the attribute (e.g., *vegetable-n* is a property of *eggplant*, *spinach*, *carrot*). For some of these concepts, our classifiers predict visual attributes. In this case, the concepts are paired with one of their visual attributes. We sample attributes for a concept  $w$  from their distribution given  $w$  (Eq. (1)).

## 6 Experimental Setup

**Evaluation Task** We evaluated the distributional models presented in Section 5 on the word association norms collected by Nelson et al. (1998).<sup>7</sup> These were established by presenting a large number of participants with a cue word (e.g., *rice*) and asking them to name an associate

word in response (e.g., *Chinese*, *wedding*, *food*, *white*). For each cue, the norms provide a set of associates and the frequencies with which they were named. We can thus compute the probability distribution over associates for each cue. Analogously, we can estimate the degree of similarity between a cue and its associates using our models. The norms contain 63,619 unique cue-associate pairs. Of these, 435 pairs were covered by McRae et al. (2005) and our models. We also experimented with 1,716 pairs that were *not* part of McRae et al.’s study but belonged to concepts covered by our attribute taxonomy (e.g., animals, vehicles), and were present in our corpus and ImageNet. Using correlation analysis (Spearman’s  $\rho$ ), we examined the degree of linear relationship between the human cue-associate probabilities and the automatically derived similarity values.<sup>8</sup>

**Parameter Settings** In order to integrate the visual attributes with the models described in Section 5 we must select the appropriate threshold value  $\delta$  (see Eq. (1)). We optimized this value on the development set and obtained best results with  $\delta = 0$ . We also experimented with thresholding the attribute prediction scores and with excluding attributes with low precision. In both cases, we obtained best results when using all attributes. We could apply CCA to the vectors representing each image separately and then compute a weighted centroid on the projected vectors. We refrained from doing this as it involves additional parameters and assumes input different from the other models. We measured the similarity between two words using the cosine of the angle. For the attribute-topic model, the number of predefined components  $C$  was set to 10. In this model, similarity was measured as defined by Griffiths et al. (2007). The underlying idea is that word association can be expressed as a conditional distribution.

With regard to the textual attributes, we obtained a 9,394-dimensional semantic space after discarding word-attribute pairs with a log-likelihood ratio score less than 19.<sup>9</sup> We also discarded attributes co-occurring with less than two different words.

<sup>8</sup>Previous work (Griffiths et al., 2007) which also predicts word association reports how many times the word with the highest score under the model was the first associate in the human norms. This evaluation metric assumes that there are many associates for a given cue which unfortunately is not the case in our study which is restricted to the concepts represented in our attribute taxonomy.

<sup>9</sup>Baroni et al. (2010) use a similar threshold of 19.51.

	Nelson	Concat	CCA	TopicAttr	TextAttr
Concat	0.24				
CCA	0.30	0.72			
TopicAttr	0.26	0.55	0.28		
TextAttr	0.21	0.80	0.83	0.34	
VisAttr	0.23	0.65	0.52	0.40	0.39

Table 5: Correlation matrix for seen Nelson et al. (1998) cue-associate pairs and five distributional models. All correlation coefficients are statistically significant ( $p < 0.01$ ,  $N = 435$ ).

## 7 Results

Our experiments were designed to answer four questions: (1) Do visual attributes improve the performance of distributional models? (2) Are there performance differences among different models, i.e., are some models better suited to the integration of visual information? (3) How do computational models fare against gold standard norming data? (4) Does the attribute-based representation bring advantages over more conventional approaches based on raw image features?

Our results are broken down into seen (Table 5) and unseen (Table 6) concepts. The former are known to the attribute classifiers and form part of our database, whereas the latter are unknown and are not included in McRae et al.’s (2005) norms. We report the correlation coefficients we obtain when human-derived cue-associate probabilities (Nelson et al., 1998) are compared against the simple concatenation model (Concat), CCA, and Andrews et al.’s (2009) attribute-topic model (TopicAttr). We also report the performance of a distributional model that is based solely on the output of our attribute classifiers, i.e., without any textual input (VisAttr) and conversely the performance of a model that uses textual information only (i.e., Strudel attributes) without any visual input (TextAttr). The results are displayed as a correlation matrix so that inter-model correlations can also be observed.

As can be seen in Table 5 (second column), two modalities are in most cases better than one when evaluating model performance on seen data. Differences in correlation coefficients between models with two versus one modality are all statistically significant ( $p < 0.01$  using a  $t$ -test), with the exception of Concat when compared against VisAttr. It is also interesting to note that TopicAttr is the least correlated model when compared against other bimodal models or single modali-

	Nelson	Concat	CCA	TopicAttr	TextAttr
Concat	0.11				
CCA	0.15	0.66			
TopicAttr	0.17	0.69	0.48		
TextAttr	0.11	0.65	0.25	0.39	
VisAttr	0.13	0.57	0.87	0.57	0.34

Table 6: Correlation matrix for unseen Nelson et al. (1998) cue-associate pairs and five distributional models. All correlation coefficients are statistically significant ( $p < 0.01$ ,  $N = 1,716$ ).

ties. This indicates that the latent space obtained by this model is most distinct from its constituent parts (i.e., visual and textual attributes). Perhaps unsurprisingly Concat, CCA, VisAttr, and TextAttr are also highly intercorrelated.

On unseen pairs (see Table 6), Concat fares worse than CCA and TopicAttr, achieving similar performance to TextAttr. CCA and TopicAttr are significantly better than TextAttr and VisAttr ( $p < 0.01$ ). This indicates that our attribute classifiers generalize well beyond the concepts found in our database and can produce useful visual information even on unseen images. Compared to Concat and CCA, TopicAttr obtains a better fit with the human association norms on the unseen data.

To answer our third question, we obtained distributional models from McRae et al.’s (2005) norms and assessed how well they predict Nelson et al.’s (1998) word-associate similarities. Each concept was represented as a vector with dimensions corresponding to attributes generated by participants of the norming study. Vector components were set to the (normalized) frequency with which participants generated the corresponding attribute when presented with the concept. We measured the similarity between two words using the cosine coefficient. Table 7 presents results for different model variants which we created by manipulating the number and type of attributes involved. The first model uses the full set of attributes present in the norms (All Attributes). The second model (Text Attributes) uses all attributes but those classified as visual (e.g., functional, encyclopaedic). The third model (Visual Attributes) considers solely visual attributes.

We observe a similar trend as with our computational models. Taking visual attributes into account increases the fit with Nelson’s (1998) association norms, whereas visual and textual attributes on their own perform worse. Interestingly, CCA’s

Models	Seen
All Attributes	0.28
Text Attributes	0.20
Visual Attributes	0.25

Table 7: Model performance on seen Nelson et al. (1998) cue-associate pairs; models are based on gold human generated attributes (McRae et al., 2005). All correlation coefficients are statistically significant ( $p < 0.01$ ,  $N = 435$ ).

Models	Seen	Unseen
Concat	0.22	0.10
CCA	0.26	0.15
TopicAttr	0.23	0.19
TextAttr	0.20	0.08
VisAttr	0.21	0.13
MixLDA	0.16	0.11

Table 8: Model performance on a subset of Nelson et al. (1998) cue-associate pairs. Seen are concepts known to the attribute classifiers and covered by MixLDA ( $N = 85$ ). Unseen are concepts covered by LDA but unknown to the attribute classifiers ( $N = 388$ ). All correlation coefficients are statistically significant ( $p < 0.05$ ).

performance is comparable to the All Attributes model (see Table 5, second column), despite using automatic attributes (both textual and visual). Furthermore, visual attributes obtained through our classifiers (see Table 5) achieve a marginally lower correlation coefficient against human generated ones (see Table 7).

Finally, to address our last question, we compared our approach against Feng and Lapata (2010) who represent visual information via quantized SIFT features. We trained their MixLDA model on their corpus consisting of 3,361 BBC news documents and corresponding images (Feng and Lapata, 2008). We optimized the model parameters on a development set consisting of cue-associate pairs from Nelson et al. (1998), excluding the concepts in McRae et al. (2005). We used a vocabulary of approximately 6,000 words. The best performing model on the development set used 500 visual terms and 750 topics and the association measure proposed in Griffiths et al. (2007). The test set consisted of 85 seen and 388 unseen cue-associate pairs that were covered by our models and MixLDA.

Table 8 reports correlation coefficients for our models and MixLDA against human probabilities. All attribute-based models significantly outperform MixLDA on seen pairs ( $p < 0.05$  using a  $t$ -test). MixLDA performs on a par with the concatenation model on unseen pairs, however CCA, TopicAttr, and VisAttr are all superior. Although these comparisons should be taken with a grain of salt, given that MixLDA and our models are trained on different corpora (MixLDA assumes that texts and images are collocated, whereas our images do not have collateral text), they seem to indicate that attribute-based information is indeed beneficial.

## 8 Conclusions

In this paper we proposed the use of automatically computed visual attributes as a way of physically grounding word meaning. Our results demonstrate that visual attributes improve the performance of distributional models across the board. On a word association task, CCA and the attribute-topic model give a better fit to human data when compared against simple concatenation and models based on a single modality. CCA consistently outperforms the attribute-topic model on seen data (it is in fact slightly better over a model that uses gold standard human generated attributes), whereas the attribute-topic model generalizes better on unseen data (see Tables 5, 6, and 8). Since the attribute-based representation is general and text-based we argue that it can be conveniently integrated with any type of distributional model or indeed other grounded models that rely on low-level image features (Bruni et al., 2012a; Feng and Lapata, 2010)

In the future, we would like to extend our database to actions and show that this attribute-centric representation is useful for more applied tasks such as image description generation and object recognition. Finally, we have only scratched the surface in terms of possible models for integrating the textual and visual modality. Interesting frameworks which we plan to explore are deep belief networks and Bayesian non-parametrics.

## Abstract

Developing natural language processing tools for low-resource languages often requires creating resources from scratch. While a variety of semi-supervised methods exist for training from incomplete data, there are open questions regarding what types of training data should be used and how much is necessary. We discuss a series of experiments designed to shed light on such questions in the context of part-of-speech tagging. We obtain timed annotations from linguists for the low-resource languages Kinyarwanda and Malagasy (as well as English) and evaluate how the amounts of various kinds of data affect performance of a trained POS-tagger. Our results show that annotation of word types is the most important, provided a sufficiently capable semi-supervised learning infrastructure is in place to project type information onto a raw corpus. We also show that finite-state morphological analyzers are effective sources of type information when few labeled examples are available.

## 1 Introduction

Low-resource languages present a particularly difficult challenge for natural language processing tasks. For example, supervised learning methods can provide high accuracy for part-of-speech (POS) tagging (Manning, 2011), but they perform poorly when little supervision is available. Good results in weakly-supervised tagging have been obtained by training sequence models such as hidden Markov models (HMM) using the Expectation-Maximization algorithm (EM), however most work in this area has still relied on relatively large amounts of data, both annotated and

unannotated, as well as an assumption that the annotations are very clean (Kupiec, 1992; Merialdo, 1994).

The ability to learn taggers using very little data is enticing: only a tiny fraction of the world's languages have enough data for standard supervised models to work well. The collection or development of resources is a time-consuming and expensive process, creating a significant barrier for an under-studied language where there are few experts and little funding. It is thus important to develop approaches that achieve good accuracy based on the amount of data that can be reasonably obtained, for example, in just a few hours by a linguist doing fieldwork on a non-native language.

Previous work explored learning taggers from weak information, but the type, amount, quality, and sources of data raise questions about the applicability of those results to real-world low-resource scenarios (Toutanova and Johnson, 2008; Ravi and Knight, 2009; Hasan and Ng, 2009; Garrette and Baldridge, 2012). Most research simulated weak supervision with tag dictionaries extracted from existing large, expertly-annotated corpora. These resources have been developed over long periods of time by trained annotators who collaborate to produce high-quality analyses. They are also biased towards including only the most likely tag for each word type, resulting in a cleaner dictionary than one would find in a real scenario. As such, these experiments do not reflect real-world constraints.

One exception to this work is Goldberg et al. (2008): they use a manually-constructed lexicon for Hebrew in order to learn an HMM tagger. However, this lexicon was constructed by trained lexicographers over a long period of time and achieves very high coverage of the language with very good quality, much better than could be achieved by our non-expert linguistics graduate student annotators in just a few hours. Cucerzan and Yarowsky

(2002) learn a POS-tagger from existing linguistic resources, namely a dictionary and a reference grammar, but these resources are not available, much less digitized, for most under-studied languages. Haghighi and Klein (2006) develop a model in which a POS-tagger is learned from a list of POS tags and just three “prototype” word types for each tag, but their approach requires a vector space to compute the distributional similarity between prototypes and other word types in the corpus. Such distributional models are not feasible for low-resource languages because they require immense amounts of raw text, much more than is available in these settings (Abney and Bird, 2010). Further, they extracted their prototype lists directly from a labeled corpus, something we are specifically avoiding. Täckström et al. (2013) evaluate the use of mixed type and token constraints generated by projecting information from a high-resource language to a low-resource language via a parallel corpus. However, large parallel corpora are not available for most low-resource languages. These are also expensive resources to create and would take considerably more effort to produce than the monolingual resources that our annotators were able to generate in a four-hour timeframe. Of course, if they are available, such parallel text links could be incorporated into our approach.

In our previous work, we developed a different strategy based on generalizing linguistic input with a computational model: linguists annotated either types or tokens for two hours, these annotations are projected onto a corpus of unlabeled tokens using label propagation and HMMs, and a final POS-tagger is trained on this larger auto-labeled corpus (Garrette and Baldridge, 2013). That approach uses much more realistic types and quantities of resources than previous work; nonetheless, it leaves many open questions regarding the effectiveness of incrementally more annotation, the role of unannotated data, and whether there is a good balance to be found using a *combination* of type- and token-supervision. We also did not consider morphological analyzers as a form of type supervision, as suggested by Merialdo (1994).

This paper addresses these questions via a series of experiments designed to quantify the effect on performance given by the amount of time spent finding or annotating training materials. We specifically look at the impact of four types of data

collection:

1. Time annotating sentences (token supervision)
2. Time creating tag dictionary (type supervision)
3. Time constructing a finite state transducer (FST) to analyze word-type morphology
4. Amount of raw data available for training

We explore these strategies in the context of POS-tagging for Kinyarwanda and Malagasy. We also include experiments for English, pretending as though it is a low-resource language. The overwhelming take away from our results is that type supervision—when backed by an effective semi-supervised learning approach—is the most important source of linguistic information. Also, morphological analyzers help for morphologically rich languages when there are few labeled types or tokens (and, it never hurts to use them). Finally, performance improves with more raw data, though we see diminishing returns past 400,000 tokens. With just four hours of type annotation, our system obtains good accuracy across the three languages: 89.8% on English, 81.9% on Kinyarwanda, and 81.2% on Malagasy.

Our results compare favorably with previous work despite using considerably less supervision and a more difficult set of tags. For example, Li et al. (2012) use the entirety of English Wiktionary directly as a tag dictionary to obtain 87.1% accuracy on English, below our result. Täckström et al. (2013) average 88.8% across 8 major languages, but for Turkish, a morphologically rich language, they achieve only 65.2%, significantly below our 81.9% for morphologically-rich Kinyarwanda.

## 2 Data

Kinyarwanda (KIN) and Malagasy (MLG) are low-resource, KIN is morphologically rich, and English (ENG) is used for comparison. For each language, sentences were divided into four sets: training data to be labeled by annotators, raw training data, development data, and test data.

**Data sources** The KIN texts are transcripts of testimonies by survivors of the Rwandan genocide provided by the Kigali Genocide Memorial Center. The MLG texts are articles from the websites<sup>1</sup> *Lakroa* and *La Gazette* and Malagasy Global Voices.<sup>2</sup> Texts in both KIN and MLG were tok-

<sup>1</sup>[www.lakroa.mg](http://www.lakroa.mg) and [www.lagazette-dgi.com](http://www.lagazette-dgi.com)

<sup>2</sup>[mg.globalvoicesonline.org/](http://mg.globalvoicesonline.org/)

	KIN		MLG		ENG - Experienced		ENG - Novice	
time	type	token	type	token	type	token	type	token
1:00	801	559 (1093)	660	422 (899)	910	522 (1124)	210	308 (599)
2:00	1814	948 (2093)	1363	785 (1923)	2660	1036 (2375)	631	646 (1429)
3:00	2539	1324 (3176)	2043	1082 (3064)	4561	1314 (3222)	1350	953 (2178)
4:00	3682	1651 (4119)	2773	1378 (4227)	6598	1697 (4376)	2185	1220 (2933)

Table 1: Annotations for each language and annotator as time increases. Shows the number of tag dictionary entries from type annotation vs. token. (The count of labeled tokens is shown in parentheses). For brevity, the table only shows hourly progress.

enized and labeled with POS tags by two linguistics graduate students, each of which was studying one of the languages. The KIN and MLG data have 12 and 23 distinct POS tags, respectively.

The Penn Treebank (PTB) (Marcus et al., 1993) is used as ENG data. Section 01 was used for token-supervised annotation, sections 02-14 were used as raw data, 15-18 for development of the FST, 19-21 as a dev set and 22-24 as a test set. The PTB uses 45 distinct POS tags.

**Collecting annotations** Linguists with non-native knowledge of KIN and MLG produced annotations for four hours (in 30-minute intervals) for two tasks. In the first task, type-supervision, the annotator was given a list of the words in the target language (ranked from most to least frequent), and they annotated each word type with its potential POS tags. The word types and frequencies used for this task were taken from the raw training data and did not include the test sets. In the second task, token-supervision, full sentences were annotated with POS tags. The 30-minute intervals allow us to investigate the incremental benefit of additional annotation of each type as well as how both annotation types might be combined within a fixed annotation budget.

Baldrige and Palmer (2009) found that annotator expertise greatly influences effectiveness of active learning for morpheme glossing, a related task. To see how differences in annotator speed and quality impact our task, we obtained ENG data from an *experienced* annotator and a *novice* one.

Ngai and Yarowsky (2000) investigated the effectiveness of rule-writing versus annotation (using active learning) for chunking, and found the latter to be far more effective. While we do not explore a rule-writing approach to POS-tagging, we do consider the impact of rule-based morphological analyzers as a component in our semi-supervised POS-tagging system.

	ENG - Exp.		ENG - Nov.

2:00	0.15	0.05	0.03	0.03
3:00	0.24	0.06	0.07	0.05
4:00	0.32	0.08	0.11	0.06

Table 2: Tag dictionary recall against the test set for ENG annotators on type and token annotations.

**Annotations** Table 1 gives statistics for all languages and annotators showing progress during the 4-hour tasks. With token-annotation, tag dictionary growth slows because high-frequency words are repeatedly annotated, producing only additional frequency and sequence information. In contrast, every type-annotation label is a new tag dictionary entry. For types, growth increases over time, reflecting the fact that high-frequency words (which are addressed first) tend to be more ambiguous and thus require more careful thought than later words. For ENG, we can compare the tagging speed of the experienced annotator with the novice: 50% more tokens and 3 times as many types. The token-tagging speed stayed fairly constant for the experienced annotator, but the novice increased his rate, showing the result of practice.

Checking the annotators' output against the gold tags in the PTB shows that both had good tagging accuracy on tokens: 94-95%. Comparing the tag dictionary entries versus the test data, precision starts in the high 80%*s* and falls to the mid-70%*s* in all cases. However, the differences in recall, shown in Table 2, are more interesting. On types, the experienced annotator maxed out at 32%, but the novice only reaches 11%. Moreover, the maximum for token annotations is much lower due to high repeat-annotation. The discrepancies between experienced and novice, and between type and token recall explain a great deal of the performance disparity seen in the experiments.

### 3 Morphological Transducers

Finite-state transducers (FSTs) accept regular languages and can be constructed easily using regular expressions, which makes them quite useful for phonology, morphology and limited areas of syntax (Karttunen, 2001). Past work has used FSTs for direct POS-tagging (Roche and Schabes, 1995), but this requires tight coupling between the FST and target tagset. We use FSTs for morphological analysis: the FST accepts a word type and produces a set of morphological features. If there are multiple possible analyses for a given word type, the FST returns them all. For instance the Kinyarwanda verb *sibatarazuka* “he is not yet resurrected” is analyzed in several ways:

- +NEG+CL2+IPL+V+arazuk+IMP
- +NEG+CL2+NOT.YET+PRES+zuk+IMP
- +NEG+CL2+NOT.YET+razuk+IMP

FSTs are particularly valuable for their ability to analyze out-of-vocabulary items. By looking for known affixes, FSTs can guess the stem of a word and produce an analysis despite not having knowledge of that stem. For morphologically complex languages like KIN, this ability is especially useful. Other factors, such as a large number of morphologically-conditioned phonological changes (seen in MLG) make out-of-vocabulary guessing more challenging because of the large number of potential stems (high ambiguity).

Development of the FSTs for all three languages was done by iteratively adding rules and lexical items with the goal of increasing coverage on a raw dataset. To accomplish this on a fixed time budget, the most frequently occurring unanalyzed tokens were examined, and their stems plus any observable morphological or phonological patterns were added to the transducer. Additionally, developers searched for known morphological alternations to locate instances of phonological change for inclusion. Coverage was checked against a raw dataset which did not include the test data used for the POS experiments.

The KIN and MLG FSTs were created by English-speaking linguists who were familiar with their respective language. They also used dictionaries and grammars. Each FST was developed in 10 hours. To evaluate the benefits of more development time, a version of the English FST was saved every 30 minutes, as shown in Table 3.

elapsed time	tokens		types	
	count	pct	count	pct
2:00	130k	61%	2.1k	12%
4:00	159k	75%	4.1k	24%
6:00	170k	80%	6.7k	39%
8:00	182k	86%	7.7k	44%
10:00	192k	91%	10.7k	62%

### 4 Approach

Learning under low-resource conditions is more difficult than scenarios in most previous POS work because the vast majority of the word types in the training and test data are not covered by the annotations. When most words are unknown, learning algorithms such as EM struggle (Garrette and Baldrige, 2012). Recall that most work on learning POS-taggers from tag dictionaries used tag dictionaries culled from *test* sets (even when considering incomplete dictionaries). We thus build on our previous approach, which exploits extremely sparse, human-generated annotations that are produced without knowledge of which words appear in the test set (Garrette and Baldrige, 2013).

This approach generalizes a small initial tag dictionary to include unannotated word types appearing in raw data. It estimates word/tag pair and tag-transition frequency information using model-minimization, which also reduces noise introduced by automatic tag dictionary expansion. The approach exploits type annotations effectively to learn parameters for out-of-vocabulary words and infer missing frequency and sequence information. This pipeline is described in detail in the previous work, so we give only a brief overview and describe our additions.

The purpose of tag dictionary expansion is to estimate label distributions for tokens in a raw cor-

pus, including words missing in the annotations. For this, a graph connecting annotated words to unannotated words via features is constructed and POS labels are pushed between these items using label propagation (LP) (Talukdar and Crammer, 2009). LP has been used successfully for extending POS labels from high-resource languages to low via parallel corpora (Das and Petrov, 2011; Täckström et al., 2013; Ding, 2011) or high- to low-resource domains (Subramanya et al., 2010), among other tasks. These works have typically used n-gram features (capturing basic syntax) and character affixes (basic morphology).

The character n-gram affix-as-morphology approach produces many features, but only a fraction of them represent actual morphemes. Incorrect features end up pushing noise around the graph, so affixes can lead to more false labels that drown out the true labels. While affixes may be sufficient for languages with limited morphology, their effectiveness diminishes for morphology-rich languages, which have much higher type-to-token ratios. More types means sparser word frequency statistics and more out-of-vocabulary items, and thus problems for EM. Here, we modify the LP graph by supplementing or replacing generic affix features with a focused set of morphological features produced by an FST. These targeted morphological features are effective during LP because words that share them are much more likely to actually share POS tags.

FSTs produce multiple analyses, which is actually advantageous for LP. Ambiguities need not be resolved since we just take the union of all morphological features for all analyses and use them as features in the graph. Note that each FST produces its own POS-tags as features, but these do *not* correspond to the target POS tagset used by the tagger. This is important because it decouples FST development and the final POS task. Thus, any FST for the language, regardless of its provenance, can be used with any target POS tagset.

Since the LP graph contains a node for each corpus token, and each node is labeled with a distribution over POS tags, the graph provides a corpus of sentences labeled with noisy tag *distributions* along with an expanded tag dictionary. This output is useful as input to EM because it contains labels for all seen word types as well as sequence and frequency information. There is a high degree of noise in the LP output, so we employ the model

minimization strategy of Ravi et al. (2010), which finds a minimal set of tag bigrams needed to explain the sentences in the raw corpus. It outputs a corpus of tagged sentences, which are used as a good starting point for EM training of an HMM. The expanded tag dictionary constrains the EM search space by providing a limited tagset for each word type, steering EM towards a desirable result.

Because the HMM trained by EM will contain zero-probabilities for words that did not appear in the training corpus, we use the “auto-supervision” step from our previous work: a Maximum Entropy Markov Model tagger is trained on a corpus that is noisily labeled by the HMM (Garrette and Baldrige, 2012). While training an HMM before the MEMM is not strictly necessary, our tests have shown that this generative-then-discriminative combination generally results in around 3% accuracy improvement.

## 5 Experiments<sup>3</sup>

To better understand the effect that each type of supervision has on tagger accuracy, we perform a series of experiments, with KIN and MLG as true low-resource languages. English experiments, for which we had both experienced and novice annotators, allow for further exploration into issues concerning data collection and preparation.

The overall best accuracies achieved by language are 81.9% for KIN using all types, 81.2% for MLG using half types and half tokens, and 89.8% for ENG using all types and the maximal amount of raw data. All of these best values were achieved using both FST and affix LP features.

All results described in this section are averaged over five folds of raw data.

### 5.1 Types versus tokens

Our primary question was the relationship between annotation type and time. Annotation must be done by someone familiar with the target language, linguistics, and the target POS tagset. For many low-resource languages, such people, and the time they have to spend, are likely to be in short supply. To make the best use of their time, we need to know which annotations are most use-

<sup>3</sup>Code and all MLG data available at [github.com/dhgarrette/low-resource-pos-tagging-2013](https://github.com/dhgarrette/low-resource-pos-tagging-2013). We are unable to provide the KIN or ENG data for download due to licensing restrictions. However, ENG data may be shared with those holding a license for the Penn Treebank and KIN data may be shared on a case-by-case basis.

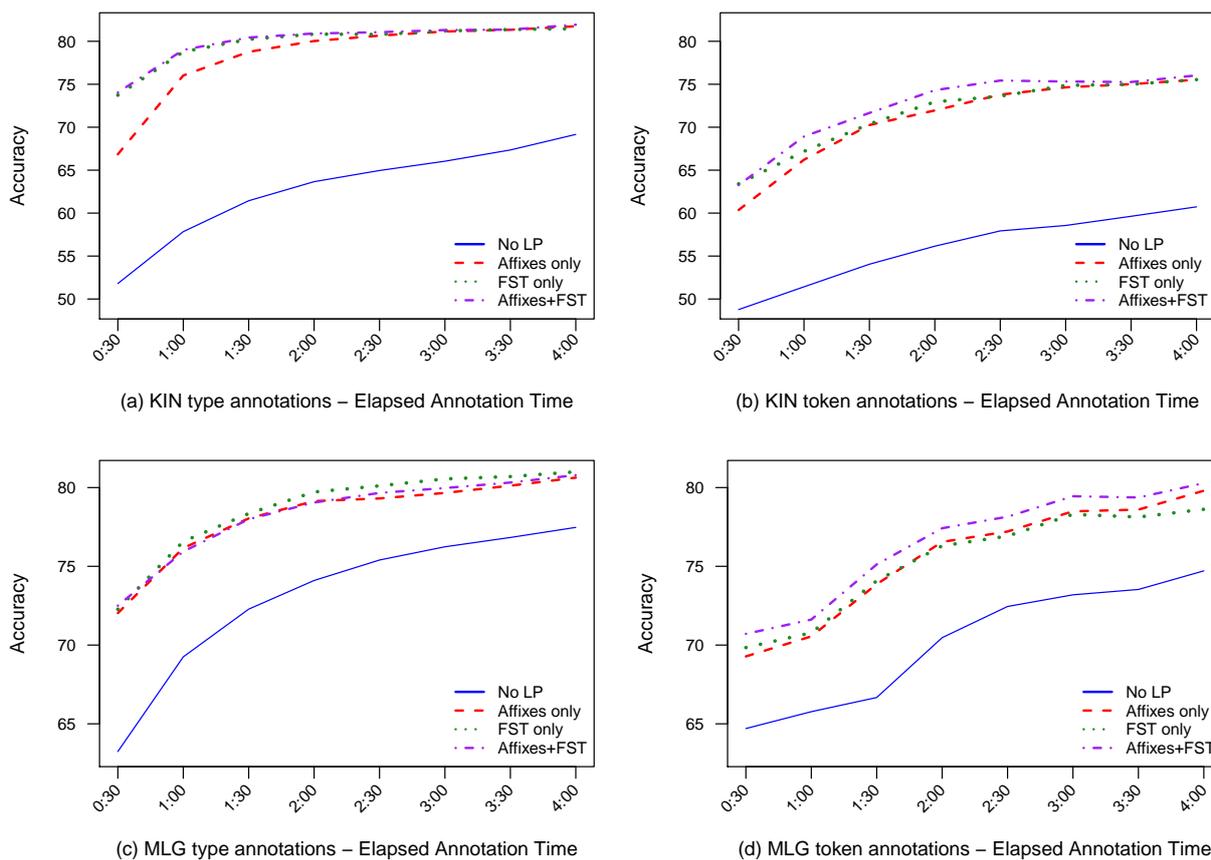

Figure 1: Annotation time vs. tagger accuracy for type-only and token-only annotations.

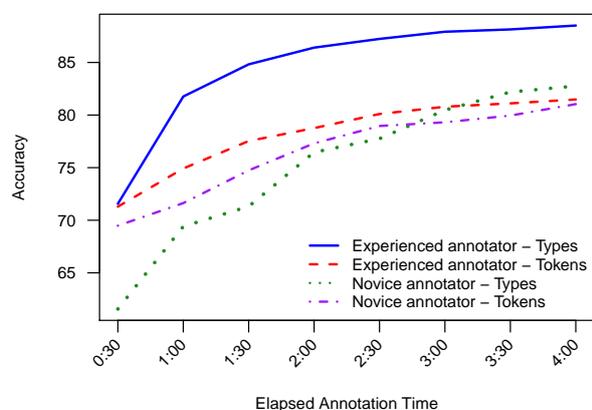

Figure 2: Annotation time vs. tagger accuracy for ENG type-only and token-only annotations with affix and FST LP features.

ful so that efforts can be concentrated there. Additionally, it is useful to identify when returns on annotation effort diminish so that annotators do not spend time doing work that is unlikely to add much value.

The annotators produced four hours each of type and token annotations, each in 30-minute increments. To assess the effects of annotation time,

we trained taggers cumulatively on each increment and determine the value of each additional half-hour of effort. Results are shown for KIN and MLG in Figure 1 and ENG in Figure 2. In all scenarios, the use of LP (and model minimization) delivers huge performance gains. Additionally, the use of FST features, usually along with affixes, yielded better results than without. This indicates the LP procedure makes effective use of the morphological features produced by the FST and that the affix features are able to capture missing information without adding too much noise to the LP graph.

Furthermore, performance is considerably better when type annotations are used than only tokens. Type annotations plateau much faster, so a shorter amount of time must be spent annotating types than if token annotations are used. For KIN it takes approximately 1.5 hours to reach near-maximum accuracy for types, but 2.5 hours for tokens. This difference is due to the fact that the type annotations started with the most frequent words whereas the token annotations were on random sentences. Thus, type annotations quickly cover a significant portion of the language’s tokens. With annotations directly on tokens, some of the highest

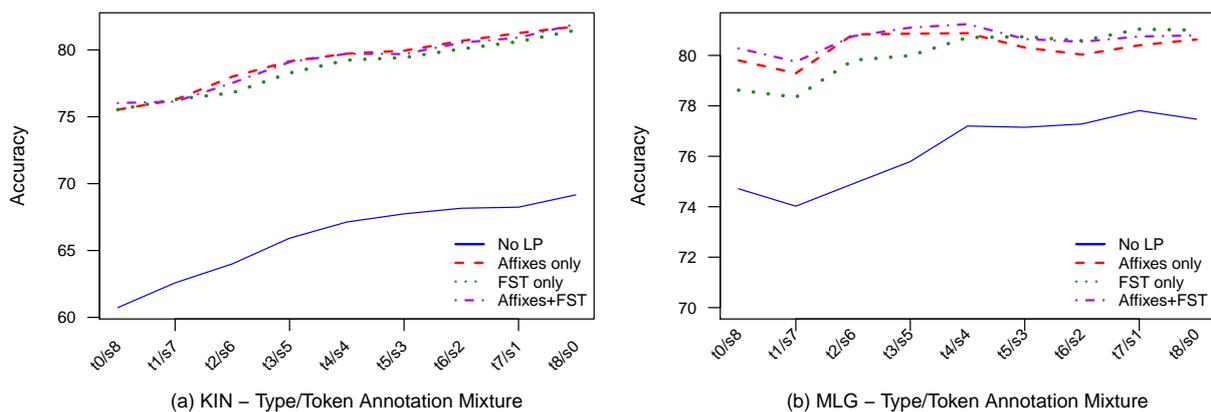

Figure 3: Annotation mixture vs. tagger accuracy. X-axis labels give annotation proportions, e.g. “t2/s6” indicates 2/8 of the time (1 hour) was spent annotating types and 6/8 (3 hours), full sentences.

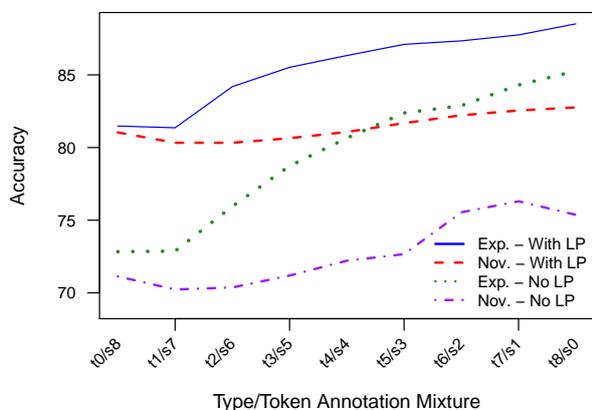

Figure 4: Annotation mixture vs. tagger accuracy on ENG using affix and FST LP features for experienced (Exp.) and novice (Nov.) annotators.

frequency types are covered, but annotation time is also ineffectively used on low-frequency types that happen to appear in those sentences.

Finally, the use of FST features yields the largest gains for KIN, but only when small amounts of annotation are available. This makes sense: KIN is a morphologically rich language, so sparsity is greater and crude affixes capture less actual morphology. With little annotated data, LP relies heavily on morphological features to make clean links between words. But, with more annotations, the gains of the FST over affix features alone diminishes: the affix features eventually capture enough of the morphology to make up the difference.

Figure 2 shows the dramatic differences between the experienced and novice ENG annotators.<sup>4</sup> For the former, results using types and to-

<sup>4</sup>The ENG graph omits “No LP” results since they followed patterns similar to KIN and MLG. Additionally, the results without FST features are not shown because they were nearly identical (though slightly lower) than with the FST.

kens were similar after 30 minutes, but type annotations proved much more useful beyond that. In contrast, the novice annotated types much more slowly, so early on there were not enough annotated types for the training to be as effective. Even so, after three hours of annotation, type annotations still win with the novice, and even beat the experienced annotator labeling tokens.

## 5.2 Mixing type and token annotations

Because type and token annotations are each better at providing different information — a tag dictionary of high-frequency words vs. sequence and frequency information — it is reasonable to expect that a combination of the two might yield higher performance by each contributing different but complementary information during training. This matters in low-resource settings because type or token annotations will likely be produced by the same people, so there is a tradeoff between spending resources on one form of annotation over the other. Understanding the best mixture of annotations can inform us on how to maximize the benefit of a set annotation budget. To this end, we ran experiments fixing the annotation time to four hours while varying the mix of type and token annotations. Results are shown for KIN and MLG in Figure 3 and ENG in Figure 4.

For KIN and ENG, tagger accuracy increases as the proportion of type annotations increases for all LP feature configurations. For MLG, however, as the reliance on the FST increases, the optimal mixture shifts toward higher type proportions. When only affix features are used, the optimal mixture is 1 hour of types and 3 hours of tokens. When FST and affix features are used, the optimum is 2 hours

each of types and tokens. When only FST features are used, it is best to use 3.5 hours of types and only 30 minutes of tokens. Because the FST operates on word types, it is effective at exploiting type annotations. Thus, when the LP focuses more on FST features, it becomes more desirable to have larger amounts of type annotations.

Types clearly win for ENG. The experienced annotator was much faster at annotating types and the speed difference was less pronounced for tokens, so accuracy is most similar when only token annotations are used. The performance disparity grows with increasing the type proportion.

Täckström et al. (2013) explore the use of mixed type and token annotations in which a tagger is learned by projecting information via parallel text. In their experiments, they—like us—found that type information is more valuable than token information. However, they were able to see gains through the complementary effects of mixing type and token annotations. It is likely that this difference in our results is due to the amount of annotated data used. It seems that the amount of type information collected in four hours is not sufficient to saturate the system, meaning that switching to annotating tokens tends to hurt performance.

### 5.3 FST development

The third set of experiments evaluate how the amount of time spent developing an FST affects the performance of trained tagger. To do this, we had our ENG FST developer save progress after each hour (for ten hours). The results show that, for ENG, the FST provided no value, regardless of how much time was spent on its development. Moreover, since large gains in accuracy can be achieved by spending a small amount of time just annotating word types with POS tags, we are led to conclude that time should be spent annotating types or tokens instead of developing an FST. While it is likely that FST development time would have a greater impact for morphologically rich languages, we suspect that greater gains can still be obtained by instead annotating types. Nonetheless, FSTs never seems to *hurt* performance, so if one is readily available, it should be used.

### 5.4 The effect of more raw data

In addition to annotations, semi-supervised tagger training requires a corpus of raw text. Raw data can be easier to acquire since it does not need the attention of a linguist. Even so, for many

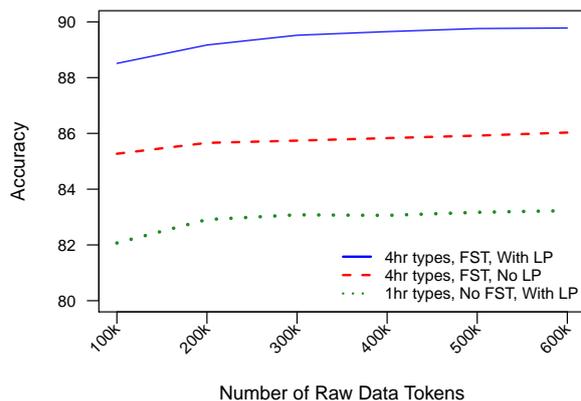

Figure 5: Amount of raw data vs. tagger accuracy for ENG using high vs. low amounts of annotation and using LP vs. no LP., for experienced annotator (novice results were similar).

low-resource languages, the amount of digitized text, such as transcripts or websites, is very limited and may, in fact, require substantial effort to accumulate, even with assistance from computational tools (Bird, 2011). Therefore, the collection of raw data can be considered another time-sensitive task for which the tradeoffs with previously-discussed annotation efforts must contend.

It could be the case that more raw data for training could make up for additional annotation and FST development effort or make the LP procedure unnecessary. Figure 5 shows that that increased raw data does provide increasing gains, but they diminish after 200k tokens. The best performance is achieved by using more annotation and LP. Most importantly, however, removing either annotations or LP results in a significant decline in accuracy, such that even with 600k training tokens, we are unable to achieve the results of high annotation and LP using only 100k tokens.

### 5.5 Correcting existing annotations

For all of the ENG experiments, we also ran “oracle” experiments using gold tags for the same sentences or a tag dictionary containing the same number of type/tag entries as the annotator produced, but containing only the most frequent entries as determined by the gold-labeled corpus. Using this simulated “perfect annotator” data shows we lose accuracy due to annotator mistakes: for our experienced annotator and maximal FST, using 4 hours of types the oracle accuracy is 90.5 vs. 88.5 while using only tokens we see 83.9 vs.

81.5. This indicates that there are gains to be made by correcting mistakes in the annotations. This is true even after the point of diminishing returns on the learning curve, meaning that even when adding *more* annotations no longer improves performance, progress can still be made by correcting errors, so it may be reasonable to ask annotators to attempt to correct errors in their past annotations. Automated techniques for facilitating error identification can be employed for this (Dickinson and Meurers, 2003).

## 6 Conclusions and Future Work

Care must be taken when drawing conclusions from small-scale annotation studies such as those presented in this paper. Nonetheless, we have explored realistic annotation scenarios for POS-tagging for low-resource languages and found several consistent patterns. Most importantly, it is clear that type annotations are the most useful input one can obtain from a linguist—provided a semi-supervised algorithm for projecting that information reliably onto raw tokens is available. In a sense, this result validates the research trajectory of efforts of the past two decades put into learning taggers from tag dictionaries: papers have successively removed layers of unrealistic assumptions, and in doing so have produced pipelines for type-supervision that easily beat token-supervision prepared in comparable amounts of time.

The result of most immediate practical value is that we show it is possible to train effective POS-taggers on actual low-resource languages given only a relatively small amount of unlabeled text and a few hours of annotation by a non-native linguist. Instead of having annotators label full sentences as one might expect the natural choice would be, it is much more effective to simply extract a list of the most frequent word types in the language and concentrate efforts on annotating these types with their potential parts of speech. Furthermore, for languages with rich morphology, a morphological transducer can yield significant performance gains when large amounts of other annotated resources are unavailable. (And it never hurts performance.)

Finally, additional raw text does improve performance. However, using substantial amounts of raw text is unlikely to produce gains larger than only a few hours spent annotating types. Thus, when deciding whether to spend time locating

larger volumes of digitized text or to spend time annotating types, choose types.

Despite the consistent superiority of type annotations in our experiments, it of course may be the case that techniques such as active learning may better select sentences for token annotation, so this should be explored in future work.

## Acknowledgements

We thank Kyle Jerro, Vijay John, Jim Evans, Yoav Goldberg, Slav Petrov, and the reviewers for their assistance and feedback. This work was supported by the U.S. Department of Defense through the U.S. Army Research Office (grant number W911NF-10-1-0533) and through a National Defense Science and Engineering Graduate Fellowship for the first author. Experiments were run on the UTCS Mastodon Cluster, provided by NSF grant EIA-0303609.

## Abstract

This paper demonstrates the need and impact of subcategorization information for SMT. We combine (i) features on source-side syntactic subcategorization and (ii) an external knowledge base with quantitative, dependency-based information about target-side subcategorization frames. A manual evaluation of an English-to-German translation task shows that the subcategorization information has a positive impact on translation quality through better prediction of case.

## 1 Introduction

When translating from a morphologically poor language to a morphologically rich language we are faced with two major problems: (i) the richness of the target-language morphology causes data sparsity problems, and (ii) information about morphological features on the target side is not sufficiently contained in the source language morphology.

We address these two problems using a two-step procedure. We first replace inflected forms by their stems or lemmas: building a translation system on a stemmed representation of the target side leads to a simpler translation task, and the morphological information contained in the source and target language parts of the translation model is more balanced. In the second step, the stemmed output of the translation is then inflected: the morphological features are predicted, and the inflected forms are generated using the stem and predicted morphological features.

In this paper, we focus on improving *case* prediction for noun phrases (NPs) in German translations. The NP feature *case* is extremely difficult to predict in German: while the NP features *gender* and *number* are part of the stem or

can be derived from the source-side input, respectively, the prediction of *case* requires information about the subcategorization of the entire clause. This is due to German being a less configurational language than English, which encodes grammatical relations (e.g. subject-hood, object-hood, etc.) through the position of constituents. German sentences exhibit a freer constituent order, and thus case is an important indicator of the grammatical functions of noun phrases. Correct case prediction is a crucial factor for the adequacy of SMT output, cf. the example in table 1 providing an erroneously inflected output (this is taken from a baseline “simple inflection prediction” system, cf. section 5.2). The translation of the English input sentence in terms of stems is perfectly acceptable; after the inflection step, however, the translation of NP<sub>4</sub> *ongoing military actions* represents a genitive modifier of the subject NP<sub>2</sub>, instead of a direct object NP of the verb *anordnen* (*to order*). The meaning is thus *why the government of the ongoing military actions ordered*, which has only one NP and is completely wrong.

The translation in table 1 needs verb subcategorization information. This is demonstrated by the invented examples (1) and (2):

- (1) [Der Mitarbeiter]<sub>NP<sub>nom</sub></sub> hat [den Bericht]<sub>NP<sub>acc</sub></sub> [dem Kollegen]<sub>NP<sub>dat</sub></sub> gegeben.  
[The employee]<sub>NP<sub>nom</sub></sub> gave [his colleague]<sub>NP<sub>dat</sub></sub> [the report]<sub>NP<sub>acc</sub></sub>
- (2) [Der Mitarbeiter]<sub>NP<sub>nom</sub></sub> hat [dem Bericht]<sub>NP<sub>dat</sub></sub> [des Kollegen]<sub>NP<sub>gen</sub></sub> zugestimmt.  
[The employee]<sub>NP<sub>nom</sub></sub> agreed [on the report]<sub>PP</sub> [of his colleague]<sub>PP</sub>

Both inflected sentences rely on the stem sequence [d Mitarbeiter] [d Bericht] [d Kollege] ⟨verb⟩, so the case assignment can only be determined by the verb: While *geben* (*to give*) has a strong preference for selecting a ditransitive subcategorization frame<sup>1</sup>, including an agentive subject (nomi-

<sup>1</sup>A ditransitive verb takes a subject and two objects.

<b>input</b>		[why] <sub>1</sub> [the government] <sub>2</sub> [ordered] <sub>3</sub> [the ongoing military actions] <sub>4</sub>
<b>output</b>	stemmed	[warum] <sub>1</sub> [d Regierung] <sub>2</sub> [d anhaltend militärisch Aktion] <sub>4</sub> [angeordnet] <sub>3</sub>
	inflected	[warum] <sub>1</sub> [ <b>die</b> Regierung] <sub>2</sub> [ <b>der</b> anhaltenden militärischen Aktionen] <sub>4</sub> [angeordnet] <sub>3</sub>

Table 1: Example for case confusion in SMT output when using a simple prediction system.

native case), a benefactive (dative case) and a patient (accusative case), *zustimmen* (to agree) has a strong preference for only selecting an agentive subject (nominative case) and an indirect object theme (dative case). So in the latter case the NP [*d Kollege*] cannot receive case from the verb and is instead the genitive modifier of the dative NP.

While for examples (1) and (2) knowledge about the syntactic verb subcategorization functions is sufficient to correctly predict the NP cases, examples (3) to (6) require subcategorization information at the syntax-semantic interface.

- (3) [Der Mitarbeiter]<sub>NPnom</sub> hat [dem Kollegen]<sub>NPdat</sub> [den Bericht]<sub>NPacc</sub> gegeben.
- (4) [Der Mitarbeiter]<sub>NPnom</sub> hat [den Bericht]<sub>NPacc</sub> [dem Kollegen]<sub>NPdat</sub> gegeben.
- (5) [Dem Kollegen]<sub>NPdat</sub> hat [der Mitarbeiter]<sub>NPnom</sub> [den Bericht]<sub>NPacc</sub> gegeben.
- (6) [Den Bericht]<sub>NPacc</sub> hat [der Mitarbeiter]<sub>NPnom</sub> [dem Kollegen]<sub>NPdat</sub> gegeben.

In all four examples, the verb and the participating noun phrases *Mitarbeiter* (employee), *Kollege* (colleague) and *Bericht* (report) are identical, and the noun phrases are assigned the same case. However, given that the stemmed output of the translation does not tell us anything about case features, in order to predict the appropriate cases of the three noun phrases, we either rely on ordering heuristics (such that the nominative NP is more likely to be in the beginning of the sentence (the German *Vorfeld*) than the accusative or dative NP, even though all three of these would be grammatical), or we need fine-grained subcategorization information beyond pure syntax. For example, both *Mitarbeiter* and *Kollege* would satisfy the agentive subject role of the verb *geben* better than *Bericht*, and *Bericht* is more likely to be the patient of *geben*.

The contribution of this paper is to improve the prediction of case in our SMT system by implementing and combining two alternative routes to integrate subcategorization information from the syntax-semantic interface: (i) We regard the translation as a function of the source language input, and project the syntactic functions of the English nouns to their German translations in the

SMT output. This subcategorization model is necessary when there are several plausible solutions for the syntactic functions of a noun in combination with a verb. For example, both *Mitarbeiter* and *Kollege* are plausible subjects and direct objects of the verb *geben*, so the information about these nouns' roles in the input sentence allows for disambiguation. (ii) The case of an NP is derived from an external knowledge base comprising quantitative, dependency-based information about German verb subcategorization frames and noun modification. The verb subcategorization information is not restricted to syntactic noun functions but models association strength for verb–noun pairs with regard to the entire subcategorization frame plus the syntactic functions of the nouns. For example, the database can tell us that while the verb *geben* is very likely to subcategorize a ditransitive frame, the verb *zustimmen* is very likely to subcategorize only a direct object, next to the obligatory subject (**subcat frame prediction**). Furthermore, we can retrieve the information that the noun *Bericht* is less likely to appear as subject of *geben* than the nouns *Mitarbeiter* and *Kollege* (**verb–noun subcat case prediction**). And we can look up that the noun *Aktion* is very unlikely to be a genitive modification of *Regierung* (cf. table 1), while *Kollege* is a plausible genitive modification of *Bericht* (**noun–noun modification case prediction**, cf. example (2)).

In summary, model (i) applies when there are no obvious preferences concerning verb–noun subcategorization or noun–noun modification. Model (ii) predicts case relying on the subcategorization and modification preferences. The combination of our two models approaches a simplified level of semantic role definition but only relies on dependency information that is considerably easier and cheaper to define and obtain than a very high quality semantic parser and/or a corpus annotated with semantic role information. Integrating semantic role information into SMT has been demonstrated by various researchers to improve translation quality (cf. Wu and Fung (2009a), Wu and Fung (2009b), Liu and Gildea (2008), Liu and Gildea (2010)). Our approach is in line with

Wu and Fung (2009b) who demonstrated that on the one hand 84% of verb syntactic functions in a 50-sentence test corpus projected from Chinese to English, and that on the other hand about 15% of the subjects were not translated into subjects, but their semantic roles were preserved across language. These two findings correspond to the expected uses of our models (i) and (ii), respectively.

## 2 Previous work

Previous work has already introduced the idea of generating inflected forms as a post-processing step for a translation system that has been stripped of (most) target-language-specific features. Toutanova et al. (2008) and Jeong et al. (2010) built translation systems that predict inflected word forms based on a large array of morphological and syntactic features, obtained from both source and target side. Kholy and Habash (2012) and Green and DeNero (2012) work on English to Arabic translation and model gender, number and definiteness, focusing primarily on improving fluency.

Fraser et al. (2012) used a phrase-based system to transfer stems and generated inflected forms based on the stems and their morphological features. For case prediction, they trained a CRF with access to lemmas and POS-tags within a given window. We re-implemented the system by Fraser et al. as a hierarchical machine translation system using a string-to-tree setup. In contrast to the flat phrase-based setting of Fraser et al. (2012), syntactic trees on the SMT output allow us to work with verb–noun structures, which are relevant for case prediction. While the CRF used for case prediction in Fraser et al. (2012) has access to lexical information, it is limited to a certain window size and has no direct information about the relation of verb–noun pairs occurring in the sentence. Using a window of a limited size is particularly problematic for German, as there can be large gaps between the verb and its subcategorized nouns; introducing information about the relation of verbs and nouns helps to bridge such gaps. Furthermore, that model was not able to make effective use of source-side features.

One of the objectives of using an inflection prediction model is morphologically well-formed output. Kirchhoff et al. (2012) evaluated user reactions to different error types in machine translation and came to the result that morphological

well-formedness has only a marginal impact on the comprehensibility of SMT output in the case of English-Spanish translation. As already discussed, German *case* is essential to the meaning of the sentence, so this result will not hold for German output.

## 3 Translation pipeline

This section presents an overview of our two-step translation process. In the first step, English input is translated to German stems. In the second step, morphological features are predicted and inflected forms are generated based on the word stems and the morphological features. In subsections 3.1 to 3.4, we present the simple version of the inflection prediction system; our new features are described in sections 4.2 and 4.3.

### 3.1 Stemmed representation/feature markup

We first parse the German side of the parallel training data with BitPar (Schmid, 2004). This maps each surface form appearing in normal text to a stem and morphological features (case, gender, number). We use this representation to create the stemmed representation for training the translation model. With the exception of stem-markup (discussed below), all morphological features are removed from the stemmed representation. The stem markup is used as part of the input to the feature prediction; the basic idea is that the given feature values are picked up by the prediction model and then propagated over the phrase.

Nouns, as the head of NPs and PPs, are annotated with *gender* and *number*. We consider gender as part of the stem, whereas the value for number is derived from the source-side: if marked for number, singular/plural nouns are distinguished during word alignment and then translated accordingly. Prepositions are also annotated with case; many prepositions are restricted to only one case, some are ambiguous and allow for either *dative* or *accusative*. Other words which are subject to feature prediction (e.g. adjectives, articles) are reduced to their stems with no feature markup, as are all remaining words. As sole exception, we keep the inflected forms of verbs (verbal inflection is not modelled). In addition to the translation model, the target-side language model, as well as the reference data for parameter tuning use this representation.

### 3.2 Building a stemmed translation model

We use a hierarchical translation system. Instead of translating phrases, a hierarchical system extracts translation rules (Galley et al., 2004) which allow the decoder to provide a tree spanning over the translated sentence. In order to avoid sparsity during rule extraction, we use a string-to-tree setup, where only the target-side part of the data is parsed. Translation rules are of the following form:

```
[X]1 allows [X]2 → [NP]1 [NP]2 erlaubt  
[X]1 allows [X]2 → [NP]1 erlaubt [NP]2
```

This example illustrates how rules can cover the different word ordering possibilities in German.

PP nodes are annotated with their respective case, as well as with the lemma of the preposition they contain. In our experiments, this enriched annotation has small improvements over the simpler setting with only head categories (details omitted). This outcome, in particular that adding the lemma of the preposition to the PP node helps to improve translation quality, has been observed before in tree restructuring work for improving translation (Huang and Knight, 2006).

### 3.3 Feature prediction and generation of inflected forms

In this section we discuss our focus, which is prediction of case, but also the prediction of number, gender and strong/weak adjectival inflection. The latter feature is German-specific; its values<sup>2</sup> (strong/weak) depend on the combination of the other features, as well as on the type of determiner (e.g. definite/indefinite/none).

Morphological features are predicted on four separate CRF models, one for each feature. The models for case, number and gender are independent of another, whereas the model for adjectival inflection requires information about these features, and is thus the last one to be computed, taking the output of the 3 other models as part of its input. In contrast, the adjectival inflection model in Fraser et al. (2012) is independent from the other features. Each model has access to stems, POS-tags and the feature to be modelled within a window of four positions to the right and the left of the current position<sup>3</sup>.

<sup>2</sup>Note that the values for strong/weak inflection are not always the same over the phrase, but follow a certain pattern depending on the settings of case, number and gender.

<sup>3</sup>Preliminary experiments showed that larger windows do not improve translation quality.

Table 2 illustrates the different steps of the inflection process: the markup (number and gender on nouns) in the stemmed output of the SMT system is part of the input to the respective feature prediction. For gender and number, the values given on the stems of the nouns are then propagated over the phrase. While the case of prepositional phrases is determined by the case annotation on prepositions, the case of nominal phrases is computed only based on the respective contexts. After predicting all morphological features, the information required to generate inflected forms is complete: based on the stems and the features, we use the morphological tool SMOR (Schmid et al., 2004) for the generation of inflected forms.

One general problem with feature-prediction is that the ill-formed SMT output is not well represented by the training data which consists of well-formed sentences. This problem was also mentioned by Stymne and Cancedda (2011) and Kholy and Habash (2012). They deal with this problem by translating the training data and annotating it with the respective features, and then adding this new data set to the original training data. As this method comes with its own problems, such as transferring the morphological annotation to not necessarily isomorphically translated text, we do not use translated data as part of the training data. Instead, we limit the power of the CRF model through experimenting with the removal of features, until we had a system that was robust to this problem.

### 3.4 Dealing with word formation issues

To reduce data sparsity, we split portmanteau prepositions. Portmanteaus are compounds of prepositions and articles, e.g. *zur* = *zu der* (*to the*). Being components of nominal phrases, they have to agree in all morphological features with the rest of the phrase. As only some combinations of articles and prepositions can form a portmanteau, the decision of whether to merge prepositions and articles is made after feature prediction. Since our focus is case prediction, we do not do special modelling of German compounds.

## 4 Using subcategorization information

Within the area of (automatic) lexical acquisition, the definition of lexical verb information has been a major focus, because verbs play a central role for the structure and the meaning of sentences and

SMT output	predicted features	inflected forms	gloss
beeinflussen<VFIN>	–	beeinflussen	influence
d<ART>	Fem.Acc.Sg.St	die	the
politisch<ADJ>	Fem.Acc.Sg.Wk	politische	political
Stabilität<NN><Fem><Sg>	Fem.Acc.Sg.Wk	Stabilität	stability

Table 2: Overview of the inflection process: the stem markup is highlighted in the SMT output.

discourse. On the one hand, this has led to a range of manually or semi-automatically developed lexical resources focusing on verb information, such as the Levin classes (Levin, 1993), VerbNet (Kipper Schuler, 2006), FrameNet<sup>4</sup> (Fillmore et al., 2003), and PropBank (Palmer et al., 2005). On the other hand, we find automatic approaches to the induction of verb subcategorization information at the syntax-semantics interface for a large number of languages, e.g. Briscoe and Carroll (1997) for English; Sarkar and Zeman (2000) for Czech; Schulte im Walde (2002a) for German; Messiant (2008) for French. This basic kind of verb knowledge has been shown to be useful in many NLP tasks such as information extraction (Surdeanu et al., 2003; Venturi1 et al., 2009), parsing (Carroll et al., 1998; Carroll and Fang, 2004) and word sense disambiguation (Kohomban and Lee, 2005; McCarthy et al., 2007).

#### 4.1 Extracting subcategorization information

As described in the introductory section, we make use of two<sup>5</sup> major kinds of subcategorization information. Verb–noun tuples referring to specific syntactic functions within verb subcategorization (**verb–noun subcat case prediction**) are integrated with an associated probability for *accusative* (direct object), *dative* (indirect object) and *nominative* (subject).<sup>6</sup> Further to the subject and object noun phrases, the subcategorization information provides quantitative triples for verb–preposition–noun pairs, thus predicting the case of NPs within prepositional phrases (we do this only when the prepositions are ambiguous, i.e., they could subcategorize either a dative or an accusative NP). In addition to modelling subcategorization information, it is also important to differentiate between subcategorized noun phrases (such as object or subject), and noun phrases

<sup>4</sup>Even though the FrameNets approach does not only include knowledge about verbal predicates, the actual lexicons are skewed towards verb behaviour.

<sup>5</sup>The third kind of information, **subcat frame prediction** is implicit, since verb–noun tuples rely on specific frames.

<sup>6</sup>Genitive objects can also occur in German verb subcategorization frames, but this is extremely rare and verb-specific and thus not considered in our model.

	V-SUBJ	V-OBJ <sub>Acc</sub>	V-OBJ <sub>Dat</sub>
EP	454,350	332,847	53,711
HGC	712,717	329,830	160,377
Both	1,089,492	607,541	206,764

Table 3: Number of verb-noun types extracted from Europarl (EP) and newspaper data (HGC).

that modify nouns (**noun–noun modification case prediction**). Typically, these NP modifiers are genitive NPs. To this end, we integrate noun–noun<sub>Gen</sub> tuples with their respective frequencies. These preferences for a certain function (i.e. subject, object or modifier) are passed on to the system at the level of nouns and integrated into the CRF through the derived probabilities.

The tuples and triples are obtained from dependency-parsed data by extracting all occurrences of the respective relations; table 3 gives an overview of the number of extracted tuple types. For the subcategorization information, the verb–noun tuples (verb–subject, verb–object<sub>Acc</sub>, verb–object<sub>Dat</sub>) are then grouped as follows:

tuple	gloss	Acc	Dat	Nom
Schema <sub>N</sub> folgen <sub>V</sub>	pattern follow	0	322	19

We compute the probabilities for the verb–noun tuple to occur in the respective functions based on the relative frequencies. In the case of *Schema<sub>N</sub> folgen<sub>V</sub>*, we find that the function of *Schema* as dative object is predominant (*to follow a pattern*), but it can also occur in the subject position (*the pattern follows*). The fact that two functions are possible for this noun are reflected in their probabilities. The probabilities are discretized into 5 buckets ( $B_{p=0}$ ,  $B_{0<p\leq 0.25}$ ,  $B_{0.25<p\leq 0.5}$ ,  $B_{0.5<p\leq 0.75}$ ,  $B_{0.75<p\leq 1}$ ). In contrast, noun modification in noun–noun<sub>Gen</sub> construction is represented by co-occurrence frequencies.<sup>7</sup>

<sup>7</sup>The frequencies are bucketed to the powers of ten, i.e.  $f = 1, 2 \leq f \leq 10, 11 \leq f \leq 100$ , etc. and also  $f = 0$ : this representation allows for a more fine-grained distinction in the low-to-mid frequency range, providing a good basis for the decision of whether a given noun–noun pair is a true noun–noun<sub>Gen</sub> structure or just a random co-occurrence of two nouns.

	Gloss	Stem	Tag	Acc	Dat	Nom	Verb	Gen	NI	Gold
1	<i>companies</i>	Unternehmen<NN>	NN	0.00	0.00	1.00	erhalten	-	-	Nom
2	<i>should</i>	sollten<VVFIN>	VVFIN	-	-	-	-	-	-	-
3	<i>financial</i>	finanziell<ADJ>	ADJ	-	-	-	-	-	-	Acc
4	<i>funding</i>	Mittel<NN>	NN	1.00	0.00	0.00	erhalten	-	-	Acc

9	<i>technologies</i>	Technologie<NN>	NN	-	-	-	-	100	Einführung<NN>	Gen
10	<i>obtain</i>	erhalten<VVFIN>	VVFIN	-	-	-	-	-	-	-

Table 4: Adding subcategorization information into SMT output. (EN input: *companies should obtain financial funding for the introduction of new technologies*). On the right, the correct labels are given.

## 4.2 Integrating subcategorization knowledge

There are two possibilities to integrate subcategorization information into the case prediction model: (i) It can be integrated into the data set using the tree-structure provided by the decoder. Here, verb-noun tuples are extracted from VP and S structures, and then the probabilities for the different functions are looked up. Similarly, for two adjacent NPs, the occurrence frequencies of the respective two nouns are looked up in the list of noun-noun<sub>Gen</sub> constructions. (ii) The subcategorization information can be integrated based on the verb-noun tuples obtained by using tuples obtained from source-side dependencies.

The classification task of the CRF consists in predicting a sequence of labels: case values for NPs/PPs or no value otherwise, cf. table 4. The model has access to the basic features *stem* and *tag*, as well as the new features based on subcategorization information (explained below), using unigrams within a window of up to four positions to the right and the left of the current position, as well as bigrams and trigrams for stems and tags (current item + left and/or right item).

An example for integrating subcategorization features is given in table 4. The first word *Unternehmen* (*companies*) is annotated as subject of *erhalten* (*obtain*) with probability 1, and *Mittel* (*funding*) is annotated as direct object of *erhalten* with probability 1. The word *Technologie* (*technology*) has been marked as a candidate for a genitive in a noun-noun<sub>Gen</sub> construction<sup>8</sup>; the co-occurrence frequency of the tuple *Einführung-Technologie* (*introduction - technology*) lies in the bucket 11...100.

In addition to the probability/frequency of the respective functions, we also provide the CRF with bigrams containing the two parts of the tuple,

<sup>8</sup>There is no annotation on *Einführung* as the preposition *für* is always in accusative case.

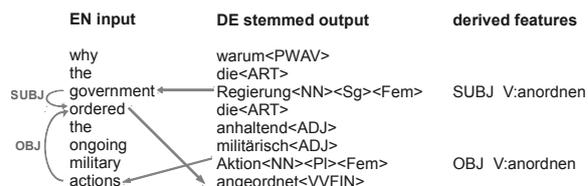

Figure 1: Deriving features from dependency-parsed English data via the word alignment.

i.e. verb+noun or the two nouns of possible noun-noun<sub>Gen</sub> constructions. As can be seen in the example in table 4, the subject (line 1) and the verb (line 10) are far apart from each other. By providing the parts of the tuple as unigrams, bigrams or trigrams to the CRF, all relevant information is available: verb, noun and the probabilities for the potential functions of the noun in the sentence. In addition to bridging the long distance between verbs and subcategorized nouns, a very common problem for German, this type of precise information also helps to close the gap between the well-formed training data and the broken SMT-output as it replaces to a certain extent the target-language context information (n-grams of stems or lemmas within a small window).

## 4.3 Integrating source-side features

For predicting case in SMT output, information about an NP's function in the input sentence is essential. Syntax-semantic functions can be isomorphic (e.g., English subjects and objects may have the same function in a German translation), but this is not necessarily the case. Despite this, an important advantage of integrating source-side features is that the well-formed source-side text can be reliably parsed, whereas SMT output is often disfluent and cannot be reliably parsed.

The English features are obtained from dependency-parsed data (Choi and Palmer, 2012). The relevant annotation of the parser is transferred

to the SMT output via word alignment. We focus on English subjects, direct objects and noun-of-noun structures (often equivalent to noun-noun<sub>Gen</sub> phrases on the German side): these structures are generally likely to correspond to each other within source and target language. In contrast to the subcategorization-based information, the difference between well-formed training data and disfluent SMT output tends to work to our benefit here: while the parallel sentences of the training data were manually translated with the objective to produce good target-language sentences, the syntactic structures of the source and target sentences are often diverging. In contrast, the SMT system often produces more isomorphic translations, which is helpful for annotating source-side features on the target language.

Figure 1 shows the process of integrating source-side features: for each German noun that is aligned with an English noun labelled as subject or direct object, this annotation is transferred to the target-side. Using the English dependency structures, the verb subcategorizing the respective noun is identified, and via the alignment, the equivalent German verb is obtained. Similarly, candidates for noun-noun<sub>Gen</sub> structures are identified by extracting and aligning English noun-of-noun phrases.

## 5 Experiments and evaluation

In this section, we present experiments using different feature combinations. We also present a manual evaluation of our best system which shows that the new features improve translation quality.

### 5.1 Data and experimental setup

We use the hierarchical translation system that comes with the Moses SMT-package and GIZA++ to compute the word alignment, using the “grow-diag-final-and” heuristics. The rule table was computed with the default parameter setting for GHKM extraction (Galley et al., 2004) in the implementation by Williams and Koehn (2012).

Our training data contains 1,485,059 parallel sentences<sup>9</sup>; the German part of the parallel data is used as the target-side language model. The dev and test sets (1025/1026 lines) are wmt-2009-a/b.

For predicting the grammatical features, we used the Wapiti Toolkit (Lavergne et al., 2010).<sup>10</sup>

<sup>9</sup>English/German data released for the 2009 ACL Workshop on Machine Translation shared task.

<sup>10</sup>To eliminate irrelevant features, we use L1 regulariza-

We train four CRFs on data prepared as shown in section 3. The corpora used for the extraction of subcategorization tuples were Europarl and German newspaper data (200 million words). We choose this particular data combination in order to provide data that matches the training data, as well as to add new data of the test set’s domain (news). The German part of Europarl was dependency-parsed with Bohnet (2010), and subcategorization information was extracted as described in Scheible et al. (2013); the newspaper data (HGC - Huge German Corpus) was parsed with Schmid (2000), and subcategorization information was extracted as described in Schulte im Walde (2002b).

### 5.2 Results

We report results of two types of systems (table 5): first, a regular translation system built on surface forms (i.e., normal text) and second, four inflection prediction systems. The first inflection prediction system (1) uses a simple case prediction model, whereas the remaining systems are enriched with (2) subcategorization information (cf. section 4.2), (3) source-side features (cf. section 4.3), and (4) both source-side features and subcategorization information. In (2) and (4), the subcategorization information was included using tuples obtained from source-side dependencies<sup>11</sup>. The simple prediction system corresponds to that presented in section 3; for all inflection prediction systems, the same SMT output and models for number, gender and strong/weak inflection were used; thus the only difference with the simple prediction system is the model for case prediction.

We present three types of evaluation: BLEU scores (Papineni et al., 2001), prediction accuracy on clean data and a manual evaluation of the best system in section 5.3.

Table 5 gives results in case-insensitive BLEU. While the inflection prediction systems (1-4) are significantly<sup>12</sup> better than the surface-form system (0), the different versions of the inflection systems are not distinguishable in terms of BLEU; however, our manual evaluation shows that the new features have a positive impact on translation quality.

tion; the regularization parameter is optimized on held out data.

<sup>11</sup>Using tuples extracted from the target-side parse tree (produced by the decoder) results in a BLEU score of 14.00.

<sup>12</sup>We used Kevin Gimpel’s implementation of pairwise bootstrap resampling with 1000 samples.

	0	1	2	3	4
	<b>surface system</b>	<b>simple prediction</b>	<b>subcat. features (tuples from EN side)</b>	<b>source-side features</b>	<b>source-side + subcat. features</b>
<b>BLEU</b>	13.43	14.02	14.05	14.10	14.17
<b>Clean</b>	–	85.05 %	85.65 %	85.61 %	85.81 %

Table 5: Results of the simple prediction vs. three systems enriched with extra features.

One problem with using BLEU as an evaluation metric is that it is a precision-oriented metric and tends to reward fluency rather than adequacy (see (Wu and Fung, 2009a; Liu and Gildea, 2010)). As we are working on improving adequacy, this will not be fully reflected by BLEU. Furthermore, not all components of an NP do necessarily change their inflection with a new case value; it might happen that the only indicator for the case of an NP is the determiner: *er sieht [den alten Mann]<sub>NPacc</sub>* (he sees the old man) vs. *er folgt [dem alten Mann]<sub>NPdat</sub>* (he follows the old man). While the case marking of NPs is essential for comprehensibility, one changed word per noun phrase is hardly enough to be reflected by BLEU.

An alternative to study the effectiveness of the case prediction model is to evaluate the prediction accuracy on parsed clean data, i.e. not on SMT output. In this case, we measure (using the dev set) how often the case of an NP is predicted correctly<sup>13</sup>. In all cases, the prediction accuracy is better for the enriched systems. This shows that the additional features improve the model, but also that a gain in prediction accuracy on clean data is not necessarily related to a gain in BLEU. We observed that the more complex the model, the less robust it is to differences between the test data and the training data. Related to this problem, we observed that high-order n-gram POS/lemma-based features in the simple prediction (sequences of lemmas and tags) are given too much weight in training and thus make it difficult for the new features to have a larger impact, so we restricted the n-gram order of this type of feature to trigrams.

### 5.3 Manual evaluation of the best system

In order to provide a better understanding of the impact of the presented features, in particular to see whether there is an improvement in adequacy, we carried out a manual evaluation comparing sys-

<sup>13</sup>The numbers in table 5 are artificially high and downplay the difference as they also include cases which are very easy to predict, such as nouns in PPs where only one value for case is possible. We measure how many case labels were correctly predicted, not correct inflected forms.

		<b>enriched preferred</b>	<b>simple preferred</b>	<b>equal</b>
(a)	<b>person 1</b>	23	11	12
	<b>person 2</b>	21	8	17
	<b>person 3</b>	26	11	9
(b)	<b>person 1</b>	23	5	18
	<b>person 2</b>	21	11	14
	<b>person 3</b>	29	8	9
(c)	<b>agreement</b>	17	2	6

Table 6: Manual evaluation of 46 sentences: without (a) and with (b) access to EN input, and the annotators’ agreement in the second part (c).

tem (4) with the simple prediction system (1). From the set of different sentences between the simple prediction system and the enriched system (144 of 1026), we evaluated those where the English input sentence was between 8 and 25 words long (46 sentences in total). We specifically restricted the test set in order to provide sentences which are less difficult to annotate, as longer sentences are often very disfluent and too hard to rate. Most of the sentences in the evaluation set differ only in the realization of one NP. For comparing the two systems, the sentences were presented in random order to 3 native speakers of German.

The evaluation consists of two parts: first, the participants were asked to decide which sentence is better without being given the English input (this measures fluency). In the second part, they should to mark that sentence which better reproduces the content of the English input sentence (this measures adequacy). The test set is the same for both tasks, the only difference being that the English input is given in the second part. The results are given in table 6. Summarizing we can say that the participants prefer the enriched system over the simple system in both parts; there is a high agreement (17 cases) in decisions over those sentences which were rated as *enriched better*.

When looking at the pairwise inter-annotator agreement for the task of annotating the test-set with the 3 possible labels *enriched preferred*, *simple preferred* and *no preference*, we find that the annotators P1 and P2 have a substantial agreement

1	<b>input simple enriched</b>	hundreds of policemen were on alert , and [a helicopter] <sub>Subj</sub> circled the area with searchlights . Hunderte von Polizisten auf Trab , und [einen Helikopter] <sub>Acc</sub> eingekreist das Gebiet mit searchlights . Hunderte von Polizisten auf Trab , und [ein Helikopter] <sub>Nom</sub> eingekreist das Gebiet mit searchlights .
2	<b>input simple enriched</b>	while 38 %percent put [their trust] <sub>Obj</sub> in viktor orbán . während 38 % [ihres Vertrauens] <sub>Gen</sub> schenken in Viktor Orbán . während 38 % [ihr Vertrauen] <sub>Acc</sub> schenken in Viktor Orbán .
3	<b>input simple enriched</b>	more than \$ 100 billion will enter [the monetary markets] <sub>Obj</sub> by means of public sales . mehr als 100 Milliarden Dollar werden durch öffentlichen Verkauf [der Geldmärkte] <sub>Gen</sub> treten . mehr als 100 Milliarden Dollar werden durch öffentlichen Verkauf [die Geldmärkte] <sub>Acc</sub> treten .

Table 7: Output from the simple system (1) and the enriched system (4).

in terms of Kappa ( $\kappa = 0.6184$ ), whereas the agreement of P3 with P1/P2 respectively leads to lower scores ( $\kappa = 0.4467$  and  $\kappa = 0.3596$ ). However, the annotators tend to agree well on sentences with the label *enriched preferred*, but largely disagree on sentences labelled as either *simple preferred* or *no preference*. The number of decisions where all three annotators agree on a label when given the English input is listed in table 6(c): for example, only two sentences were given the label *baseline is better* by all three annotators. This outcome shows how difficult it is to rate disfluent SMT output. For evaluating the case prediction system, the distinction between *enriched preferred* and *enriched dispreferred* is the most important question to answer. Redefining the annotation task to annotating only two values by grouping the labels *simple preferred* and *no preference* into one annotation possibility leads to  $\kappa = 0.7391$ ,  $\kappa = 0.4048$  and  $\kappa = 0.5652$ .

#### 5.4 Examples

Table 7 shows some examples for output from the simple system and the system using source-side and subcategorization features. In the first sentence, the subject NP *a helicopter* was inflected as a direct object in the simple system, but as a subject in the enriched system, which was preferred by all three annotators. In the second sentence, the NP *their trust*, i.e. a direct object of *put*, was incorrectly predicted as genitive-modifier of *38 %* (i.e. *38 % of their trust*) in the simple system. The enriched system made use of the preference for accusative for the pair *Vertrauen schenken* (*place trust*), correctly inflecting this NP as direct object. Interestingly, only two annotators preferred the enriched system, whereas one was undecided. The third sentence illustrates how difficult it is to rate case marking on disfluent SMT output: there are two possibilities to translate *enter the money market*; the direct equivalent of the English phrase (*den Geldmarkt<sub>Acc</sub> betreten*), or via the use

of a prepositional phrase (*auf den Geldmarkt<sub>Acc</sub> treten*: “*to step into the money market*”). The SMT-output contains a mix of both, i.e. the verb *treten* (instead of *betreten*), but without the preposition, which cannot lead to a fully correct inflection. While the inflection of the simple system (a genitive construction meaning *the public sales of the money market*) is definitely wrong, the inflection obtained in the enriched system is not useful either, due to the structure of the translation<sup>14</sup>. This difficulty is also reflected by the annotators, who gave twice the label *no preference* and once the label *enriched better*.

## 6 Conclusion

We illustrated the necessity of using external knowledge sources like subcategorization information for modelling case for English to German translation. We presented a translation system making use of a subcategorization database together with source-side features. Our method is language-independent with regard to the source language; furthermore, no language-specific high-quality semantic annotation is needed for the target language, but the data required to model the subcategorization preferences can be obtained using standard NLP techniques. We showed in a manual evaluation that the proposed features have a positive impact on translation quality.

## Abstract

We propose a Name-aware Machine Translation (MT) approach which can tightly integrate name processing into MT model, by jointly annotating parallel corpora, extracting name-aware translation grammar and rules, adding name phrase table and name translation driven decoding. Additionally, we also propose a new MT metric to appropriately evaluate the translation quality of informative words, by assigning different weights to different words according to their importance values in a document. Experiments on Chinese-English translation demonstrated the effectiveness of our approach on enhancing the quality of overall translation, name translation and word alignment over a high-quality MT baseline<sup>1</sup>.

## 1 Introduction

A shrinking fraction of the world's Web pages are written in English, therefore the ability to access pages across a range of languages is becoming increasingly important. This need can be addressed in part by cross-lingual information access tasks such as entity linking (McNamee et al., 2011; Cassidy et al., 2012), event extraction (Hakkani-Tur et al., 2007), slot filling (Snover et al., 2011) and question answering (Parton et al., 2009; Parton and McKeown, 2010). A key bottleneck of high-quality cross-lingual information access lies in the performance of Machine Translation (MT). Traditional MT approaches focus on the fluency and accuracy of the overall translation but fall short in their ability to translate certain content words including critical information, especially names.

<sup>1</sup>Some of the resources and open source programs developed in this work are made freely available for research purpose at <http://nlp.cs.qc.cuny.edu/NAMT.tgz>

A typical statistical MT system can only translate 60% person names correctly (Ji et al., 2009). Incorrect segmentation and translation of names which often carry central meanings of a sentence can also yield incorrect translation of long contexts. Names have been largely neglected in the prior MT research due to the following reasons:

- The current dominant automatic MT scoring metrics (such as Bilingual Evaluation Understudy (BLEU) (Papineni et al., 2002)) treat all words equally, but names have relative low frequency in text (about 6% in newswire and only 3% in web documents) and thus are vastly outnumbered by function words and common nouns, etc..
- Name translations pose a greater complexity because the set of names is open and highly dynamic. It is also important to acknowledge that there are many fundamental differences between the translation of names and other tokens, depending on whether a name is rendered phonetically, semantically, or a mixture of both (Ji et al., 2009).
- The artificial settings of assigning low weights to information translation (compared to overall word translation) in some large-scale government evaluations have discouraged MT developers to spend time and explore resources to tackle this problem.

We propose a novel Name-aware MT (NAMT) approach which can tightly integrate name processing into the training and decoding processes of an end-to-end MT pipeline, and a new name-aware metric to evaluate MT which can assign different weights to different tokens according to their importance values in a document. Compared to previous methods, the novel contributions of our approach are:

1. Tightly integrate joint bilingual name tagging into MT training by coordinating tagged

names in parallel corpora, updating word segmentation, word alignment and grammar extraction (Section 3.1).

2. Tightly integrate name tagging and translation into MT decoding via name-aware grammar (Section 3.2).
3. Optimize name translation and context translation simultaneously and conduct name translation driven decoding with language model (LM) based selection (Section 3.2).
4. Propose a new MT evaluation metric which can discriminate names and non-informative words (Section 4).

## 2 Baseline MT

As our baseline, we apply a high-performing Chinese-English MT system (Zheng, 2008; Zheng et al., 2009) based on hierarchical phrase-based translation framework (Chiang, 2005). It is based on a weighted synchronous context-free grammar (SCFG). All SCFG rules are associated with a set of features that are used to compute derivation probabilities. The features include:

- Relative frequency in two directions  $P(\gamma|\alpha)$  and  $P(\alpha|\gamma)$ , estimating the likelihoods of one side of the rule  $r: X \rightarrow \langle \gamma, \alpha \rangle$  translating into the other side, where  $\gamma$  and  $\alpha$  are strings of terminals and non-terminals in the source side and target side. Non-terminals in  $\gamma$  and  $\alpha$  are in one-to-one correspondence.
- Lexical weights in two directions:  $P_w(\gamma|\alpha)$  and  $P_w(\alpha|\gamma)$ , estimating likelihoods of words in one side of the rule  $r: X \rightarrow \langle \gamma, \alpha \rangle$  translating into the other side (Koehn et al., 2003).
- Phrase penalty: a penalty  $\exp(1)$  for a rule with no non-terminal being used in derivation.
- Rule penalty: a penalty  $\exp(1)$  for a rule with at least one non-terminal being used in derivation.
- Glue rule penalty: a penalty  $\exp(1)$  if a glue rule used in derivation.
- Translation length: number of words in translation output.

Our previous work showed that combining multiple LMs trained from different sources can lead to significant improvement. The LM used for decoding is a log-linear combination of four word n-gram LMs which are built on different English

corpora (details described in section 5.1), with the LM weights optimized on a development set and determined by minimum error rate training (MERT), to estimate the probability of a word given the preceding words. All four LMs were trained using modified Kneser-Ney smoothing algorithm (Chen and Goodman, 1996) and converted into Bloom filter LMs (Talbot and Brants, 2008) supporting memory map.

The scaling factors for all features are optimized by minimum error rate training algorithm to maximize BLEU score (Och, 2003). Given an input sentence in the source language, translation into the target language is cast as a search problem, where the goal is to find the highest-probability derivation that generates the source-side sentence, using the rules in our SCFG. The source-side derivation corresponds to a synchronous target-side derivation and the terminal yield of this target-side derivation is the output of the system. We employ our CKY-style chart decoder, named SRInterp, to solve the search problem.

## 3 Name-aware MT

We tightly integrate name processing into the above baseline to construct a NAMT model. Figure 1 depicts the general procedure.

### 3.1 Training

This basic training process of NAMT requires us to apply a bilingual name tagger to annotate parallel training corpora. Traditional name tagging approaches for single languages cannot address this requirement because they were all built on data and resources which are specific to each language without using any cross-lingual features. In addition, due to separate decoding processes the results on parallel data may not be consistent across languages. We developed a bilingual joint name tagger (Li et al., 2012) based on conditional random fields that incorporates both monolingual and cross-lingual features and conducts joint inference, so that name tagging from two languages can mutually enhance each other and therefore inconsistent results can be corrected simultaneously. This joint name tagger achieved 86.3% bilingual pair F-measure with manual alignment and 84.4% bilingual pair F-measure with automatic alignment as reported in (Li et al., 2012). Given a parallel sentence pair we first apply Giza++ (Och and Ney, 2003) to align words, and apply this joint

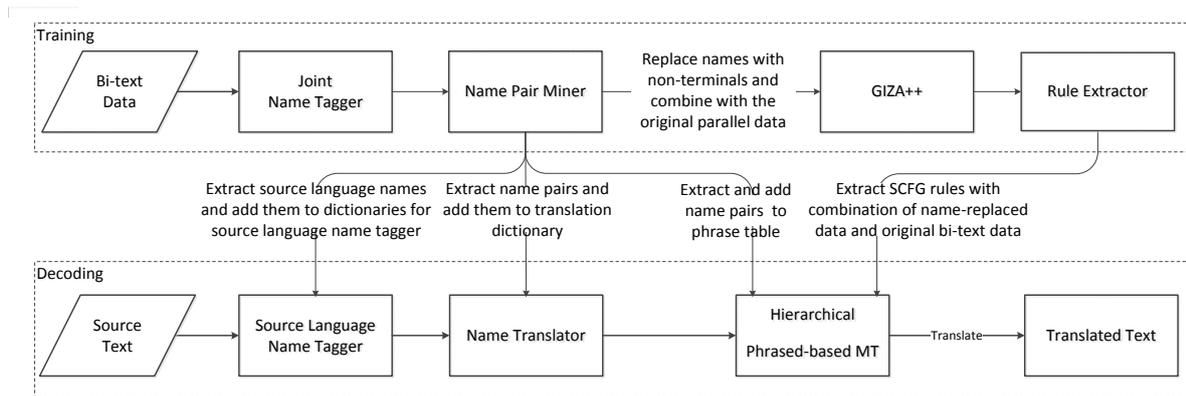

Figure 1: Architecture of Name-aware Machine Translation System.

t bilingual name tagger to extract three types of names: (Person (PER), Organization (ORG) and Geo-political entities (GPE)) from both the source side and the target side. We pair two entities from two languages, if they have the same entity type and are mapped together by word alignment. We ignore two kinds of names: multi-word names with conflicting boundaries in two languages and names only identified in one side of a parallel sentence.

We built a NAMT system from such name-tagged parallel corpora. First, we replace tagged name pairs with their entity types, and then use Giza++ and symmetrization heuristics to regenerate word alignment. Since the name tags appear very frequently, the existence of such tags yields improvement in word alignment quality. The re-aligned parallel corpora are used to train our NAMT system based on SCFG. Since the joint name tagger ensures that each tagged source name has a corresponding translation on the target side (and vice versa), we can extract SCFG rules by treating the tagged names as non-terminals.

However, the original parallel corpora contain many high-frequency names, which can already be handled well by the baseline MT. Some of these names carry special meanings that may influence translations of the neighboring words, and thus replacing them with non-terminals can lead to information loss and weaken the translation model. To address this issue, we merged the name-replaced parallel data with the original parallel data and extract grammars from the combined corpus. For example, given the following sentence pair:

- 中国 反对 外来 势力 介入 安哥拉 冲突 .
- China appeals to world for non involvement in Angola conflict .

after name tagging it becomes

- GPE 反对 外来 势力 介入 GPE 冲突 .
- GPE appeals to world for non involvement in GPE conflict .

Both sentence pairs are kept in the combined data to build the translation model.

### 3.2 Decoding

During decoding phase, we extract names with the baseline monolingual name tagger described in (Li et al., 2012) from a source document. Its performance is comparable to the best reported results on Chinese name tagging on Automatic Content Extraction (ACE) data (Ji and Grishman, 2006; Florian et al., 2006; Zitouni and Florian, 2008; Nguyen et al., 2010). Then we apply a state-of-the-art name translation system (Ji et al., 2009) to translate names into the target language. The name translation system is composed of the following steps: (1) Dictionary matching based on 150,041 name translation pairs; (2) Statistical name transliteration based on a structured perceptron model and a character based MT model (Dayne and Shahram, 2007); (3) Context information extraction based re-ranking.

In our NAMT framework, we add the following extensions to name translation.

We developed a name origin classifier based on Chinese last name list (446 name characters) and name structure parsing features to distinguish Chinese person names and foreign person names (Ji, 2009), so that pinyin conversion is applied for Chinese names while name transliteration is applied only for foreign names. This classifier works reasonably well in most cases (about 92% classification accuracy), except when a common Chinese last name appears as the first character of a foreign

name, such as “朱莉” which can be translated either as “Jolie” or “Zhu Li”.

For those names with fewer than five instances in the training data, we use the name translation system to provide translations; for the rest of the names, we leave them to the baseline MT model to handle. The joint bilingual name tagger was also exploited to mine bilingual name translation pairs from parallel training corpora. The mapping score between a Chinese name and an English name was computed by the number of aligned tokens. A name pair is extracted if the mapping score is the highest among all combinations and the name types on both sides are identical. It is necessary to incorporate word alignment as additional constraints because the order of names is often changed after translation. Finally, the extracted 9,963 unique name translation pairs were also used to create an additional name phrase table for NAMT. Manual evaluation on 2,000 name pairs showed the accuracy is 86%.

The non-terminals in SCFG rules are rewritten to the extracted names during decoding, therefore allow unseen names in the test data to be translated. Finally, based on LMs, our decoder exploits the dynamically created phrase table from name translation, competing with originally extracted rules, to find the best translation for the input sentence.

#### 4 Name-aware MT Evaluation

Traditional MT evaluation metrics such as BLEU (Papineni et al., 2002) and Translation Edit Rate (TER) (Snover et al., 2006) assign the same weights to all tokens equally. For example, incorrect translations of “the” and “Bush” will receive the same penalty. However, for cross-lingual information processing applications, we should acknowledge that certain informationally critical words are more important than other common words. In order to properly evaluate the translation quality of NAMT methods, we propose to modify the BLEU metric so that they can dynamically assign more weights to names during evaluation.

BLEU considers the correspondence between a system translation and a human translation:

$$\text{BLEU} = BP \cdot \exp\left(\sum_{n=1}^N w_n \log p_n\right) \quad (1)$$

where  $BP$  is brevity penalty defined as follows:

$$BP = \begin{cases} 1 & \text{if } c > r, \\ e^{(1-r/c)} & \text{if } c \leq r. \end{cases} \quad (2)$$

where  $w_n$  is a set of positive weights summing to one and usually uniformly set as  $w_n = 1/N$ ,  $c$  is the length of the system translation and  $r$  is the length of reference translation, and  $p_n$  is modified n-gram precision defined as:

$$p_n = \frac{\sum_{C \in \text{Candidates}} \sum_{\text{n-gram} \in C} \text{Count}_{clip}(\text{n-gram})}{\sum_{C' \in \text{Candidates}} \sum_{\text{n-gram}' \in C'} \text{Count}_{clip}(\text{n-gram}')} \quad (3)$$

where  $C$  and  $C'$  are translation candidates in the candidate sentence set, if a source sentence is translated to many candidate sentences.

As in BLEU metric, we first count the maximum number of times an n-gram occurs in any single reference translation. The total count of each candidate n-gram is clipped at sentence level by its maximum reference count. Then we add up the weights of clipped n-grams and divide them by the total weight of all n-grams.

Based on BLEU score, we design a name-aware BLEU metric as follows. Depending on whether a token  $t$  is contained in a name in reference translation, we assign a weight  $weight_t$  to  $t$  as follows:

$$weight_t = \begin{cases} 1 - e^{-tf(t,d) \cdot idf(t,D)}, & \text{if } t \text{ never appears in names} \\ 1 + \frac{PE}{Z}, & \text{if } t \text{ occurs in name(s)} \end{cases} \quad (4)$$

where  $PE$  is the sum of penalties of non-name tokens and  $Z$  is the number of tokens within all names:

$$PE = \sum_{t \text{ never appears in names}} e^{-tf(t,d) \cdot idf(t,D)} \quad (5)$$

In this paper, the  $tf \cdot idf$  score is computed at sentence level, therefore,  $D$  is the sentence set and each  $d \in D$  is a sentence.

The weight of an n-gram in reference translation is the sum of weights of all tokens it contains.

$$weight_{ngram} = \sum_{t \in ngram} weight_t \quad (6)$$

Next, we compute the weighted modified n-gram precision  $Count_{weight-clip}(\text{n-gram})$  as follows:

$$Count_{weight-clip}(\text{n-gram}) = \sum_{\text{if the } ngram_i \text{ is correctly translated}} weight_{ngram_i} \quad (7)$$

The  $Count_{clip}(n\text{-gram})$  in the equation 3 is substituted with above  $Count_{weight-clip}(n\text{-gram})$ . When we sum up the total weight of all n-grams of a candidate translation, some n-grams may contain tokens which do not exist in reference translation. We assign the lowest weight of tokens in reference translation to these rare tokens.

We also add an item, name penalty  $NP$ , to penalize the output sentences which contain too many or too few names:

$$NP = e^{-\left(\frac{u}{v}-1\right)^2/2\sigma} \quad (8)$$

where  $u$  is the number of name tokens in system translation and  $v$  is the number of name tokens in reference translation.

Finally the name-aware BLEU score is defined as:

$$BLEU_{NA} = BP \cdot NP \cdot \exp\left(\sum_{n=1}^N w_n \log wp_n\right) \quad (9)$$

This new metric can also be applied to evaluate MT approaches which emphasize other types of facts such as events, by simply replacing name tokens by other fact tokens.

## 5 Experiments

In this section we present the experimental results of NAMT compared to the baseline MT.

### 5.1 Data Set

We used a large Chinese-English MT training corpus from various sources and genres (including newswire, web text, broadcast news and broadcast conversations) for our experiments. We also used some translation lexicon data and Wikipedia translations. The majority of the data sets were collected or made available by LDC for U.S. DARPA Translingual Information Detection, Extraction and Summarization (TIDES) program, Global Autonomous Language Exploitation (GALE) program, Broad Operational Language Translation (BOLT) program and National Institute of Standards and Technology (NIST) MT evaluations. The training corpus includes 1,686,458 sentence pairs. The joint name tagger extracted 1,890,335 name pairs (295,087 Persons, 1,269,056 Geopolitical entities and 326,192 Organizations).

Four LMs, denoted LM1, LM2, LM3, and LM4, were trained from different English corpora. LM1 is a 7-gram LM trained on the tar-

get side of Chinese-English and Egyptian Arabic-English parallel text, English monolingual discussion forums data R1-R4 released in BOLT Phase 1 (LDC2012E04, LDC2012E16, LDC2012E21, LDC2012E54), and English Gigaword Fifth Edition (LDC2011T07). LM2 is a 7-gram LM trained only on the English monolingual discussion forums data listed above. LM3 is a 4-gram LM trained on the web genre among the target side of all parallel text (i.e., web text from pre-BOLT parallel text and BOLT released discussion forum parallel text). LM4 is a 4-gram LM trained on the English broadcast news and conversation transcripts released under the DARPA GALE program. Note that for LM4 training data, some transcripts were quick transcripts and quick rich transcripts released by LDC, and some were generated by running flexible alignment of closed captions or speech recognition output from LDC on the audio data (Venkataraman et al., 2004).

In order to demonstrate the effectiveness and generality of our approach, we evaluated our approach on seven test sets from multiple genres and domains. We asked four annotators to annotate names in four reference translations of each sentence and an expert annotator to adjudicate results. The detailed statistics and name distribution of each test data set is shown in Table 1. The percentage of names occurred fewer than 5 times in training data are listed in the brackets in the last column of the table.

### 5.2 Overall Performance

Besides the new name-aware MT metric, we also adopt two traditional metrics, TER to evaluate the overall translation performance and Named Entity Weak Accuracy (NEWA) (Hermjakob et al., 2008) to evaluate the name translation performance.

TER measures the amount of edits required to change a system output into one of the reference translations. Specifically:

$$TER = \frac{\# \text{ of edits}}{\text{average } \# \text{ of reference words}} \quad (10)$$

Possible edits include insertion, substitution deletion and shifts of words.

The NEWA metric is defined as follows. Using a manually assembled name variant table, we also support the matching of name variants (e.g., “World Health Organization” and “WHO”).

$$NEWA = \frac{\text{Count } \# \text{ of correctly translated names}}{\text{Count } \# \text{ of names in references}} \quad (11)$$

Corpus	Genre	Sentence #	Word # in source	Token # in reference	GPE(%)	PER(%)	ORG(%)	All names (% occurred < 5)
BOLT 1	forum	1,200	20,968	24,193	875(82.9)	90(8.5)	91(8.6)	1,056 (51.4)

		NPhrase	50.5	50.3	54.4	40.7	41.3	42.2	40.7
		NAMT	<b>60.4</b>	<b>52.3</b>	<b>55.4</b>	<b>41.6</b>	<b>45.0</b>	<b>51.0</b>	<b>44.8</b>

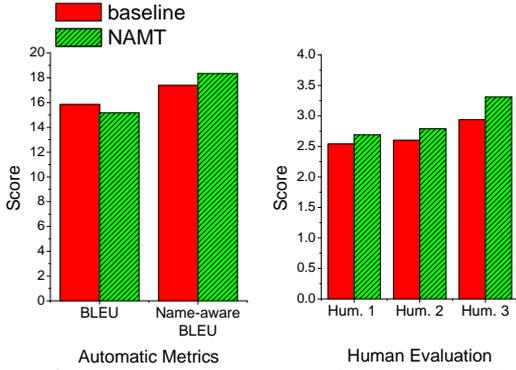

**Table 2:** Translation Performance (%).

For better comparison with NAMT, besides the original baseline, we develop the other baseline system by adding name translation table into the phrase table (NPhrase).

Table 2 presents the performance of overall translation and name translation. We can see that except for the BOLT3 data set with BLEU metric, our NAMT approach consistently outperformed the baseline system for all data sets with all metrics, and provided up to 23.6% relative error reduction on name translation. According to Wilcoxon Matched-Pairs Signed-Ranks Test, the improvement is not significant with BLEU metric, but is significant at 98% confidence level with all of the other metrics. The gains are more significant for formal genres than informal genres mainly because most of the training data for name tagging and name translation were from newswire. Furthermore, using external name translation table only did not improve translation quality in most test sets except for BOLT2. Therefore, it is important to use name-replaced corpora for rule extraction to fully take advantage of improved word alignment.

Many errors from the baseline MT approach oc-

curred because some parts of out-of-vocabulary names were mistakenly segmented into common words. For example, the baseline MT system mistakenly translated a person name “孙红雷 (*Sun Honglei*)” into “*Sun red thunder*”. In informal genres such as discussion forums and web blogs, even common names often appear in rare forms due to misspelling or morphing. For example, “奥巴马 (*Obama*)” was mistakenly translated into “*Ma Olympic*”. Such errors can be compounded when word re-ordering was applied. For example, the following sentence: “郭美美的力量还真是强大啊，真是佩服她 (*Guo Meimei’s strength really is formidable, I really admire her*)” was mistakenly translated into “*Guo the strength of the America and the America also really strong, ah, really admire her*” by the baseline MT system because the person name “郭美美 (*Guomeimei*)” was mistakenly segmented into three words “郭 (*Guo*)”, “美 (*the America*)” and “美 (*the America*)”. But our NAMT approach successfully identified and translated this name and also generated better overall translation: “*Guo Meimei’s power is also really strong, ah, really admire her*”.

**Figure 2:** Scores based on Automatic Metrics and Human Evaluation.

### 5.3 Name-aware BLEU vs The Human Evaluation

In order to investigate the correlation between name-aware BLEU scores and human judgment results, we asked three bi-lingual speakers to judge our translation output from the baseline system and the NAMT system, on a Chinese subset of 250 sentences (each sentence has two corresponding translations from baseline and NAMT) extracted randomly from 7 test corpora. The annotators rated each translation from 1 (very bad) to 5 (very good) and made their judgments based on whether the translation is understandable and conveys the same meaning.

We computed the name-aware BLEU scores on the subset and also the aggregated average scores from human judgments. Figure 2 shows that NAMT consistently achieved higher scores with both name-aware BLEU metric and human judgment. Furthermore, we calculated three Pearson product-moment correlation coefficients between human judgment scores and name-aware BLEU scores of these two MT systems. Give the sample size and the correlation coefficient value, the high significance value of 0.99 indicates that name-aware BLEU tracks human judgment well.

### 5.4 Word Alignment

It is also important to investigate the impact of our NAMT approach on improving word alignment. We conducted the experiment on the Chinese-English Parallel Treebank (Li et al., 2010) with ground-truth word alignment. The detailed procedure following NAMT framework is as follows: (1) Ran the joint bilingual name tagger; (2) Replaced each name string with its name type (PER, ORG or GPE), and ran Giza++ on the replaced sentences; (3) Ran Giza++ on the words within

Words	Method	P	R	F
Overall Words	Baseline Giza++	69.8	47.8	56.7
	Joint Name Tagging	<b>70.4</b>	<b>48.1</b>	<b>57.1</b>
	Ground-truth Name Tagging (Upper-bound)	71.3	48.9	58.0
Words Within Names	Baseline Giza++	86.0	31.4	46.0
	Joint Name Tagging	<b>77.6</b>	<b>37.2</b>	<b>50.3</b>

**Table 3:** Impact of Joint Bilingual Name Tagging on Word Alignment (%).

each name pair. (4) Merged (2) and (3) to produce the final word alignment results. In order to compare with the upper-bound gains, we also measured the performance of applying ground-truth name tagging with the above procedures.

The experiment results are shown in Table 3. For the words within names, our approach provided significant gains by enhancing F-measure from 46.0% to 50.3%. Only 10.6% words are within names, therefore the upper-bound gains on overall word alignment is only 1.3%. Our joint name tagging approach achieved 0.4% (statistically significant) improvement over the baseline. In Figure 3 we categorized the sentences according to the percentage of name words in each sentence and measured the improvement for each category. We can clearly see that as the sentences include more names, the gains achieved by our approach tend to be greater.

### 5.5 Remaining Error Analysis

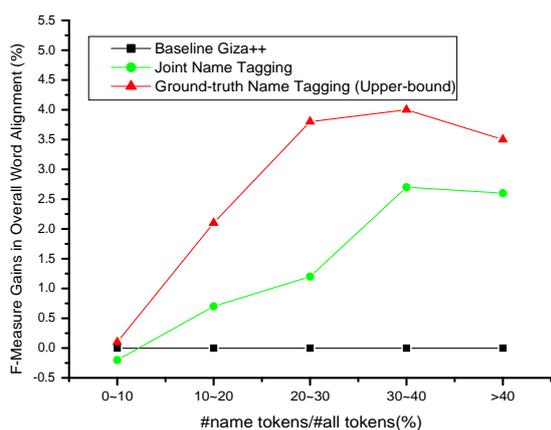

Although the proposed model has significantly enhanced translation quality, some challenges remain. We analyze some major sources of the remaining errors as follows.

#### 1. Name Structure Parsing.

We found that the gains of our NAMT approach were mainly achieved for names with one or two components. When the name structure becomes too complicated to parse, name tagging and name translation are likely to produce errors, especially for long nested organizations. For example, “古田县 检察院 反渎局” (Anti-malfeasance Bureau of Gutian County Procuratorate) consists of a nested organization name with a GPE as modifier: “古田县 检察院” (Gutian County Procuratorate) and an ORG name: “反渎局” (Anti-malfeasance Bureau).

#### 2. Name abbreviation tagging and translation.

Some organization abbreviations are also difficult to extract because our name taggers have

**Figure 3:** Word alignment gains according to the percentage of name words in each sentence.

not incorporated any coreference resolution techniques. For example, without knowing that “FAW” refers to “*First Automotive Works*” in “*FAW has also utilized the capital market to directly finance, and now owns three domestic listed companies*”, our system mistakenly labeled it as a GPE. The same challenge exists in name alignment and translation (for example, “民革 (Min Ge)” refers to “*中国国民党革命委员会*” (Revolutionary Committee of the Chinese Kuomintang).

### 3. Cross-lingual information transfer

English monolingual features normally generate higher confidence than Chinese features for ORG names. On the other hand, some good propagated Chinese features were not able to correct English results. For example, in the following sentence pair: “根据中国，老挝和联合国难民署三方达成的... (*in accordance with the tripartite agreement reached by China, Laos and the UNHCR on*)...”, even though the tagger can successfully label “联合国难民署/UNHCR” as an organization because it is a common Chinese name, English features based on previous GPE contexts still incorrectly predicted “UNHCR” as a GPE name.

## 6 Related Work

Two types of humble strategies were previously attempted to build name translation components which operate in tandem and loosely integrate into conventional statistical MT systems:

1. *Pre-processing*: identify names in the source texts and propose name translations to the MT system; the name translation results can be simply but aggressively transferred from the source to the target side using word alignment, or added into phrase table in order to

enable the LM to decide which translations to choose when encountering the names in the texts (Ji et al., 2009). Heuristic rules or supervised models can be developed to create “do-not-translate” list (Babych and Hartley, 2003) or learn “when-to-transliterate” (Hermjakob et al., 2008).

2. *Post-processing*: in a cross-lingual information retrieval or question answering framework, online query names can be utilized to obtain translation and post-edit MT output (Parton et al., 2009; Ma and McKeown, 2009; Parton and McKeown, 2010; Parton et al., 2012).

It is challenging to decide when to use name translation results. The simple transfer method ensures all name translations appear in the MT output, but it heavily relies on word alignment and does not take into account word re-ordering or the words found in a name’s context; therefore it could mistakenly break some context phrase structures due to name translation or alignment errors. The LM selection method often assigns an inappropriate weight to the additional name translation table because it is constructed independently from translation of context words; therefore after weighted voting most correct name translations are not used in the final translation output. Our experimental results 2 confirmed this weakness. More importantly, in these approaches the MT model was still mostly treated as a “black-box” because neither the translation model nor the LM was updated or adapted specifically for names.

Recently the wider idea of incorporating semantics into MT has received increased interests. Most of them designed some certain semantic representations, such as predicate-argument structure or semantic role labeling (Wu and Fung, 2009; Liu and Gildea, 2009; Meyer et al., 2011; Bojar and Wu, 2012), word sense disambiguation (Carpuat and Wu, 2007b; Carpuat and Wu, 2007a) and graph-structured grammar representation (Jones et al., 2012). Lo et al. (2012) proposed a semantic role driven MT metric. However, none of these work declaratively exploited results from information extraction for MT.

Some statistical MT systems (e.g. (Zens et al., 2005), (Aswani and Gaizauskas, 2005)) have attempted to use text normalization to improve word alignment for dates, numbers and job titles. But little reported work has shown the impact of joint

name tagging on overall word alignment.

Most of the previous name translation work combined supervised transliteration approaches with LM based re-scoring (Knight and Graehl, 1998; Al-Onaizan and Knight, 2002; Huang et al., 2004). Some recent research used comparable corpora to mine name translation pairs (Feng et al., 2004; Kutsumi et al., 2004; Udupa et al., 2009; Ji, 2009; Fung and Yee, 1998; Rapp, 1999; Shao and Ng, 2004; Lu and Zhao, 2006; Hassan et al., 2007). However, most of these approaches required large amount of seeds, suffered from Information Extraction errors, and relied on phonetic similarity, context co-occurrence and document similarity for re-scoring. In contrast, our name pair mining approach described in this paper does not require any machine translation or transliteration features.

## 7 Conclusions and Future Work

We developed a name-aware MT framework which tightly integrates name tagging and name translation into training and decoding of MT. Experiments on Chinese-English translation demonstrated the effectiveness of our approach over a high-quality MT baseline in both overall translation and name translation, especially for formal genres. We also proposed a new name-aware evaluation metric. In the future we intend to improve the framework by training a discriminative model to automatically assign weights to combine name translation and baseline translation with additional features including name confidence values, name types and global validation evidence, as well as conducting LM adaptation through bilingual topic modeling and clustering based on name annotations. We also plan to jointly optimize MT and name tagging by propagating multiple word segmentation and name annotation hypotheses in lattice structure to statistical MT and conduct lattice-based decoding (Dyer et al., 2008). Furthermore, we are interested in extending this framework to translate other out-of-vocabulary terms.

## Abstract

In this paper we show that even for the case of 1:1 substitution ciphers—which encipher plaintext symbols by exchanging them with a unique substitute—finding the optimal decipherment with respect to a bigram language model is NP-hard. We show that in this case the decipherment problem is equivalent to the quadratic assignment problem (QAP). To the best of our knowledge, this connection between the QAP and the decipherment problem has not been known in the literature before.

## 1 Introduction

The decipherment approach for MT has recently gained popularity for training and adapting translation models using only monolingual data. The general idea is to find those translation model parameters that maximize the probability of the translations of a given source text in a given language model of the target language.

In general, the process of translation has a wide range of phenomena like substitution and reordering of words and phrases. In this paper we only study models that substitute tokens—i.e. words or letters—with a unique substitute. It therefore serves as a very basic case for decipherment and machine translation.

Multiple techniques like integer linear programming (ILP),  $A^*$  search, genetic algorithms, and Bayesian inference have been used to tackle the decipherment problem for 1:1 substitution ciphers. The existence of such a variety of different approaches for solving the same problem already shows that there is no obvious way to solve the problem optimally.

In this paper we show that decipherment of 1:1 substitution ciphers is indeed NP-hard and thus ex-

plain why there is no single best approach to the problem. The literature on decipherment provides surprisingly little on the analysis of the complexity of the decipherment problem. This might be related to the fact that a statistical formulation of the decipherment problem has not been analyzed with respect to  $n$ -gram language models: This paper shows the close relationship of the decipherment problem to the quadratic assignment problem. To the best of our knowledge the connection between the decipherment problem and the quadratic assignment problem was not known.

The remainder of this paper is structured as follows: In Section 2 we review related work. Section 3 introduces the decipherment problem and describes the notation and definitions used throughout this paper. In Section 4 we show that decipherment using a unigram language model corresponds to solving a linear sum assignment problem (LSAP). Section 5 shows the connection between the quadratic assignment problem and decipherment using a bigram language model. Here we also give a reduction of the traveling salesman problem (TSP) to the decipherment problem to highlight the additional complexity in the decipherment problem.

## 2 Related Work

In recent years a large number of publications on the automatic decipherment of substitution ciphers has been published. These publications were mostly dominated by rather heuristic methods and did not provide a theoretical analysis of the complexity of the decipherment problem: (Knight and Yamada, 1999) and (Knight et al., 2006) use the EM algorithm for various decipherment problems, like e.g. word substitution ciphers. (Ravi and Knight, 2008) and (Corlett and Penn, 2010) are able to obtain optimal (i.e. without search errors) decipherments of short cryptograms given an  $n$ -

gram language model. (Ravi and Knight, 2011), (Nuhn et al., 2012), and (Dou and Knight, 2012) treat natural language translation as a deciphering problem including phenomena like reordering, insertion, and deletion and are able to train translation models using only monolingual data.

In this paper we will show the connection between the decipherment problem and the linear sum assignment problem as well as the quadratic assignment problem: Regarding the linear sum assignment problem we will make use of definitions presented in (Burkard and el a, 1999). Concerning the quadratic assignment problem we will use basic definitions from (Beckmann and Koopmans, 1957). Further (Burkard et al., 1998) gives a good overview over the quadratic assignment problem, including different formulations, solution methods, and an analysis of computational complexity. The paper also references a vast amount of further literature that might be interesting for future research.

### 3 Definitions

In the following we will use the machine translation notation and denote the **ciphertext** with  $f_1^N = f_1 \dots f_j \dots f_N$  which consists of cipher tokens  $f_j \in V_f$ . We denote the **plaintext** with  $e_1^N = e_1 \dots e_i \dots e_N$  (and its vocabulary  $V_e$  respectively). We define

$$e_0 = f_0 = e_{N+1} = f_{N+1} = \$ \quad (1)$$

with “\$” being a special sentence boundary token. We use the abbreviations  $\bar{V}_e = V_e \cup \{\$\}$  and  $\bar{V}_f$  respectively.

A **general substitution cipher** uses a table  $s(e|f)$  which contains for each cipher token  $f$  a probability that the token  $f$  is substituted with the plaintext token  $e$ . Such a table for substituting cipher tokens  $\{A, B, C, D\}$  with plaintext tokens  $\{a, b, c, d\}$  could for example look like

	a	b	c	d
A	0.1	0.2	0.3	0.4
B	0.4	0.2	0.1	0.3
C	0.4	0.1	0.2	0.3
D	0.3	0.4	0.2	0.1

The **1:1 substitution cipher** encrypts a given plaintext into a ciphertext by replacing each plaintext token with a unique substitute: This means that the table  $s(e|f)$  contains all zeroes, except for

one “1.0” per  $f \in V_f$  and one “1.0” per  $e \in V_e$ . For example the text

abadcab

would be enciphered to

BCBADBC

when using the substitution

	a	b	c	d
A	0	0	0	1
B	1	0	0	0
C	0	1	0	0
D	0	0	1	0

We formalize the 1:1 substitutions with a bijective function  $\phi : V_f \rightarrow V_e$ . The general **decipherment goal** is to obtain a mapping  $\phi$  such that the probability of the deciphered text is maximal:

$$\hat{\phi} = \arg \max_{\phi} p(\phi(f_1)\phi(f_2)\phi(f_3)\dots\phi(f_N)) \quad (2)$$

Here  $p(\dots)$  denotes the **language model**. Depending on the structure of the language model Equation 2 can be further simplified.

Given a ciphertext  $f_1^N$ , we define the **unigram count**  $N_f$  of  $f \in \bar{V}_f$  as<sup>1</sup>

$$N_f = \sum_{i=0}^{N+1} \delta(f, f_i) \quad (3)$$

This implies that  $N_f$  are integer counts  $> 0$ . We similarly define the **bigram count**  $N_{ff'}$  of  $f, f' \in \bar{V}_f$  as

$$N_{ff'} = \sum_{i=1}^{N+1} \delta(f, f_{i-1}) \cdot \delta(f', f_i) \quad (4)$$

This definition implies that

- (a)  $N_{ff'}$  are integer counts  $> 0$  of bigrams found in the ciphertext  $f_1^N$ .
- (b) Given the first and last token of the cipher  $f_1$  and  $f_N$ , the bigram counts involving the sentence boundary token \$ need to fulfill

$$N_{\$f} = \delta(f, f_1) \quad (5)$$

$$N_{f\$} = \delta(f, f_N) \quad (6)$$

- (c) For all  $f \in V_f$

$$\sum_{f' \in V_f} N_{ff'} = \sum_{f' \in V_f} N_{f'f} \quad (7)$$

must hold.

<sup>1</sup>Here  $\delta$  denotes the Kronecker delta.

Similarly, we define language model matrices  $S$  for the unigram and the bigram case. The **unigram language model**  $S_f$  is defined as

$$S_f = \log p(f) \quad (8)$$

which implies that

(a)  $S_f$  are real numbers with

$$S_f \in [-\infty, 0] \quad (9)$$

(b) The following normalization constraint holds:

$$\sum_{f \in V_f} \exp(S_f) = 1 \quad (10)$$

Similarly for the **bigram language model matrix**  $S_{ff'}$ , we define

$$S_{ff'} = \log p(f'|f) \quad (11)$$

This definition implies that

(a)  $S_{ff'}$  are real numbers with

$$S_{ff'} \in [-\infty, 0] \quad (12)$$

(b) For the sentence boundary symbol, it holds that

$$S_{\S\S} = -\infty \quad (13)$$

(c) For all  $f \in \overline{V_f}$  the following normalization constraint holds:

$$\sum_{f' \in \overline{V_f}} \exp(S_{ff'}) = 1 \quad (14)$$

## 4 Decipherment Using Unigram LMs

### 4.1 Problem Definition

When using a unigram language model, Equation 2 simplifies to finding

$$\hat{\phi} = \arg \max_{\phi} \prod_{i=1}^N p(\phi(f_i)) \quad (15)$$

which can be rewritten as

$$\hat{\phi} = \arg \max_{\phi} \sum_{f \in V_f} N_f S_{\phi}(f) \quad (16)$$

When defining  $c_{ff'} = N_f \log p(f')$ , for  $f, f' \in V_f$ , Equation 16 can be brought into the form of

$$\hat{\phi} = \arg \max_{\phi} \sum_{f \in V_f} c_{f\phi}(f) \quad (17)$$

Figure 1 shows an illustration of this problem.

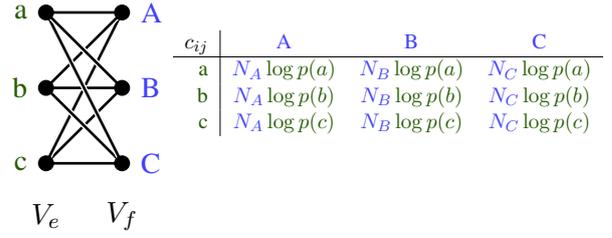

Figure 1: Linear sum assignment problem for a cipher with  $V_e = \{a, b, c\}$ ,  $V_f = \{A, B, C\}$ , unigram counts  $N_f$ , and unigram probabilities  $p(e)$ .

## 4.2 The Linear Sum Assignment Problem

The practical problem behind the linear sum assignment problem can be described as follows: Given jobs  $\{j_1, \dots, j_n\}$  and workers  $\{w_1, \dots, w_n\}$ , the task is to assign each job  $j_i$  to a worker  $w_j$ . Each assignment incurs a cost  $c_{ij}$  and the total cost for assigning all jobs and workers is to be minimized.

This can be formalized as finding the assignment

$$\hat{\phi} = \arg \min_{\phi} \sum_{i=1}^n c_{i\phi(i)} \quad (18)$$

The general LSAP can be solved in polynomial time using the Hungarian algorithm (Kuhn, 1955). However, since the matrix  $c_{ij}$  occurring for the decipherment using a unigram language model can be represented as the product  $c_{ij} = a_i \cdot b_j$  the decipherment problem can be solved more easily: In the Section “Optimal Matching”, (Bauer, 2010) shows that in this case the optimal assignment is found by sorting the jobs  $j_i$  by  $a_i$  and workers  $w_j$  by  $b_j$  and then assigning the jobs  $j_i$  to workers  $w_j$  that have the same rank in the respective sorted lists. Sorting and then assigning the elements can be done in  $\mathcal{O}(n \log n)$ .

## 5 Decipherment Using Bigram LMs

### 5.1 Problem Definition

When using a 2-gram language model, Equation 2 simplifies to

$$\hat{\phi} = \arg \max_{\phi} \left\{ \prod_{j=1}^{N+1} p(\phi(f_j) | \phi(f_{j-1})) \right\} \quad (19)$$

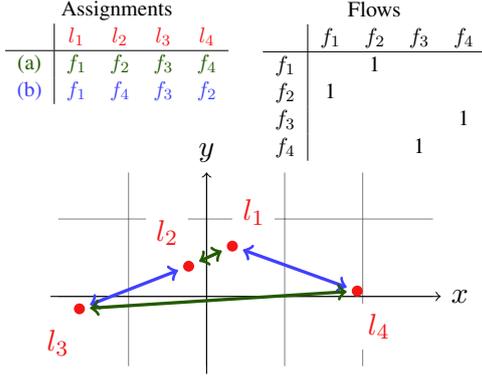

Figure 2: Hypothetical quadratic assignment problem with locations  $l_1 \dots l_4$  and facilities  $f_1 \dots f_4$  with all flows being zero except  $f_1 \leftrightarrow f_2$  and  $f_3 \leftrightarrow f_4$ . The distance between locations  $l_1 \dots l_4$  is implicitly given by the locations in the plane, implying a euclidean metric. Two example assignments (a) and (b) are shown, with (b) having the lower overall costs.

Using the definitions from Section 3, Equation 19 can be rewritten as

$$\hat{\phi} = \arg \max_{\phi} \left\{ \sum_{f \in V_f} \sum_{f' \in V_f} N_{ff'} S_{\phi(f)\phi(f')} \right\} \quad (20)$$

(Bauer, 2010) arrives at a similar optimization problem for the “combined method of frequency matching” using bigrams and mentions that it can be seen as a combinatorial problem for which an efficient way of solving is not known. However, he does not mention the close connection to the quadratic assignment problem.

## 5.2 The Quadratic Assignment Problem

The quadratic assignment problem was introduced by (Beckmann and Koopmans, 1957) for the following real-life problem:

Given a set of facilities  $\{f_1, \dots, f_n\}$  and a set of locations  $\{l_1, \dots, l_n\}$  with distances for each pair of locations, and flows for each pair of facilities (e.g. the amount of supplies to be transported between a pair of facilities) the problem is to assign the facilities to locations such that the sum of the distances multiplied by the corresponding flows (which can be interpreted as total transportation costs) is minimized. This is visualized in Figure 2.

Following (Beckmann and Koopmans, 1957) we can express the quadratic assignment problem

as finding

$$\hat{\phi} = \arg \min_{\phi} \left\{ \sum_{i=1}^n \sum_{j=1}^n a_{ij} b_{\phi(i)\phi(j)} + \sum_{i=1}^n c_{i\phi(i)} \right\} \quad (21)$$

where  $A = (a_{ij}), B = (b_{ij}), C = (c_{ij}) \in \mathbb{N}^{n \times n}$  and  $\phi$  a permutation

$$\phi : \{1, \dots, n\} \rightarrow \{1, \dots, n\}. \quad (22)$$

This formulation is often referred to as Koopman-Beckman QAP and often abbreviated as QAP( $A, B, C$ ). The so-called *pure* or *homogeneous* QAP

$$\hat{\phi} = \arg \min_{\phi} \left\{ \sum_{i=1}^n \sum_{j=1}^n a_{ij} b_{\phi(i)\phi(j)} \right\} \quad (23)$$

is obtained by setting  $c_{ij} = 0$ , and is often denoted as QAP( $A, B$ ).

In terms of the real-life problem presented in (Beckmann and Koopmans, 1957) the matrix  $A$  can be interpreted as distance matrix for locations  $\{l_1 \dots l_n\}$  and  $B$  as flow matrix for facilities  $\{f_1 \dots f_n\}$ .

(Sahni and Gonzalez, 1976) show that the quadratic assignment problem is strongly NP-hard.

We will now show the relation between the quadratic assignment problem and the decipherment problem.

### 5.3 Decipherment Problem $\preceq$ Quadratic Assignment Problem

Every decipherment problem is directly a quadratic assignment problem, since the matrices  $N_{ff'}$  and  $S_{ff'}$  are just special cases of the general matrices  $A$  and  $B$  required for the quadratic assignment problem. Thus a reduction from the decipherment problem to the quadratic assignment problem is trivial. This means that all algorithms capable of solving QAPs can directly be used to solve the decipherment problem.

### 5.4 Quadratic Assignment Problem $\preceq$ Decipherment Problem

Given QAP( $A, B$ ) with integer matrices  $A = (a_{ij}), B = (b_{ij}) i, j \in \{1, \dots, n\}$  we construct the count matrix  $N_{ff'}$  and language model matrix  $S_{ff'}$  in such a way that the solution for the decipherment problem implies the solution to the

quadratic assignment problem, and vice versa. We will use the vocabularies  $\bar{V}_e = \bar{V}_f = \{1, \dots, n+3\}$ , with  $n+3$  being the special sentence boundary token “\$”. The construction of  $N_{ff'}$  and  $S_{ff'}$  is shown in Figure 3.

To show the validity of our construction, we will

1. Show that  $N_{ff'}$  is a valid count matrix.
2. Show that  $S_{ff'}$  is a valid bigram language model matrix.
3. Show that the decipherment problem and the newly constructed quadratic assignment problem are equivalent.

We start by showing that  $N_{ff'}$  is a valid count matrix:

- (a) By construction,  $N_{ff'}$  has integer counts that are greater or equal to 0.
- (b) By construction,  $N_{ff'}$  at boundaries is:
  - $N_{f\$} = \delta(f, 1)$
  - $N_{f\$} = \delta(f, n+2)$

- (c) Regarding the properties  $\sum_{f'} N_{ff'} = \sum_{f'} N_{f'f}$ :

- For all  $f \in \{1, \dots, n\}$  the count properties are equivalent to

$$\tilde{a}_{f*} + \sum_{f'} \tilde{a}_{ff'} = \tilde{a}_{*f} + \sum_{f'} \tilde{a}_{f'f} + \delta(f, 1) \quad (24)$$

which holds by construction of  $\tilde{a}_{*f}$  and  $\tilde{a}_{f*}$ .

- For  $f = n+1$  the count property is equivalent to

$$1 + \sum_{f'} \tilde{a}_{f'*} = 2 + \sum_{f'} \tilde{a}_{*f'} \quad (25)$$

which follows from Equation (24) by summing over all  $f \in \{1, \dots, n\}$ .

- For  $f = n+2$  and  $f = n+3$ , the condition is fulfilled by construction.

We now show that  $S_{ff'}$  is a valid bigram language model matrix:

- (a) By construction,  $S_{ff'} \in [-\infty, 0]$  holds.
- (b) By construction,  $S_{\$\$} = -\infty$  holds.

- (c) By the construction of  $\tilde{b}_{f*}$ , the values  $S_{ff'}$  fulfill  $\sum_{f'} \exp(S_{ff'}) = 1$  for all  $f$ . This works since all entries  $\tilde{b}_{ff'}$  are chosen to be smaller than  $-\log(n+2)$ .

We now show the equivalence of the quadratic assignment problem and the newly constructed decipherment problem. For this we will use the definitions

$$\tilde{A} = \{1, \dots, n\} \quad (26)$$

$$\tilde{B} = \{n+1, n+2, n+3\} \quad (27)$$

We first show that solutions of the constructed decipherment problem with score  $> -\infty$  fulfill  $\phi(f) = f$  for  $f \in \tilde{B}$ .

All mappings  $\phi$ , with  $\phi(f) = f'$  for any  $f \in \tilde{A}$  and  $f' \in \tilde{B}$  will induce a score of  $-\infty$  since for  $f \in \tilde{A}$  all  $N_{ff} > 0$  and  $S_{ff'} = -\infty$  for  $f' \in \tilde{B}$ . Thus any  $\phi$  with score  $> -\infty$  will fulfill  $\phi(f) \in \tilde{B}$  for  $f \in \tilde{B}$ . Further, by enumerating all six possible permutations, it can be seen that only the  $\phi$  with  $\phi(f) = f$  for  $f \in \tilde{B}$  induces a score of  $> -\infty$ . Thus we can rewrite

$$\sum_{f=1}^{n+3} \sum_{f'=1}^{n+3} N_{ff'} S_{\phi(f)\phi(f')} \quad (28)$$

to

$$\underbrace{\sum_{f \in \tilde{A}} \sum_{f' \in \tilde{A}} N_{ff'} S_{\phi(f)\phi(f')}}_{(AA)} + \underbrace{\sum_{f \in \tilde{A}} \sum_{f' \in \tilde{B}} N_{ff'} S_{\phi(f)f'}}_{(AB)} + \underbrace{\sum_{f \in \tilde{B}} \sum_{f' \in \tilde{A}} N_{ff'} S_{f\phi(f')}}_{(BA)} + \underbrace{\sum_{f \in \tilde{B}} \sum_{f' \in \tilde{B}} N_{ff'} S_{ff'}}_{(BB)}$$

Here

- (AB) is independent of  $\phi$  since

$$\forall f \in \tilde{A}, f' \in \{n+1, n+2, n+3\} : S_{ff'} = S_{1f'} \quad (29)$$

and

$$\forall f \in \tilde{A} : N_{f,n+2} = 0 \quad (30)$$

- (BA) is independent of  $\phi$  since

$$\forall f' \in \tilde{A}, f \in \tilde{B} : S_{ff'} = S_{f1} \quad (31)$$

- (BB) is independent of  $\phi$ .

$$N_{ff'} = \left( \begin{array}{cccc|ccc} \tilde{a}_{11} & \tilde{a}_{12} & \cdots & \tilde{a}_{1n} & \tilde{a}_{1*} & 0 & 0 \\ \tilde{a}_{21} & \tilde{a}_{22} & \cdots & \tilde{a}_{2n} & \tilde{a}_{2*} & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \vdots \\ \tilde{a}_{n1} & \tilde{a}_{n2} & \cdots & \tilde{a}_{nn} & \tilde{a}_{n*} & 0 & 0 \\ \hline \tilde{a}_{*1} & \tilde{a}_{*2} & \cdots & \tilde{a}_{*n} & 0 & 2 & 0 \\ 0 & 0 & \cdots & 0 & 1 & 0 & 1 \\ \hline 1 & 0 & \cdots & 0 & 0 & 0 & 0 \end{array} \right)$$

$$S_{ff'} = \left( \begin{array}{cccc|ccc} \tilde{b}_{11} & \tilde{b}_{12} & \cdots & \tilde{b}_{1n} & \varepsilon_2 & \tilde{b}_{1*} & \varepsilon_2 \\ \tilde{b}_{21} & \tilde{b}_{22} & \cdots & \tilde{b}_{2n} & \varepsilon_2 & \tilde{b}_{2*} & \varepsilon_2 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \vdots \\ \tilde{b}_{n1} & \tilde{b}_{n2} & \cdots & \tilde{b}_{nn} & \varepsilon_2 & \tilde{b}_{n*} & \varepsilon_2 \\ \hline \varepsilon_1 & \varepsilon_1 & \cdots & \varepsilon_1 & -\infty & \varepsilon_1 & -\infty \\ \varepsilon_2 & \varepsilon_2 & \cdots & \varepsilon_2 & \varepsilon_2 & -\infty & \varepsilon_2 \\ \hline \varepsilon_0 & \varepsilon_0 & \cdots & \varepsilon_0 & -\infty & -\infty & -\infty \end{array} \right)$$

$$\tilde{a}_{ff'} = a_{ff'} - \min_{\tilde{f}\tilde{f}'} \{a_{\tilde{f}\tilde{f}'}\} + 1$$

$$\tilde{b}_{ff'} = b_{ff'} - \max_{\tilde{f}\tilde{f}'} \{b_{\tilde{f}\tilde{f}'}\} - \log(n+2)$$

$$\tilde{a}_{f*} = \max \left\{ \sum_{f'=1}^n a_{ff'} - a_{ff'}, 0 \right\} + \delta(f, 1)$$

$$\tilde{b}_{f*} = \log \left( 1 - \sum_{f'=1}^n \exp(\tilde{b}_{ff'}) - \frac{2}{n+2} \right)$$

$$\tilde{a}_{*f'} = \max \left\{ \sum_{f=1}^n a_{ff'} - a_{ff'}, 0 \right\}$$

$$\varepsilon_i = -\log(n+i)$$

Figure 3: Construction of matrices  $N_{ff'}$  and  $S_{ff'}$  of the decipherment problem from matrices  $A = (a_{ij})$  and  $B = (b_{ij})$  of the quadratic assignment problem  $QAP(A, B)$ .

Thus, with some constant  $c$ , we can finally rewrite Equation 28 as

$$c + \sum_{f=1}^n \sum_{f'=1}^n N_{ff'} S_{\phi(f)\phi(f')} \quad (32)$$

Inserting the definition of  $N_{ff'}$  and  $S_{ff'}$  (simplified using constants  $c'$ , and  $c''$ ) we obtain

$$c + \sum_{f=1}^n \sum_{f'=1}^n (a_{ff'} + c') (b_{\phi(f)\phi(f')} + c'') \quad (33)$$

which is equivalent to the original quadratic assignment problem

$$\arg \max \left\{ \sum_{f=1}^n \sum_{f'=1}^n a_{ff'} b_{\phi(f)\phi(f')} \right\} \quad (34)$$

Thus we have shown that a solution to the quadratic assignment problem in Equation 34 is a solution to the decipherment problem in Equation 20 and vice versa. Assuming that calculating elementary functions can be done in  $\mathcal{O}(1)$ , setting up  $N_{ff'}$  and  $S_{ff'}$  can be done in polynomial time.<sup>2</sup> Thus we have given a polynomial time reduction from the quadratic assignment problem to

<sup>2</sup>This is the case if we only require a fixed number of digits precision for the log and exp operations.

the decipherment problem: Since the quadratic assignment problem is NP-hard, it follows that the decipherment problem is NP-hard, too.

### 5.5 Traveling Salesman Problem $\preceq$ Decipherment Problem

Using the above construction we can immediately construct a decipherment problem that is equivalent to the traveling salesman problem by using the quadratic assignment problem formulation of the traveling salesman problem.

Without loss of generality<sup>3</sup> we assume that the TSP's distance matrix fulfills the constraints of a bigram language model matrix  $S_{ff'}$ . Then the count matrix  $N_{ff'}$  needs to be chosen as

$$N_{ff'} = \left( \begin{array}{ccccccc} 0 & 1 & 0 & \cdots & 0 & 0 & 0 \\ 0 & 0 & 1 & \cdots & 0 & 0 & 0 \\ 0 & 0 & 0 & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 0 & 1 & 0 \\ 0 & 0 & 0 & \cdots & 0 & 0 & 1 \\ 1 & 0 & 0 & \cdots & 0 & 0 & 0 \end{array} \right) \quad (35)$$

which fulfills the constraints of a bigram count matrix.

<sup>3</sup>The general case can be covered using the reduction shown in Section 5.

This matrix corresponds to a ciphertext of the form

$$\$abcd\$ \quad (36)$$

and represents the tour of the traveling salesman in an intuitive way. The mapping  $\phi$  then only decides in which order the cities are visited, and only costs between two successive cities are counted.

This shows that the TSP is only a special case of the decipherment problem.

## 6 Conclusion

We have shown the correspondence between solving 1:1 substitution ciphers and the linear sum assignment problem and the quadratic assignment problem: When using unigram language models, the decipherment problem is equivalent to the linear sum assignment problem and solvable in polynomial time. For a bigram language model, the decipherment problem is equivalent to the quadratic assignment problem and is NP-hard.

We also pointed out that all available algorithms for the quadratic assignment problem can be directly used to solve the decipherment problem.

To the best of our knowledge, this correspondence between the decipherment problem and the quadratic assignment problem has not been known previous to our work.

## Abstract

This paper studies the problem of non-monotonic sentence alignment, motivated by the observation that coupled sentences in real bitexts do not necessarily occur monotonically, and proposes a semisupervised learning approach based on two assumptions: (1) sentences with high affinity in one language tend to have their counterparts with similar relatedness in the other; and (2) initial alignment is readily available with existing alignment techniques. They are incorporated as two constraints into a semisupervised learning framework for optimization to produce a globally optimal solution. The evaluation with real-world legal data from a comprehensive legislation corpus shows that while existing alignment algorithms suffer severely from non-monotonicity, this approach can work effectively on both monotonic and non-monotonic data.

## 1 Introduction

Bilingual sentence alignment is a fundamental task to undertake for the purpose of facilitating many important natural language processing applications such as statistical machine translation (Brown et al., 1993), bilingual lexicography (Klavans et al., 1990), and cross-language information retrieval (Nie et al., 1999). Its objective is to identify correspondences between bilingual sentences in given bitexts. As summarized by Wu (2010), existing sentence alignment techniques rely mainly on sentence length and bilingual lexical resource. Approaches based on the former perform effectively on cognate languages but not on the others. For instance, the statistical correlation of sentence length between English and Chinese is not as high as that between two Indo-European languages (Wu, 1994). Lexicon-based

approaches resort to word correspondences in a bilingual lexicon to match bilingual sentences. A few sentence alignment methods and tools have also been explored to combine the two. Moore (2002) proposes a multi-pass search procedure using both sentence length and an automatically-derived bilingual lexicon. Hunalign (Varga et al., 2005) is another sentence aligner that combines sentence length and a lexicon. Without a lexicon, it backs off to a length-based algorithm and then automatically derives a lexicon from the alignment result. Soon after, Ma (2006) develops the lexicon-based aligner Champollion, assuming that different words have different importance in aligning two sentences.

Nevertheless, most existing approaches to sentence alignment follow the monotonicity assumption that coupled sentences in bitexts appear in a similar sequential order in two languages and crossings are not entertained in general (Langlais et al., 1998; Wu, 2010). Consequently the task of sentence alignment becomes handily solvable by means of such basic techniques as dynamic programming. In many scenarios, however, this prerequisite monotonicity cannot be guaranteed. For example, bilingual clauses in legal bitexts are often coordinated in a way not to keep the same clause order, demanding fully or partially crossing pairings. Figure 1 shows a real excerpt from a legislation corpus. Such monotonicity seriously impairs the existing alignment approaches founded on the monotonicity assumption.

This paper is intended to explore the problem of non-monotonic alignment within the framework of semisupervised learning. Our approach is motivated by the above observation and based on the following two assumptions. First, monolingual sentences with high affinity are likely to have their translations with similar relatedness. Following this assumption, we propose the conception of monolingual consistency which, to the best of

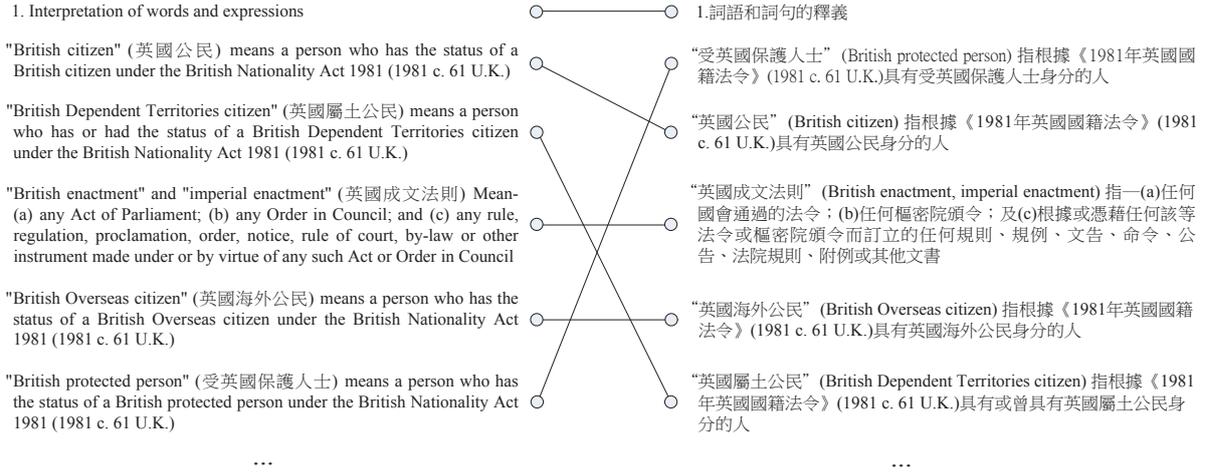

Figure 1: A real example of non-monotonic sentence alignment from BLIS corpus.

our knowledge, has not been taken into account in any previous work of alignment. Second, initial alignment of certain quality can be obtained by means of existing alignment techniques. Our approach attempts to incorporate both monolingual consistency of sentences and bilingual consistency of initial alignment into a semisupervised learning framework to produce an optimal solution. Extensive evaluations are performed using real-world legislation bitexts from BLIS, a comprehensive legislation database maintained by the Department of Justice, HKSAR. Our experimental results show that the proposed method can work effectively while two representatives of existing aligners suffer severely from the non-monotonicity.

## 2 Methodology

### 2.1 The Problem

An alignment algorithm accepts as input a bitext consisting of a set of source-language sentences,  $\mathcal{S} = \{s_1, s_2, \dots, s_m\}$ , and a set of target-language sentences,  $\mathcal{T} = \{t_1, t_2, \dots, t_n\}$ . Different from previous works relying on the monotonicity assumption, our algorithm is generalized to allow the pairings of sentences in  $\mathcal{S}$  and  $\mathcal{T}$  to cross arbitrarily. Figure 2(a) illustrates monotonic alignment with no crossing correspondences in a bipartite graph and 2(b) non-monotonic alignment with scrambled pairings. Note that it is relatively straightforward to identify the type of many-to-many alignment in monotonic alignment using techniques such as dynamic programming if there is no scrambled pairing or the scrambled pairings are local, limited to a short distance. However, the situation of non-monotonic alignment is much

more complicated. Sentences to be merged into a bundle for matching against another bundle in the other language may occur consecutively or discontinuously. For the sake of simplicity, we will not consider non-monotonic alignment with many-to-many pairings but rather assume that each sentence may align to only one or zero sentence in the other language.

Let  $\mathcal{F}$  represent the correspondence relation between  $\mathcal{S}$  and  $\mathcal{T}$ , and therefore  $\mathcal{F} \subset \mathcal{S} \times \mathcal{T}$ . Let matrix  $F$  denote a specific alignment solution of  $\mathcal{F}$ , where  $F_{ij}$  is a real score to measure the likelihood of matching the  $i$ -th sentence  $s_i$  in  $\mathcal{S}$  against the  $j$ -th sentence  $t_j$  in  $\mathcal{T}$ . We then define an alignment function  $\mathcal{A} : F \rightarrow A$  to produce the final alignment, where  $A$  is the alignment matrix for  $\mathcal{S}$  and  $\mathcal{T}$ , with  $A_{ij} = 1$  for a correspondence between  $s_i$  and  $t_j$  and  $A_{ij} = 0$  otherwise.

### 2.2 Semisupervised Learning

A semisupervised learning framework is introduced to incorporate the monolingual and bilingual consistency into alignment scoring

$$Q(F) = Q_m(F) + \lambda Q_b(F), \quad (1)$$

where  $Q_m(F)$  is the term for monolingual constraint to control the consistency of sentences with high affinities,  $Q_b(F)$  for the constraint of initial alignment obtained with existing techniques, and  $\lambda$  is the weight between them. Then, the optimal alignment solution is to be derived by minimizing the cost function  $Q(F)$ , i.e.,

$$F^* = \arg \min_F Q(F). \quad (2)$$

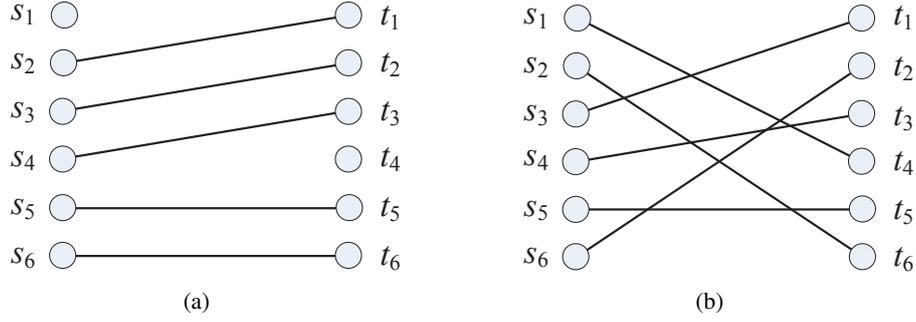

Figure 2: Illustration of monotonic (a) and non-monotonic alignment (b), with a line representing the correspondence of two bilingual sentences.

In this paper,  $\mathcal{Q}_m(F)$  is defined as

$$\frac{1}{4} \sum_{i,j=1}^m W_{ij} \sum_{k,l=1}^n V_{kl} \left( \frac{F_{ik}}{\sqrt{D_{ii}E_{kk}}} - \frac{F_{jl}}{\sqrt{D_{jj}E_{ll}}} \right)^2, \quad (3)$$

where  $W$  and  $V$  are the symmetric matrices to represent the monolingual sentence affinity matrices in  $\mathcal{S}$  and  $\mathcal{T}$ , respectively, and  $D$  and  $E$  are the diagonal matrices with entries  $D_{ii} = \sum_j W_{ij}$  and  $E_{ii} = \sum_j V_{ij}$ . The idea behind (3) is that to minimize the cost function, the translations of those monolingual sentences with close relatedness reflected in  $W$  and  $V$  should also keep similar closeness. The bilingual constraint term  $\mathcal{Q}_b(F)$  is defined as

$$\mathcal{Q}_b(F) = \sum_{i=1}^m \sum_{j=1}^n (F_{ij} - \hat{A}_{ij})^2, \quad (4)$$

where  $\hat{A}$  is the initial alignment matrix obtained by  $\mathcal{A} : \hat{F} \rightarrow \hat{A}$ . Note that  $\hat{F}$  is the initial relation matrix between  $\mathcal{S}$  and  $\mathcal{T}$ .

The monolingual constraint term  $\mathcal{Q}_m(F)$  defined above corresponds to the *smoothness constraint* in the previous semisupervised learning work by Zhou et al. (2004) that assigns higher likelihood to objects with larger similarity to share the same label. On the other hand,  $\mathcal{Q}_b(F)$  corresponds to their *fitting constraint*, which requires the final alignment to maintain the maximum consistency with the initial alignment.

Taking the derivative of  $\mathcal{Q}(F)$  with respect to  $F$ , we have

$$\frac{\partial \mathcal{Q}(F)}{\partial F} = 2F - 2SFT + 2\lambda F - 2\lambda \hat{A}, \quad (5)$$

where  $S$  and  $T$  are the normalized matrices of  $W$  and  $V$ , calculated by  $S = D^{-1/2}WD^{-1/2}$  and

$T = E^{-1/2}VE^{-1/2}$ . Then, the optimal  $F^*$  is to be found by solving the equation

$$(1 + \lambda) F^* - SF^*T = \lambda \hat{A}, \quad (6)$$

which is equivalent to  $\alpha F^* - F^* \beta = \gamma$  with  $\alpha = (1 + \lambda) S^{-1}$ ,  $\beta = T$  and  $\gamma = \lambda S^{-1} \hat{A}$ . This is in fact a Sylvester equation (Barlow et al., 1992), whose numerical solution can be found by many classical algorithms. In this research, it is solved using LAPACK,<sup>1</sup> a software library for numerical linear algebra. Non-positive entries in  $F^*$  indicate unrealistic correspondences of sentences and are thus set to zero before applying the alignment function.

### 2.3 Alignment Function

Once the optimal  $F^*$  is acquired, the remaining task is to design an alignment function  $\mathcal{A}$  to convert it into an alignment solution. An intuitive approach is to use a heuristic search for local optimization (Kit et al., 2004), which produces an alignment with respect to the largest scores in each row and each column. However, this does not guarantee a globally optimal solution. Figure 3 illustrates a mapping relation matrix onto an alignment matrix, which also shows that the optimal alignment cannot be achieved by heuristic search.

Banding is another approach frequently used to convert a relation matrix to alignment (Kay and Röscheisen, 1993). It is founded on the observation that true monotonic alignment paths usually lie close to the diagonal of a relation matrix. However, it is not applicable to our task due to the non-monotonicity involved. We opt for converting a relation matrix into specific alignment by solving

<sup>1</sup><http://www.netlib.org/lapack/>

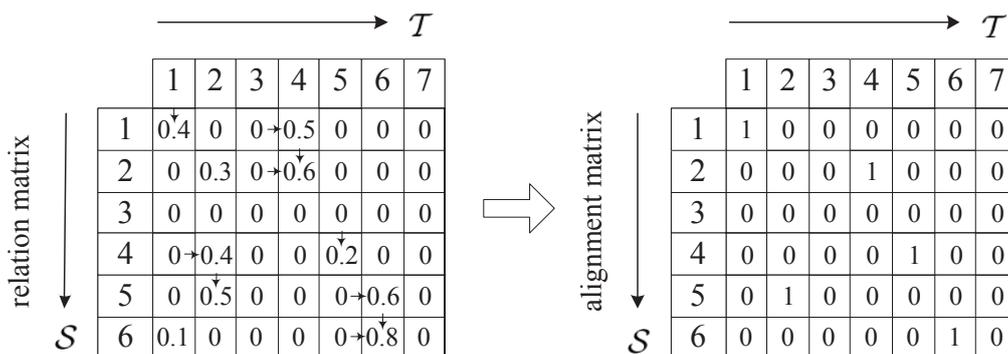

Figure 3: Illustration of sentence alignment from relation matrix to alignment matrix. The scores marked with arrows are the best in each row/column to be used by the heuristic search. The right matrix represents the corresponding alignment matrix by our algorithm.

the following optimization

$$A = \arg \max_X \sum_{i=1}^m \sum_{j=1}^n X_{ij} F_{ij} \quad (7)$$

$$s.t. \sum_{i=1}^m X_{ij} \leq 1, \sum_{j=1}^n X_{ij} \leq 1, X_{ij} \in \{0, 1\}$$

This turns sentence alignment into a problem to be resolved by binary linear programming (BIP), which has been successfully applied to word alignment (Taskar et al., 2005). Given a scoring matrix, it guarantees an optimal solution.

## 2.4 Alignment Initialization

Once the above alignment function is available, the initial alignment matrix  $\hat{A}$  can be derived from an initial relation matrix  $\hat{F}$  obtained by an available alignment method. This work resorts to another approach to initializing the relation matrix. In many genres of bitexts, such as government transcripts or legal documents, there are a certain number of common strings on the two sides of bitexts. In legal documents, for example, translations of many key terms are usually accompanied with their source terms. Also, common numberings can be found in enumerated lists in bitexts. These kinds of *anchor strings* provide quite reliable information to link bilingual sentences into pairs, and thus can serve as useful cues for sentence alignment. In fact, they can be treated as a special type of highly reliable “bilexicon”.

The anchor strings used in this work are derived by searching the bitexts using word-level inverted indexing, a basic technique widely used in information retrieval (Baeza-Yates and Ribeiro-Neto, 2011). For each index term, a list of postings is

created. Each posting includes a sentence identifier, the in-sentence frequency and positions of this term. The positions of terms are intersected to find common anchor strings. The anchor strings, once found, are used to calculate the initial affinity  $\hat{F}_{ij}$  of two sentences using Dice’s coefficient

$$\hat{F}_{ij} = \frac{2|C_{1i} \cap C_{2j}|}{|C_{1i}| + |C_{2j}|} \quad (8)$$

where  $C_{1i}$  and  $C_{2j}$  are the anchor sets in  $s_i$  and  $t_j$ , respectively, and  $|\cdot|$  is the cardinality of a set.

Apart from using anchor strings, other avenues for the initialization are studied in the evaluation section below, i.e., using another aligner and an existing lexicon.

## 2.5 Monolingual Affinity

Although various kinds of information from a monolingual corpus have been exploited to boost statistical machine translation models (Liu et al., 2010; Su et al., 2012), we have not yet been exposed to any attempt to leverage monolingual sentence affinity for sentence alignment. In our framework, an attempt to this can be made through the computation of  $W$  and  $V$ . Let us take  $W$  as an example, where the entry  $W_{ij}$  represents the affinity of sentence  $s_i$  and sentence  $s_j$ , and it is set to 0 for  $i = j$  in order to avoid self-reinforcement during optimization (Zhou et al., 2004).

When two sentences in  $\mathcal{S}$  or  $\mathcal{T}$  are not too short, or their content is not divergent in meaning, their semantic similarity can be estimated in terms of common words. Motivated by this, we define  $W_{ij}$  (for  $i \neq j$ ) based on the Gaussian kernel as

$$W_{ij} = \exp \left( -\frac{1}{2\sigma^2} \left( 1 - \frac{v_i^T v_j}{\|v_i\| \|v_j\|} \right)^2 \right) \quad (9)$$

where  $\sigma$  is the standard deviation parameter,  $v_i$  and  $v_j$  are vectors of  $s_i$  and  $s_j$  with each component corresponding to the *tf-idf* value of a particular term in  $\mathcal{S}$  (or  $\mathcal{T}$ ), and  $\|\cdot\|$  is the norm of a vector. The underlying assumption here is that words appearing frequently in a small number of sentences but rarely in the others are more significant in measuring sentence affinity.

Although semantic similarity estimation is a straightforward approach to deriving the two affinity matrices, other approaches are also feasible. An alternative approach can be based on sentence length under the assumption that two sentences with close lengths in one language tend to have their translations also with close lengths.

## 2.6 Discussion

The proposed semisupervised framework for non-monotonic alignment is in fact generalized beyond, and can also be applied to, monotonic alignment. Towards this, we need to make use of sentence sequence information. One way to do it is to incorporate sentence positions into Equation (1) by introducing a position constraint  $Q_p(F)$  to enforce that bilingual sentences in closer positions should have a higher chance to match one another. For example, the new constraint can be defined as

$$Q_p(F) = \sum_{i=1}^m \sum_{j=1}^n |p_i - q_j| F_{ij}^2,$$

where  $p_i$  and  $q_j$  are the absolute (or relative) positions of two bilingual sentences in their respective sequences. Another way follows the banding assumption that the actual couplings only appear in a narrow band along the main diagonal of relation matrix. Accordingly, all entries of  $F^*$  outside this band are set to zero before the alignment function is applied. Kay and Röscheisen (1993) illustrate that this can be done by modeling the maximum deviation of true couplings from the diagonal as  $O(\sqrt{n})$ .

## 3 Evaluation

### 3.1 Data Set

Our data set is acquired from the Bilingual Laws Information System (BLIS),<sup>2</sup> an electronic database of Hong Kong legislation maintained by the Department of Justice, HKSAR. BLIS

<sup>2</sup><http://www.legislation.gov.hk>

provides Chinese-English bilingual texts of ordinances and subsidiary legislation in effect on or after 30 June 1997. It organizes the legal texts into a hierarchy of chapters, sections, subsections, paragraphs and subparagraphs, and displays the content of a such hierarchical construct (usually a section) on a single web page.

By web crawling, we have collected in total 31,516 English and 31,405 Chinese web pages, forming a bilingual corpus of 31,401 bitexts after filtering out null pages. A text contains several to two hundred sentences. Many bitexts exhibit partially non-monotonic order of sentences. Among them, 175 bitexts are randomly selected for manual alignment. Sentences are identified based on punctuations. OpenNLP Tokenizer<sup>3</sup> is applied to segment English sentences into tokens. For Chinese, since there is no reliable segmenter for this genre of text, we have to treat each Chinese character as a single token. In addition, to calculate the monolingual sentence affinity, stemming of English words is performed with the Porter Stemmer (Porter, 1980) after anchor string mining.

The manual alignment of the evaluation data set is performed upon the initial alignment by Hunalign (Varga et al., 2005), an effective sentence aligner that uses both sentence length and a bilexicon (if available). For this work, Hunalign relies solely on sentence length. Its output is then double-checked and corrected by two experts in bilingual studies, resulting in a data set of 1747 1-1 and 70 1-0 or 0-1 sentence pairs.

The standard deviation  $\sigma$  in (9) is an important parameter for the Gaussian kernel that has to be determined empirically (Zhu et al., 2003; Zhou et al., 2004). In addition, the  $Q$  function also involves another parameter  $\lambda$  to adjust the weight of the bilingual constraint. This work seeks an approach to deriving the optimal parameters without any external training data beyond the initial alignment. A three-fold cross-validation is thus performed on the initial 1-1 alignment and the parameters that give the best average performance are chosen.

### 3.2 Monolingual Consistency

To demonstrate the validity of the monolingual consistency, the semantic similarity defined by  $\frac{v_i^T v_j}{\|v_i\| \|v_j\|}$  is evaluated as follows. 500 pairs of English sentences with the highest similarities are selected, excluding *null* pairings (1-0 or 0-1 type).

<sup>3</sup><http://opennlp.apache.org/>

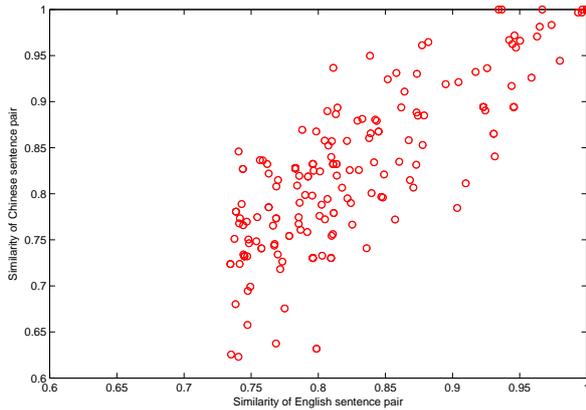

Figure 4: Demonstration of monolingual consistency. The horizontal axis is the similarity of English sentence pairs and the vertical is the similarity of the corresponding pairs in Chinese.

Type	Total	initAlign		NonmoAlign	
		Pred	Corr	Pred	Corr
1-0	70	662	66	70	50
1-1	1747	1451	1354	1747	1533

Table 1: Performance of the initial alignment and our aligner, where the *Pred* and *Corr* columns are the numbers of predicted and correct pairings.

All of these high-affinity pairs have a similarity score higher than 0.72. A number of duplicate sentences (e.g., date) with exceptionally high similarity 1.0 are dropped. Also, the similarity of the corresponding translations of each selected pair is calculated. These two sets of similarity scores are then plotted in a scatter plot, as in Figure 4. If the monolingual consistency assumption holds, the plotted points would appear nearby the diagonal. Figure 4 confirms this, indicating that sentence pairs with high affinity in one language do have their counterparts with similarly high affinity in the other language.

### 3.3 Impact of Initial Alignment

The 1-1 initial alignment plays the role of labeled instances for the semisupervised learning. It is of critical importance to the learning performance. As shown in Table 1, our alignment function predicts 1451 1-1 pairings by virtue of anchor strings, among which 1354 pairings are correct, yielding a relatively high precision in the non-monotonic circumstance. It also predicts *null* alignment for many sentences that contain no anchor. This explains why it outputs 662 1-0 pairings when there

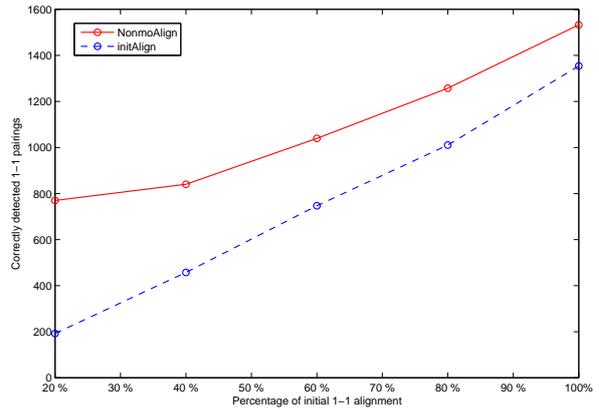

Figure 5: Performance of non-monotonic alignment along the percentage of initial 1-1 alignment.

are only 70 1-0 true ones. Starting from this initial alignment, our aligner (let us call it *NonmoAlign*) discovers 179 more 1-1 pairings.

A question here is concerned with how the scale of initial alignment affects the final alignment. To examine this, we randomly select 20%, 40%, 60% and 80% of the 1451 1-1 detected pairings as the initial alignments for a series of experiments. The random selection for each proportion is performed ten times and their average alignment performance is taken as the final result and plotted in Figure 5. An observation from this figure is that the aligner consistently discovers significantly more 1-1 pairings on top of an initial 1-1 alignment, which has to be accounted for by the monolingual consistency. Another observation is that the alignment performance goes up along the increase of the percentage of initial alignment while performance gain slows down gradually. When the percentage is very low, the aligner still works quite effectively.

### 3.4 Non-Monotonic Alignment

To test our aligner with non-monotonic sequences of sentences, we have them randomly scrambled in our experimental data. This undoubtedly increases the difficulty of sentence alignment, especially for the traditional approaches critically relying on monotonicity.

The baseline methods used for comparison are Moore’s aligner (Moore, 2002) and Hunalign (Varga et al., 2005). Hunalign is configured with the option [-realign], which triggers a three-step procedure: after an initial alignment, Hunalign heuristically enriches its dictionary using word co-occurrences in identified sentence pairs; then, it re-runs the alignment process using the updated

Type	Moore			Hunalign			NonmoAlign		
	$P$	$R$	$F_1$	$P$	$R$	$F_1$	$P$	$R$	$F_1$
1-1	0.104	0.104	0.104	0.407	0.229	0.293	0.878	0.878	0.878
1-0	0.288	0.243	0.264	0.033	0.671	0.062	0.714	0.714	0.714
Micro	0.110	0.110	0.110	0.184	0.246	0.210	0.871	0.871	0.871

Table 2: Performance comparison with the baseline methods.

dictionary. According to Varga et al (2005), this setting gives a higher alignment quality than otherwise. In addition, Hunalign can use an external bilexicon. For a fair comparison, the identified anchor set is fed to Hunalign as a special bilexicon. The performance of alignment is measured by precision ( $P$ ), recall ( $R$ ) and F-measure ( $F_1$ ). Micro-averaged performance scores of precision, recall and F-measure are also computed to measure the overall performance on 1-1 and 1-0 alignment. The final results are presented in Table 2, showing that both Moore’s aligner and Hunalign underperform ours on non-monotonic alignment. The particularly poor performance of Moore’s aligner has to be accounted for by its requirement of more than thousands of sentences in bitext input for reliable estimation of its parameters. Unfortunately, our available data has not reached that scale yet.

### 3.5 Partially Non-Monotonic Alignment

Full non-monotonic bitexts are rare in practice. But partial non-monotonic ones are not. Unlike traditional alignment approaches, ours does not found its performance on the degree of monotonicity. To test this, we construct five new versions of the data set for a series of experiments by randomly choosing and scrambling 0%, 10%, 20%, 40%, 60% and 80% sentence parings. In theory, partial non-monotonicity of various degrees should have no impact on the performance of our aligner. It is thus not surprised that it achieves the same result as reported in last subsection. NonmoAlign initialized with Hunalign (marked as NonmoAlign\_Hun) is also tested. The experimental results are presented in Figure 6. It shows that both Moore’s aligner and Hunalign work relatively well on bitexts with a low degree of non-monotonicity, but their performance drops dramatically when the non-monotonicity is increased. Despite the improvement at low non-monotonicity by seeding our aligner with Hunalign, its performance decreases likewise when the degree of non-monotonicity increases, due to the quality de-

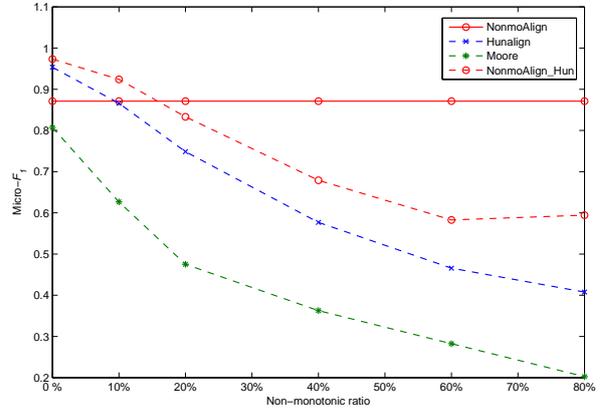

Figure 6: Performance of alignment approaches at different degrees of non-monotonicity.

crease of the initial alignment by Hunalign.

### 3.6 Monotonic Alignment

The proposed alignment approach is also expected to work well on monotonic sentence alignment. An evaluation is conducted for this using a monotonic data set constructed from our data set by discarding all its 126 crossed pairings. Of the two strategies discussed above, banding is used to help our aligner incorporate the sequence information. The initial relation matrix is built with the aid of a dictionary automatically derived by Hunalign. Entries of the matrix are derived by employing a similar strategy as in Varga et al. (2005). The evaluation results are presented in Table 3, which shows that NonmoAlign still achieves very competitive performance on monotonic sentence alignment.

## 4 Related Work

The research of sentence alignment originates in the early 1990s. Gale and Church (1991) and Brown (1991) report the early works using length statistics of bilingual sentences. The general idea is that the closer two sentences are in length, the more likely they are to align. A notable difference of their methods is that the former uses sentence

Type	Moore			Hunalign			NonmoAlign		
	$P$	$R$	$F_1$	$P$	$R$	$F_1$	$P$	$R$	$F_1$

1-0	0.359	0.329	0.343	0.330	0.457	0.383	0.729	0.729	0.729
Micro	0.809	0.807	0.808	0.961	0.951	0.956	0.976	0.976	0.976

Table 3: Performance of monotonic alignment in comparison with the baseline methods.

length in number of characters while the latter in number of tokens. Both use dynamic programming to search for the best alignment. As shown in Chen (1993) and Wu (1994), however, sentence-length based methods suffer when the texts to be aligned contain small passages, or the languages involved share few cognates. The subsequent stage of sentence alignment research is accompanied by the advent of a handful of well-designed alignment tools. Moore (2002) proposes a three-pass procedure to find final alignment. Its bitext input is initially aligned based on sentence length. This step generates a set of strictly-selected sentence pairs for use to train an IBM translation model 1 (Brown et al., 1993). Its final step realigns the bitext using both sentence length and the discovered word correspondences. Hunalign (Varga et al., 2005), originally proposed as an ingredient for building parallel corpora, has demonstrated an outstanding performance on sentence alignment. Like many other aligners, it employs a similar strategy of combining sentence length and lexical data. In the absence of a lexicon, it first performs an initial alignment wholly relying on sentence length and then automatically builds a lexicon based on this alignment. Using an available lexicon, it produces a rough translation of the source text by converting each token to the one of its possible counterparts that has the highest frequency in the target corpus. Then, the relation matrix of a bitext is built of similarity scores for the rough translation and the actual translation at sentence level. The similarity of two sentences is calculated in terms of their common pairs and length ratio.

To deal with noisy input, Ma (2006) proposes a lexicon-based sentence aligner - Champollion. Its distinctive feature is that it assigns different weights to words in terms of their *tf-idf* scores, assuming that words with low sentence frequencies in a text but high occurrences in some local sentences are more indicative of alignment. Under this assumption, the similarity of any two sentences is calculated accordingly and then a dy-

namic programming algorithm is applied to produce final alignment. Following this work, Li et al. (2010) propose a revised version of Champollion, attempting to improve its speed without performance loss. For this purpose, the input bitexts are first divided into smaller aligned fragments before applying Champollion to derive finer-grained sentence pairs. In another related work by Deng et al. (2007), a generative model is proposed, accompanied by two specific alignment strategies, i.e., dynamic programming and divisive clustering. Although a non-monotonic search process that tolerates two successive chunks in reverse order is involved, their work is essentially targeted at monotonic alignment.

## 5 Conclusion

In this paper we have proposed and tested a semisupervised learning approach to non-monotonic sentence alignment by incorporating both monolingual and bilingual consistency. The utility of monolingual consistency in maintaining the consonance of high-affinity monolingual sentences with their translations has been demonstrated. This work also exhibits that bilingual consistency of initial alignment of certain quality is useful to boost alignment performance. Our evaluation using real-world data from a legislation corpus shows that the proposed approach outperforms the baseline methods significantly when the bitext input is composed of non-monotonic sentences. Working on partially non-monotonic data, this approach also demonstrates a superior performance. Although initially proposed for non-monotonic alignment, it works well on monotonic alignment by incorporating the constraint of sentence sequence.

## Abstract

This paper studies the problem of mining named entity translations from comparable corpora with some “asymmetry”. Unlike the previous approaches relying on the “symmetry” found in parallel corpora, the proposed method is tolerant to asymmetry often found in comparable corpora, by distinguishing different semantics of relations of entity pairs to selectively propagate seed entity translations on weakly comparable corpora. Our experimental results on English-Chinese corpora show that our selective propagation approach outperforms the previous approaches in named entity translation in terms of the mean reciprocal rank by up to 0.16 for organization names, and 0.14 in a low comparability case.

## 1 Introduction

Identifying and understanding entities is a crucial step in understanding text. This task is more challenging in the presence of multilingual text, because translating named entities (NEs), such as persons, locations, or organizations, is a non-trivial task. Early research on NE translation used phonetic similarities, for example, to mine the translation ‘Mandelson’ → ‘曼德尔森’ [ManDeErSen] with similar sounds. However, not all NE translations are based on transliterations, as shown in Table 1—Some translations, especially the names of most organizations, are based on semantic equivalences. Furthermore, names can be abbreviated in one or both languages, e.g., the ‘World Trade Organization’ (世界贸易组织) can be called the ‘WTO’ (世贸组织). Another challenging example is that, a translation can be arbitrary, e.g., ‘Jackie Chan’ → ‘成龙’ [ChengLong]. There are many approaches

English	Chinese
World Trade Organization	世界贸易组织
WTO	[ShiJieMaoYiZuZhi] 世贸组织 [ShiMaoZuZhi]
Jackie Chan	成龙 [ChengLong]

Table 1: Examples of non-phonetic translations.

that deal with some of these challenges (Lam et al., 2007; Yang et al., 2009), e.g., by combining phonetic similarity and a dictionary. However, arbitrary translations still cannot be handled by examining the NE pair itself. Corpus-based approaches (Kupiec, 1993; Feng, 2004), by mining external signals from a large corpus, such as parathetical translation “成龙 (Jackie Chan)”, complement the problem of transliteration-based approaches, but the coverage of this approach is limited to popular entities with such evidence.

The most effective known approach to NE translation has been a holistic framework (You et al., 2010; Kim et al., 2011; You et al., 2012) combining transliteration- and corpus-based methods. In these approaches, both 1) arbitrary translations and 2) lesser-known entities can be handled, by propagating the translation scores of known entities to lesser-known entities if they co-occur frequently in both corpora. For example, a lesser-known entity Tom Watson can be translated if Mandelson and Tom Watson co-occur frequently in an English corpus, and their Chinese translations also co-occur frequently in a Chinese corpus, i.e., if the co-occurrences in the two corpora are “symmetric”.

A research question we ask in this paper is: What if comparable corpora are not comparable enough to support this *symmetry* assumption? We found that this is indeed the case. For example, even English and Chinese news from the same publisher may have different focus—the Chinese version focuses more on Chinese Olympic

teams and Chinese local news. In the presence of such asymmetry, all previous approaches, building upon symmetry, quickly deteriorate by propagating false positives. For example, co-occurrence of Mandelson and Tom Watson may not appear in a Chinese corpus, which may lead to the translation of Tom Watson into another Chinese entity Gordon Brown which happens to co-occur with the Chinese translation of Mandelson.

Our key contribution is to avoid such false propagation, by discerning the semantics of relations. For example, relations between Mandelson and Tom Watson, should be semantically different from Chinese relations between ‘戈登·布朗’ (Gordon Brown) and ‘曼德尔森’ (Mandelson). A naive approach would be finding documents with a similar *topic* such as politics, and scientific discovery, and allowing propagation only when the topic agrees. However, we found that a topic is a unit that is too coarse for this task because most articles on Mandelson will invariably fall into the same topic<sup>1</sup>. In clear contrast, we *selectively propagate* seed translations, only when the relations in the two corpora share the same semantics.

This selective propagation can be especially effective for translating challenging types of entities such as *organizations* including the WTO used with and without abbreviation in both languages. Applying a holistic approach (You et al., 2012) on organizations leads to poor results, 0.06 in terms of the F1-score. A naive approach to increase the precision would be to consider multi-type co-occurrences, hoping that highly precise translations of some type, e.g., persons with an F1-score of 0.69 (You et al., 2012), can be propagated to boost the precision on organizations. In our experiments, this naive multi-type propagation still leads to an unsatisfactory F1-score of 0.12. Such a low score can be explained by the following example. When translating ‘WTO’ using the co-occurrence with ‘Mandelson’, other co-occurrences such as (London, Mandelson) and (EU, Mandelson) produce a lot of noise because the right translation of WTO does not share much phonetic/semantic similarity. Our understanding of relation semantics, can distinguish “Mandelson was born in London” from “Mandelson visited the WTO”, to stop false propagations, which generates an F1-score 0.25 higher than the existing ap-

<sup>1</sup>The MRR for organization names achieved by a topic model-based approach was 0.15 lower than our best.

proaches.

More formally, we enable *selective propagation* of seed translations on weakly comparable corpora, by 1) clarifying the detailed meaning of relational information of co-occurring entities, and 2) identifying the contexts of the relational information using statement-level context comparison. In other words, we propagate the translation score of a known translation pair to a neighbor pair *if* the semantics of their relations in English and Chinese corpora are *equivalent* to accurately propagate the scores. For example, if we know ‘Russia’ → ‘俄罗斯’<sub>(1)</sub> and *join* → 加入<sub>(2)</sub>, then from a pair of statements “Russia<sub>(1)</sub> joins<sub>(2)</sub> the WTO<sub>(3)</sub>” and “俄罗斯<sub>(1)</sub> 加入<sub>(2)</sub> 世贸组织<sub>(3)</sub>”, we can propagate the translation score of (Russia, 俄罗斯)<sub>(1)</sub> to (WTO, 世贸组织)<sub>(3)</sub>. However, we do not exploit a pair of statements “Russia joined the WTO” and “俄罗斯谴责<sub>(2)</sub> 摩洛哥” because 谴责<sub>(2)</sub> does not mean *join*<sub>(2)</sub>. Furthermore, we mine a similar English-Chinese document pair that can be found by comparing the entity relationships, such as “Mandelson visited Moscow” and “Mandelson met Alexei Kudrin”, within the English document and the Chinese document to leverage similar contexts to assure that we use symmetric parts.

For this goal, we first extract *relations* among entities in documents, such as *visit* and *join*, and mine semantically equivalent relations across the languages, e.g., English and Chinese, such as *join* → 加入. Once these relation translations are mined, similar document pairs can be identified by comparing each constituent relationship among entities using their relations. Knowing document similarity improves NE translation, and improved NE translation can boost the accuracy of document and relationship similarity. This iterative process can continue until convergence.

To the best of our knowledge, our approach is the first to translate a broad range of multilingual relations and exploit them to enhance NE translation. In particular, our approach leverages semantically similar document pairs to exclude incomparable parts that appear in one language only. Our method outperforms the previous approaches in translating NE up to 0.16 in terms of the mean reciprocal rank (MRR) for organization names. Moreover, our method shows robustness, with 0.14 higher MRR than seed translations, on less comparable corpora.

## 2 Related Work

This work is related to two research streams: NE translation and semantically equivalent relation mining.

### Entity translation

Existing approaches on NE translation can be categorized into 1) transliteration-based, 2) corpus-based, and 3) hybrid approaches.

Transliteration-based approaches (Wan and Verspoor, 1998; Knight and Graehl, 1998) are the foundations of many decent methods, but they alone suffer from ambiguity (e.g., 史蒂夫 and 始第夫 have the same sounds) and cannot handle non-transliterated cases such as ‘Jackie Chan (成龙[ChengLong])’. Some methods (Lam et al., 2007; Yang et al., 2009) rely on meanings of constituent letters or words to handle organization name translation such as ‘Bank of China (中国银行)’, whose translation is derived from ‘China (中国)’, and ‘a bank (银行)’. However, many names often originate from abbreviation (such as ‘WTO’); hence we cannot always leverage meanings.

Corpus-based approaches (Kupiec, 1993; Lin et al., 2008; Jiang et al., 2009) exploit high-quality bilingual evidence such as parenthetical translation, e.g., “成龙 (Jackie Chan)”, (Lin et al., 2008), semi-structural patterns (Jiang et al., 2009), and parallel corpus (Kupiec, 1993). However, the coverage of the corpus-based approaches is limited to popular entities with such bilingual evidences. On the other hand, our method can cover entities with monolingual occurrences in corpora, which significantly improves the coverage.

The most effective known approach is a holistic framework that combines those two approaches (You et al., 2012; You et al., 2010; Kim et al., 2011). You et al. (2010; 2012) leverage two graphs of entities in each language, that are generated from a pair of corpora, with edge weights quantified as the strength of the relatedness of entities. Then, two graphs are iteratively aligned using the common neighbors of two entities. Kim et al. (2011) build such graphs using the context similarity, measured with a bag of words approach, of entities in news corpora to translate NEs. However, these approaches assume the symmetry of the two graphs. This assumption holds if two corpora are parallel, but such resources are scarce. But our approach exploits comparable parts from corpora.

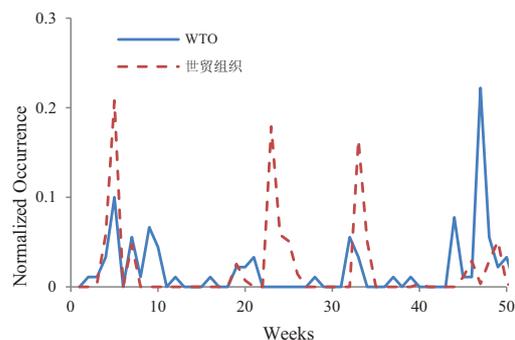

Figure 1: Dissimilarity of temporal distributions of ‘WTO’ in English and Chinese corpora.

Other interesting approaches such as (Klementiev and Roth, 2006; Kim et al., 2012) rely on temporal distributions of entities. That is, two entities are considered to be similar if the two entities in different languages have similar occurrence distributions over time. However, the effectiveness of this feature also depends on the comparability of entity occurrences in time-stamped corpora, which may not hold as shown in Figure 1. In clear contrast, our method can find and compare articles, on different dates, describing the same NE. Moreover, our method does not require time stamps.

### Semantically similar relation mining

Recently, similar relation mining in one language has been studied actively as a key part of automatic knowledge base construction. In automatically constructed knowledge bases, finding semantically similar relations can improve understanding of the Web describing content with many different expressions. As such an effort, PATTY (Nakashole et al., 2012) finds similar relations with almost the same support sets—the sets of NE pairs that co-occur with the relations. However, because of the regional locality of information, bilingual corpora contain many NE pairs that appear in only one of the support sets of the semantically identical relations. NELL (Mohamed et al., 2011) finds related relations using seed pairs of one given relation; then, using K-means clustering, it finds relations that are semantically similar to the given relation. Unfortunately, this method requires that we set K manually, and extract relations for each given relation. Therefore, this is unsuitable to support general relations.

There are only few works on translating relations or obtaining multi-lingual similar relations. Schone et al. (2011) try to find relation patterns

in multiple languages for given seed pairs of a relation. Because this approach finds seed pairs in Wikipedia infoboxes, the number of retrievable relations is restricted to five. Kim et al. (2010) seek more diverse types of relations, but it requires parallel corpora, which are scarce.

### 3 Framework Overview

In this section, we provide an overview of our framework for translating NEs, using news corpora in English and Chinese as a running example. Because such corpora contain asymmetric parts, the goal of our framework is to overcome asymmetry by distinguishing the semantics of relations, and leveraging document context defined by the relations of entities.

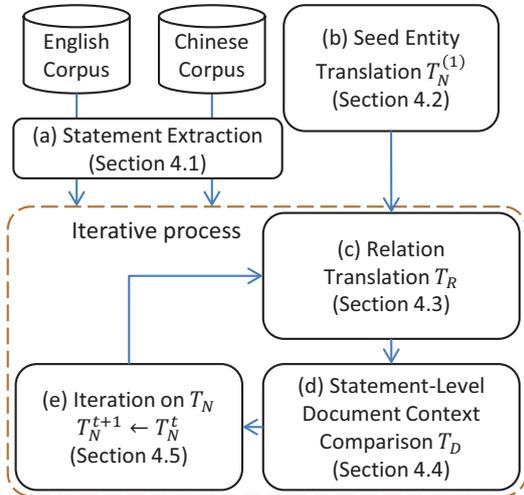

Figure 2: Framework overview.

For this purpose, we build a mutual bootstrapping framework (Figure 2), between entity translation and relation translation using extracted relationships of entities (Figure 2 (a), Section 4.1). More formally, we use the following process:

1. Base condition (Figure 2 (a), Section 4.2): Initializing  $T_N^{(1)}(e_E, e_C)$ , a seed entity translation score, where  $e_E$  is an English entity, and  $e_C$  is a Chinese entity.  $T_N^{(1)}$  can be initialized by phonetic similarity or other NE translation methods.
2. Iteration: Obtaining  $T_N^{t+1}$  using  $T_N^t$ .
  - 1) Using  $T_N^t$ , we obtain a set of relation translations with a semantic similarity score,  $T_R^t(r_E, r_C)$ , for an English relation  $r_E$  and a Chinese relation  $r_C$  (Figure 2 (b), Section 4.3) (e.g.,  $r_E = \text{visit}$  and  $r_C = \text{访问}$ ).

- 2) Using  $T_N^t$  and  $T_R^t$ , we identify a set of semantically similar document pairs that describe the same event with a similarity score  $T_D^t(d_E, d_C)$  where  $d_E$  is an English document and  $d_C$  is a Chinese document (Figure 2 (c), Section 4.4).
- 3) Using  $T_N^t$ ,  $T_R^t$  and  $T_D^t$ , we compute  $T_N^{t+1}$ , an improved entity translation score (Figure 2 (d), Section 4.5).

Each sub-goal reinforces the result of others in the  $(t + 1)$ -th iteration, and by iteratively running them, we can improve the quality of translations. Note that, hereinafter, we omit  $(t)$  for readability when there is no ambiguity.

## 4 Methods

In this section, we describe our method in detail. First, we explain how we extract statements, which are units of relational information, from documents in Section 4.1, and how we obtain seed name translations in Section 4.2. Next, we present our method for discovering relation translations across languages in Section 4.3. In Section 4.4, we use the name translations and the relation translations to compare document contexts which can boost the precision of NE translation. In Section 4.5, we describe how we use the resources obtained so far to improve NE translation.

### 4.1 Statement Extraction

We extract relational statements, which we exploit to propagate translation scores, from an English news corpus and a Chinese news corpus. A *relational statement*, or simply a *statement* is a triple  $(x, r, y)$ , representing a relationship between two names,  $x$  and  $y$ . For example, from “Mandelson recently visited Moscow,” we obtain this statement: (Mandelson, visit, Moscow). We follow a standard procedure to extract statements, as similarly adopted by Nakashole et al. (2012), using Stanford CoreNLP (Klein and Manning, 2003) to lemmatize and parse sentences. Here, we refer readers to existing work for further details because this is not our key contribution.

### 4.2 Seed Entity Translation

We need a few seed translation pairs to initiate the framework. We build a seed translation score  $T_N^{(1)}(e_E, e_C)$  indicating the similarity of an English entity  $e_E$  and a Chinese entity  $e_C$  using an existing method. For example, most methods would give high value for

$T_N^{(1)}$  (Mandelson, 曼德尔森 [ManDeErSen]). In this work, we adopted (You et al., 2012) with (Lam et al., 2007) as a base translation matrix to build the seed translation function. We also use a dictionary to obtain non-NE translations such as ‘government’. We use an English-Chinese general word dictionary containing approximately 80,000 English-Chinese translation word pairs that was also used by Kim et al. (2011) to measure the similarity of context words of entities.

### 4.3 Relation Translation

We need to identify relations that have the equivalent semantics across languages, (e.g., *visit* → 访问), to enable selective propagation of translation scores. Formally, our goal is to measure a pairwise relation translation score  $T_R(r_E, r_C)$  for an English relation  $r_E \in R_E$  and a Chinese relation  $r_C \in R_C$  where  $R_E$  is a set of all English relations and  $R_C$  is a set of all Chinese relations.

We first explain a basic feature to measure the similarity of two relations, its limitations, and how we address the problems. A basic clue is that relations of the same meaning are likely to be mentioned with the same entity pairs. For example, if we have (Mandelson, visit, Moscow) as well as (Mandelson, head to, Moscow) in the corpus, this is a positive signal that the two relations may share the same meaning. Such NE pairs are called *support pairs* of the two relations.

We formally define this clue for relations in the same language, and then describe that in the bilingual setting. A *support intersection*  $H_m(r^i, r^j)$ , a set of support pairs, for monolingual relations  $r^i$  and  $r^j$  is defined as

$$H_m(r^i, r^j) = H(r^i) \cap H(r^j) \quad (1)$$

where  $H(r)$  is the *support set* of a relation  $r$  defined as  $H(r) = \{(x, y) | (x, r, y) \in \mathbf{S}\}$ , and  $\mathbf{S}$  is either  $\mathbf{S}_E$ , a set of all English statements, or  $\mathbf{S}_C$ , a set of all Chinese statements that we extracted in Section 4.1.

Likewise, we can define a support intersection for relations in the different languages using the translation score  $T_N(e_E, e_C)$ . For an English relation  $r_E$  and a Chinese relation  $r_C$ ,

$$H_b(r_E, r_C) = \{(x_E, x_C, y_E, y_C) | \begin{aligned} &T_N(x_E, x_C) \geq \theta \\ &\text{and } T_N(y_E, y_C) \geq \theta \\ &\text{for } (x_E, r_E, y_E) \in \mathbf{S}_E \\ &\text{and } (x_C, r_C, y_C) \in \mathbf{S}_C \end{aligned}\} \quad (2)$$

where  $\theta = 0.6$  is a harsh threshold to exclude most of the false translations by  $T_N$ .

Finally, we define a support intersection, a set of support pairs between two relations  $r^i$  and  $r^j$  of any languages,

$$H(r^i, r^j) = \begin{cases} H_b(r^i, r^j) & \text{if } r^i \in R_E \text{ and } r^j \in R_C \\ H_b(r^j, r^i) & \text{if } r^j \in R_E \text{ and } r^i \in R_C \\ H_m(r^i, r^j) & \text{otherwise} \end{cases} \quad (3)$$

Intuitively,  $|H(r^i, r^j)|$  indicates the strength of the semantic similarity of two relations  $r^i$  and  $r^j$  of any languages. However, as shown in Table 2, we cannot use this value directly to measure the similarity because the support intersection of semantically similar *bilingual* relations (e.g.,  $|H(\text{head to}, \text{访问})| = 2$ ) is generally very low, and normalization cannot remedy this problem as we can see from  $|H(\text{visit}, \text{访问})| = 27$  and  $|H(\text{visit})| = 1617$ .

Set	Cardinality
$H(\text{visit})$	1617
$H(\text{访问})$	2788
$H(\text{visit}, \text{访问})$	27
$H(\text{head to}, \text{访问})$	2

Table 2: Evidence cardinality in the corpora.

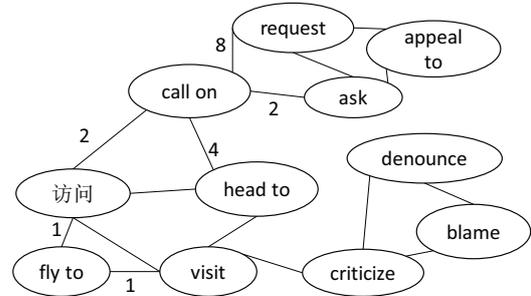

Figure 3: Network of relations. Edges indicate that the relations have a non-empty support intersection, and edge labels show the size of the intersection.

We found that the connectivity among similar relations is more important than the strength of the similarity. For example, as shown in Figure 3, *visit* is connected to most of the *visit*-relations such as *head to*, 访问. Although *visit* is connected to *criticize*, *visit* is not connected to other *criticize*-relations such as *denounce* and *blame*, whereas *criticize*, *denounce*, and *blame* are inter-

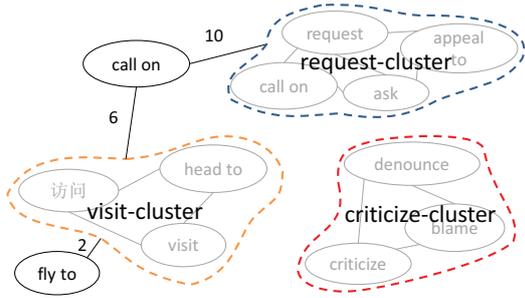

Figure 4: Relation clusters and a few individual relations. Edge labels show the size of the intersection.

connected. To exploit this feature, we use a random walk-based graph clustering method.

Formally, we use Markov clustering (Van Dongen, 2000) on a graph  $G = (V, E)$  of relations, where  $V = R_E \cup R_C$  is a set of all English and Chinese relations. An edge  $(r^i, r^j)$  indicates that two relations in any languages are similar, and its weight is quantified by a sigmoid function on a linear transformation of  $|H(r^i, r^j)|$  that was empirically found to produce good results.

Each resultant cluster forms a set of bilingual similar relations,  $c = \{r^{c1}, \dots, r^{cM}\}$ , such as *visit-cluster*, which consists of *visit*, *head to*, and *访问* in Figure 4. However, this cluster may not contain all similar relations. A relation may have multiple meanings (e.g., *call on*) so it can be clustered to another cluster, or a relation might not be clustered when its support set is too small (e.g., *fly to*). For such relations, rather than assigning zero similarity to *visit*-relations, we compute a cluster membership function based on support pairs of the cluster members and the target relation, and then formulate a pairwise relation translation score.

Formally, we learn the membership function of a relation  $r$  to a cluster  $c$  using support vector regression (Joachims, 1999) with the following features based on the support set of cluster  $c$ ,  $H(c) = \bigcup_{r \in c} H(r)$ , and the support intersection of  $r$  and  $c$ ,  $H(r, c) = \bigcup_{r^* \in c} H(r, r^*)$ .

- $f^1(r, c) = |H(r, c)|/|H(r)|$ : This quantifies the degree of inclusion,  $H(c) \in H(r)$ .
- $f^2(r, c) = |H(r, c)|/|H(c)|$ : This quantifies the degree of inclusion,  $H(r) \in H(c)$ .
- $f^3(r, c) = |H_{\text{within}}(r, c)|/|H_{\text{within}}(c)|$ : This is a variation of  $f^2$  that considers only noun phrase pairs shared at least once by relations in  $c$ .

- $f^4(r, c) = |H_{\text{within}}(r, c)|/|H_{\text{shared}}(c)|$ : This is a variation of  $f^2$  that considers only noun phrase pairs shared at least once by any pair of relations.
- $f^5(r, c) = |\{r^* \in c | H(r, r^*) > 0\}|/|c|$ : This is the degree of connectivity to the cluster members.

where  $H_{\text{within}}(r, c) = \bigcup_{r^* \in c} H(r, c) \cap H(r, r^*)$ , the intersection, considering translation, of  $H(r)$  and noun phrase pairs shared at once by relations in  $c$ ,  $H_{\text{within}}(c) = \bigcup_{r^* \in c} H(r^*, c - \{r^*\})$ , and  $H_{\text{shared}}(c) = \bigcup_{r^* \in R_E \cup R_C} H(r^*, c)$ , the noun phrase pairs shared at once by any relations. The use of  $H_{\text{within}}$  and  $H_{\text{shared}}$  is based on the observation that a noun phrase pair that appear in only one relation tends to be an incorrectly chunked entity such as ‘World Trade’ from the ‘World Trade Organization’.

Based on this membership function  $S(r, c)$ , we compute pairwise relation similarity. We consider that two relations are similar if they have at least one cluster that the both relations belong to, which can be measured with  $S(r, c)$ . More formally, pairwise similarity of relations  $r^i$  and  $r^j$  is defined as

$$T_R(r^i, r^j) = \max_{c \in \mathcal{C}} S(r^i, c) \cdot S(r^j, c) \quad (4)$$

where  $\mathcal{C}$  is a set of all clusters.

#### 4.4 Statement-level Document Context Comparison

A brute-force statement matching approach often fails due to ambiguity created by ignoring context, and missing information in  $T_N$  or  $T_R$ . Therefore, we detect similar document pairs to boost the statement matching process. Unlike the previous approaches (e.g., bag-of-words), we focus on the relationships of entities within documents using the extracted statements.

Formally, we compute the similarity of two statements  $s_E = (x_E, r_E, y_E)$  and  $s_C = (x_C, r_C, y_C)$  in different languages as follows:

$$T_S(s_E, s_C) = T_N(x_E, x_C) T_R(r_E, r_C) T_N(y_E, y_C) \quad (5)$$

With this definition, we can find similar statements described with different vocabularies in different languages.

To compare a document pair, we use the following equation to measure the similarity of an

English document  $d_E^i$  and a Chinese document  $d_C^j$  based on their statements  $S_E^i$  and  $S_C^j$ , respectively:

$$T_D(d_E^i, d_C^j) = \frac{\sum_{(s_E, s_C) \in B} T_S(s_E^{i,r}, s_C^{j,r})}{|S_E^i| + |S_C^j| - |B|} \quad (6)$$

where  $B \subset S_E^i \times S_C^j$  is a greedy approximate solution of maximum bipartite matching (West, 1999) on a bipartite graph  $G_B = (V_B = (S_E^i, S_C^j), E_B)$  with edge weights that are defined by  $T_S$ . The maximum bipartite matching finds a subset of edges in  $S_E^i \times S_C^j$  that maximize the sum of the selected edge weights and that do not share a node as their anchor point.

#### 4.5 Iteration on $T_N$

In this section, we describe how we use the statement similarity function  $T_S$ , and the document similarity function  $T_D$  to improve and derive the next generation entity translation function  $T_N^{(t+1)}$ . We consider that a pair of an English entity  $e_E$  and a Chinese entity  $e_C$  are likely to indicate the same real world entity if they have 1) semantically similar relations to the same entity 2) under the same context. Formally, we define an increment function as follows.

$$\Delta T_N(e_E, e_C) = \sum_{d_E^i} \sum_{d_C^j} T_D(d^i, d^j) \max_{(s_E, s_C) \in B^*} T_S(s_E, s_C) \quad (7)$$

where  $B^*$  is a subset of  $B \subset S_E^i \times S_C^j$  such that the connected statements mention  $e_E$  and  $e_C$ , and  $B$  is the greedy approximate solution of maximum bipartite matching for the set  $S_E^i$  of statements of  $d_E^i$  and the set  $S_C^j$  of statements of  $d_C^j$ . In other words,  $B^*$  is a set of matching statement pairs mentioning the translation target  $e_E$  and  $e_C$  in the document pair. Then, we use the following equation to improve the original entity translation function.

$$T_N^{(t+1)}(e_E, e_C) = (1 - \lambda) \frac{\Delta T_N(e_E, e_C)}{\sum_{e_C^*} \Delta T_N(e_E, e_C^*)} + \lambda T_N(e_E, e_C) \quad (8)$$

where  $\lambda$  is a mixing parameter in  $[0, 1]$ . We set  $\lambda = 0.6$  in our experiments.

With this update, we obtain the improved NE translations considering the relations that an entity has to other entities under the same context to achieve higher precision.

## 5 Experiments

In this section, we present experimental settings and results of translating entity names using our methods compared with several baselines.

### 5.1 Data and Evaluation

We processed news articles for an entire year in 2008 by Xinhua news who publishes news in both English and Chinese, which were also used by Kim et al. (2011) and Shao and Ng (2004). The English corpus consists of 100,746 news articles, and the Chinese corpus consists of 88,031 news articles. The news corpora are not *parallel* but *comparable* corpora, with asymmetry of entities and relationship as the asymmetry in the number of documents also suggest. Examples of such locality in Xinhua news include the more extensive coverage of Chinese teams in the Olympics and domestic sports in the Chinese news. Our framework finds and leverages comparable parts from the corpora without document-content-external information such as time stamps. We also show that, under the decreasing comparability, our method retains higher MRR than the baselines.

We follow the evaluation procedures used by You et al. (2012) and Kim et al. (2011) to fairly and precisely compare the effectiveness of our methods with baselines. To measure performance, we use mean reciprocal rank (MRR) to evaluate a translation function  $T$ :

$$MRR(T) = \frac{1}{|Q|} \sum_{(u,v) \in Q} \frac{1}{rank_T(u,v)} \quad (9)$$

where  $Q$  is the set of gold English-Chinese translation pairs  $(u, v)$  and  $rank_T(u, v)$  is the rank of  $T(u, v)$  in  $\{T(u, w) | w \text{ is a Chinese entity}\}$ . In addition, we use precision, recall, and F1-score.

As gold translation pairs, we use the evaluation data used by You et al. (2012) with additional labels, especially for organizations. The labeling task is done by randomly selecting English entities and finding their Chinese translation from the Chinese corpus. We only use entities with translations that appear in the Chinese corpus. We present the evaluation results for persons and organizations to show the robustness of the methods. In total, we identified 490 English entities in the English news with Chinese translations in the Chinese news. Among the 490 entities, 221 NEs are persons and 52 NEs are organizations.

	Person			Organization				
	MRR	P.	R.	F1	MRR	P.	R.	F1
$T_N^{(2)}$	<b>0.80</b>	<b>0.81</b>	<b>0.79</b>	<b>0.80</b>	<b>0.53</b>	<b>0.56</b>	<b>0.52</b>	<b>0.54</b>
$T_N^{(1)}$	0.77	0.80	0.77	0.78	0.44	0.49	0.44	0.46
$T_{PH+P}^S$	0.73	0.70	0.67	0.69	0.14	0.17	0.04	0.06
$T_{PH+P}^M$	0.68	0.70	0.68	0.69	0.08	0.31	0.08	0.12
$T_{HB}$	0.71	0.59	0.59	0.59	0.37	0.29	0.29	0.29
$T_{Dict}$	0.09	1.00	0.09	0.17	1.00	0.17	0.17	0.30

Table 3: Evaluation results of the methods.

## 5.2 Baselines

We compare our methods with the following baselines.

- $T_{PH+P}^S$  (You et al., 2012) is a holistic method that uses a transliteration method as base translations, and then reinforces them to achieve higher quality. This method uses only a single type of entities to propagate the translation scores.
- $T_{PH+P}^M$  is the holistic method revised to use naive multi-type propagation that uses multiple types of entities to reinforce the translation scores.
- $T_{HB}$  is a linear combination of transliteration and semantic translation methods (Lam et al., 2007) tuned to achieve the highest MRR.
- $T_{Dict}$  is a dictionary-only method. This dictionary is used by both  $T_{HB}$  and  $T_N$ .

Only the translation pairs of scores above 0.35 are used for  $T_{PH+P}$  to maximize the F1-score to measure precision, recall and F1-score. For our method  $T_N^{(t)}$ , we use the result with  $(t) = 1$ , the seed translations, and  $(t) = 2$ , which means that only one pass of the whole framework is performed to improve the seed translation function. In addition, we use translation pairs with scores above 0.05 to measure precision, recall, and F1-score. Note that these thresholds do not affect MRRs.

## 5.3 NE Translation Results

We show the result of the quantitative evaluation in Table 3, where the highest values are boldfaced, except  $T_{Dict}$  which shows 1.00 precision because it is a manually created dictionary. For both the person and organization cases, our method  $T_N^{(2)}$  outperforms the state-of-the-art methods in terms

English name	$T_N^{(2)}$	$T_N^{(1)}$	$T_{HB}$
Mandelson	<b>曼德尔森</b> [ManDeErSen]	<b>曼德尔森</b> [ManDeErSen]	<b>曼德尔森</b> [ManDeErSen]
WTO	<b>世贸组织</b> [ShiMaoZuZhi]	上合组织 [ShangHeZuZhi]	巴解组织 [BaJieZuZhi]
White House	<b>白宫</b> [BaiGong]	加州 [JiaZhou]	加州 [JiaZhou]
Microsoft	<b>微软公司</b> [WeiRuanGongSi]	美国司法部 [MeiGuoSiFaBu]	米罗诺夫 [MiLuoNuoFu]

Table 4: Example translations from the different methods. Boldface indicates correct translations.

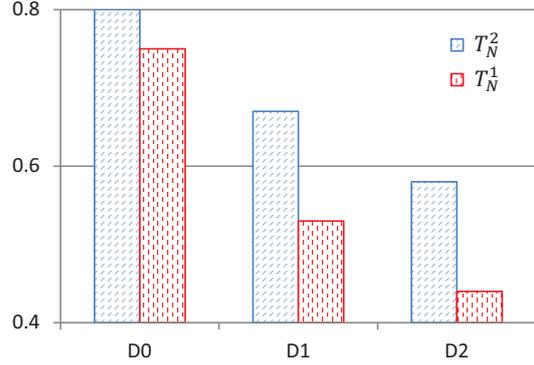

Figure 6: MRR with decreasing comparability.

of precision, recall, F1-score and MRR. With only one iteration of selective propagation, the seed translation is improved to achieve the 0.09 higher MRR.

The baselines show lower, but comparable MRRs and F1-scores for persons that mostly consist of transliterated cases. However, not all translations have phonetic similarity, especially organization names, as the low F1-score of  $T_{PH+P}^S$ , 0.06, for organizations suggests. The naive multi-type propagation  $T_{PH+P}^M$  shows decreased MRR for both persons and organizations compared to the single-type propagation  $T_{PH+P}^S$ , which shows a negative influence of diverse relation semantics of entities of different types.  $T_{HB}$  achieves a better MRR than  $T_{PH+P}$  due to the semantic translation of organization names. However, despite the increased recall of  $T_{HB}$  over that of  $T_{Dict}$ , the precision of  $T_{HB}$  is unsatisfactory because  $T_{HB}$  maps abbreviated names such as ‘WTO’ with other NEs. On the other hand, our method achieves the highest MRR and precision in both the person and organization categories.

As shown in Table 4,  $T_{HB}$  translates ‘WTO’ inaccurately, linking it to an incorrect organization ‘巴解组织’ (Palestine Liberation Organization).

The European Union (EU) Trade Commissioner (1) Peter Mandelson traveled to Moscow on Thursday for talks on ... Mandelson said it is a priority to see (2) Russia join the WTO, ...

欧盟贸易委员 (1) 彼得曼德尔森14日启程前往莫斯科, ... 德尔森在行前发表的声明中说, (2) 俄罗斯加入世贸组织是欧盟优先考虑的事项之一, ...

Figure 5: Example of similar document pairs.

Moreover, the use of the corpora by  $T_N^{(1)}$  could not fix this problem, and it finds another organization related to trade, ‘上合组织’ (Shanghai Cooperation Organization). In contrast, our selective propagation method  $T_N^{(2)}$ , which uses the wrong seed translation by  $T_N^{(1)}$ , ‘上合组织’ (Shanghai Cooperation Organization), successfully translates the WTO using statements such as (Russia, join, WTO), and its corresponding Chinese statement (俄罗斯, 加入, 世贸组织). Similarly, both the baseline  $T_{HB}$  and the seed translation  $T_N^{(1)}$  matched *Microsoft* to incorrect Chinese entities that are phonetically similar as indicated by the underlined text. In contrast,  $T_N^{(2)}$  finds the correct translation despite the phonetic dissimilarity.

#### 5.4 NE Translation Results with Low Corpus Comparability

We tested the methods using less comparable data to evaluate the robustness with the following derived datasets:

- D0: All news articles are used.
- D1: January-December English and July-December Chinese articles are used.
- D2: April-September English and July-December Chinese articles are used.

Figure 6 shows the MRR comparisons of our method  $T_N^{(2)}$  and  $T_N^{(1)}$  on all test entities. Because the commonly appearing NEs are decreasing, the performance decline is inevitable. However, we can see that the MRR of the seed translation method drops significantly on D1 and D2, whereas our method shows 0.14 higher MRR for both cases.

#### 5.5 Similar Documents

In this section, we show an example of similar documents in Figure 5. Both articles describe the same event about the visit of Mandelson to Moscow for the discussion on the joining of Russia to the WTO. The extracted statements are the exact translations of each corresponding part as indicated by the arrows. We stress this is an extreme case for illustration, where the two sentences are almost an exact translation, except for a minor asymmetry involving the date (Thursday in English, and 14th in Chinese). In most similar documents, the asymmetry is more significant. The seed translation score  $T_N^1(\text{WTO}, \text{世贸组织})$  is not enough to match the entities. However, the context similarity, due to other similar statements such as (1), allows us to match (2). This match helps translation of ‘WTO’ by inspecting the organization that Russia considers to join in both documents.

#### 6 Conclusions

This paper proposed a bootstrapping approach for entity translation using multilingual relational clustering. Further, the proposed method could find similar document pairs by comparing statements to enable us to focus on comparable parts of evidence. We validated the quality of our approach using real-life English and Chinese corpora, and its performance significantly exceeds that of previous approaches.

#### Acknowledgment

## Abstract

Wikipedia infoboxes are a valuable source of structured knowledge for global knowledge sharing. However, infobox information is very incomplete and imbalanced among the Wikipedias in different languages. It is a promising but challenging problem to utilize the rich structured knowledge from a source language Wikipedia to help complete the missing infoboxes for a target language.

In this paper, we formulate the problem of cross-lingual knowledge extraction from multilingual Wikipedia sources, and present a novel framework, called WikiCiKE, to solve this problem. An instance-based transfer learning method is utilized to overcome the problems of topic drift and translation errors. Our experimental results demonstrate that WikiCiKE outperforms the monolingual knowledge extraction method and the translation-based method.

## 1 Introduction

In recent years, the automatic knowledge extraction using Wikipedia has attracted significant research interest in research fields, such as the semantic web. As a valuable source of structured knowledge, Wikipedia infoboxes have been utilized to build linked open data (Suchanek et al., 2007; Bollacker et al., 2008; Bizer et al., 2008; Bizer et al., 2009), support next-generation information retrieval (Hotho et al., 2006), improve question answering (Bouma et al., 2008; Fernández et al., 2009), and other aspects of data exploitation (McIlraith et al., 2001; Volkel et al., 2006; Hogan et al., 2011) using semantic web standards, such as RDF (Pan and Horrocks, 2007;

Heino and Pan, 2012) and OWL (Pan and Horrocks, 2006; Pan and Thomas, 2007; Fokoue et al., 2012), and their reasoning services.

However, most infoboxes in different Wikipedia language versions are missing. Figure 1 shows the statistics of article numbers and infobox information for six major Wikipedias. Only 32.82% of the articles have infoboxes on average, and the numbers of infoboxes for these Wikipedias vary significantly. For instance, the English Wikipedia has 13 times more infoboxes than the Chinese Wikipedia and 3.5 times more infoboxes than the second largest Wikipedia of German language.

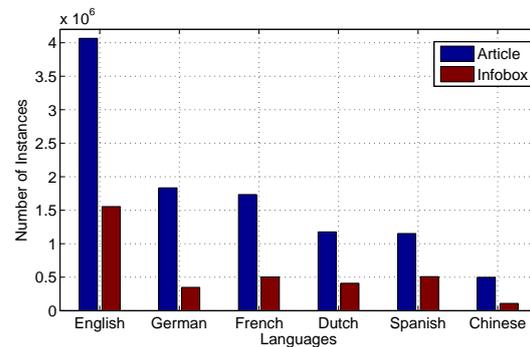

Figure 1: Statistics for Six Major Wikipedias.

To solve this problem, KYLIN has been proposed to extract the missing infoboxes from unstructured article texts for the English Wikipedia (Wu and Weld, 2007). KYLIN performs well when sufficient training data are available, and such techniques as shrinkage and retraining have been used to increase recall from English Wikipedia's long tail of sparse infobox classes (Weld et al., 2008; Wu et al., 2008). The extraction performance of KYLIN is limited by the number of available training samples.

Due to the great imbalance between different Wikipedia language versions, it is difficult to gather sufficient training data from a single Wikipedia. Some translation-based cross-lingual knowledge

extraction methods have been proposed (Adar et al., 2009; Bouma et al., 2009; Adafre and de Rijke, 2006). These methods concentrate on translating existing infoboxes from a richer source language version of Wikipedia into the target language. The recall of new target infoboxes is highly limited by the number of equivalent cross-lingual articles and the number of existing source infoboxes. Take Chinese-English<sup>1</sup> Wikipedias as an example: current translation-based methods only work for 87,603 Chinese Wikipedia articles, 20.43% of the total 428,777 articles. Hence, the challenge remains: how could we supplement the missing infoboxes for the rest 79.57% articles?

On the other hand, the numbers of existing infobox attributes in different languages are highly imbalanced. Table 1 shows the comparison of the numbers of the articles for the attributes in template PERSON between English and Chinese Wikipedia. Extracting the missing value for these attributes, such as *awards*, *weight*, *influences* and *style*, inside the single Chinese Wikipedia is intractable due to the rarity of existing Chinese attribute-value pairs.

Attribute	en	zh	Attribute	en	zh
<i>name</i>	82,099	1,486	<i>awards</i>	2,310	38
<i>birth date</i>	77,850	1,481	<i>weight</i>	480	12
<i>occupation</i>	66,768	1,279	<i>influences</i>	450	6
<i>nationality</i>	20,048	730	<i>style</i>	127	1

Table 1: The Numbers of Articles in TEMPLATE PERSON between English(en) and Chinese(zh).

In this paper, we have the following hypothesis: *one can use the rich English (auxiliary) information to assist the Chinese (target) infobox extraction*. In general, we address the problem of cross-lingual knowledge extraction by using the imbalance between Wikipedias of different languages. For each attribute, we aim to learn an extractor to find the missing value from the unstructured article texts in the target Wikipedia by using the rich information in the source language. Specifically, we treat this cross-lingual information extraction task as a transfer learning-based binary classification problem.

The contributions of this paper are as follows:

1. We propose a transfer learning-based cross-lingual knowledge extraction framework

<sup>1</sup>Chinese-English denotes the task of Chinese Wikipedia infobox completion using English Wikipedia

called **WikiCiKE**. The extraction performance for the target Wikipedia is improved by using rich infoboxes and textual information in the source language.

2. We propose the TrAdaBoost-based extractor training method to avoid the problems of topic drift and translation errors of the source Wikipedia. Meanwhile, some language-independent features are introduced to make WikiCiKE as general as possible.
3. Chinese-English experiments for four typical attributes demonstrate that WikiCiKE outperforms both the monolingual extraction method and current translation-based method. The increases of 12.65% for precision and 12.47% for recall in the template named person are achieved when only 30 target training articles are available.

The rest of this paper is organized as follows. Section 2 presents some basic concepts, the problem formalization and the overview of WikiCiKE. In Section 3, we propose our detailed approaches. We present our experiments in Section 4. Some related work is described in Section 5. We conclude our work and the future work in Section 6.

## 2 Preliminaries

In this section, we introduce some basic concepts regarding Wikipedia, formally defining the key problem of cross-lingual knowledge extraction and providing an overview of the WikiCiKE framework.

### 2.1 Wiki Knowledge Base and Wiki Article

We consider each language version of Wikipedia as a *wiki knowledge base*, which can be represented as  $K = \{a_i\}_{i=1}^p$ , where  $a_i$  is a disambiguated article in  $K$  and  $p$  is the size of  $K$ .

Formally we define a *wiki article*  $a \in K$  as a 5-tuple  $a = (\textit{title}, \textit{text}, \textit{ib}, \textit{tp}, C)$ , where

- *title* denotes the title of the article  $a$ ,
- *text* denotes the unstructured text description of the article  $a$ ,
- *ib* is the infobox associated with  $a$ ; specifically,  $\textit{ib} = \{(\textit{attr}_i, \textit{value}_i)\}_{i=1}^q$  represents the list of attribute-value pairs for the article  $a$ ,

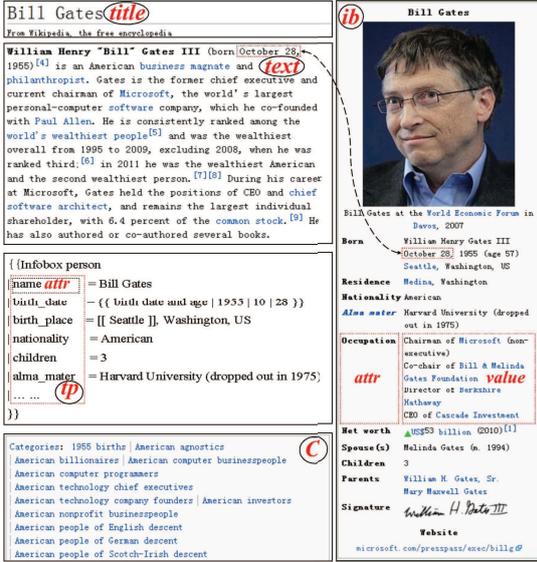

Figure 2: Simplified Article of “Bill Gates”.

- $tp = \{attr_i\}_{i=1}^r$  is the infobox template associated with  $ib$ , where  $r$  is the number of attributes for one specific template, and
- $C$  denotes the set of categories to which the article  $a$  belongs.

Figure 2 gives an example of these five important elements concerning the article named “Bill Gates”.

In what follows, we will use named subscripts, such as  $a_{Bill\ Gates}$ , or index subscripts, such as  $a_i$ , to refer to one particular instance interchangeably. We will use “name in TEMPLATE PERSON” to refer to the attribute  $attr_{name}$  in the template  $tp_{PERSON}$ . In this cross-lingual task, we use the source ( $S$ ) and target ( $T$ ) languages to denote the languages of auxiliary and target Wikipedias, respectively. For example,  $K_S$  indicates the source wiki knowledge base, and  $K_T$  denotes the target wiki knowledge base.

## 2.2 Problem Formulation

Mining new infobox information from unstructured article texts is actually a multi-template, multi-slot information extraction problem. In our task, each template represents an infobox template and each slot denotes an attribute. In the WikiCiKE framework, for each attribute  $attr_T$  in an infobox template  $tp_T$ , we treat the task of missing value extraction as a binary classification problem. It predicts whether a particular word (token) from the article  $text$  is the extraction target (Finn and Kushmerick, 2004; Lafferty et al., 2001).

Given an attribute  $attr_T$  and an instance (word/token)  $x_i$ ,  $X_S = \{x_i\}_{i=1}^n$  and  $X_T = \{x_i\}_{i=n+1}^{n+m}$  are the sets of instances (words/tokens) in the source and the target language respectively.  $x_i$  can be represented as a feature vector according to its context. Usually, we have  $n \gg m$  in our setting, with much more attributes in the source than those in the target. The function  $g : X \mapsto Y$  maps the instance from  $X = X_S \cup X_T$  to the true label of  $Y = \{0, 1\}$ , where 1 represents the extraction target (positive) and 0 denotes the background information (negative). Because the number of target instances  $m$  is inadequate to train a good classifier, we combine the source and target instances to construct the training data set as  $TD = TD_S \cup TD_T$ , where  $TD_S = \{x_i, g(x_i)\}_{i=1}^n$  and  $TD_T = \{x_i, g(x_i)\}_{i=n+1}^{n+m}$  represent the source and target training data, respectively.

Given the combined training data set  $TD$ , our objective is to estimate a hypothesis  $f : X \mapsto Y$  that minimizes the prediction error on testing data in the target language. Our idea is to determine the useful part of  $TD_S$  to improve the classification performance in  $TD_T$ . We view this as a transfer learning problem.

## 2.3 WikiCiKE Framework

WikiCiKE learns an extractor for a given attribute  $attr_T$  in the target Wikipedia. As shown in Figure 3, WikiCiKE contains four key components: (1) **Automatic Training Data Generation**: given the target attribute  $attr_T$  and two wiki knowledge bases  $K_S$  and  $K_T$ , WikiCiKE first generates the training data set  $TD = TD_S \cup TD_T$  automatically. (2) **WikiCiKE Training**: WikiCiKE uses a transfer learning-based classification method to train the classifier (extractor)  $f : X \mapsto Y$  by using  $TD_S \cup TD_T$ . (3) **Template Classification**: WikiCiKE then determines proper candidate articles which are suitable to generate the missing value of  $attr_T$ . (4) **WikiCiKE Extraction**: given a candidate article  $a$ , WikiCiKE uses the learned extractor  $f$  to label each word in the  $text$  of  $a$ , and generate the extraction result in the end.

## 3 Our Approach

In this section, we will present the detailed approaches used in WikiCiKE.

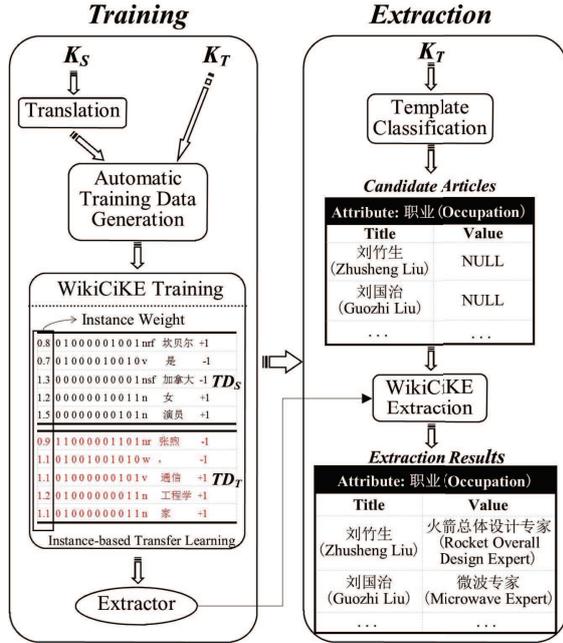

Figure 3: WikiCiKE Framework.

### 3.1 Automatic Training Data Generation

To generate the training data for the target attribute  $attr_T$ , we first determine the equivalent cross-lingual attribute  $attr_S$ . Fortunately, some templates in non-English Wikipedia (e.g. Chinese Wikipedia) explicitly match their attributes with their counterparts in English Wikipedia. Therefore, it is convenient to align the cross-lingual attributes using English Wikipedia as bridge. For attributes that can not be aligned in this way, currently we manually align them. The manual alignment is worthwhile because thousands of articles belong to the same template may benefit from it and at the same time it is not very costly. In Chinese Wikipedia, the top 100 templates have covered nearly 80% of the articles which have been assigned a template.

Once the aligned attribute mapping  $attr_T \leftrightarrow attr_S$  is obtained, we collect the articles from both  $K_S$  and  $K_T$  containing the corresponding  $attr$ . The collected articles from  $K_S$  are translated into the target language. Then, we use a uniform automatic method, which primarily consists of word labeling and feature vector generation, to generate the training data set  $TD = \{(x, g(x))\}$  from these collected articles.

For each collected article  $a = \{title, text, ib, tp, C\}$  and its *value* of  $attr$ , we can automatically label each word  $x$  in *text* according to whether  $x$  and its neighbors are

contained by the *value*. The *text* and *value* are processed as bags of words  $\{x\}_{text}$  and  $\{x\}_{value}$ . Then for each  $x_i \in \{x\}_{text}$  we have:

$$g(x_i) = \begin{cases} 1 & x_i \in \{x\}_{value}, |\{x\}_{value}| = 1 \\ 1 & x_{i-1}, x_i \in \{x\}_{value} \text{ OR } x_i, x_{i+1} \in \{x\}_{value}, \\ & |\{x\}_{value}| > 1 \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

After the word labeling, each instance (word/token) is represented as a feature vector. In this paper, we propose a general feature space that is suitable for most target languages. As shown in Table 2, we classify the features used in WikiCiKE into three categories: format features, POS tag features and token features.

Category	Feature	Example
Format feature	First token of sentence	你好, 世界! <i>Hello World!</i>
	In first half of sentence	你好, 世界! <i>Hello World!</i>
	Starts with two digits	12月31日 31 <sup>th</sup> Dec.
	Starts with four digits	1999年 夏天 1999's summer
	Contains a cash sign	10 ¥ or 10 \$
	Contains a percentage symbol	10%
	Stop words	的, 地, 这... of, the, a, an
	Pure number	365
	Part of an anchor text	电影导演 <i>Movie Director</i>
	Begin of an anchor text	游戏设计师 <i>Game Designer</i>
POS tag features	POS tag of current token	
	POS tags of previous 5 tokens	
	POS tags of next 5 tokens	
Token features	Current token	
	Previous 5 tokens	
	Next 5 tokens	
	Is current token contained by title	
	Is one of previous 5 tokens contained by title	

Table 2: Feature Definition.

The target training data  $TD_T$  is directly generated from articles in the target language Wikipedia. Articles from the source language Wikipedia are translated into the target language in advance and then transformed into training data  $TD_S$ . In next section, we will discuss how to train an extractor from  $TD = TD_S \cup TD_T$ .

### 3.2 WikiCiKE Training

Given the attribute  $attr_T$ , we want to train a classifier  $f : X \mapsto Y$  that can minimize the prediction

error for the testing data in the target language. Traditional machine learning approaches attempt to determine  $f$  by minimizing some loss function  $L$  on the prediction  $f(x)$  for the training instance  $x$  and its real label  $g(x)$ , which is

$$\hat{f} = \operatorname{argmin}_{f \in \Theta} \sum L(f(x), g(x)) \text{ where } (x, g(x)) \in TD_T \quad (2)$$

In this paper, we use TrAdaBoost (Dai et al., 2007), which is an instance-based transfer learning algorithm that was first proposed by Dai to find  $\hat{f}$ . TrAdaBoost requires that the source training instances  $X_S$  and target training instances  $X_T$  be drawn from the same feature space. In WikiCiKE, the source articles are translated into the target language in advance to satisfy this requirement. Due to the topic drift problem and translation errors, the joint probability distribution  $P_S(x, g(x))$  is not identical to  $P_T(x, g(x))$ . We must adjust the source training data  $TD_S$  so that they fit the distribution on  $TD_T$ . TrAdaBoost iteratively updates the weights of all training instances to optimize the prediction error. Specifically, the weight-updating strategy for the source instances is decided by the loss on the target instances.

For each  $t = 1 \sim T$  iteration, given a weight vector  $\mathbf{p}_t$  normalized from  $\mathbf{w}_t$  ( $\mathbf{w}_t$  is the weight vector before normalization), we call a basic classifier  $F$  that can address weighted instances and then find a hypothesis  $f$  that satisfies

$$\hat{f}_t = \operatorname{argmin}_{f \in \Theta_F} \sum L(\mathbf{p}_t, f(x), g(x)) \quad (3)$$

$$(x, g(x)) \in TD_S \cup TD_T$$

Let  $\epsilon_t$  be the prediction error of  $\hat{f}_t$  at the  $t^{\text{th}}$  iteration on the target training instances  $TD_T$ , which is

$$\epsilon_t = \frac{1}{\sum_{k=n+1}^{n+m} w_k^t} \times \sum_{k=n+1}^{n+m} (w_k^t \times |\hat{f}_t(x_k) - y_k|) \quad (4)$$

With  $\epsilon_t$ , the weight vector  $\mathbf{w}_t$  is updated by the function:

$$\mathbf{w}_{t+1} = h(\mathbf{w}_t, \epsilon_t) \quad (5)$$

The weight-updating strategy  $h$  is illustrated in Table 3.

Finally, a final classifier  $\hat{f}$  can be obtained by combining  $\hat{f}_{T/2} \sim \hat{f}_T$ .

TrAdaBoost has a convergence rate of  $O(\sqrt{\ln(n/N)})$ , where  $n$  and  $N$  are the number of source samples and number of maximum iterations respectively.

		TrAdaBoost	AdaBoost
Target samples	+	$w_t$	$w_t$
	-	$w_t \times \beta_t^{-1}$	$w_t \times \beta_t^{-1}$
Source samples	+	$w_t \times \beta^{-1}$	No source training
	-	$w_t \times \beta$	sample available

+: correctly labelled      -: miss-labelled  
 $w_t$ : weight of an instance at the  $t^{\text{th}}$  iteration  
 $\beta_t = \epsilon_t \times (1 - \epsilon_t)$   
 $\beta = 1/(1 + \sqrt{2 \ln nT})$

Table 3: Weight-updating Strategy of TrAdaBoost.

### 3.3 Template Classification

Before using the learned classifier  $f$  to extract missing infobox value for the target attribute  $attr_T$ , we must select the correct articles to be processed. For example, the article  $a_{New York}$  is not a proper article for extracting the missing value of the attribute  $attr_{birth\_day}$ .

If  $a$  already has an incomplete infobox, it is clear that the correct  $tp$  is the template of its own infobox  $ib$ . For those articles that have no infoboxes, we use the classical 5-nearest neighbor algorithm to determine their templates (Roussopoulos et al., 1995) using their category labels, outlinks, inlinks as features (Wang et al., 2012). Our classifier achieves an average precision of 76.96% with an average recall of 63.29%, and can be improved further. In this paper, we concentrate on the WikiCiKE training and extraction components.

### 3.4 WikiCiKE Extraction

Given an article  $a$  determined by template classification, we generate the missing *value* of *attr* from the corresponding *text*. First, we turn the *text* into a word sequence and compute the feature vector for each word based on the feature definition in Section 3.1. Next we use  $f$  to label each word, and we get a labeled sequence  $text^l$  as  $text^l = \{x_1^{f(x_1)} \dots x_{i-1}^{f(x_{i-1})} x_i^{f(x_i)} x_{i+1}^{f(x_{i+1})} \dots x_n^{f(x_n)}\}$  where the superscript  $f(x_i) \in \{0, 1\}$  represents the positive or negative label by  $f$ . After that, we extract the adjacent positive tokens in *text* as the predict value. In particular, the longest positive token sequence and the one that contains other positive token sequences are preferred in extraction. E.g., a positive sequence “comedy movie director” is preferred to a shorter sequence “movie director”.

## 4 Experiments

In this section, we present our experiments to evaluate the effectiveness of WikiCiKE, where we focus on the Chinese-English case; in other words, the target language is Chinese and the source language is English. It is part of our future work to try other language pairs which two Wikipedias of these languages are imbalanced in infobox information such as English-Dutch.

### 4.1 Experimental Setup

#### 4.1.1 Data Sets

Our data sets are from Wikipedia dumps<sup>2</sup> generated on April 3, 2012. For each attribute, we collect both labeled articles (articles that contain the corresponding attribute *attr*) and unlabeled articles in Chinese. We split the labeled articles into two subsets  $A_T$  and  $A_{test}$  ( $A_T \cap A_{test} = \emptyset$ ), in which  $A_T$  is used as target training articles and  $A_{test}$  is used as the first testing set. For the unlabeled articles, represented as  $A'_{test}$ , we manually label their infoboxes with their texts and use them as the second testing set. For each attribute, we also collect a set of labeled articles  $A_S$  in English as the source training data. Our experiments are performed on four attributes, which are *occupation*, *nationality*, *alma mater* in TEMPLATE PERSON, and *country* in TEMPLATE FILM. In particular, we extract values from the first two paragraphs of the texts because they usually contain most of the valuable information. The details of data sets on these attributes are given in Table 4.

Attribute	$ A_S $	$ A_T $	$ A_{test} $	$ A'_{test} $
<i>occupation</i>	1,000	500	779	208
<i>alma mater</i>	1,000	200	215	208
<i>nationality</i>	1,000	300	430	208
<i>country</i>	1,000	500	1,000	—

$|A|$ : the number of articles in  $A$

Table 4: Data Sets.

#### 4.1.2 Comparison Methods

We compare our WikiCiKE method with two different kinds of methods, the monolingual knowledge extraction method and the translation-based method. They are implemented as follows:

1. **KE-Mon** is the monolingual knowledge extractor. The difference between WikiCiKE and KE-Mon is that KE-Mon only uses the Chinese training data.

<sup>2</sup><http://dumps.wikimedia.org/>

2. **KE-Tr** is the translation-based extractor. It obtains the *values* by two steps: finding their counterparts (if available) in English using Wikipedia cross-lingual links and attribute alignments, and translating them into Chinese.

We conduct two series of evaluation to compare WikiCiKE with KE-Mon and KE-Tr, respectively.

1. We compare WikiCiKE with KE-Mon on the first testing data set  $A_{test}$ , where most values can be found in the articles' texts in those labeled articles, in order to demonstrate the performance improvement by using cross-lingual knowledge transfer.
2. We compare WikiCiKE with KE-Tr on the second testing data set  $A'_{test}$ , where the existences of values are not guaranteed in those randomly selected articles, in order to demonstrate the better recall of WikiCiKE.

For implementation details, the *weighted-SVM* is used as the basic learner  $f$  both in WikiCiKE and KE-Mon (Zhang et al., 2009), and Baidu Translation API<sup>3</sup> is used as the translator both in WikiCiKE and KE-Tr. The Chinese texts are pre-processed using ICTCLAS<sup>4</sup> for word segmentation.

#### 4.1.3 Evaluation Metrics

Following Lavelli's research on evaluation of information extraction (Lavelli et al., 2008), we perform evaluation as follows.

1. We evaluate each *attr* separately.
2. For each *attr*, there is exactly one *value* extracted.
3. No alternative occurrence of real *value* is available.
4. The overlap ratio is used in this paper rather than "exactly matching" and "containing".

Given an extracted *value*  $v' = \{w'\}$  and its corresponding real *value*  $v = \{w\}$ , two measurements for evaluating the overlap ratio are defined: **recall**: the rate of matched tokens w.r.t. the real *value*. It can be calculated using

$$R(v', v) = \frac{|v \cap v'|}{|v|}$$

<sup>3</sup><http://openapi.baidu.com/service>

<sup>4</sup><http://www.ictclas.org/>

**precision**: the rate of matched tokens w.r.t. the extracted *value*. It can be calculated using

$$P(v', v) = \frac{|v \cap v'|}{|v'|}$$

We use the average of these two measures to evaluate the performance of our extractor as follows:

$$R = \text{avg}(R_i(v', v)) \quad a_i \in A_{\text{test}}$$

$$P = \text{avg}(P_i(v', v)) \quad a_i \in A_{\text{test}} \text{ and } v_i' \neq \emptyset$$

The *recall* and *precision* range from 0 to 1 and are first calculated on a single instance and then averaged over the testing instances.

## 4.2 Comparison with KE-Mon

In these experiments, WikiCiKE trains extractors on  $A_S \cup A_T$ , and KE-Mon trains extractors just on  $A_T$ . We incrementally increase the number of target training articles from 10 to 500 (if available) to compare WikiCiKE with KE-Mon in different situations. We use the first testing data set  $A_{\text{test}}$  to evaluate the results.

Figure 4 and Table 5 show the experimental results on TEMPLATE PERSON and FILM. We can see that WikiCiKE outperforms KE-Mon on all three attributions especially when the number of target training samples is small. Although the *recall* for *alma mater* and the *precision* for *nationality* of WikiCiKE are lower than KE-Mon when only 10 target training articles are available, WikiCiKE performs better than KE-Mon if we take into consideration both *precision* and *recall*.

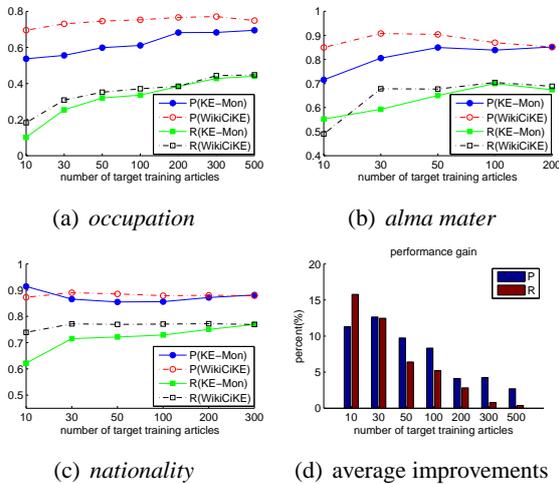

Figure 4: Results for TEMPLATE PERSON.

Figure 4(d) shows the average improvements yielded by WikiCiKE w.r.t KE-Mon on TEMPLATE PERSON. We can see that WikiCiKE yields significant improvements when only a few articles are available in target language and the improvements tend to decrease as the number of target articles is increased. In this case, the articles in the target language are sufficient to train the extractors alone.

#	KE-Mon		WikiCiKE	
	P	R	P	R
10	81.1%	63.8%	<b>90.7%</b>	66.3%
30	78.8%	64.5%	87.5%	69.4%
50	80.7%	66.6%	87.7%	<b>72.3%</b>
100	82.8%	68.2%	87.8%	72.1%
200	83.6%	70.5%	87.1%	73.2%
300	85.2%	72.0%	89.1%	76.2%
500	86.2%	73.4%	88.7%	75.6%

# Number of the target training articles.

Table 5: Results for *country* in TEMPLATE FILM.

## 4.3 Comparison with KE-Tr

We compare WikiCiKE with KE-Tr on the second testing data set  $A'_{\text{test}}$ .

From Table 6 it can be clearly observed that WikiCiKE significantly outperforms KE-Tr both in *precision* and *recall*. The reasons why the recall of KE-Tr is extremely low are two-fold. First, because of the limit of cross-lingual links and infoboxes in English Wikipedia, only a very small set of values is found by KE-Tr. Furthermore, many values obtained using the translator are incorrect because of translation errors. WikiCiKE uses translators too, but it has better tolerance to translation errors because the extracted value is from the target article texts instead of the output of translators.

Attribute	KE-Tr		WikiCiKE	
	P	R	P	R
<i>occupation</i>	27.4%	3.40%	64.8%	26.4%
<i>nationality</i>	66.3%	4.60%	70.0%	<b>55.0%</b>
<i>alma mater</i>	66.7%	0.70%	<b>76.3%</b>	8.20%

Table 6: Results of WikiCiKE vs. KE-Tr.

## 4.4 Significance Test

We conducted a significance test to demonstrate that the difference between WikiCiKE and KE-Mon is significant rather than caused by statistical errors. As for the comparison between WikiCiKE and KE-Tr, significant improvements brought by

WikiCiKE can be clearly observed from Table 6 so there is no need for further significance test. In this paper, we use McNemar’s significance test (Dietterich and Thomas, 1998).

Table 7 shows the results of significance test calculated for the average on all tested attributes. When the number of target training articles is less than 100, the  $\chi$  is much less than 10.83 that corresponds to a significance level 0.001. It suggests that the chance that WikiCiKE is not better than KE-Mon is less than 0.001.

#	10	30	50	100	200	300	500
$\chi$	179.5	107.3	51.8	32.8	4.1	4.3	0.3

# Number of the target training articles.

Table 7: Results of Significance Test.

#### 4.5 Overall Analysis

As shown in above experiments, we can see that WikiCiKE outperforms both KE-Mon and KE-Tr. When only 30 target training samples are available, WikiCiKE reaches comparable performance of KE-Mon using 300-500 target training samples. Among all of the 72 attributes in TEMPLATE PERSON of Chinese Wikipedia, 39 (54.17%) and 55 (76.39%) attributes have less than 30 and 200 labeled articles respectively. We can see that WikiCiKE can save considerable human labor when no sufficient target training samples are available.

We also examined the errors by WikiCiKE and they can be categorized into three classes. For attribute *occupation* when 30 target training samples are used, there are 71 errors. The first category is caused by incorrect word segmentation (40.85%). In Chinese, there is no space between words so we need to segment them before extraction. The result of word segmentation directly decide the performance of extraction so it causes most of the errors. The second category is because of the incomplete infoboxes (36.62%). In evaluation of KE-Mon, we directly use the values in infoboxes as golden values, some of them are incomplete so the correct predicted values will be automatically judged as the incorrect in these cases. The last category is mismatched words (22.54%). The predicted value does not match the golden value or a part of it. In the future, we can improve the performance of WikiCiKE by polishing the word segmentation result.

## 5 Related Work

Some approaches of knowledge extraction from the open Web have been proposed (Wu et al., 2012; Yates et al., 2007). Here we focus on the extraction inside Wikipedia.

### 5.1 Monolingual Infobox Extraction

KYLIN is the first system to autonomously extract the missing infoboxes from the corresponding article texts by using a self-supervised learning method (Wu and Weld, 2007). KYLIN performs well when enough training data are available. Such techniques as shrinkage and retraining are proposed to increase the recall from English Wikipedia’s long tail of sparse classes (Wu et al., 2008; Wu and Weld, 2010). Different from Wu’s research, WikiCiKE is a cross-lingual knowledge extraction framework, which leverags rich knowledge in the other language to improve extraction performance in the target Wikipedia.

### 5.2 Cross-lingual Infobox Completion

Current translation based methods usually contain two steps: cross-lingual attribute alignment and value translation. The attribute alignment strategies can be grouped into two categories: cross-lingual link based methods (Bouma et al., 2009) and classification based methods (Adar et al., 2009; Nguyen et al., 2011; Aumüller et al., 2005; Adafre and de Rijke, 2006; Li et al., 2009). After the first step, the value in the source language is translated into the target language. E. Adar’s approach gives the overall precision of 54% and recall of 40% (Adar et al., 2009). However, recall of these methods is limited by the number of equivalent cross-lingual articles and the number of infoboxes in the source language. It is also limited by the quality of the translators. WikiCiKE attempts to mine the missing infoboxes directly from the article texts and thus achieves a higher recall compared with these methods as shown in Section 4.3.

### 5.3 Transfer Learning

Transfer learning can be grouped into four categories: instance-transfer, feature-representation-transfer, parameter-transfer and relational-knowledge-transfer (Pan and Yang, 2010). TrAdaBoost, the instance-transfer approach, is an extension of the AdaBoost algorithm, and demonstrates better transfer ability than tradition-

al learning techniques (Dai et al., 2007). Transfer learning have been widely studied for classification, regression, and cluster problems. However, few efforts have been spent in the information extraction tasks with knowledge transfer.

## 6 Conclusion and Future Work

In this paper we proposed a general cross-lingual knowledge extraction framework called WikiCiKE, in which extraction performance in the target Wikipedia is improved by using rich infoboxes in the source language. The problems of topic drift and translation error were handled by using the TrAdaBoost model. Chinese-English experimental results on four typical attributes showed that WikiCiKE significantly outperforms both the current translation based methods and the monolingual extraction methods. In theory, WikiCiKE can be applied to any two wiki knowledge based of different languages.

We have been considering some future work. Firstly, more attributes in more infobox templates should be explored to make our results much stronger. Secondly, knowledge in a minor language may also help improve extraction performance for a major language due to the cultural and religion differences. A bidirectional cross-lingual extraction approach will also be studied. Last but not least, we will try to extract multiple *attr-value* pairs at the same time for each article.

Furthermore, our work is part of a more ambitious agenda on exploitation of linked data. On the one hand, being able to extract data and knowledge from multilingual sources such as Wikipedia could help improve the coverage of linked data for applications. On the other hand, we are also investigating how to possibly integrate information, including subjective information (Sensoy et al., 2013), from multiple sources, so as to better support data exploitation in context dependent applications.

# Bridging Languages through Etymology: The case of cross language text categorization

Vivi Nastase and Carlo Strapparava

Human Language Technologies, Fondazione Bruno Kessler

Trento, Italy

{nastase, strappa}@fbk.eu

## Abstract

We propose the hypothesis that word etymology is useful for NLP applications as a bridge between languages. We support this hypothesis with experiments in cross-language (English-Italian) document categorization. In a straightforward bag-of-words experimental set-up we add etymological ancestors of the words in the documents, and investigate the performance of a model built on English data, on Italian test data (and viceversa). The results show not only statistically significant, but a large improvement – a jump of almost 40 points in F1-score – over the raw (vanilla bag-of-words) representation.

## 1 Introduction

When exposed to a document in a language he does not know, a reader might be able to glean some meaning from words that are the same (e.g. names) or similar to those in a language he knows. As an example, let us say that an Italian speaker is reading an English text that contains the word *expense*, which he does not know. He may be reminded however of the Latin word *expensa* which is also the etymological root of the Italian word *spesa*, which usually means “cost”/“shopping”, and may thus infer that the English word refers to the cost of things. In the experiments presented here we investigate whether an automatic text categorization system could benefit from knowledge about the etymological roots of words. The cross language text categorization (CLTC) task consists of categorizing documents in a target language  $L_t$  using a model built from labeled examples in a source language  $L_s$ . The task becomes more difficult when the data consists of comparable corpora in the two languages – documents on the same topics (e.g. sports, economy) – instead of parallel corpora – there exists a one-to-one correspondence

between documents in the corpora for the two languages, one document being the translation of the other.

To test the usefulness of etymological information we work with comparable collections of news articles in English and Italian, whose articles are assigned one of four categories: *culture\_and\_school*, *tourism*, *quality\_of\_life*, *made\_in\_Italy*. We perform a progression of experiments, which embed etymological information deeper and deeper into the model. We start with the basic set-up, representing the documents as bag-of-words, where we train a model on the English training data, and use this model to categorize documents from the Italian test data (and viceversa). The results are better than random, but quite low. We then add the etymological roots of the words in the data to the bag-of-words, and notice a large – 21 points – increase in performance in terms of F1-score. We then use the bag-of-words representation of the training data to build a semantic space using LSA, and use the generated word vectors to represent the training and test data. The improvement is an additional 16 points in F1-score.

Compared to related work, presented in Section 3, where cross language text categorization is approached through translation or mapping of features (i.e. words) from the source to the target language, word etymologies are a novel source of cross-lingual knowledge. Instead of mapping features between languages, we introduce new features which are shared, and thus do not need translation or other forms of mapping.

The experiments presented show unequivocally that word etymology is a useful addition to computational models, just as they are to readers who have such knowledge. This is an interesting and useful result, especially in the current research landscape where using and exploiting multi-linguality is a desired requirement.

## 2 Word Etymology

Word etymology gives us a glimpse into the evolution of words in a language. Words may be adopted from a language because of cultural, scientific, economic, political or other reasons (Hitchings, 2009). In time these words “adjust” to the language that adopted them – their sense may change to various degrees – but they are still semantically related to their etymological roots. To illustrate the point, we show an example that the reader, too, may find amusing: on the ticket validation machine on Italian buses, by way of instruction, it is written *Per obliterare il biglietto ....* A native/frequent English speaker would most probably key in on, and be puzzled by, the word *obliterare*, very similar to the English *obliterate*, whose most used sense is *to destroy completely / cause to physically disappear*. The Italian *obliterare* has the “milder” sense of *cancellare* – *cancel* (which is also shared by the English *obliterate*, but is less frequent according to Merriam-Webster), and both come from the Latin *obliterare* – erase, efface, cause to disappear. While there has been some sense migration – in English the more (physically) destructive sense of the word has higher prominence, while in Italian the word is closer in meaning to its etymological root – the Italian and the English words are still semantically related.

Dictionaries customarily include etymologi-

cal information for their entries, and recently, Wikipedia’s Wiktionary has joined this trend. The etymological information can, and indeed has been extracted and prepared for machine consumption (de Melo and Weikum, 2010): Etymological WordNet<sup>1</sup> contains 6,031,431 entries for 2,877,036 words (actually, morphemes) in 397 languages. A few sample entries from this resource are shown in Figure 1.

The information in Etymological WordNet is organized around 5 relations: *etymology* with its inverse *etymological\_origin\_of*; *is\_derived\_from* with its inverse *has\_derived\_form*; and the symmetrical *etymologically\_related*. The *etymology* relation links a word with its etymological ancestors, and it is the relation used in the experiments presented here. Prefixes and suffixes – such as *ex-* and *-ly* shown in Figure 1 – are filtered out, as they bring in much noise by relating words that merely share such a morpheme (e.g. *absurdly* and *admirably*) but are otherwise semantically distant. *has\_derived\_form* is also used, to capture morphological variations.

The depth of the etymological hierarchy (considering the *etymology* relations) is 10. Figure 1 shows an example of a word with several levels of etymological ancestry.

### 3 Cross Language Text Categorization

Text categorization (also text classification), “the task of automatically sorting a set of documents into categories (or classes or topics) from a predefined set” (Sebastiani, 2005), allows for the quick selection of documents from the same domain, or the same topic. It is a very well research area, dating back to the 60s (Borko and Bernick, 1962). The most frequently, and successfully, used document representation is the bag-of-words (BoWs). Results using this representation achieve accuracy in the 90%. Most variations include feature filtering or weighing, and variations in learning algorithms (Sebastiani, 2005).

Within the area of cross-language text categorization (CLTC) several methods have been explored for producing the model for a target language  $L_t$  using information and data from the source language  $L_s$ . In a precursor task to CLTC, cross language information retrieval (CLIR), Dumais et al. (1997) find semantic correspondences in parallel (different language) corpora through latent semantic analysis (LSA). Most CLTC methods rely heavily on machine translation (MT). MT has been used: to cast the cross-language text

categorization problem to the monolingual setting (Fortuna and Shawe-Taylor, 2005); to cast the cross-language text categorization problem into two monolingual settings for active learning (Liu et al., 2012); to translate and adapt a model built on language  $L_s$  to language  $L_t$  (Rigutini et al., 2005), (Shi et al., 2010); to produce parallel corpora for multi-view learning (Guo and Xiao, 2012). Wan et al. (2011) also use machine translation, but enhance the processing through domain adaptation by feature weighing, assuming that the training data in one language and the test data in the other come from different domains, or can exhibit different linguistic phenomena due to linguistic and cultural differences. Prettenhofer and Stein (2010) use a word translation oracle to produce *pivots* – pairs of semantically similar words – and use the data partitions induced by these words to find cross language structural correspondences.

In a computationally lighter framework, not dependent on MT, Gliozzo and Strapparava (2006) and Wu et al. (2008) use bilingual lexicons and aligned WordNet synsets to obtain shared features between the training data in language  $L_s$  and the testing data in language  $L_t$ . Gliozzo and Strapparava (2005), the first to use comparable as op-

posed to parallel corpora for CLTC, use LSA to build multilingual domain models.

The bag-of-words document representation maps a document  $d_i$  from a corpus  $D$  into a  $k$ -dimensional space  $\mathbb{R}^k$ , where  $k$  is the dimension of the (possibly filtered) vocabulary of the corpus:  $W = \{w_1, \dots, w_k\}$ . Position  $j$  in the vector representation of  $d_i$  corresponds to word  $w_j$ , and it may have different values, among the most commonly used being: binary values –  $w_j$  appears (1) or not (0) in  $d_i$ ; frequency of occurrence of  $w_j$  in  $d_i$ , absolute or normalized (relative to the size of the document or the size of the vocabulary); the  $tf * idf(w_j, d_i, D)$ .

For the task of cross language text categorization, the problem of sharing a model across languages is that the dimensions, a.k.a the vocabulary, of the two languages are largely different. Limited overlap can be achieved through shared names and words. As we have seen in the literature review, machine translation and bilingual dictionaries can be used to cast these dimensions from the source language  $L_s$  to the target language  $L_t$ . In this work we explore expanding the shared dimensions through word etymologies. Figure 2 shows schematically the binary  $k$  dimensional representation for English and Italian data, and shared dimensions.

Cross language text categorization could be used to obtain comparable corpora for building translation models. In such a situation, relying on a framework that itself relies on machine translation is not helpful. Bilingual lexicons are available for frequently studied languages, but less so for those poorer in resources. Considering such shortcomings, we look into additional linguistic information, in particular word etymology. This information impacts the data representation, by introducing new shared features between the different language corpora without the need for translation or other forms of mapping. The newly produced representation can be used in conjunction with any of the previously proposed algorithms.

Word etymologies are a novel source of linguistic information in NLP, possibly because resources that capture this information in a machine readable format are also novel. Fang et al. (2009) used limited etymological information extracted from the Collins English Dictionary (CED) for text categorization on the British National Corpus (BNC): information on the provenance of words (ranges of

probability distribution of etymologies in different versions of Latin – New Latin, Late Latin, Medieval Latin) was used in a “home-made” range classifier.

The experiments presented in this paper use the bag-of-words document representation with absolute frequency values. To this basic representation we add word etymological ancestors and run classification experiments. We then use LSA – previously shown by (Dumais et al., 1997) and (Gliozzo and Strapparava, 2005) to be useful for this task – to induce the latent semantic dimensions of documents and words respectively, hypothesizing that word etymological ancestors will lead to semantic dimensions that transcend language boundaries. The vectors obtained through LSA (on the training data only) for words that are shared by the English training data and the Italian test data (names, and most importantly, etymological ancestors of words in the original documents) are then used for re-representing the training and test data. The same process is applied for Italian training and English test data. Classification is done using support vector machines (SVMs).

### 3.1 Data

The data we work with consists of comparable corpora of news articles in English and Italian. Each news article is annotated with one of the four categories: *culture\_and\_school*, *tourism*, *quality\_of\_life*, *made\_in\_Italy*. Table 1 shows the dataset statistics. The average document length is approximately 300 words.

### 3.2 Raw cross-lingual text categorization

As is commonly done in text categorization (Sebastiani, 2005), the documents in our data are represented as bag-of-words, and classification is done using support vector machines (SVMs).

One experimental run consists of 4 binary experiments – one class versus the rest, for each of the 4 classes. The results are reported through micro-averaged precision, recall and F1-score for the targeted class, as well as overall accuracy. The high results, on a par with text categorization experiments in the field, validates our experimental set-up.

For the cross language categorization experiments described in this paper, we use the data described above, and train on one language (English/Italian), and test on the other, using the same

Categories	English			Italian		
	Training	Test	Total	Training	Test	Total
quality_of_life	5759	1989	7748	5781	1901	7682
made_in_Italy	5711	1864	7575	6111	2068	8179
tourism	5731	1857	7588	6090	2015	8105
culture_and_school	3665	1245	4910	6284	2104	8388
Total	20866	6955	27821	24266	8088	32354

Table 1: Dataset statistics

<i>monolingual BoW categorization</i>				
	Prec	Rec	F1	Acc
Train EN / Test EN	0.92	0.92	0.92	0.96
Train IT / Test IT	0.94	0.94	0.94	0.97

Table 2: Performance for monolingual raw text categorization

experimental set-up as for the monolingual scenario (4 binary problems). The categorization baseline (BoW\_baseline in Figure 4) was obtained in this set-up. This baseline is higher than the random baseline or the positive class baseline<sup>2</sup> (all instances are assigned the target class in each of the 4 binary classification experiments) due to shared words and names between the two languages.

### 3.3 Enriching the bag-of-word representation with word etymology

As personal experience has shown us that etymological information is useful for comprehending a text in a different language, we set out to test whether this information can be useful in an automatic processing setting. We first verified whether the vocabularies of our two corpora, English and Italian, have shared word etymologies. Relying on word etymologies from the Etymological dictionary, we found that from our data’s vocabulary, 518 English terms and 543 Italian terms shared 490 direct etymological ancestors. Etymological ancestors also help cluster related terms within one language – 887 etymological ancestors for 4727 English and 864 ancestors for 5167 Italian terms. This overlap further increases when adding derived forms (through the *has\_derived\_form* relation). The fact that this overlap exists strengthens the motivation to try using etymological ancestors for the task of text categorization.

In this first step of integrating word etymology

<sup>2</sup>In this situation the random and positive class baseline are the same: 25% F1 score.

into the experiment, we extract for each word in each document in the dataset its ancestors from the Etymological dictionary. Because each word  $w_j$  in a document  $d_i$  has associated an absolute frequency value  $f_{ij}$  (the number of occurrences of  $w_j$  in  $d_i$ ), for the added etymological ancestors  $e_k$  in document  $D_i$  we associate as value the sum of frequencies of their etymological children in  $d_i$ :

$$f_{ie_k} = \sum_{\substack{w_j \in d_i \\ w_j \text{ etymology } e_k}} f_{ij}$$

We make the depth of extraction a parameter, and generate data representation when considering only direct etymological antecedents (depth 1) and then up to a distance of N. For our dataset we noticed that the representation does not change after N=4, so this is the maximum depth we consider. The bag-of-words representation for each document is expanded with the corresponding etymological features.

expansion	training data vocabulary size	vocabulary overlap with testing
Train EN /Test IT		
raw	71122	14207 (19.9%)
depth 1	78936	18275 (23.1%)
depth 2	79068	18359 (23.2%)
depth 3	79100	18380 (23.2%)
depth 4	79103	18382 (23.2%)
Train IT /Test EN		
raw	78750	14110 (17.9%)
depth 1	83656	18682 (22.3%)
depth 2	83746	18785 (22.4%)
depth 3	83769	18812 (22.5%)
depth 4	83771	18814 (22.5%)

Table 3: Feature expansion with word etymologies

Table 3 shows the training data vocabulary size and increase in the overlap between the training and test data with the addition of etymological fea-

tures. The increase is largest when introducing the immediate etymological ancestors, of approximately 4000 new (overlapping) features for both combinations of training and testing. Without etymological features the overlap was approximately 14000 for both configurations. The results obtained with this enriched BoW representation for etymological ancestor depth 1, 2 and 3 are presented in Figure 4.

### 3.4 Cross-lingual text categorization in a latent semantic space adding etymology

Shared word etymologies can serve as a bridge between two languages as we have seen in the previous configuration. When using shared word etymologies in the bag-of-words representation, we only take advantage of the shallow association between these new features and the classes within which they appear. But through the co-occurrence of the etymological features and other words in different documents in the training data, we can induce a deeper representation for the words in a document, that captures better the relationship between the features (words) and the classes to which the documents belong. We use latent semantic analysis (LSA) (Deerwester et al., 1990) to perform this representational transformation. The process relies on the assumption that word co-occurrences across different documents are the surface manifestation of shared semantic dimensions. Mathematically, the  $\langle \text{word} \times \text{document} \rangle$  matrix  $D$  is expressed as a product of three matrices:

$$D = V\Sigma U^T$$

by performing singular value decomposition (SVD).  $V$  would correspond roughly to a  $\langle \text{word} \times \text{latent semantic dimension} \rangle$  matrix,  $U^T$  is the transposed of a  $\langle \text{document} \times \text{latent semantic dimension} \rangle$  matrix, and  $\Sigma$  is a diagonal matrix whose values are indicative of the “strength” of the semantic dimensions. By reducing the size of  $\Sigma$ , for example by selecting the dimensions with the top  $K$  values, we can obtain an approximation of the original matrix  $D \approx D_K = V_K \Sigma_K U_K^T$ , where we restrict the latent semantic dimensions taken into account to the  $K$  chosen ones. Figure 3 shows schematically the process.

We perform this decomposition and dimension reduction step on the  $\langle \text{word} \times \text{document} \rangle$  matrix built from the training data only, and using  $K=400$ . Both the training and test data are then

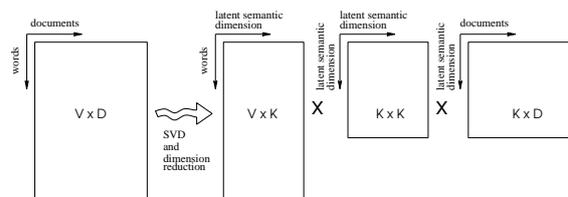

Figure 3: Schematic view of LSA

re-represented through the new word vectors from matrix  $V_K$ . Because the LSA space was built only from the training data, only the shared words and shared etymological ancestors are used to produce representations of the test data. The categorization is done again with SVM. The results of this experiment are shown in Figure 4, together with an LSA baseline – using the raw data and relying on shared words and names as overlap.

## 4 Discussion

The experiments whose results we present here were produced using unfiltered data – all words in the datasets, all etymological ancestors up to the desired depth, no filtering based on frequency of occurrence. Feature filtering is commonly done in machine learning when the data has many features, and in text categorization when using the bag-of-words representation in particular. We chose not to perform this step for two main reasons: (i) filtering is sensitive to the chosen threshold; (ii) LSA thrives on word co-occurrences, which would be drastically reduced by word removal. The point that etymology information is a useful addition to the task of cross-language text categorization can be made without finding the optimal filtering set-up.

The baseline experiments show that despite the relatively large word overlap (approx. 14000 terms), cross-language text categorization gives low results. Adding a first batch of etymological information – approximately 4000 shared immediate ancestors – leads to an increase of 18 points in terms of F1-score on the BoW experimental set-up for English training/Italian testing, and 21 points for Italian training/English testing. Further additions of etymological ancestors at depths 2 and 3 results in an increase of 21 points in terms of F1-score for English training/Italian testing, and 27 points for Italian training/English testing. The higher increase in performance on this experimental configuration for Italian training/English testing is explained by the higher term overlap be-

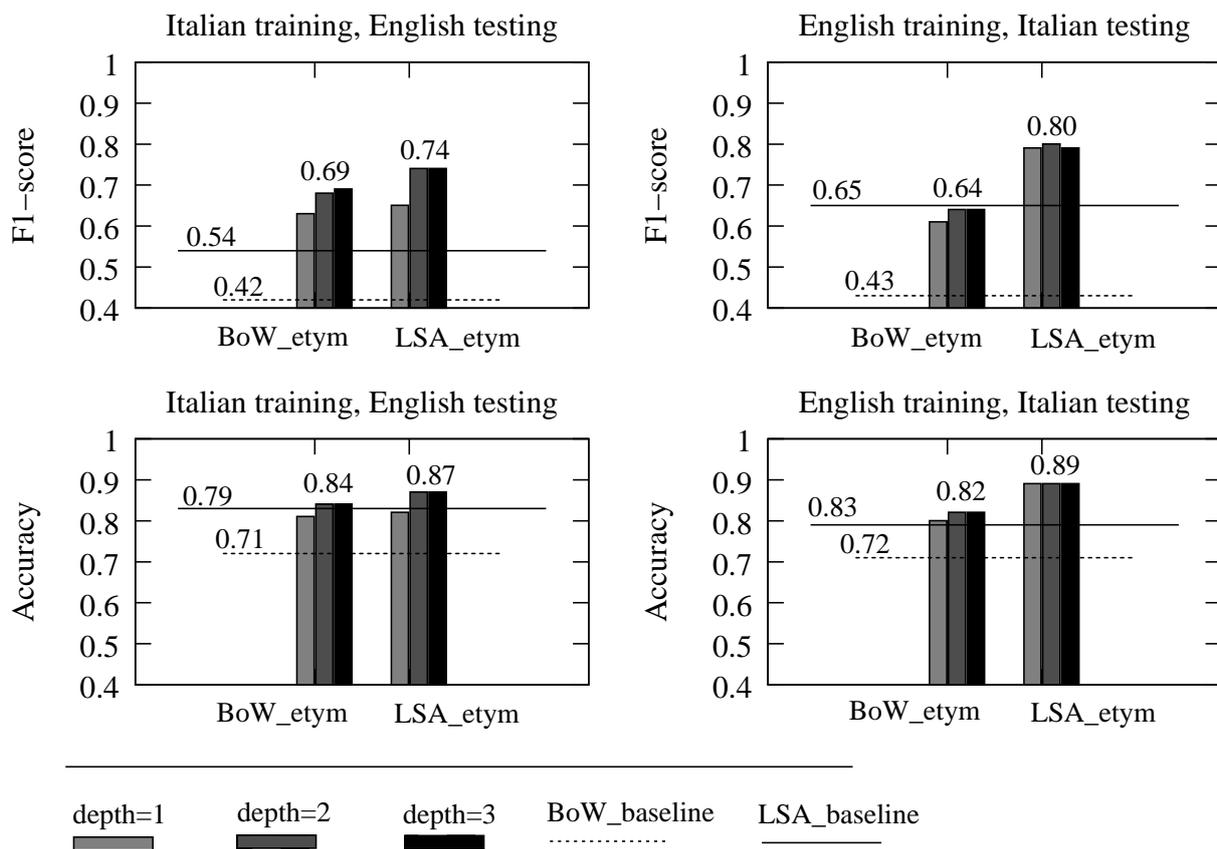

Figure 4: CLTC results with etymological features

tween the training and test data, as evidenced by the statistics in Table 3.

The next processing step induced a representation of the shared words that encodes deeper level dependencies between words and documents based on word co-occurrences in documents. The LSA space built on the training data leads to a vector representation of the shared words, including the shared etymological ancestors, that captures more than the obvious word-document co-occurrences. Using this representation leads to a further increase of 15 points in F1-score for English training/Italian testing set-up over the BoW representation, and 14 points over the baseline LSA-based categorization. The increase for the Italian training/English testing is 5 points over the BoW representation, but 20 points over the baseline LSA. We saw that the high performance BoW on Italian training/English testing is due to the high term overlap. The clue to why the increase when using LSA is lower than for English training/Italian testing is in the way LSA operates – it relies heavily on word co-occurrences in finding the latent semantic dimensions of documents and words. We expect then that in the Italian training

collection, words are “less shared” among documents, which means a lower average document frequency. Figure 5 shows the changes in average document frequency for the two training collections, starting with the raw data (depth 0), and with additional etymological features.

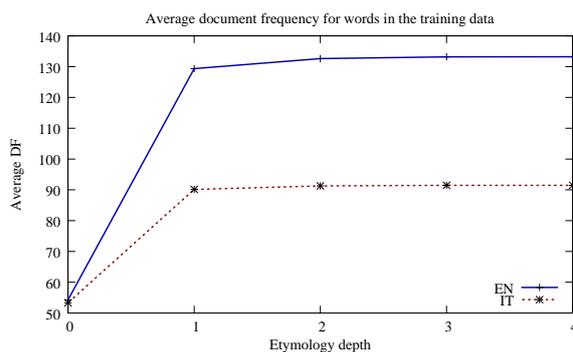

Figure 5: Document frequency changes with the addition of etymological features

The shape of the document frequency curves mirror the LSA results – the largest increase is the effect of adding the set of direct etymological ancestors, and additions of further, more distant, ancestors lead to smaller improvements.

We have performed the experiments described above on two releases of the Etymological dictionary. The results described in the paper were obtained on the latest release (February 2013). The difference in results on the two dictionary versions was significant: a 4 and 5 points increase respectively in micro-averaged F1-score in the bag-of-words setting for English training/Italian testing and Italian training/English testing, and a 2 and 6 points increase in the LSA setting. This indicates that more etymological information is better, and the dynamic nature of Wikipedia and the Wiktionary could lead to an ever increasing and better etymological resource for NLP applications.

## 5 Conclusion

The motivation for this work was to test the hypothesis that information about word etymology is useful for computational approaches to language, in particular for text classification. Cross-language text classification can be used to build comparable corpora in different languages, using a single language starting point, preferably one with more resources, that can thus spill over to other languages. The experiments presented have shown clearly that etymological ancestors can be used to provide the necessary bridge between the languages we considered – English and Italian. Models produced on English data when using etymological information perform with high accuracy (89%) and high F1-score (80) on Italian test data, with an increase of almost 40 points over a simple bag-of-words model, which, for crossing language boundaries, relies exclusively on shared names and words. Training on Italian data and testing on English data performed almost as well (87% accuracy, 75 F1-score). We plan to expand our experiments to more languages with shared etymologies, and investigate what characteristics of languages and data indicate that etymological information is beneficial for the task at hand.

We also plan to explore further uses for this language bridge, at a finer semantic level. Monolingual and cross-lingual textual entailment in particular would be interesting applications, because they require finding shared meaning on two text fragments. Word etymologies would allow recognizing words with shared ancestors, and thus with shared meaning, both within and across languages.

## Abstract

Just as *observing* is more than just *seeing*, *comparing* is far more than mere *matching*. It takes understanding, and even inventiveness, to discern a useful basis for judging two ideas as similar in a particular context, especially when our perspective is shaped by an act of linguistic creativity such as metaphor, simile or analogy. Structured resources such as WordNet offer a convenient hierarchical means for converging on a common ground for comparison, but offer little support for the divergent thinking that is needed to creatively view one concept as another. We describe such a means here, by showing how the web can be used to harvest many divergent views for many familiar ideas. These lateral views complement the vertical views of WordNet, and support a system for idea exploration called *Thesaurus Rex*. We show also how *Thesaurus Rex* supports a novel, generative similarity measure for WordNet.

## 1 Seeing is Believing (*and* Creating)

Similarity is a cognitive phenomenon that is both complex and subjective, yet for practical reasons it is often modeled as if it were simple and objective. This makes sense for the many situations where we want to align our similarity judgments with those of others, and thus focus on the same conventional properties that others are also likely to focus upon. This reliance on the consensus viewpoint explains why WordNet (Fellbaum, 1998) has proven so useful as a basis for computational measures of lexico-semantic similarity

(e.g. see Pederson *et al.* 2004, Budanitsky & Hirst, 2006; Seco *et al.* 2006). These measures reduce the similarity of two lexical concepts to a single number, by viewing similarity as an objective estimate of the overlap in their salient qualities. This convenient perspective is poorly suited to creative or insightful comparisons, but it is sufficient for the many mundane comparisons we often perform in daily life, such as when we organize books or look for items in a supermarket. So if we do not know in which aisle to locate a given item (such as *oatmeal*), we may tacitly know how to locate a similar product (such as *cornflakes*) and orient ourselves accordingly.

Yet there are occasions when the recognition of similarities spurs the *creation* of similarities, when the act of comparison spurs us to invent new ways of looking at an idea. By placing *pop tarts* in the breakfast aisle, food manufacturers encourage us to view them as a breakfast food that is not dissimilar to *oatmeal* or *cornflakes*. When ex-PM Tony Blair published his memoirs, a mischievous activist encouraged others to move his book from *Biography* to *Fiction* in bookshops, in the hope that buyers would see it in a new light. Whenever we use a novel metaphor to convey a non-obvious viewpoint on a topic, such as “*cigarettes are time bombs*”, the comparison may spur us to insight, to see aspects of the topic that *make* it more similar to the vehicle (see Ortony, 1979; Veale & Hao, 2007).

In formal terms, assume agent A has an insight about concept X, and uses the metaphor *X is a Y* to also provoke this insight in agent B. To arrive at this insight for itself, B must intuit what X and Y have in common. But this commonality is surely more than a standard categorization of X, or else it would not count as an insight about X. To understand the metaphor, B must place X

in a new category, so that X can be seen as more similar to Y. Metaphors shape the way we perceive the world by re-shaping the way we make similarity judgments. So if we want to imbue computers with the ability to make and to understand creative metaphors, we must first give them the ability to look beyond the narrow viewpoints of conventional resources.

Any measure that models similarity as an objective function of a conventional worldview employs a *convergent* thought process. Using WordNet, for instance, a similarity measure can vertically converge on a common superordinate category of both inputs, and generate a single numeric result based on their distance to, and the information content of, this common generalization. So to find the most conventional ways of seeing a lexical concept, one simply ascends a narrowing concept hierarchy, using a process de Bono (1970) calls *vertical thinking*. To find novel, non-obvious and useful ways of looking at a lexical concept, one must use what Guilford (1967) calls *divergent thinking* and what de Bono calls *lateral thinking*. These processes cut across familiar category boundaries, to simultaneously place a concept in many different categories so that we can see it in many different ways.

de Bono argues that vertical thinking is selective while lateral thinking is generative. Whereas vertical thinking concerns itself with the “right” way or a single “best” way of looking at things, lateral thinking focuses on producing alternatives to the status quo. To be as useful for creative tasks as they are for conventional tasks, we need to re-imagine our computational similarity measures as generative rather than selective, expansive rather than reductive, divergent as well as convergent and lateral as well as vertical. Though WordNet is ideally structured to support vertical, convergent reasoning, its comprehensive nature means it can also be used as a solid foundation for building a more lateral and divergent model of similarity. Here we will use the web as a source of diverse perspectives on familiar ideas, to complement the conventional and often narrow views codified by WordNet.

Section 2 provides a brief overview of past work in the area of similarity measurement, before section 3 describes a simple bootstrapping loop for acquiring richly diverse perspectives from the web for a wide variety of familiar ideas. These perspectives are used to enhance a WordNet-based measure of lexico-semantic similarity in section 4, by broadening the range of informative viewpoints the measure can select from.

Similarity is thus modeled as a process that is both generative *and* selective. This lateral-and-vertical approach is evaluated in section 5, on the Miller & Charles (1991) data-set. A web app for the lateral exploration of diverse viewpoints, named *Thesaurus Rex*, is also presented, before closing remarks are offered in section 6.

## 2 Related Work and Ideas

WordNet’s taxonomic organization of noun-senses and verb-senses – in which very general categories are successively divided into increasingly informative sub-categories or instance-level ideas – allows us to gauge the overlap in information content, and thus of meaning, of two lexical concepts. We need only identify the deepest point in the taxonomy at which this content starts to diverge. This point of divergence is often called the LCS, or *least common subsumer*, of two concepts (Pederson *et al.*, 2004). Since sub-categories add new properties to those they inherit from their parents – Aristotle called these properties the *differentia* that stop a category system from trivially collapsing into itself – the depth of a lexical concept in a taxonomy is an intuitive proxy for its information content. Wu & Palmer (1994) use the depth of a lexical concept in the WordNet hierarchy as such a proxy, and thereby estimate the similarity of two lexical concepts as twice the depth of their LCS divided by the sum of their individual depths.

Leacock and Chodorow (1998) instead use the length of the shortest path between two concepts as a proxy for the conceptual distance between them. To connect any two ideas in a hierarchical system, one must vertically ascend the hierarchy from one concept, change direction at a potential LCS, and then descend the hierarchy to reach the second concept. (Aristotle was also first to suggest this approach in his *Poetics*). Leacock and Chodorow normalize the length of this path by dividing its size (in nodes) by twice the depth of the deepest concept in the hierarchy; the latter is an upper bound on the distance between any two concepts in the hierarchy. Negating the log of this normalized length yields a corresponding similarity score. While the role of an LCS is merely implied in Leacock and Chodorow’s use of a *shortest path*, the LCS is pivotal nonetheless, and like that of Wu & Palmer, the approach uses an essentially vertical reasoning process to identify a single “best” generalization.

Depth is a convenient proxy for information content, but more nuanced proxies can yield

more rounded similarity measures. Resnick (1995) draws on information theory to define the information content of a lexical concept as the negative log likelihood of its occurrence in a corpus, either explicitly (via a direct mention) or by presupposition (via a mention of any of its sub-categories or instances). Since the likelihood of a general category occurring in a corpus is higher than that of any of its sub-categories or instances, such categories are more predictable, and less informative, than rarer categories whose occurrences are less predictable and thus more informative. The negative log likelihood of the most informative LCS of two lexical concepts offers a reliable estimate of the amount of information shared by those concepts, and thus a good estimate of their similarity. Lin (1998) combines the intuitions behind Resnick's metric and that of Wu and Palmer to estimate the similarity of two lexical concepts as an information ratio: twice the information content of their LCS divided by the sum of their individual information contents.

Jiang and Conrath (1997) consider the converse notion of *dissimilarity*, noting that two lexical concepts are dissimilar to the extent that each contains information that is not shared by the other. So if the information content of their most informative LCS is a good measure of what they *do* share, then the sum of their individual information contents, minus twice the content of their most informative LCS, is a reliable estimate of their dissimilarity.

Seco *et al.* (2006) presents a minor innovation, showing how Resnick's notion of information content can be calculated without the use of an external corpus. Rather, when using Resnick's metric (or that of Lin, or Jiang and Conrath) for measuring the similarity of lexical concepts in WordNet, one can use the category structure of WordNet itself to estimate information content. Typically, the more general a concept, the more descendants it will possess. Seco *et al.* thus estimate the information content of a lexical concept as the log of the sum of all its unique descendants (both direct and indirect), divided by the log of the total number of concepts in the entire hierarchy. Not only is this *intrinsic* view of information content convenient to use, without recourse to an external corpus, Seco *et al.* show that it offers a better estimate of information content than its extrinsic, corpus-based alternatives, as measured relative to average human similarity ratings for the 30 word-pairs in the Miller & Charles (1991) test set.

A similarity measure can draw on other

sources of information besides WordNet's category structures. One might eke out additional information from WordNet's textual glosses, as in Lesk (1986), or use category structures other than those offered by WordNet. Looking beyond WordNet, entries in the online encyclopedia Wikipedia are not only connected by a dense topology of lateral links, they are also organized by a rich hierarchy of overlapping categories. Strube and Ponzetto (2006) show how Wikipedia can support a measure of similarity (and relatedness) that better approximates human judgments than many WordNet-based measures. Nonetheless, WordNet can be a valuable component of a hybrid measure, and Agirre *et al.* (2009) use an SVM (support vector machine) to combine information from WordNet with information harvested from the web. Their best similarity measure achieves a remarkable **0.93** correlation with human judgments on the Miller & Charles word-pair set.

Similarity is not always applied to pairs of concepts; it is sometimes analogically applied to pairs of *pairs* of concepts, as in proportional analogies of the form *A is to B as C is to D* (e.g., *hacks are to writers as mercenaries are to soldiers*, or *chisels are to sculptors as scalpels are to surgeons*). In such analogies, one is really assessing the similarity of the unstated relationship between each pair of concepts: thus, mercenaries are soldiers whose allegiance is paid for, much as hacks are writers with income-driven loyalties; sculptors use chisels to carve stone, while surgeons use scalpels to cut or carve flesh. Veale (2004) used WordNet to assess the similarity of  $A:B$  to  $C:D$  as a function of the combined similarity of  $A$  to  $C$  and of  $B$  to  $D$ . In contrast, Turney (2005) used the web to pursue a more divergent course, to represent the tacit relationships of  $A$  to  $B$  and of  $C$  to  $D$  as points in a high-dimensional space. The dimensions of this space initially correspond to linking phrases on the web, before these dimensions are significantly reduced using *singular value decomposition*.

In the infamous SAT test, an analogy  $A:B::C:D$  has four other pairs of concepts that serve as likely distractors (e.g. *singer:songwriter* for *hack:writer*) and the goal is to choose the most appropriate  $C:D$  pair for a given  $A:B$  pairing. Using variants of Wu and Palmer (1994) on the 374 SAT analogies of Turney (2005), Veale (2004) reports a success rate of 38–44% using only WordNet-based similarity. In contrast, Turney (2005) reports up to 55% success on the same analogies, partly because his approach aims

to match implicit relations rather than explicit concepts, and in part because it uses a divergent process to gather from the web as rich a perspective as it can on these latent relationships.

## 2.1 Clever Comparisons Create Similarity

Each of these approaches to similarity is a *user* of information, rather than a *creator*, and each fails to capture how a creative comparison (such as a metaphor) can spur a listener to view a topic from an atypical perspective. Camac & Glucksberg (1984) provide experimental evidence for the claim that “metaphors do not use preexisting associations to achieve their effects [...] people use metaphors to create new relations between concepts.” They also offer a salutary reminder of an often overlooked fact: every comparison exploits information, but each is also a source of new information in its own right. Thus, “this cola is acid” reveals a different perspective on *cola* (e.g. as a *corrosive substance* or an *irritating food*) than “this acid is cola” highlights for *acid* (such as e.g., a *familiar substance*)

Veale & Keane (1994) model the role of similarity in realizing the long-term perlocutionary effect of an informative comparison. For example, to compare surgeons to butchers is to encourage one to see all surgeons as more *bloody*, *crude* or *careless*. The reverse comparison, of butchers to surgeons, encourages one to see butchers as more *skilled* and *precise*. Veale & Keane present a network model of memory, called *Sapper*, in which activation can spread between related concepts, thus allowing one concept to prime the properties of a neighbor. To interpret an analogy, *Sapper* lays down new activation-carrying bridges in memory between analogical counterparts, such as between *surgeon* & *butcher*, *flesh* & *meat*, and *scalpel* & *cleaver*. Comparisons can thus have lasting effects on how *Sapper* sees the world, changing the pattern of activation that arises when it primes a concept.

Veale (2003) adopts a similarly dynamic view of similarity in WordNet, showing how an analogical comparison can result in the automatic addition of new categories and relations to WordNet itself. Veale considers the problem of finding an analogical mapping between different parts of WordNet’s noun-sense hierarchy, such as between instances of *Greek god* and *Norse god*, or between the letters of different alphabets, such as of Greek and Hebrew. But no structural similarity measure for WordNet exhibits enough discernment to e.g. assign a higher similarity to

*Zeus* & *Odin* (each is the supreme deity of its pantheon) than to a pairing of *Zeus* and any other *Norse god*, just as no structural measure will assign a higher similarity to *Alpha* & *Aleph* or to *Beta* & *Beth* than to any random letter pairing.

A fine-grained category hierarchy permits fine-grained similarity judgments, and though WordNet is useful, its sense hierarchies are not especially fine-grained. However, we can automatically make WordNet subtler and more discerning, by adding new fine-grained categories to unite lexical concepts whose similarity is not reflected by any existing categories. Veale (2003) shows how a property that is found in the glosses of two lexical concepts, of the same depth, can be combined with their LCS to yield a new fine-grained parent category, so e.g. “supreme” + *deity* = *Supreme-deity* (for *Odin*, *Zeus*, *Jupiter*, etc.) and “1st” + *letter* = *1st-letter* (for *Alpha*, *Aleph*, etc.) Selected aspects of the textual similarity of two WordNet glosses – the key to similarity in Lesk (1986) – can thus be reified into an explicitly categorical WordNet form.

## 3 Divergent (Re)Categorization

To tap into a richer source of concept properties than WordNet’s glosses, we can use web n-grams. Consider these descriptions of a *cowboy* from the Google n-grams (Brants & Franz, 2006). The numbers to the right are Google frequency counts.

a	<i>lonesome</i>	cowboy	432
a	<i>mounted</i>	cowboy	122
a	<i>grizzled</i>	cowboy	74
a	<i>swaggering</i>	cowboy	68

To find the stable properties that can underpin a meaningful fine-grained category for *cowboy*, we must seek out the properties that are so often presupposed to be salient of all cowboys that one can use them to anchor a simile, such as “*swaggering like a cowboy*” or “*as grizzled as a cowboy*”. So for each property *P* suggested by Google n-grams for a lexical concept *C*, we generate a *like*-simile for verbal behaviors such as *swaggering* and an *as-as*-simile for adjectives such as *lonesome*. Each is then dispatched to Google as a phrasal query. We value quality over size, as these similes will later be used to find diverse viewpoints on the web via bootstrapping. We thus manually filter each web simile, to weed out any that are ill-formed, and those intended to be seen as ironic by their authors. This gives us a body of 12,000+ valid web similes.

Veale (2011, 2012, 2013) notes that web uses of the pattern “as *P* as *C*” are rife with irony. In contrast, web instances of “*P S* such as *C*” – where *S* denotes a superordinate of *C* – are rarely ironic. Hao & Veale (2010) exploit this fact to filter ironic comparisons from web similes, by re-expressing each “as *P* as *C*” simile as “*P* \* such as *C*” (using a wildcard \* to match any values for *S*) and looking for attested uses of this new form on the web. Since each hit will also yield a value for *S* via the wildcard \*, and a fine-grained category *P-S* for *C*, we use this approach here to harvest fine-grained categories from the web from most of our similes.

Once *C* is seen to be an exemplary member of the category *P-S*, such as *cola* in *fizzy-drink*, a targeted web search is used to find other members of *P-S*, via the anchored query “*P S* such as \* and *C*”. For example, “*fizzy drinks* such as \* and *cola*” will retrieve web texts in which \* is matched to *soda* or *lemonade*. Each new member can then be used to instantiate a further query, as in “*fizzy drinks* such as \* and *soda*”, to retrieve other members of *P-S*, such as *champagne* and *root beer*. This bootstrapping process runs in successive cycles, using doubly-anchored patterns that – following Kozareva *et al.* (2008) and Veale *et al.* (2009) – explicitly mention both the category to be populated (*P-S*) and a recently acquired member of this category (*C*).

As cautioned by Kozareva *et al.*, it is reckless to bootstrap from members to categories to members again if each enfilade of queries is likely to return noisy results. A reliable filter must be applied at each stage, to ensure that any member *C* that is placed in a category *P-S* is a sensible member of the category *S*. Only by filtering in this way can we stop the rapid accumulation of noise. For instance, a WordNet-based filter discards any categorization “*P S* such as *X* and *C*” where *X* does not denote a WordNet entry for which *S* does not denote a valid hypernym. Such a filter offers no creative latitude, however, since it forces every pairing of *C* and *P-S* to precisely obey WordNet’s category hierarchy. We thus use instead the *near-miss* filter described in Veale *et al.* (2009), in which *X* must denote a descendant of some direct hypernym of some sense of *S*. The filter does not (and cannot) determine whether *P* is salient for *X*. It merely assumes that if *P* is salient for *C*, it is salient for *X*.

Five successive cycles of bootstrapping are performed, using the 12,000+ web similes as a starting point. Consider *cola*: after 1 cycle, we acquire 14 new categories, such as *effervescent-*

*beverage* and *sweet-beverage*. After 2 cycles we acquire 43 categories; after 3 cycles, 72; after 4 cycles, 93; and after 5 cycles, we acquire 102 fine-grained perspectives on *cola*, such as *stimulating-drink* and *corrosive-substance*.

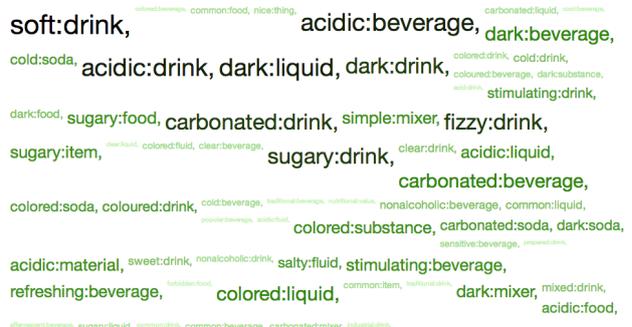

Figure 1. *Fine-grained perspectives for cola found by Thesaurus Rex on the web. See also Figures 3 and 4.*

These alternative viewpoints, for a broad array of concepts, are gleaned from the collective intelligence of the web. Some are more discerning and informative than others – see for instance *war & divorce* in Figure 4 – though as de Bono (1971) notes, lateral thinking does not privilege a narrow set of “correct” viewpoints, rather it generates a broad array of interesting alternatives, none of which are ever “wrong”, even if some prove more useful than others in a given context.

#### 4 Measuring and Creating Similarity

Which perspectives will be most useful and informative to a WordNet-based similarity metric? Simply, a perspective *M-C<sub>x</sub>* for a concept *C<sub>y</sub>* can be coherently added to WordNet *iff* *C<sub>x</sub>* denotes a hypernym of some sense of *C<sub>y</sub>* in WordNet. For purposes of quantifying the similarity of two terms *t<sub>1</sub>* and *t<sub>2</sub>* – by finding the WordNet senses of these terms that exhibit the highest similarity – we can augment WordNet with the perspectives on *t<sub>1</sub>* and *t<sub>2</sub>* that are coherent with WordNet’s hierarchy. So for *t<sub>1</sub>=cola* & *t<sub>2</sub>=acid, corrosive-substance* offers a coherent new perspective on each, slotting in beneath the matching WordNet sense of *substance*.

A category system is a structured feature space. We estimate the similarity of *C<sub>1</sub>* and *C<sub>2</sub>* as the cosine of the angle between the feature vectors that are constructed for each. The dimensions of these vectors are the atomic hypernyms (direct or indirect) of *C<sub>1</sub>* and *C<sub>2</sub>* in WordNet; the value of a dimension *H* in a vector is the information content (IC) of the WordNet hypernym *H*:

$$(1) \text{ IC}(H) = -\log\left(\frac{\text{size}(H)}{\sum_{c \in \text{WN}} \text{size}(c)}\right)$$

Here  $\text{size}(H)$  is the total number of lexical concepts in category  $H$  in WordNet, excluding any instance-level concepts, as these illustrative individuals are not evenly distributed across WordNet categories.

We also want any fine-grained perspective  $M-H$  to influence our similarity metric, provided it can be coherently tied into WordNet as a shared hypernym of the two lexical concepts being compared. The absolute information content of a category  $M-H$  that is newly added to WordNet is given by (2):

$$(2) \text{ IC}_{abs}(M-H) = -\log\left(\frac{\text{size}(M-H)}{\sum_{m-h \in \text{WN}} \text{size}(m-h)}\right)$$

where  $\text{size}(M-H)$  is the number of lexical concepts in WordNet for which  $M-H$  can be added as a new hypernym. The denominator in (2) denotes the sum total of the size of *all* fine-grained categories that can be coherently added to WordNet for *any* term.

The IC of  $M-H$  relative to  $H$  is estimated via the geometric mean of  $\text{IC}_{abs}(M-H)$  and  $\text{IC}(H)$  is given by (3):

$$(3) \text{ IC}(M-H) = \sqrt{\text{IC}_{abs}(M-H) \cdot \text{IC}(H)}$$

For a shared dimension  $H$  in the feature vectors of concepts  $C_1$  and  $C_2$ , if at least one fine-grained perspective  $M-H$  has been added to WordNet between  $H$  and  $C_1$  and between  $H$  and  $C_2$ , then the value of dimension  $H$  for  $C_1$  and for  $C_2$  is given by (4):

$$(4) \text{ weight}(H) = \max(\text{IC}(H), \max_M \text{IC}(M-H))$$

When no shared perspective  $M-H$  can be added under  $H$ , then  $\text{weight}(H) = \text{IC}(H)$ . A fine-grained perspective  $M-H$  will thus influence a similarity judgment between  $C_1$  and  $C_2$  only if  $M-H$  can be coherently added to WordNet as a hypernym of  $C_1$  and  $C_2$ , and if  $M-H$  enriches our view of  $H$ . Unlike Resnick (1995), Lin (1998) and Seco *et al.* (2006), this vector-space approach does not hinge on the information content of a single LCS, so any shared hypernym  $H$  or perspective  $M-H$  can shape a similarity judgment according to its informativeness.

## 5 Empirical Evaluation

Many fascinating perspectives on familiar ideas are bootstrapped from the web using similes as a starting point. These perspectives drive an exploratory web-aid to lateral thinking we call *Thesaurus Rex*, while the cosine-distance metric constructed from WordNet and these many fine-grained categories is called, simply, *Rex*. When *Rex* provides a numeric estimate of similarity for two ideas, *Thesaurus Rex* provides an enhanced insight into why these ideas are similar, e.g. by explaining that *cola & acid* are not just substances, they are *corrosive* substances.

We evaluate *Rex* by estimating how closely its judgments correlate with those of human judges on the 30-pair word set of Miller & Charles (M&C), who aggregated the judgments of multiple human raters into mean ratings for these pairs. We evaluate three variants of *Rex* on M&C: **Rex-lat**, which combines WordNet with all of *Thesaurus Rex*; **Rex-wn**, which uses only WordNet, with nothing at all from *Thesaurus Rex*; and **Rex-pop**, which enriches WordNet with only *popular* perspectives from *Thesaurus Rex*. A perspective is considered popular if it is discovered 5 or more times in the bootstrapping process, using 5 different anchors. While *corrosive-substance* is a popular category for *acid*, it not so for *cola* or *juice*. Popularity thus approximates what Ortony (1979) calls *salience*.

**Table 1.** Product-moment correlations (Pearson's  $r$ ) with mean human ratings on all 30 word pairs of the Miller & Charles similarity data-set.

\* As re-evaluated by Seco *et al.* (2006) for all 30 pairs

Table 1 lists coefficients of correlation (Pearson's  $r$ ) with mean human ratings for a range of WordNet-based metrics. Table 1 includes the hybrid *WordNet+web+SVM* metric of Agirre *et al.* (2009) – who report a correlation of **.93** – and the Mutual-Information-based *PMI<sub>max</sub>* metric of Han *et al.* (2009). The latter achieves good results for 27 of the 30 M&C pairs by enriching a PMI metric with an automatically-generated thesaurus. Yet while informative, this thesaurus is

not organized as an explanatory system of hierarchical categories as it is in *Thesaurus Rex*.

**Rex-wn** does no better than Seco *et al.* (2006) on the M&C dataset, suggesting that *Rex*'s vectors of IC-weighted hypernyms are no more discerning than a single informative LCS. However, such vectors also permit *Rex* to incorporate additional, fine-grained perspectives from *Thesaurus Rex*, allowing **Rex-lat** in turn to achieve a comparable correlation to that of Li *et al.* (2003) – .89. Yet the formulation in (2) favors unusual or idiosyncratic perspectives that are unlikely to generalize across independent judges. The mean ratings of M&C are the stuff of consensus, not individual creativity, and outside the realm of creative metaphor it often makes sense to safely align our judgments with those of others.

By limiting its use of *Thesaurus Rex* to the perspectives that other judges are most likely to use, **Rex-pop** obtains a correlation of .93 with mean human ratings on all 30 M&C pairs. This result is comparable to that reported by Agirre *et al.* (2009), who use SVM-based supervised learning to combine the judgments of two metrics, one based on WordNet and another on the analysis of web contexts of both input terms. However, *Rex* has the greater capacity for insight, since it augments the structured category system of WordNet with structured categories of its own. At each level of the WordNet hierarchy, *Rex* finds the fine-grained category that can best inform its judgments. Because *Rex* makes highly selective use of the diverse products of lateral thinking, this selectivity also produces concise explanations for its judgments.

## 5.1 Generative Uses of Similarity

A similarity metric offers a numerical measure of how closely one idea can cluster with another. It can also indicate how well one object may serve as a substitute for another, as when a *letter opener* is used as a *knife*, or *tofu* is used instead of *meat*. This need for substitution can be grist for creativity, yet most similarity metrics can only assess a suggested substitution, rather than suggest one for themselves. If they are to actively shape a creative decision, our similarity metrics must be made more generative.

A similarity metric can learn to be generative, by observing how people typically cluster words and ideas that are made similar by their contexts of use. The Google 3-grams contain many instances of the clustering pattern “*X+s and Y+s*”, as in “cowboys and pirates” or “doctors and lawyers”, and so a comprehensive trawl yields many

insights into the pairings of ideas that we implicitly see as comparable. We harvest all such Google 3-grams, to build a symmetric *comparability graph* in which any two comparable terms are adjacent nodes. For any node, we can generate a diverse set of comparable ideas just by reading off its adjacent nodes. *Thesaurus Rex* can be used to find an embracing category for many such pairs of nodes, while *Rex* estimates the similarity of any two adjacent nodes. A comparability graph of 28,000 nodes is produced from the Google 3-grams, with a sparse adjacency matrix of just 1,264,827 (0.16%) non-zero entries.

Is this dense enough for a task requiring generative similarity? Almuhareb & Poesio (2004) describe one such task: they sample 214 words from across 13 WordNet categories, and ask if these 214 words can be partitioned into 13 clusters that mirror the WordNet categories from which they were drawn. They then collect tens of thousands of web contexts for these 214 words, to extract a feature representation of each. We instead use *Rex* to generate, as features, a diverse set of comparable terms for each word. (We also assume that each word is a feature of itself). The *Rex* comparability graph suggests a pool of 8,300 features for all 214 words. The clustering toolkit CLUTO is used to partition the original 214 words into 13 clusters guided only by these comparability features. The resulting 13 clusters have an average purity of **93.4%** relative to WordNet, suggesting that categorization tasks which require implicit comparability judgments are well served by a generative approach to similarity.

## 5.2 Learning From Similarity Judgments

*Rex* augments the narrow worldview of WordNet with the more diverse viewpoints it gleans from the web, not by viewing them as separate knowledge sources, but by actually updating WordNet itself. The relative performance of **Rex-pop** > **Rex-lat** > **Rex-wn** on the M&C dataset shows that selective use of a divergent perspective permits WordNet to better serve its popular role as a judge of similarity. It is worth asking then whether these passing additions to WordNet should not be made permanent.

*Rex* estimates a similarity score for each of the 1,264,827 pairings of comparable terms it finds in the Google 3-grams. These scores are then cached to support generative similarity, and to permit fast lookup of scores for common comparisons. This lookup table is a lightweight means of using *Rex* in a range of creative substitution or generation tasks. Though the table is

sparse, §5.1 shows that it implicitly captures key nuances of category structure. The 39,826 unique fine-grained categories added by **Rex-pop** (versus the 44,238 categories added by **Rex-lat**) in the course of its 1,264,827 comparisons thus suggest credible enhancements to WordNet. Figure 2 graphs the distribution of new categories and their membership sizes when **Rex-pop** is used on this scale.

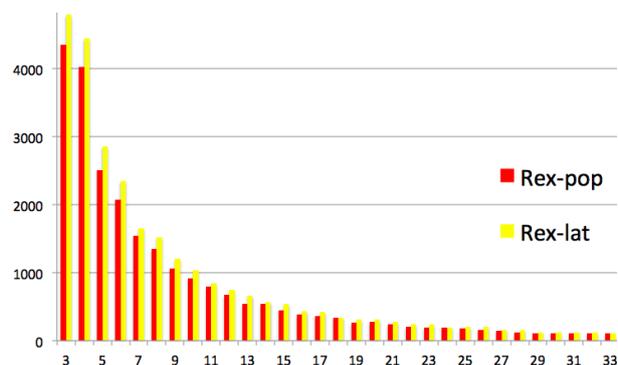

Figure 2. The number of new categories (Y-axis) with a given membership size (X-axis) added to WordNet when **Rex-pop/lat** are used on a large, web scale.

The *Goldilocks* categories are those that are not so small as to lack generality, and not so large as to lack information content. For example, **Rex-pop** suggests the addition of 15,125 new fine-grained categories to WordNet with membership sizes ranging from 5 to 25. This is a large but manageable number of categories that should be further considered for future addition to WordNet, or indeed to any similarly curated knowledge resource.

## 6 Summary and Conclusions

de Bono (1970) argues that the best solutions arise from using lateral and vertical thinking *in unison*. Lateral thinking is divergent and generative, while vertical thinking is convergent and analytical. The former can thus be used to create a pool of interesting candidates for the latter to selectively consider. *Thesaurus Rex* uses the web to generate a rich pool of alternate perspectives on familiar ideas, and *Rex* selects from this pool to perform vertical reasoning with WordNet to yield precise similarity judgments. *Rex* also uses the most informative perspective to concisely *explain* each comparison, or – when used in generative mode – to *suggest* a creative comparison. For instance, to highlight the potential toxicity of *coffee*, *Thesaurus Rex* suggests comparisons with *alcohol*, *tobacco* or *pesticide*, as all have been categorized as toxic substances on the web. A web app based on *Thesaurus Rex*, to support this

kind of lateral thinking, is accessible online at this URL:

<http://boundinanutshell.com/therex2>

Screenshots from the *Thesaurus Rex* application are provided in Figures 3 and 4 overleaf. Because *Thesaurus Rex* targets the acquisition of fine-grained perspectives, ranging from the off-beat to the obvious, it acquires an order-of-magnitude more categories from the web than can be found in WordNet itself. *Rex* dips selectively into this wealth of perspectives (and **Rex-pop** is more selective still), though many of *Rex*'s needs can be anticipated by looking to how ideas are implicitly grouped into *ad-hoc categories* (Barsalou, 1983) in constructions such as “*X+s and Y+s*”. Using the Google n-grams as a source of tacit grouping constructions, we have created a comprehensive lookup table that provides *Rex* similarity scores for the most common (if often implicit) comparisons.

Comparability is not the same as similarity, and a non-zero similarity score does not mean that two concepts would ever be considered comparable by a human. This poses a problem for the generation of sensible comparisons. However, *Rex*'s lookup table captures the implicit pragmatics of comparability, making *Rex* usable in generative tasks where a metric must both suggest and evaluate comparisons. Human similarity mechanisms are evaluative *and* generative, convergent *and* divergent. Our computational mechanisms should be no less so.

# Discovering User Interactions in Ideological Discussions

Arjun Mukherjee Bing Liu

Department of Computer Science

University of Illinois at Chicago

arjun4787@gmail.com liub@cs.uic.edu

## Abstract

Online discussion forums are a popular platform for people to voice their opinions on any subject matter and to discuss or debate any issue of interest. In forums where users discuss social, political, or religious issues, there are often heated debates among users or participants. Existing research has studied mining of user stances or camps on certain issues, opposing perspectives, and contention points. In this paper, we focus on identifying the nature of interactions among user pairs. The central questions are: How does each pair of users interact with each other? Does the pair of users mostly agree or disagree? What is the lexicon that people often use to express agreement and disagreement? We present a topic model based approach to answer these questions. Since agreement and disagreement expressions are usually multi-word phrases, we propose to employ a ranking method to identify highly relevant phrases prior to topic modeling. After modeling, we use the modeling results to classify the nature of interaction of each user pair. Our evaluation results using real-life discussion/debate posts demonstrate the effectiveness of the proposed techniques.

## 1 Introduction

Online discussion/debate forums allow people with common interests to freely ask and answer questions, to express their views and opinions on any subject matter, and to discuss issues of common interest. A large part of such discussions is about social, political, and religious issues. On such issues, there are often heated discussions/debates, i.e., people agree or disagree and argue with one another. Such ideological discussions on a myriad of social and political issues have practical implications in the fields of communication and political science as they give social scientists an opportunity to study real-life discussions/debates of almost any issue and analyze participant behaviors in a large scale.

In this paper, we present such an application, which aims to perform fine-grained analysis of user-interactions in online discussions.

There have been some related works that focus on discovering the general topics and ideological perspectives in online discussions (Ahmed and Xing, 2010), placing users in support/oppose camps (Agarwal et al., 2003), and classifying user stances (Somasundaran and Wiebe, 2009). However, these works are at a rather coarser level and have not considered more fine-grained characteristics of debates/discussions where users interact with each other by quoting/replying each other to express agreement or disagreement and argue with one another. In this work, we want to mine the following information:

1. The nature of interaction of each pair of users or participants who have engaged in the discussion of certain issues, i.e., whether the two persons mostly agree or disagree with each other in their interactions.
2. What language expressions are often used to express agreement (e.g., “I agree” and “you’re right”) and disagreement (e.g., “I disagree” and “you speak nonsense”).

We note that although agreement and disagreement expressions are distinct from traditional sentiment expressions (words and phrases) such as *good*, *excellent*, *bad*, and *horrible*, agreement and disagreement clearly express a kind of sentiment as well. They are usually emitted during interactive exchanges of arguments in ideological discussions. This idea prompted us to introduce the concept of *AD-sentiment*. We define the polarity of agreement expressions as *positive* and the polarity of disagreement expressions as *negative*. We refer agreement and disagreement expressions as *AD-sentiment expressions*, or *AD-expressions* for short. AD-expressions are crucial for the analysis of interactive discussions and debates just as sentiment expressions are instrumental in sentiment analysis (Liu, 2012). We thus regard this work as an extension to traditional sentiment

analysis (Pang and Lee, 2008; Liu, 2012).

In our earlier work (Mukherjee and Liu, 2012a), we proposed three topic models to mine contention points, which also extract AD-expressions. In this paper, we further improve the work by coupling an information retrieval method to rank good candidate phrases with topic modeling in order to discover more accurate AD-expressions. Furthermore, we apply the resulting AD-expressions to the new task of classifying the arguing or interaction nature of each pair of users. Using discovered AD-expressions for classification has an important advantage over traditional classification because they are domain independent. We employ a semi-supervised generative model called JTE-P to jointly model AD-expressions, pair interactions, and discussion topics simultaneously in a single framework. With such complex interactions mined, we can produce many useful summaries of discussions. For example, we can discover the most contentious pairs for each topic and ideological camps of participants, i.e., people who often agree with each other are likely to belong to the same camp. The proposed framework also facilitates tracking users' ideology shifts and the resulting arguing nature.

The proposed methods have been evaluated both qualitatively and quantitatively using a large number of real-life discussion/debate posts from four domains. Experimental results show that the proposed model is highly effective in performing its tasks and outperforms several baselines.

## 2 Related Work

There are several research areas that are related to our work. We compare with them below.

**Sentiment analysis:** Sentiment analysis determines positive and negative opinions expressed on entities and aspects (Hu and Liu, 2004). Main tasks include aspect extraction (Hu and Liu, 2004; Popescu and Etzioni, 2005), polarity identification (Hassan and Radev, 2010; Choi and Cardie, 2010) and subjectivity analysis (Wiebe, 2000). As discussed earlier, agreement and disagreement are a special form of sentiments and are different from the sentiment studied in the mainstream research. Traditional sentiment is mainly expressed with sentiment terms (e.g., *great* and *bad*), while agreement and disagreement are inferred by AD-expressions (e.g., *I agree* and *I disagree*), which we also call AD-sentiment expressions. Thus, this work expands the sentiment analysis research.

**Topic models:** Our work is also related to topic modeling and joint modeling of topics and other information as we jointly model several aspects of discussions/debates.

Topic models like pLSA (Hofmann, 1999) and LDA (Blei et al., 2003) have proved to be very successful in mining topics from large text collections. There have been various extensions to multi-grain (Titov and McDonald, 2008), labeled (Ramage et al., 2009), and sequential (Du et al., 2010) topic models. Yet other approaches extend topic models to produce author specific topics (Rosen-Zvi et al., 2004), author persona (Mimno and McCallum, 2007), social roles (McCallum et al., 2007), etc. However, these models do not model debates and hence are unable to discover AD-expressions and interaction natures of author pairs.

Also related are topic models in sentiment analysis which are often referred to as Aspect and Sentiment models (ASMs). ASMs come in two main flavors: Type-1 ASMs discover aspect (or topic) words sentiment-wise (i.e., discovering positive and negative topic words and sentiments for each topic without separating topic and sentiment terms) (e.g., Lin and He, 2009; Brody and Elhadad, 2010; Jo and Oh, 2011). Type-2 ASMs separately discover both aspects and sentiments (e.g., Mei et al., 2007; Zhao et al., 2010). Recently, domain knowledge induced ASMs have also been proposed (Mukherjee and Liu, 2012b; Chen et al., 2013). The generative process of ASMs is, however, different from our model. Specifically, Type-1 ASMs use asymmetric hyper-parameters for aspects while Type-2 assumes that sentiments and aspects are emitted in the same sentence. However, AD-expressions are emitted differently. They are mostly interleaved with users' topical viewpoints and span different sentences. Further, we capture the key characteristic of discussions by encoding pair-wise user interactions. Existing models do not model pair interactions.

In terms of discussions and comments, Yano et al., (2009) proposed the CommentLDA model which builds on the work of LinkLDA (Erosheva et al., 2004). Mukherjee and Liu (2012d) mined comment expressions. These works, however, don't model pair interactions in debates.

**Support/oppose camp classification:** Several works have attempted to put debate authors into support/oppose camps. Agrawal et al. (2003) used a graph based method. Murakami and Raymond (2010) used a rule-based method. In (Galley et al., 2004; Hillard et al., 2003), speaker

utterances were classified into agreement, disagreement and backchannel classes.

**Stances in online debates:** Somasundaran and Wiebe (2009), Thomas et al. (2006), Bansal et al. (2008), Burfoot et al. (2011), and Anand et al. (2011) proposed methods to recognize stances in online debates. Some other research directions include subgroup detection (Abu-Jbara et al., 2012), tolerance analysis (Mukherjee et al., 2013), mining opposing perspectives (Lin and Hauptmann, 2006), linguistic accommodation (Mukherjee and Liu, 2012c), and contention point mining (Mukherjee and Liu, 2012a). For this work, we adopt the JTE-P model in (Mukherjee and Liu, 2012a), and make two major advances. We propose a new method to improve the AD-expression mining and a new task of classifying pair interaction nature to determine whether each pair of users who have interacted based on replying relations mostly agree or disagree with each other.

### 3 Model

We now introduce the JTE-P model with additional details. JTE-P is a semi-supervised generative model motivated by the joint occurrence of expression types (*agreement* and *disagreement*), topics in discussion posts, and user pairwise interactions. Before proceeding, we make the following observation about online discussions.

In a typical debate/discussion post, the user (author) mentions a few topics (using semantically related topical terms) and expresses some viewpoints with one or more AD-expression types (using agreement and disagreement expressions). AD-expressions are directed towards other user(s), which we call *target*(s). In this work, we focus on explicit mentions (i.e., using @name or quoting other authors' posts). In our crawled dataset, 77% of all posts exhibit explicit quoting/reply-to relations excluding the first posts of threads which start the discussions and usually have nobody to quote/reply-to. Such author-target exchanges usually go back and forth between pairs of users populating a thread of discussion. The discussion topics and AD-expressions emitted are thus caused by the author-pairs' topical interests and their nature of interaction (agreeing vs. disagreeing).

In our discussion data obtained from Volconvo.com, we found that a pair of users typically exhibited a dominant arguing nature

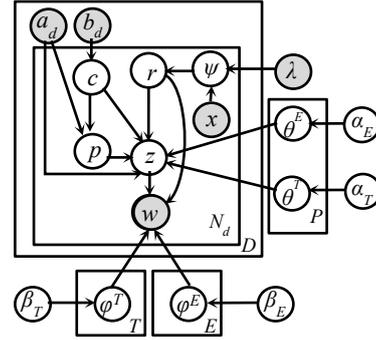

Figure 1: JTE-P Model in plate notation.

Variable/Function	Description
$d; a_d$	A document (post) $d$ ; author $a_d$ of document, $d$
$b_d = [b_1 \dots b_n]$	List of <i>targets</i> to whom $a_d$ replies/quotes in $d$ .
$p = (a, a')$	Pair of two authors interacting by reply/quote.
$\theta_p^T; \theta_p^E(\theta_{p,Ag}^E, \theta_{p,DisAg}^E)$	Pair $p$ 's distribution over topics; expression types (Agreement: $\theta_{p,Ag}^E$ , Disagreement: $\theta_{p,DisAg}^E$ )
$\varphi_t^T; \varphi_{e \in \{Ag, DisAg\}}^E$	Topic $t$ 's; Expression type $e$ 's distribution over vocabulary terms
$T; E$	Total number of topics; expression types
$V; P$	Total number of vocabulary terms; pairs
$w_{d,j}; N_d$	$j^{th}$ term in $d$ ; Total # of terms in $d$
$\psi_{d,j}$	Distribution over topics and AD-expressions
$x_{d,j}$	Associated feature context of the observed term $w_{d,j}$
$\lambda$	Learned Max-Ent parameters
$r_{d,j} \in \{\hat{t}, \hat{e}\}$	Binary indicator/switch variable (topic ( $\hat{t}$ ) or AD-expression ( $\hat{e}$ )) for $w_{d,j}$
$z_{d,j}$	Topic/Expression type of $w_{d,j}$
$\alpha_T; \alpha_E; \beta_T; \beta_E$	Dirichlet priors of $\theta_p^T; \theta_p^E; \varphi_t^T; \varphi_e^E$
$n_{p,t}^{PT}, n_{p,e}^{PE}$	# of times topic $t$ ; expression type $e$ assigned to $p$
$n_{t,v}^{CT}, n_{e,v}^{CE}$	# of times term $v$ appears in topic $t$ ; expression type $e$

Table 1: List of Notations

(agreeing vs. disagreeing) towards each other across various topics or threads. We believe this is because our data consists of topics like elections, theism, terrorism, vegetarianism, etc. which are often heated and attract people with pre-determined, strong, and polarized stances<sup>1</sup>.

This observation motivates the generative process of our model. Referring to the notations in Table 1, we explain the generative process of JTE-P. Given a document (post)  $d$ , its author,  $a_d$ , and the list of *targets* to whom  $a_d$  replies/quotes

<sup>1</sup> These hardened perspectives are supported by theoretical studies in communications like the polarization effect (Sunstein, 2002), and the hostile media effect, a scenario where partisans rigidly hold on to their stances (Hansen and Hyunjung, 2011).

in  $d$ ,  $b_d = [b_1 \dots b_n]$ , the document  $d$  exhibits shared topics and arguing nature of various pairs,  $p = (a_d, c)$ , where  $c \in b_d$ . More precisely, the pair specific topic and AD-expression distributions  $(\theta_p^T; \theta_p^E)$  “shape” the topics and AD-expressions emitted in  $d$  as agreement and disagreement on topical viewpoints are directed towards certain target authors. Each topic  $(\varphi_t^T)$  and AD-expression type  $(\varphi_e^E)$  is characterized by a multinomial distribution over terms (words/phrases). Assume we have  $t = 1 \dots T$  topics and  $e = 1 \dots E$  expression types in our corpus. Note that in our case of discussion/debate forums, we hypothesize  $E = 2$  as in debates, we mostly find two expression types: *agreement* and *disagreement* (more details in §6.1). Like most generative models for text, a post (document) is viewed as a bag of  $n$ -grams and each  $n$ -gram (word/phrase) takes one value from a predefined vocabulary. In this work, we use up to 4-grams, i.e.,  $n = 1, 2, 3, 4$ . Instead of using all  $n$ -grams, a relevance based ranking method is proposed to select a subset of highly relevant  $n$ -grams for model building (details in §4). For notational convenience, we use *terms* to denote both *words* (unigrams) and *phrases* ( $n$ -grams).

JTE-P is a switching graphical model (Ahmed and Xing, 2010; Zhao et al., 2010) performing a switch between AD-expressions and topics.  $\psi_{d,j}$  denotes the distribution over topics and AD-expressions with  $r_{d,j} \in \{\hat{t}, \hat{e}\}$  denoting the binary indicator/switch variable (topic or AD-expression) for the  $j^{\text{th}}$  term of  $d$ ,  $w_{d,j}$ . To perform the switch we use a maximum entropy (Max-Ent) model. The idea is motivated by the observation that topical and AD-expression terms usually play different roles in a sentence. Topical terms (e.g., “elections” and “income tax”) tend to be noun and noun phrases while AD-expression terms (“I refute”, “how can you say”, and “probably agree”) usually contain pronouns, verbs, wh-determiners, and modals. In order to utilize the part-of-speech (POS) tag information, we place the topic/AD-expression distribution  $\psi_{d,j}$  (the prior over the indicator variable  $r_{d,j}$ ) in the term plate (see Figure 1) and set it from a Max-Ent model conditioned on the observed feature context  $x_{d,j}$  associated with  $w_{d,j}$  and the learned Max-Ent parameters,  $\lambda$  (details in §6.1). In this work, we use both lexical and POS features of the previous, current, and next POS tags/lexemes of the term  $w_{d,j}$  as the contextual information, i.e.,  $x_{d,j} = [POS_{w_{d,j-1}}, POS_{w_{d,j}}, POS_{w_{d,j+1}}, w_{d,j-1}, w_{d,j}, w_{d,j+1}]$ , which is used to

produce the feature functions for Max-Ent. For phrasal terms ( $n$ -grams), all POS tags and lexemes of  $w_{d,j}$  are considered as contextual information for computing feature functions in Max-Ent. We now detail the generative process of JTE-P (plate notation in Figure 1) as follows:

1. For each AD-expression type  $e$ , draw  $\varphi_e^E \sim \text{Dir}(\beta_E)$
2. For each topic  $t$ , draw  $\varphi_t^T \sim \text{Dir}(\beta_T)$
3. For each pair  $p$ , draw  $\theta_p^E \sim \text{Dir}(\alpha_E)$ ;  $\theta_p^T \sim \text{Dir}(\alpha_T)$
4. For each forum discussion post  $d \in \{1 \dots D\}$ :
  - i. Given the author  $a_d$  and the list of targets  $b_d$ , for each term  $w_{d,j}$ ,  $j \in \{1 \dots N_d\}$ :
    - a. Draw a target  $c \sim \text{Uni}(b_d)$
    - b. Form pair  $p = (a_d, c)$ ,  $c \in b_d$
    - c. Set  $\psi_{d,j} \leftarrow \text{MaxEnt}(x_{d,j}; \lambda)$
    - d. Draw  $r_{d,j} \sim \text{Bern}(\psi_{d,j})$
    - e. if  $(r_{d,j} = \hat{e})$  //  $w_{d,j}$  is an AD-expression term  
Draw  $z_{d,j} \sim \text{Mult}(\theta_p^E)$   
else //  $r_{d,j} = \hat{t}$ ,  $w_{d,j}$  is a topical term  
Draw  $z_{d,j} \sim \text{Mult}(\theta_p^T)$
    - f. Emit  $w_{d,j} \sim \text{Mult}(\varphi_{z_{d,j}}^{r_{d,j}})$

*Dir*, *Mult*, *Bern*, and *Uni* correspond to the Dirichlet, Multinomial, Bernoulli, and Uniform distributions respectively. To learn JTE-P, we employ approximate posterior inference using Monte Carlo Gibbs sampling. Denoting the random variables  $\{w, z, p, r\}$  associated with each term by singular subscripts  $\{w_k, z_k, p_k, r_k\}$ ,  $k_{1..K}$ ,  $K = \sum_d N_d$ , a single Gibbs sweep consists of performing the following sampling.

$$p(z_k = t, p_k = p, r_k = \hat{t} | \dots) \propto \frac{1}{|b_d| \sum_{y \in \{\hat{e}, \hat{t}\}} \exp(\sum_{i=1}^n \lambda_i f_i(x_{d,j}, \hat{t}))} \times \frac{n_{p,t}^{PT} + \alpha_T}{n_{p,(\cdot)}^{PT} + T \alpha_T} \frac{n_{t,v}^{CT} + \beta_T}{n_{t,(\cdot)}^{CT} + V \beta_T} \quad (1)$$

$$p(z_k = e, p_k = p, r_k = \hat{e} | \dots) \propto \frac{1}{|b_d| \sum_{y \in \{\hat{e}, \hat{t}\}} \exp(\sum_{i=1}^n \lambda_i f_i(x_{d,j}, \hat{e}))} \times \frac{n_{p,e}^{PE} + \alpha_E}{n_{p,(\cdot)}^{PE} + E \alpha_E} \frac{n_{e,v}^{CE} + \beta_E}{n_{e,(\cdot)}^{CE} + V \beta_E} \quad (2)$$

Count variables  $n_{t,v}^{CT}$ ,  $n_{e,v}^{CE}$ ,  $n_{p,t}^{PT}$ , and  $n_{p,e}^{PE}$  are detailed in Table 1. Omission of a latter index denoted by  $(\cdot)$  represents the marginalized sum over the latter index.  $k = (d, j)$  denotes the  $j^{\text{th}}$  term of document  $d$  and the subscript  $-k$  denotes the counts excluding the term at  $(d, j)$ .  $\lambda_{1..n}$  are the parameters of the learned Max-Ent model corresponding to the  $n$  binary feature functions  $f_{1..n}$  for Max-Ent. These learned Max-Ent  $\lambda$  parameters in conjunction with the observed feature context,  $x_{d,j}$  feed the supervision signal for topic/expression switch parameter,  $r$  which is updated during inference in equations (1) and (2).

## 4 Phrase Ranking based on Relevance

We now detail our method of pre-processing  $n$ -grams (phrases) based on relevance to select a subset of highly relevant  $n$ -grams for model building. This has two advantages: (i). A large number of irrelevant  $n$ -grams slow inference. (ii). Filtering irrelevant terms in the vocabulary improves the quality of AD-expressions. Before proceeding, we review some existing approaches. Topics in most topic models like LDA are usually unigram distributions. This offers a great computational advantage compared to more complex models which consider word ordering (Wallach, 2006; Wang et al., 2007). This thread of research models bigrams by encoding them into the generative process. For each word, a topic is sampled first, then its status as a unigram or bigram is sampled, and finally the word is sampled from a topic-specific unigram or bigram distribution. This method, however, is expensive computationally and has a limitation for arbitrary length  $n$ -grams. In (Tomokiyo and Hurst, 2003), a language model approach is used for bigram phrase extraction.

Yet another thread of research *post-processes* the discovered topical unigrams to form multi-word phrases using likelihood scores (Blei and Lafferty, 2009). This approach considers adjacent word pairs and identifies  $n$ -grams which occur much more often than one would expect by chance alone by computing likelihood ratios. While this is reasonable, a significant  $n$ -gram with high likelihood score may *not* necessarily be relevant to the problem domain. For instance, in our case of discovering AD-expressions, the likelihood score<sup>2</sup> of  $p_1$  = “the government of” happens to be more than  $p_2$  = “I completely disagree”. Clearly, the former is irrelevant for the task of discovering AD-expressions. The reason for this is that likelihood scores or other statistical test scores rely on the relative counts in the multi-way contingency table to compute significance. Since the relative counts of different fragments of the irrelevant phrase  $p_1$ , e.g. “the government”, and “government of”, happen to appear more than the corresponding counts in the contingency table of  $p_2$ , the tests assign a higher score. This is nothing wrong per se because the statistical tests only judge significance of an  $n$ -gram, but a significant  $n$ -gram may not necessarily be relevant in a given problem domain.

<sup>2</sup> Computed using N-gram statistics package, NSP; <http://n-gram.sourceforge.net>

Thus, the existing approaches have some major shortcomings for our task. As our goal is to enhance the expressiveness of our models by considering relevant  $n$ -grams preserving the advantages of exchangeable modeling, we employ a *pre-processing* technique to rank  $n$ -grams based on relevance and consider certain number of top ranked  $n$ -grams based on *coverage* (details follow) in our vocabulary. The idea works as follows.

We first induce a unigram JTE-P whereby we cluster the relevant AD-expression unigrams in  $\phi_{Ag}^E$  and  $\phi_{DisAg}^E$ . Our notion of *relevance* of AD-expressions is already encoded into the model using priors set from Max-Ent. Next, we rank the candidate phrases ( $n$ -grams) using our probabilistic ranking function. The ranking function is grounded on the following hypothesis: a relevant phrase is one whose unigrams are closely related to (or appear with high probabilities in) the given AD-expression type,  $e$  : Agreement ( $Ag$ ) or disagreement ( $DisAg$ ). Continuing from the previous example, given the expression type  $\phi_{e=DisAg}^E$ ,  $p_2$  is relevant while  $p_1$  is not as “government” and “disagree” are highly unlikely and likely respectively to be clustered in  $\phi_{e=DisAg}^E$ . Thus, we want to rank phrases based on  $P(Rel = 1|e, p)$  where  $e$  denotes the expression type (Agreement/Disagreement),  $p$  denotes a candidate phrase. Following the probabilistic relevance model in (Lafferty and Zhai, 2003), we use a similar technique to that in (Zhao et al., 2011) for deriving our relevance ranking function as follows:

$$P(Rel = 1|e, p) = \frac{P(Rel=1|e, p)}{P(Rel=0|e, p) + P(Rel=1|e, p)} = \frac{1}{1 + \frac{P(Rel=0|e, p)}{P(Rel=1|e, p)}} = \frac{1}{1 + \frac{P(Rel=0, p|e)}{P(Rel=1, p|e)}} = \frac{1}{1 + \frac{[P(p|Rel=0, e) \times P(Rel=0|e)]}{[P(p|Rel=1, e) \times P(Rel=1|e)]}} \quad (3)$$

We further define  $\varepsilon = \frac{P(Rel=0|e)}{P(Rel=1|e)}$ . Without loss of generality, one can say that  $P(Rel = 0|e) \gg P(Rel = 1|e)$ , because there are many more irrelevant phrases than relevant ones, i.e.,  $\varepsilon \gg 1$ . Thus, taking log, from equation (3), we get,

$$\log P(Rel = 1|e, p) = \log \left( \frac{1}{1 + \varepsilon \times \frac{P(p|Rel=0, e)}{P(p|Rel=1, e)}} \right) \approx \log \left( \frac{P(p|Rel=1, e)}{P(p|Rel=0, e)} \times \frac{1}{\varepsilon} \right) = \log \left( \frac{P(p|Rel=1, e)}{P(p|Rel=0, e)} \right) - \log \varepsilon \quad (4)$$

Thus, our ranking function actually computes the relevance score  $\log \left( \frac{P(p|Rel=1, e)}{P(p|Rel=0, e)} \right)$ . The last term,  $\log \varepsilon$  being a constant is ignored because it cancels out while comparing candidate  $n$ -grams.

We now estimate the relevance score of a phrase  $p = (w_1, w_2, \dots, w_n)$ . Using the conditional independence assumption of words given the indicator variable  $Rel$  and expression type  $e$ , we have:

$$\log \left( \frac{P(p|Rel=1,e)}{P(p|Rel=0,e)} \right) = \sum_{i=1}^n \log \frac{P(w_i|Rel=1,e)}{P(w_i|Rel=0,e)} \quad (5)$$

Given the expression model  $\varphi_e^E$  previously learned by inducing the unigram JTE-P, it is intuitive to set  $P(w_i|Rel=1,e)$  to the point estimate of the posterior on  $\varphi_{e,w_i}^E = \frac{n_{e,w_i}^{EV} + \beta_E}{n_{e,(c)}^{EV} + V\beta_E}$ , where  $n_{e,w_i}^{EV}$  is the number of times  $w_i$  was assigned to AD-expression type  $e$  and  $n_{e,(c)}^{EV}$  denotes the marginalized sum over the latter index. On the other hand,  $P(w_i|Rel=0,e)$  can be estimated using a Laplace smoothed ( $\mu = 1$ ) background model, i.e.,  $(w_i|Rel=0,e) = \frac{n_{w_i} + \mu}{n_V + V\mu}$ , where  $n_{w_i}$  denotes the number of times  $w_i$  appears in the whole corpus and  $n_V$  denotes the number of terms in the entire corpus.

Next, we throw light on the issue of choosing the number of top  $k$  phrases from the ranked candidate  $n$ -grams. Precisely, we want to analyze the coverage of our proposed ranking based on relevance models. By coverage, we mean that having selected top  $k$  candidate  $n$ -grams based on the proposed relevance ranking, we want to get an estimate of how many relevant terms from a sample of the collection were covered. To compute coverage, we randomly sampled 500 documents from the corpus and listed the candidate  $n$ -grams<sup>3</sup> in the collection of sampled 500 documents. For this and subsequent human judgment tasks, we use two judges (graduate students well versed in English). We asked our judges to mark all relevant AD-expressions. Agreement study yielded  $\kappa_{\text{Cohen}} = 0.77$  showing substantial agreement according to scale<sup>4</sup> provided in (Landis and Koch, 1977). This is understandable as identifying AD-expressions is a relatively easy task. Finally, a term was considered to be relevant if both judges marked it so. We then computed the coverage to see how many of the relevant terms in the random sample were also present in top  $k$  phrases from the ranked candidate  $n$ -grams. We summarize the

<sup>3</sup> These are terms appearing at least 20 times in the entire collection. We do this for computational reasons as there can be many  $n$ -grams and  $n$ -grams with very low frequency are less likely to be relevant.

<sup>4</sup> No agreement ( $\kappa < 0$ ), slight agreement ( $0 < \kappa \leq 0.2$ ), fair agreement ( $0.2 < \kappa \leq 0.4$ ), moderate agreement ( $0.4 < \kappa \leq 0.6$ ), substantial agreement ( $0.6 < \kappa \leq 0.8$ ), and almost perfect agreement ( $0.8 < \kappa \leq 1.0$ ).

coverage results below in Table 2.

	$k$	3000	4000	5000
JTE-P	Agreement	81.34	84.24	87.01
	Disagreement	84.96	87.86	89.64

Table 2: Coverage (in %) of AD-expressions.

We find that choosing top  $k = 5000$  candidate  $n$ -grams based on our proposed ranking, we obtain a coverage of 87% for agreement and 89.64 for disagreement expression types which are reasonably good. Thus, we choose top 5000 candidate  $n$ -grams for each expression type and add them to the vocabulary beyond all unigrams.

Like expression types  $e_{1..E}$ , we also ranked candidate phrases for topics  $t_{1..T}$  using  $P(Rel=1|t,p)$ . However, for topics, selecting  $k$  based on coverage of each topic is more difficult because we induce 50 topics and it is also much more difficult to manually find relevant topical phrases in the sampled data as a topical phrase may belong to more than one topic. We selected top 2000 ranked candidate phrases for each topic using  $P(Rel=1|t,p)$  as we feel that is sufficient for a topic. Note that phrases for topics are not as crucial as for AD-expressions because topics can more or less be defined by unigrams.

## 5 Classifying Pair Interaction Nature

We now determine whether two users (also called a user pair) mostly agree or disagree with each other in their exchanges, i.e., their pair interaction or arguing nature. This is a relatively new task. We first summarize the closest related works. In (Galley et al., 2004; Hillard et al., 2003; Thomas et al., 2006, Bansal et al., 2008), conversational speeches (i.e., U.S. Congress meeting transcripts) are classified into for or against an issue using various types of features: *durational* (e.g., time taken by a speaker; speech rate, etc.), *structural* (e.g., no. of speakers per side, no. of votes cast by a speaker on a bill, etc.), and *lexical* (e.g., first word, last word,  $n$ -grams, etc.). Burfoot et al., (2011) builds on the work of (Thomas et al., 2006) and proposes collective classification using speaker contextual features (e.g., speaker intentions based on vote labels). However, above works do not discover pair interactions (arguing nature) in debate authors. Online discussion forums are textual rather than conversational (e.g., U.S. Congress meeting transcripts). Thus, the *durational*, *structural*, and *contextual* features used in prior works are not directly applicable.

Instead, the model posterior on  $\theta_p^E$  for JTE-P

can actually give an estimate of the overall interaction nature of a pair, i.e., the probability masses assigned to expression types,  $e = Ag$  (Agreement) and  $e = DisAg$  (Disagreement). As  $\theta_p^E \sim Dir(\alpha_E)$ , we have  $\theta_{p,e=Ag}^E + \theta_{p,e=DisAg}^E = 1$ . Hence, if the probability mass assigned to any one of the expression types (agreement, disagreement)  $> 0.5$  then according to the model posterior, that expression type is dominant, i.e., if  $\theta_{p,Ag}^E > 0.5$ , the pair is agreeing else disagreeing.

However, this approach is not the best. As we will see in the experiment section, supervised classification using labeled training data with discovered AD-expressions as features performs better.

## 6 Empirical Evaluation

We now evaluate the proposed techniques in the context of the JTE-P model. We first evaluate the discovered AD-expressions by comparing results with and without using the phrase ranking method in Section 4, and then evaluate the classification of interaction nature of pairs.

### 6.1 Dataset and Experiment Settings

We crawled debate/discussion forum posts from Volconvo.com. The forum is divided into various domains. Each domain consists of multiple threads of discussions. For each post, we extracted the post id, author, domain, ids of all posts to which it replies/quotes, and the post content. In all, we extracted 26137, 34986, 22354, and 16525 posts from Politics, Religion, Society and Science domains respectively.

**Experiment Data:** As it is not interesting to study pairs who only exchanged a few posts, we restrict to pairs with at least 20 post exchanges. This resulted in 1241 authors and 1461 pairs. The reduced dataset consists of 1095586 tokens (after  $n$ -gram preprocessing in §4), 40102 posts with an average of 27 posts or interactions per pair. Data from all 4 domains are combined for modeling.

**Parameter Settings:** For all our experiments, we set the hyper-parameters to the heuristic values  $\alpha_T = 50/T$ ,  $\alpha_E = 50/E$ ,  $\beta_T = \beta_E = 0.1$  suggested in (Griffiths and Steyvers, 2004). We set the number of topics,  $T = 50$  and the number of AD-expression types,  $E = 2$  (agreement and disagreement) as in discussion/debate forums, there are usually two expression types<sup>5</sup>. To learn

<sup>5</sup> Values for  $E > 2$  were also tried. However, they did not produce any new dominant expression type. There was also a slight increase in the model perplexity showing that values of  $E > 2$  do not fit the debate forum data well.

the Max-Ent parameters  $\lambda$ , we randomly sampled 500 terms from the held-out data (10 threads in our corpus which were excluded from the evaluation of tasks in §6.2, §6.3) appearing at least 10 times and labeled them as topical (361) or AD-expressions (139) and used the corresponding features of each term (in the context of posts where it occurs, §3) to train the Max-Ent model.

### 6.2 AD-Expression Evaluation

We first list some discovered top AD-expressions in Table 3 for qualitative inspection. From Table 3, we can see that JTE-P can cluster many correct AD-expressions, e.g., “I accept”, “I agree”, “you’re correct”, etc. in agreement and “I disagree”, “don’t accept”, “I refute”, etc. in disagreement. In addition, it also discovers and clusters highly specific and more “distinctive” expressions beyond those used in Max-Ent training, e.g., “valid point”, “I do support”, and “rightly said” in agreement; and phrases like “can you prove”, “I don’t buy your”, and “you fail to” in disagreement. Note that terms in black in Table 3 were used in Max-Ent training. The newly discovered terms are marked *blue* in italics. Clustering errors are in **red** (bold).

For quantitative evaluation, topic models are often compared using perplexity. However, perplexity does not reflect our purpose since we are not trying to evaluate how well the AD-expressions in an unseen discussion data fit our learned models. Instead our focus is to evaluate how well our learned AD-expression types perform in clustering semantic phrases of agreement/disagreement. Since AD-expressions (according to top terms in  $\phi^E$ ) produced by JTE-P are rankings, we choose *precision @ n* ( $p@n$ ) as our metric.  $p@n$  is commonly used to evaluate a ranking when the total number of correct items is unknown (e.g., Web search results, aspect terms in topic models for sentiment analysis (Zhao et al., 2010), etc.). This situation is similar to our AD-expression rankings,  $\phi^E$ . Further, as  $\phi^E \sim Dir$ , the Dirichlet smoothing effect ensures that every term in the vocabulary has some non-zero mass to agreement or disagreement expression type. Thus, it is the ranking of terms in each AD-expression type that matters (i.e., whether the model is able to rank highly relevant terms at the top).

The above method evaluates the original ranking. Another way of evaluating the AD-expression rankings is to evaluate only those newly discovered terms, i.e., beyond those

Disagreement expressions ( $\varphi_{e=Disagreement}^E$ )	
I, disagree, I don't, I disagree, <b>argument</b> , reject, <b>claim</b> , I reject, I refute, <b>and</b> , <b>your</b> , I refuse, <b>won't</b> , <b>the claim</b> , nonsense, <i>I contest</i> , dispute, <b>I think</b> , completely disagree, don't accept, don't agree, incorrect, <b>doesn't</b> , <i>hogwash</i> , <i>I don't buy your</i> , <i>I really doubt</i> , your nonsense, <b>true</b> , <i>can you prove</i> , argument fails, <i>you fail to</i> , <b>your assertions</b> , <i>bullshit</i> , <i>sheer nonsense</i> , <i>doesn't make sense</i> , <i>you have no clue</i> , <i>how can you say</i> , <i>do you even</i> , <i>contradict yourself</i> , ...	
Agreement expressions ( $\varphi_{e=Agreement}^E$ )	
agree, <b>I</b> , correct, yes, true, accept, I agree, <b>don't</b> , indeed correct, <b>your</b> , I accept, <b>point</b> , <b>that</b> , I concede, is valid, <b>your claim</b> , <b>not really</b> , <i>would agree</i> , <b>might</b> , <i>agree completely</i> , yes indeed, absolutely, you're correct, <i>valid point</i> , <b>argument</b> , <b>the argument</b> , proves, <i>do accept</i> , support, agree with you, <i>rightly said</i> , <b>personally</b> , well put, <i>I do support</i> , <i>personally agree</i> , <b>doesn't necessarily</b> , exactly, <i>very well put</i> , <i>kudos</i> , <i>point taken</i> , ...	

Table 3: Top terms (comma delimited) of two expression types. **Red** (bold) terms denote possible errors. *Blue* (italics) terms are newly discovered; rest (black) terms have been used in Max-Ent training.

$P@n$	JTE-P (all terms)						JTE-P (excluding labeled ME terms)

W+POS 1-4 grams + IG (top 2%)	0.65	0.67	0.66	0.84	0.82	0.83
W+POS 1-4 grams + $\chi^2$ (top 1%)	0.65	0.68	0.66	0.84	0.83	0.83
W+POS 1-4 grams + $\chi^2$ (top 2%)	0.64	0.68	0.69	0.84	0.82	0.83
AD-Expressions, $\Phi^E$ (top 1000)	0.73	0.74	0.73	0.87	0.87	0.87
AD-Expressions, $\Phi^E$ (top 2000)	0.77	0.81	0.78	0.90	0.88	0.89

Table 6: Precision (P), recall (R), and F<sub>1</sub> scores of pair interaction evaluation. Improvements in F<sub>1</sub> using AD-expression features ( $\varphi^E$ ) are statistically significant ( $p<0.01$ ) using paired  $t$ -test across 5-fold CV.

labeled terms used in Max-Ent training. For this evaluation, we remove those terms that have been used in Max-Ent (ME) training. We report both results in Table 4. We also studied inter-rater agreement using two judges who independently labeled the top  $n$  terms as correct or incorrect. A term was marked correct if both judges deemed it so which was then used to compute  $p@n$ . Agreement using  $\kappa_{Cohen}$  was greater than 0.78 for all  $p@n$  computations implying substantial and good agreements as identifying whether a phrase implies agreement or disagreement or none is an easy task.  $P@n$  excluding ME labeled terms (Table 4, second

column) are slightly lower than those using all terms but are still decent. This is because  $p@n$  excluding ME labeled terms removes many correct AD-expressions used in training.

Further to evaluate the sensitivity of performance on the amount of labeled terms for Max-Ent, we computed  $p@n$  across different sizes of labeled terms. Table 4 shows  $p@n$  for agreement and disagreement expressions across different sizes of labeled terms ( $L$ ). We find that more labeled terms improves  $p@n$  which is intuitive. We used 500 labeled terms in all our subsequent experiments. The result in Table 4 uses relevance ranking (§4).

We now compare with the performance of the model without using phrase relevance ranking.  $P@n$  results using all tokens (4356787) are shown in Table 5 (with 500 labeled terms for Max-Ent training). Clearly,  $P@n$  is lower than in Table 4 (last row; with phrase relevance ranking) because without phrase relevance ranking (Table 5) many irrelevant terms can rank high due to co-occurrences which may not be semantically related. This shows that relevance ranking of phrases is beneficial.

### 6.3 Pair Interaction Nature

We now evaluate the overall interaction nature of each pair of users. The evaluation of this task requires human judges to read all the posts where the two users forming the pair have interacted. Thus, it is hard to evaluate all 1461 pairs in our dataset. Instead, we randomly sampled 500 pairs ( $\approx 34\%$  of the population) for evaluation. Two human judges were asked to independently read all the post interactions of 500 pairs and label each pair as overall “disagreeing” or overall “agreeing” or “none”. The  $\kappa_{Cohen}$  for this task was 0.81. Pairs were finally labeled as agreeing or disagreeing if both judges deemed them so. This resulted in 320 disagreeing and 152 agreeing pairs. Out of the rest 28 pairs, 10 were marked “none” by both judges while 18 pairs had disagreement in labels. We only focus on the 472 agreeing and disagreeing pairs.

As we have labeled data for 472 pairs, we can treat identifying pair arguing nature as a text classification problem where all interactions between a pair are merged in one document representing the pair along with the label given by judges: agreeing or disagreeing. To compare classification performance, we use two feature sets: (i) standard word + POS 1-4 grams and (ii) AD-expressions from  $\varphi^E$ . We use TF-IDF as our feature value assignment scheme. We also try two well-known feature selection schemes Chi-Squared Test ( $\chi^2$ ) and Information Gain (IG). We use the linear kernel<sup>6</sup> SVM (SVM<sup>light</sup> system in (Joachims, 1999)) as our text classifier. For feature selection using  $\chi^2$  and IG, we use two settings: top 1% and 2% of all features ranked according to the selection metric. Also, for estimated AD-expressions (according to probabilities in  $\varphi^E$ ), we experiment with top 1000 and 2000 AD-expressions terms for both agreement and disagreement. We summarize

<sup>6</sup> Other kernels polynomial, RBF, and sigmoid did not perform as well.

comparison results using 5-fold Cross Validation (CV) with two classes: agreeing and disagreeing in Table 6. JTE-P-posterior represents the method using simply the model posterior on  $\theta_p^E$  to make the decision (see §5). From Table 6, we can make the following observations.

Predicting agreeing arguing nature is harder than that of disagreeing across all feature settings. Feature selection improves performance.  $\chi^2$  and IG perform similarly. AD-expressions,  $\varphi^E$  yields the best performance showing that the discovered AD-expressions are of high quality and reflect the user pair arguing nature well. Selecting certain top terms in  $\varphi^E$  can also be viewed as a form of feature selection. Although prediction performance using model posterior (JTE-P-posterior) is slightly lower than supervised SVM (Table 6, second row), the  $F_1$  scores are decent. Using the discovered AD-expressions (Table 6, last row) as features renders a statistically significant (see Table 6 caption) improvement over other baseline feature settings. This shows that discovered AD-expressions are useful for downstream applications, e.g., the task of identifying pair interactions.

## 7 Conclusion

This paper studied the problem of modeling user pair interactions in online discussions with the purpose of discovering the interaction or arguing nature of each author pair and various AD-expressions emitted in debates. A novel technique was also proposed to rank  $n$ -gram phrases where relevance based ranking was used in conjunction with a semi-supervised generative model. This method enables us to find better AD-expressions. Experiments using real-life online debate data showed the effectiveness of the model. In our future work, we intend to extend the model to account for stances, and issue specific interactions which would pave the way for user profiling and behavioral modeling.

## Acknowledgments

We would like thank Sharon Meraz (Department of communication, University of Illinois at Chicago) and Dennis Chong (Department of Political Science, Northwestern University) for several valuable discussions. This work was supported in part by a grant from the National Science Foundation (NSF) under grant no. IIS-1111092.

# Multilingual Affect Polarity and Valence Prediction in Metaphor-Rich Texts

Zornitsa Kozareva

USC Information Sciences Institute  
4676 Admiralty Way  
Marina del Rey, CA 90292-6695  
kozareva@isi.edu

## Abstract

Metaphor is an important way of conveying the affect of people, hence understanding how people use metaphors to convey affect is important for the communication between individuals and increases cohesion if the perceived affect of the concrete example is the same for the two individuals. Therefore, building computational models that can automatically identify the affect in metaphor-rich texts like “*The team captain is a rock.*”, “*Time is money.*”, “*My lawyer is a shark.*” is an important challenging problem, which has been of great interest to the research community.

To solve this task, we have collected and manually annotated the affect of metaphor-rich texts for four languages. We present novel algorithms that integrate triggers for cognitive, affective, perceptual and social processes with stylistic and lexical information. By running evaluations on datasets in English, Spanish, Russian and Farsi, we show that the developed affect polarity and valence prediction technology of metaphor-rich texts is portable and works equally well for different languages.

## 1 Introduction

Metaphor is a figure of speech in which a word or phrase that ordinarily designates one thing is used to designate another, thus making an implicit comparison (Lakoff and Johnson, 1980; Martin, 1988; Wilks, 2007). For instance, in

“*My lawyer is a shark*”

the speaker may want to communicate that his/her lawyer is strong and aggressive, and that he will

attack in court and persist until the goals are achieved. By using the metaphor, the speaker actually conveys positive affect because having an aggressive lawyer is good if one is being sued.

There has been a substantial body of work on metaphor identification and interpretation (Wilks, 2007; Shutova et al., 2010). However, in this paper we focus on an equally interesting, challenging and important problem, which concerns the automatic identification of affect carried by metaphors. Building such computational models is important to understand how people use metaphors to convey affect and how affect is expressed using metaphors. The existence of such models can be also used to improve the communication between individuals and to make sure that the speakers perceived the affect of the concrete metaphor example in the same way.

The questions we address in this paper are: “*How can we build computational models that can identify the polarity and valence associated with metaphor-rich texts?*” and “*Is it possible to build such automatic models for multiple languages?*”. Our main contributions are:

- We have developed multilingual metaphor-rich datasets in English, Spanish, Russian and Farsi that contain annotations of the *Positive* and *Negative* polarity and the valence (from  $-3$  to  $+3$  scale) corresponding to the intensity of the affect conveyed in the metaphor.
- We have proposed and developed automated methods for solving the polarity and valence tasks for all four languages. We model the polarity task as a classification problem, while the valence task as a regression problem.
- We have studied the influence of different information sources like the metaphor itself, the context in which it resides, the source and

target domains of the metaphor, in addition to contextual features and trigger word lists developed by psychologists (Tausczik and Pennebaker, 2010).

- We have conducted in depth experimental evaluation and showed that the developed methods significantly outperform baseline methods.

The rest of the paper is organized as follows. Section 2 describes related work, Section 3 briefly talks about metaphors. Sections 4 and 5 describe the polarity classification and valence prediction tasks for affect of metaphor-rich texts. Both sections have information on the collected data for English, Spanish, Russian and Farsi, the conducted experiments and obtained results. Finally, we conclude in Section 6.

## 2 Related Work

A substantial body of work has been done on determining the affect (sentiment analysis) of texts (Kim and Hovy, 2004; Strapparava and Mihalcea, 2007; Wiebe and Cardie, 2005; Yessenalina and Cardie, 2011; Breck et al., 2007). Various tasks have been solved among which polarity and valence identification are the most common. While polarity identification aims at finding the *Positive* and *Negative* affect, valence is more challenging as it has to map the affect on a  $[-3, +3]$  scale depending on its intensity (Polanyi and Zaenen, 2004; Strapparava and Mihalcea, 2007).

Over the years researchers have developed various approaches to identify polarity of words (Esuli and Sebastiani, 2006), phrases (Turney, 2002; Wilson et al., 2005), sentences (Choi and Cardie, 2009) even documents (Pang and Lee, 2008). Multiple techniques have been employed, from various machine learning classifiers, to clustering and topic models. Various domains and textual sources have been analyzed such as Twitter, Blogs, Web documents, movie and product reviews (Turney, 2002; Kennedy and Inkpen, 2005; Niu et al., 2005; Pang and Lee, 2008), but yet what is missing is affect analyzer for metaphor-rich texts.

While the affect of metaphors is well studied from its linguistic and psychological aspects (Blanchette et al., 2001; Tomlinson and Love, 2006; Crowdord, 2009), to our knowledge the building of computational models for polarity and valence identification in metaphor-rich texts is still

a novel task (Smith et al., 2007; Veale, 2012; Veale and Li, 2012; Reyes and Rosso, 2012; Reyes et al., 2013). Little (almost no) effort has been put into multilingual computational affect models of metaphor-rich texts. Our research specifically targets the resolution of these problems and shows that it is possible to build such computational models. The experimental result provide valuable contributions and fundings, which could be used by the research community to build upon.

## 3 Metaphors

Although there are different views on metaphor in linguistics and philosophy (Black, 1962; Lakoff and Johnson, 1980; Gentner, 1983; Wilks, 2007), the common among all approaches is the idea of an interconceptual mapping that underlies the production of metaphorical expressions. There are two concepts or conceptual domains: the target (also called topic in the linguistics literature) and the source (or vehicle), and the existence of a link between them gives rise to metaphors.

The texts “*Your claims are **indefensible**.*” and “*He **attacked** every weak point in my argument.*” do not directly talk about argument as a war, however the winning or losing of arguments, the attack or defense of positions are structured by the concept of war. There is no physical battle, but there is a verbal battle and the structure of an argument (attack, defense) reflects this (Lakoff and Johnson, 1980).

As we mentioned before, there has been a lot of work on the automatic identification of metaphors (Wilks, 2007; Shutova et al., 2010) and their mapping into conceptual space (Shutova, 2010a; Shutova, 2010b), however these are beyond the scope of this paper. Instead we focus on an equally interesting, challenging and important problem, which concerns the automatic identification of affect carried by metaphors. To conduct our study, we use human annotators to collect metaphor-rich texts (Shutova and Teufel, 2010) and tag each metaphor with its corresponding polarity (*Positive/Negative*) and valence  $[-3, +3]$  scores. The next sections describe the affect polarity and valence tasks we have defined, the collected and annotated metaphor-rich data for each one of the English, Spanish, Russian and Farsi languages, the conducted experiments and obtained results.

## 4 Task A: Polarity Classification

### 4.1 Problem Formulation

**Task Definition:** Given metaphor-rich texts annotated with *Positive* and *Negative* polarity labels, the goal is to build an automated computational affect model, which can assign to previously unseen metaphors one of the two polarity classes.

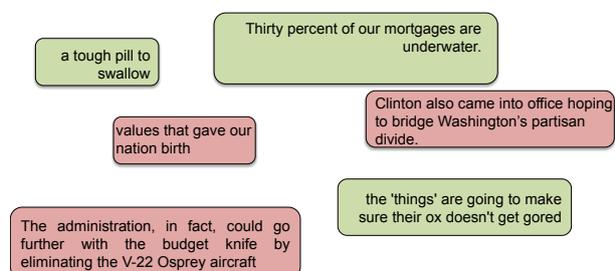

Figure 1: Polarity Classification

Figure 1 illustrates the polarity task in which the metaphors were classified into *Positive* or *Negative*. For instance, the metaphor “*tough pill to swallow*” has *Negative* polarity as it stands for something being hard to digest or comprehend, while the metaphor “*values that gave our nation birth*” has a *Positive* polarity as giving birth is like starting a new beginning.

### 4.2 Classification Algorithms

We model the metaphor polarity task as a classification problem in which, for a given collection of  $N$  training examples, where  $m_i$  is a metaphor and  $c_i$  is the polarity of  $m_i$ , the objective is to learn a classification function  $f : m_i \rightarrow c_i$  in which 1 stands for positive polarity and 0 stands for negative polarity. We tested five different machine learning algorithms such as Naive Bayes, SVM with polynomial kernel, SVM with RBF kernel, AdaBoost and Stacking, out of which AdaBoost performed the best. In our experimental study, we use the freely available implementations in Weka (Witten and Frank, 2005).

**Evaluation Measures:** To evaluate the goodness of the polarity classification algorithms, we calculate the f-score and accuracy on 10-fold cross validation.

### 4.3 Data Annotation

To conduct our experimental study, we have used annotated data provided by the Language Computer Corporation (LCC)<sup>1</sup>, which developed anno-

<sup>1</sup><http://www.languagecomputer.com/>

tation toolkit specifically for the task of metaphor detection, interpretation and affect assignment. They hired annotators to collect and annotate data for the English, Spanish, Russian and Farsi languages. The domain for which the metaphors were collected was *Governance*. It encompasses electoral politics, the setting of economic policy, the creation, application and enforcement of rules and laws. The metaphors were collected from political speeches, political websites, online newspapers among others (Mohler et al., 2013).

The annotation toolkit allowed annotators to provide for each metaphor the following information: the metaphor, the context in which the metaphor was found, the meaning of the metaphor in the source and target domains from the perspective of a native speaker. For example, in the **Context:** *And to all nations, we will speak for the values that gave our nation birth.*; the annotators tagged the **Metaphor:** *values that gave our nation birth*; and listed as **Source:** *mother gave birth to baby*; and **Target:** *values of freedom and equality motivated the creation of America*. The same annotators also provided the affect associated with the metaphor. The agreements of the annotators as measured by LCC are: .83, .87, .80 and .61 for the English, Spanish, Russian and Farsi languages.

In our study, the maximum length of a metaphor is a sentence, but typically it has the span of a phrase. The maximum length of a context is three sentences before and after the metaphor, but typically it has the span of one sentence before and after. In our study, the source and target domains are provided by the human annotators who agree on these definitions, however the source and target can be also automatically generated by an interpretation system or a concept mapper. The generation of source and target information is beyond the scope of this paper, but studying their impact on affect is important. At the same time, we want to show that if the technology for source/target detection and interpretation is not yet available, then how far can one reach by using the metaphor itself and the context around it. Later depending on the availability of the information sources and toolkits one can decide whether to integrate such information or to ignore it. In the experimental sections, we show how the individual information sources and their combination affects the resolution of the metaphor polarity and valence prediction tasks.

Table 1 shows the positive and negative class

distribution for each one of the four languages.

	Negative	Positive
ENGLISH	2086	1443
SPANISH	196	434
RUSSIAN	468	418
FARSI	384	252

Table 1: Polarity Class Distribution for Four Languages

The majority of the the annotated examples are for English. However, given the difficulty of finding bilingual speakers, we still managed to collect around 600 examples for Spanish and Farsi, and 886 examples for Russian.

#### 4.4 N-gram Evaluation and Results

N-gram features are widely used in a variety of classification tasks, therefore we also use them in our polarity classification task. We studied the influence of unigrams, bigrams and a combination of the two, and saw that the best performing feature set consists of the combination of unigrams and bigrams. In this paper, we will refer from now on to n-grams as the combination of unigrams and bigrams.

Figure 2 shows a study of the influence of the different information sources and their combination with n-gram features for English.

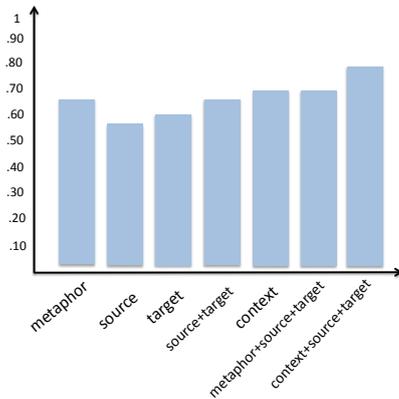

Figure 2: Influence of Information Sources for Metaphor Polarity Classification of English Texts

For each information source (metaphor, context, source, target and their combinations), we built a separate n-gram feature set and model, which was evaluated on 10-fold cross validation. The results from this study show that for English, the more information sources one combines, the higher the classification accuracy becomes.

Table 2 shows the influence of the information sources for Spanish, Russian and Farsi with the n-gram features. The best f-scores for each language are shown in bold. For Farsi and Russian high performances are obtained both with the context and with the combination of the context, source and target information. While for Spanish they reach similar performance.

	SPANISH	RUSSIAN	FARSI
Metaphor	71.6	71.0	62.4
Source	67.1	62.4	55.4
Target	68.9	67.2	62.4
Context	73.5	<b>77.1</b>	<b>67.4</b>
S+T	<b>76.6</b>	68.7	62.4
M+S+T	76.0	75.4	64.2
C+S+T	<b>76.5</b>	<b>76.5</b>	<b>68.4</b>

Table 2: N-gram features, F-scores on 10-fold validation for Spanish, Russian and Farsi

#### 4.5 LIWC as a Proxy for Metaphor Polarity

**LIWC Repository:** In addition to the n-gram features, we also used the Linguistic Inquiry and Word Count (LIWC) repository (Tausczik and Pennebaker, 2010), which has 64 word categories corresponding to different classes like emotional states, psychological processes, personal concerns among other. Each category contains a list of words characterizing it. For instance, the LIWC category *discrepancy* contains words like *should*, *could* among others, while the LIWC category *inhibition* contains words like *block*, *stop*, *constrain*. Previously LIWC was successfully used to analyze the emotional state of bloggers and tweeters (Quercia et al., 2011) and to identify deception and sarcasm in texts (Ott et al., 2011; González-Ibáñez et al., 2011). When LIWC analyzes texts it generates statistics like number of words found in category  $C_i$  divided by the total number of words in the text. For our metaphor polarity task, we use LIWC’s statistics of all 64 categories and feed this information as features for the machine learning classifiers. LIWC repository contains conceptual categories (dictionaries) both for the English and Spanish languages.

**LIWC Evaluation and Results:** In our experiments LIWC is applied to English and Spanish metaphor-rich texts since the LIWC category dictionaries are available for both languages. Table 3 shows the obtained accuracy and f-score results in English and Spanish for each one of the information sources.

	ENGLISH		SPANISH	
	Acc	Fscore	Acc	Fscore
Metaphor	<b>98.8</b>	<b>98.8</b>	87.9	87.2
Source	<b>98.6</b>	<b>98.6</b>	<b>97.3</b>	<b>97.3</b>
Target	<b>98.2</b>	<b>98.2</b>	<b>97.9</b>	<b>97.9</b>
Context	91.4	91.4	<b>93.3</b>	<b>93.2</b>
S+T	98.0	98.0	76.3	75.5
M+S+T	95.8	95.7	86.8	86.0
C+S+T	87.9	88.0	79.2	78.5

Table 3: LIWC features, Accuracy and F-scores on 10-fold validation for English and Spanish

The best performances are reached with individual information sources like metaphor, context, source or target instead of their combinations. The classifiers obtain similar performance for both languages.

**LIWC Category Relevance to Metaphor Polarity:** We also study the importance and relevance of the LIWC categories for the metaphor polarity task. We use information gain (IG) to measure the amount of information in bits about the polarity class prediction, if the only information available is the presence of a given LIWC category (feature) and the corresponding polarity class distribution. IG measures the expected reduction in entropy (uncertainty associated with a random feature) (Mitchell, 1997).

Figure 3 illustrates how certain categories occur more with the positive (in red color) vs negative (in green color) class. With the positive metaphors we observe the LIWC categories for present tense, social, affect and family, while for the negative metaphors we see LIWC categories for past tense, inhibition and anger.

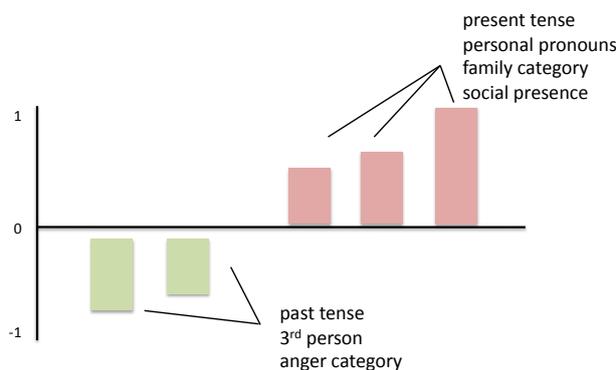

Figure 3: LIWC category relevance to Metaphor Polarity

In addition, we show in Figure 4 examples of the top LIWC categories according to IG ranking

for each one of the information sources.

Metaphor	Context	Source	Target
I	I		conj.
conj.	you		anger
anger		hate kill annoyed	affect
discrepancy		home	work
swear words	should could would	swear words	
inhibition	friend	religion	
body	affect	space	
relativity	sad		
home	inhibition	block constrain stop	
ingest	ingest		
work	work		

Figure 4: Example of LIWC Categories and Words

For metaphor texts, these categories are *I*, *conjunction*, *anger*, *discrepancy*, *swear words* among others; for contexts the categories are pronouns like *I*, *you*, *past tense*, *friends*, *affect* and so on. Our study shows that some of the LIWC categories are important across all information sources, but overall different triggers activate depending on the information source and the length of the text used.

#### 4.6 Comparative study

Figure 5 shows a comparison of the accuracy of our best performing approach for each language. For English and Spanish these are the LIWC models, while for Russian and Farsi these are the n-gram models. We compare the performance of the algorithms with a majority baseline, which assigns the majority class to each example. For instance, in English there are 3529 annotated examples, of which 2086 are positive and 1443 are negative. Since the positive class is the predominant one for this language and dataset, a majority classifier would have .59 accuracy in returning the positive class as an answer. Similarly, we compute the majority baseline for the rest of the languages.

	Accuracy	Majority Baseline	Difference
English	98.80	59.11	+39.69
Spanish	97.90	68.88	+29.02
Russian	77.00	52.82	+24.18
Farsi	72.20	60.30	+11.90

Figure 5: Best Accuracy Model and Comparison against a Majority Baseline for Metaphor Polarity Classification

As we can see from Figure 5 that all classifiers significantly outperform the majority base-

line. For Farsi the increment is +11.90, while for English the increment is +39.69. This means that the built classifiers perform much better than a random classifier.

#### 4.7 Lessons Learned

To summarize, in this section we have defined the task of polarity classification and we have presented a machine learning solution. We have used different feature sets and information sources to solve the task. We have conducted exhaustive evaluations for four different languages namely English, Spanish, Russian and Farsi. The learned lessons from this study are: (1) for n-gram usage, the larger the context of the metaphor, the better the classification accuracy becomes; (2) if present source and target information can further boost the performance of the classifiers; (3) LIWC is a useful resource for polarity identification in metaphor-rich texts; (4) analyzing the usages of tense like past vs. present and pronouns are important triggers for positive and negative polarity of metaphors; (5) some categories like *family*, *social presence* indicate positive polarity, while others like *inhibition*, *anger* and *swear words* are indicative of negative affect; (6) the built models significantly outperform majority baselines.

### 5 Task B: Valence Prediction

#### 5.1 Problem Formulation

**Task Definition:** Given metaphor-rich texts annotated with valence score (from  $-3$  to  $+3$ ), where  $-3$  indicates strong negativity,  $+3$  indicates strong positivity,  $0$  indicates neutral, the goal is to build a model that can predict without human supervision the valence scores of new previously unseen metaphors.

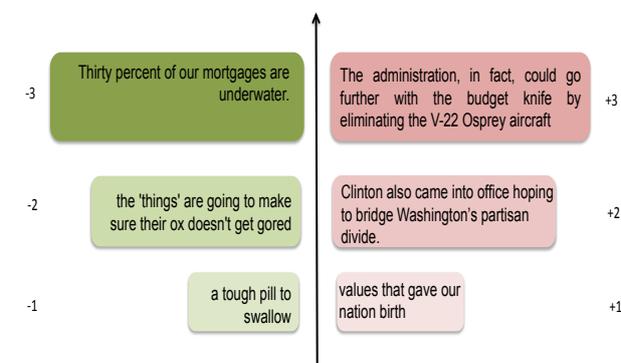

Figure 6: Valence Prediction

Figure 6 shows an example of the valence prediction task in which the metaphor-rich texts must be arranged by the intensity of the emotional state provoked by the texts. For instance,  $-3$  corresponds to very strong negativity,  $-2$  strong negativity,  $-1$  weak negativity (similarly for the positive classes). In this task we also consider metaphors with neutral affect. They are annotated with the  $0$  label and the prediction model should be able to predict such intensity as well. For instance, the metaphor “*values that gave our nation birth*”, is considered by American people that giving birth sets new beginning and has a positive score  $+1$ , but “*budget knife*” is more positive  $+3$  since tax cut is more important. As any sentiment analysis task, affect assignment of metaphors is also a subjective task and the produced annotations express the values, beliefs and understanding of the annotators.

#### 5.2 Regression Model

We model the valence task a regression problem, in which for a given metaphor  $m$ , we seek to predict the valence  $v$  of  $m$ . We do this via a parametrized function  $f: \hat{v} = f(m; w)$ , where  $w \in R^d$  are the weights. The objective is to learn  $w$  from a collection of  $N$  training examples  $\{ \langle m_i, v_i \rangle \}_{i=1}^N$ , where  $m_i$  are the metaphor examples and  $v_i \in R$  is the valence score of  $m_i$ .

Support vector regression (Drucker et al., 1996) is a well-known method for training a regression model by solving the following optimization problem:

$$\min_{w \in R^s} \frac{1}{2} \|w\|^2 + \frac{C}{N} \sum_{i=1}^N \underbrace{\max(0, |v_i - f(m_i; w)| - \epsilon)}_{\epsilon\text{-insensitive loss function}}$$

where  $C$  is a regularization constant and  $\epsilon$  controls the training error. The training algorithm finds weights  $w$  that define a function  $f$  minimizing the empirical risk. Let  $h$  be a function from seeds into some vector-space representation  $\subseteq R^d$ , then the function  $f$  takes the form:  $f(m; w) = h(m)^T w = \sum_{i=1}^N \alpha_i K(m, m_i)$ , where  $f$  is re-parameterized in terms of a polynomial kernel function  $K$  with dual weights  $\alpha_i$ .  $K$  measures the similarity between two metaphoric texts. Full details of the regression model and its implementation are beyond the scope of this paper; for more details see (Schölkopf and Smola, 2001; Smola et al., 2003). In our experimental study, we use the freely available implementation of SVM in Weka (Witten and Frank, 2005).

**Evaluation Measures:** To evaluate the quality of the valence prediction model, we compare the actual valence score of the metaphor given by human annotators denoted with  $y$  against those valence scores predicted by the regression model denoted with  $x$ . We estimate the goodness of the regression model calculating both the correlation coefficient  $cc_{x,y} = \frac{n \sum x_i y_i - \sum x_i \sum y_i}{\sqrt{n \sum x_i^2 - (\sum x_i)^2} \sqrt{n \sum y_i^2 - (\sum y_i)^2}}$  and the mean squared error  $mse_{x,y} = \frac{\sum_{i=1}^n (x_i - \hat{x})^2}{n}$ . The two evaluation measures should be interpreted in the following manner. Intuitively the higher the correlation score is, the better the correlation between the actual and the predicted valence scores will be. Similarly the smaller the mean squared error rate, the better the regression model fits the valence predictions to the actual score.

### 5.3 Data Annotation

To conduct our valence prediction study, we used the same human annotators from the polarity classification task for each one of the English, Spanish, Russian and Farsi languages. We asked the annotators to map each metaphor on a  $[-3, +3]$  scale depending on the intensity of the affect associated with the metaphor.

Table 4 shows the distribution (number of examples) for each valence class and for each language.

	-3	-2	-1	0	+1	+2	+3
ENGLISH	1057	817	212	582	157	746	540
SPANISH	106	65	27	17	40	132	262
RUSSIAN	118	42	308	13	202	149	67
FARSI	147	117	120	49	91	63	98

Table 4: Valence Score Distribution for Each Language

### 5.4 Empirical Evaluation and Results

For each language and information source we built separate valence prediction regression models. We used the same features for the regression task as we have used in the classification task. Those include n-grams (unigrams, bigrams and combination of the two), LIWC scores. Table 5 shows the obtained correlation coefficient (CC) and mean squared error (MSE) results for each one of the four languages (English, Spanish, Russian and Farsi) using the dataset described in Table 4.

The Farsi and Russian regression models are based only on n-gram features, while the English and Spanish regression models have both n-gram and LIWC features. Overall, the CC for English

and Spanish is higher when LIWC features are used. This means that the LIWC based valence regression model approximates the predicted values better to those of the human annotators. The better valence prediction happens when the metaphor itself is used by LIWC. The MSE for English and Spanish is the lowest, meaning that the prediction is the closest to those of the human annotators. In Russian and Farsi the lowest MSE is when the combined metaphor, source and target information sources are used. For English and Spanish the smallest MSE or so called prediction error is 1.52 and 1.30 respectively, while for Russian and Farsi is 1.62 and 2.13 respectively.

### 5.5 Lessons Learned

To summarize, in this section we have defined the task of valence prediction of metaphor-rich texts and we have described a regression model for its solution. We have studied different feature sets and information sources to solve the task. We have conducted exhaustive evaluations in all four languages namely English, Spanish, Russian and Farsi. The learned lessons from this study are: (1) valence prediction is a much harder task than polarity classification both for human annotation and for the machine learning algorithms; (2) the obtained results showed that despite its difficulty this is still a plausible problem; (3) similarly to the polarity classification task, valence prediction with LIWC is improved when shorter contexts (the metaphor/source/target information source) are considered.

## 6 Conclusion

People use metaphor-rich language to express affect and often affect is expressed through the usage of metaphors. Therefore, understanding that the metaphor “*I was **boiling inside** when I saw him.*” has *Negative* polarity as it conveys feeling of anger is very important for interpersonal or multicultural communications.

In this paper, we have introduced a novel corpus of metaphor-rich texts for the English, Spanish, Russian and Farsi languages, which was manually annotated with the polarity and valence scores of the affect conveyed by the metaphors. We have studied the impact of different information sources such as the metaphor in isolation, the context in which the metaphor was used, the source and target domain meanings of the metaphor and

	RUSSIAN N-gram		FARSI N-gram		ENGLISH N-gram		SPANISH N-gram		ENGLISH LIWC		SPANISH LIWC	
	CC	MSE	CC	MSE	CC	MSE	CC	MSE	CC	MSE	CC	MSE
Metaphor	.45	1.71	.25	2.25	.36	2.50	.37	2.54	.74	1.52	.87	1.20
Source	.22	1.89	.11	2.42	.40	2.27	.22	2.43	.81	1.30	.85	1.28
Target	.25	1.91	.15	2.47	.37	2.41	.32	2.36	.72	1.56	.85	1.29
Context	.43	1.83	.32	2.38	.37	2.59	.40	2.37	.40	2.16	.67	1.92
S+T	.29	1.83	.18	2.38	.40	2.40	.41	2.19	.70	1.60	.78	1.53
M+S+T	.45	1.62	.29	2.13	.43	2.34	.43	2.14	.67	1.67	.78	1.53

Table 5: Valence Prediction, Correlation Coefficient and Mean Squared Error for English, Spanish, Russian and Farsi

their combination in order to understand how such information helps and impacts the interpretation of the affect associated with the metaphor. We have conducted exhaustive evaluation with multiple machine learning classifiers and different features sets spanning from lexical information to psychological categories developed by (Tausczik and Pennebaker, 2010). Through experiments carried out on the developed datasets, we showed that the proposed polarity classification and valence regression models significantly improve baselines (from 11.90% to 39.69% depending on the language) and work well for all four languages. From the two tasks, the valence prediction problem was more challenging both for the human annotators and the automated system. The mean squared error in valence prediction in the range  $[-3, +3]$ , where  $-3$  indicates strong negative and  $+3$  indicates strong positive affect for English, Spanish and Russian was around 1.5, while for Farsi was around 2.

The current findings and learned lessons reflect the properties of the collected data and its annotations. In the future we are interested in studying the affect of metaphors for domains different than *Governance*. We want to conduct studies with the help of social sciences who would research whether the tagging of affect in metaphors depends on the political affiliation, age, gender or culture of the annotators. Not on a last place, we would like to improve the built valence prediction models and to collect more data for Spanish, Russian and Farsi.

## Abstract

Standard methods for part-of-speech tagging suffer from data sparseness when used on highly inflectional languages (which require large lexical tagset inventories). For this reason, a number of alternative methods have been proposed over the years. One of the most successful methods used for this task, called Tiered Tagging (Tufiş, 1999), exploits a reduced set of tags derived by removing several recoverable features from the lexicon morpho-syntactic descriptions. A second phase is aimed at recovering the full set of morpho-syntactic features. In this paper we present an alternative method to Tiered Tagging, based on local optimizations with Neural Networks and we show how, by properly encoding the input sequence in a general Neural Network architecture, we achieve results similar to the Tiered Tagging methodology, significantly faster and without requiring extensive linguistic knowledge as implied by the previously mentioned method.

## 1 Introduction

Part-of-speech tagging is a key process for various tasks such as information extraction, text-to-speech synthesis, word sense disambiguation and machine translation. It is also known as lexical ambiguity resolution and it represents the process of assigning a uniquely interpretable label to every word inside a sentence. The labels are called POS tags and the entire inventory of POS tags is called a tagset.

There are several approaches to part-of-speech tagging, such as Hidden Markov Models (HMM) (Brants, 2000), Maximum Entropy Classifiers (Berger et al., 1996; Ratnaparkhi, 1996), Bayesian Networks (Samuelsson, 1993), Neural

Networks (Marques and Lopes, 1996) and Conditional Random Fields (CRF) (Lafferty et al., 2001). All these methods are primarily intended for English, which uses a relatively small tagset inventory, compared to highly inflectional languages. For the later mentioned languages, the lexicon tagsets (called morpho-syntactic descriptions (Calzolari and Monachini, 1995) or MSDs) may be 10-20 times or even larger than the best known tagsets for English. For instance Czech MSD tagset requires more than 3000 labels (Collins et al., 1999), Slovene more than 2000 labels (Erjavec and Krek, 2008), and Romanian more than 1100 labels (Tufiş, 1999). The standard tagging methods, using such large tagsets, face serious data sparseness problems due to lack of statistical evidence, manifested by the non-robustness of the language models. When tagging new texts that are not in the same domain as the training data, the accuracy decreases significantly. Even tagging in-domain texts may not be satisfactorily accurate.

One of the most successful methods used for this task, called Tiered Tagging (Tufiş, 1999), exploits a reduced set of tags derived by removing several *recoverable* features from the lexicon morpho-syntactic descriptions. According to the MULTEXT EAST lexical specifications (Erjavec and Monachini, 1997), the Romanian tagset consists of a number of 614 MSD tags (by exploiting the case and gender regular syncretism) for wordforms and 10 punctuation tags (Tufiş et al., 1997), which is still significantly larger than the tagset of English. The MULTEXT EAST version 4 (Erjavec, 2010) contains specifications for a total of 16 languages: Bulgarian, Croatian, Czech, Estonian, English, Hungarian, Romanian,

Serbian, Slovene, the Resian dialect of Slovene, Macedonian, Persian, Polish, Russian, Slovak, and Ukrainian

The strategy of the Tiered Tagging methodology is to use a reduced tagset (called CTAG-set), where a CTAG is a generalization of a MSD, from which recoverable context-irrelevant features are removed. For instance, the attribute for gender (masculine ‘m’ or feminine ‘f’) from MSDs ‘Ncfsrn’ and ‘Ncmsrn’ is deleted to obtain the CTAG ‘NSRN’, because the gender information can be deterministically recovered based on the CTAG and the wordform itself. The recovering of the left out attributes (Figure 1) is based on the lexicons, linguistic rules and, in the case of unknown words, on ML techniques (Ceaşu, 2006). When tagging with CTAGs, one can use any statistical POS tagging method such as HMMs, Maximum Entropy Classifiers, Bayesian Networks, CRFs, etc., followed by the CTAG to MSD recovery.

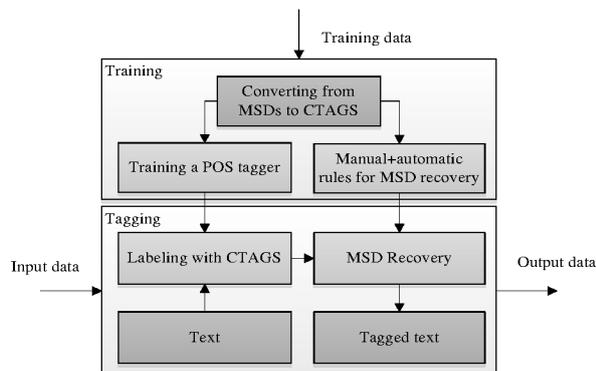

Figure 1 - Tiered Tagging methodology

The language dependent process of manually inferring linguistic rules for MSD recovery requires good knowledge of the target language and also extensive amounts of time invested in testing and re-design. It is difficult even for a native speaker to create such rules without in-depth linguistic knowledge.

In this article, we propose an alternative solution based on local optimizations with feed-forward neural networks. Our method eliminates the need for the two stage processing, is much faster at run time and is comparatively accurate with the Tiered Tagging implemented in the TTL tagger (Ion, 2007), available in the METASHARE Platform<sup>1</sup>.

<sup>1</sup> <http://ws.racai.ro:9191/>

## 2 Large tagset part-of-speech tagging with feed-forward neural networks

Although removing the recoverable attributes, as proposed in the Tiered Tagging approach, helps the goal of squeezing the lexical tagset to a reasonable size, valuable information for contextual disambiguation is also lost. For example, the gender agreement rule, valid in many languages, cannot be exploited unless the gender attribute is present in the tags.

Our proposal to deal with large tagsets without removing contextually useful information is based on Feed Forward Neural Networks (FFNN). FFNN are known for their simplicity and robustness in finding and recombining patterns inside data.

Several neural network architectures have been proposed for the task of part-of-speech tagging. Schmid (1994) proposed a FFNN architecture for part-of-speech tagging obtaining a 96.22% accuracy. In his paper, he argues that neural networks are preferable to other methods, when the training set is small. He compares his results with a HMM tagger (94.24%) and a trigram tagger (96.02%), both trained and tested on the same corpora as his FFNN tagger (the Penn-Treebank corpus). A similar approach is presented by Marques and Lopes (1996). In their paper, the authors come to similar conclusions as those presented in Schmid (1994). We support these findings with an additional argument, namely the better fit for managing large tagsets.

In both approaches mentioned before, the network is trained so that from the input vector, to output a real valued vector. Each value in the output vector is generated by a distinct neuron, and corresponds to a unique tag in the tagset (e.g. 100 tags means the network contains 100 neurons on the output layer). The input vector for predicting the tag of the current word encodes the tags for the previously tagged words and the probable tags for the current and following two words, estimated using Maximum Likelihood Estimation (MLE):

$$P(t|w) = \frac{C(w, t)}{C(w)} \quad (1)$$

- $P(t|w)$  - The probability of the word  $w$  having tag  $t$
- $C(w, t)$  - The total number of times, the word  $w$  appears with tag  $t$  in the training corpus
- $C(w)$  - The total number of times, the word  $w$  appears in the training corpus

In the case of out-of-vocabulary (OOV) words, both approaches use suffix analysis to determine the most probable tags that can be assigned to the current word.

To clarify how these two methods work, if we want to train the network to label the current word, using a context window of 1 (previous tag, current possible tags, and possible tags for the next word) and if we have, say 100 tags in the tagset, the input is a real valued vector of 300 sub-unit elements and the output is a vector which contains 100 elements, also sub-unit real numbers. As mentioned earlier, each value in the output vector corresponds to a distinct tag from tagset and the tag assigned to the current word is chosen to correspond to the maximum value inside the output vector.

The previously proposed methods still suffer from the same issue of data sparseness when applied to MSD tagging. However, in our approach, we overcome the problem through a different encoding of the input data (see section 2.1).

The power of neural networks results mainly from their ability to attain activation functions over different patterns via their learning algorithm. By properly encoding the input sequence, the network chooses which input features contribute in determining the output features for MSDs (e.g. patterns composed of part of speech, gender, case, type etc. contribute independently in selecting the optimal output sequence). This way, we removed the need for explicit MSD to CTAG conversion and MSD recovery from CTAGs.

## 2.1 The MSD binary encoding scheme

A MSD language independently encodes a part of speech (POS) with the associated lexical attribute values as a string of positional ordered character codes (Erjavec, 2004). The first character is an upper case character denoting the part of speech (e.g. 'N' for nouns, 'V' for verbs, 'A' for adjectives, etc.) and the following characters (lower letters or '-') specify the instantiations of the characteristic lexical attributes of the POS. For example, the MSD 'Ncfsrn', specifies a noun (the first character is 'N') the type of which is common ('c', the second character), feminine gender ('f'), singular number ('s'), in nominative/accusative case ('r') and indefinite form ('n'). If a specific attribute is not relevant for a language, or for a given combination of feature-values, the character '-' is used in the corresponding position. For a

language which does not morphologically mark the gender and definiteness features, the earlier exemplified MSD will be encoded as 'Nc-sr-'.

In order to derive a binary vector for each of the 614 MSDs of Romanian we proceeded to:

1. List and sort all possible POSes of Romanian (16 POSes) and form a binary vector with 16 positions in which position  $k$  is equal 1 only if the respective MSD has the corresponding POS (i.e. the  $k$ -th POS in the sorted list of POSes);
2. List and sort all possible values of all lexical attributes (disregarding the wildcard '-') for all POSes (94 values) and form another binary vector with 94 positions such that the  $k$ -th position of this vector is 1 if the respective MSD has an attribute with the corresponding value;
3. Concatenate the vectors from steps 1 and 2 and obtain the binary codification of a MSD as a 110-position binary vector.

## 2.2 The training and tagging procedure

The tagger automatically assigns four dummy tokens (two at the beginning and two at the end) to the target utterance and the neural network is trained to automatically assign a MSD given the context (two previously assigned tags and the possible tags for the current and following two words) of the current word (see below for details).

In our framework a training example consists of the features extracted for a single word inside an utterance as input and its MSD within that utterance as output. The features are extracted from a window of 5 words centered on the current word. A single word is characterized by a vector that encodes either its assigned MSD or its possible MSDs. To encode the possible MSDs we use equation 2, where each possible attribute  $a$ , has a single corresponding position inside the encoded vector.

$$P(a|w) = \frac{C(w, a)}{C(w)} \quad (2)$$

*Note that we changed the probability estimates to account for attributes not tags.*

To be precise, for every word  $w_k$ , we obtain its input features by concatenating a number of 5 vectors. The first two vectors encode the MSDs assigned to the previous two words ( $w_{k-1}$  and  $w_k$ ).

2). The next three vectors are used to encode the possible MSDs for the current word ( $w_k$ ) and the following two words ( $w_{k+1}$  and  $w_{k+2}$ ).

During training, we also compute a list of suffixes with associated MSDs, which is used at run-time to build the possible MSDs vector for unknown words. When such words are found within the test data, we approximate their possible MSDs vector using a variation of the method proposed by Brants (2000).

When the tagger is applied to a new utterance, the system iteratively calculates the output MSD for each individual word. Once a label has been assigned to a word, the word's associated vector is edited so it will have the value of 1 for each attribute present in its newly assigned MSD.

As a consequence of encoding each individual attribute separately for MSDs, the tagger can assign new tags (that were never associated with the current word in the training corpus). Although this is a nice behavior for dealing with unknown words it is often the case that it assigns attribute values that are not valid for the wordform. To overcome these types of errors we use an additional list of words with their allowed MSDs. For an OOV word, the list is computed as a union from all MSDs that appeared with the suffixes that apply to that word.

When the tagger has to assign a MSD to a given word, it selects one from the possible wordform's MSDs in its wordform/MSDs associated list using a simple distance function:

$$\min_{e \in P} \sum_{k=0}^n |o_k - e_k| \quad (3)$$

$P$  - The list of all possible MSDs for the given word  
 $n$  - The length of the MSD encoding (110 bits)  
 $o$  - The output of the Neural Network for the current word  
 $e$  - Binary encoding for a MSD in  $P$

### 3 Network hyperparameters

In our experiments, we used a fully connected, feed forward neural network with 3 layers (1 input layer, 1 hidden layer and 1 output layer)

and a sigmoid activation function (equation 3). While other network architectures such as recurrent neural networks may prove to be more suitable for this task, they are extremely hard to train, thus, we traded the advantages of such architectures for the robustness and simplicity of the feed-forward networks.

$$f(t) = \frac{1}{1 + e^{-t}} \quad (3)$$

$f(t)$  - Neuron output  
 $t$  - The weighted sum of all the neuron outputs from the previous layer

Based on the size of the vectors used for MSD encoding, the output layer has 110 neurons and the input layer is composed of 550 (5 x 110) neurons.

In order to fully characterize our system, we took into account the following parameters: accuracy, runtime speed, training speed, hidden layer configuration and the number of optimal training iterations. These parameters have complex dependencies and relations among each other. For example, the accuracy, the optimal number of training iterations, the training and the runtime speed are all highly dependent on the hidden layer configuration. Small hidden layer give high training and runtime speeds, but often under-fit the data. If the hidden layer is too large, it can easily over-fit the data and also has a negative impact on the training and runtime speed. The number of optimal training iterations changes with the size of the hidden layer (larger layers usually require more training iterations).

To obtain the trade-offs between the above mentioned parameters we devised a series of experiments, in all of which we used the "1984" MSD annotated corpus, which is composed of 118,025 words. We randomly kept out approximately 1/10 (11,960 words) of the training corpus for building a cross-validation set. The baseline accuracy on the cross-validation set (i.e. returning the most probable tag) is 93.29%. We also used an additional inflectional wordform/MSD lexicon composed of approximately 1 million hand-validated entries.

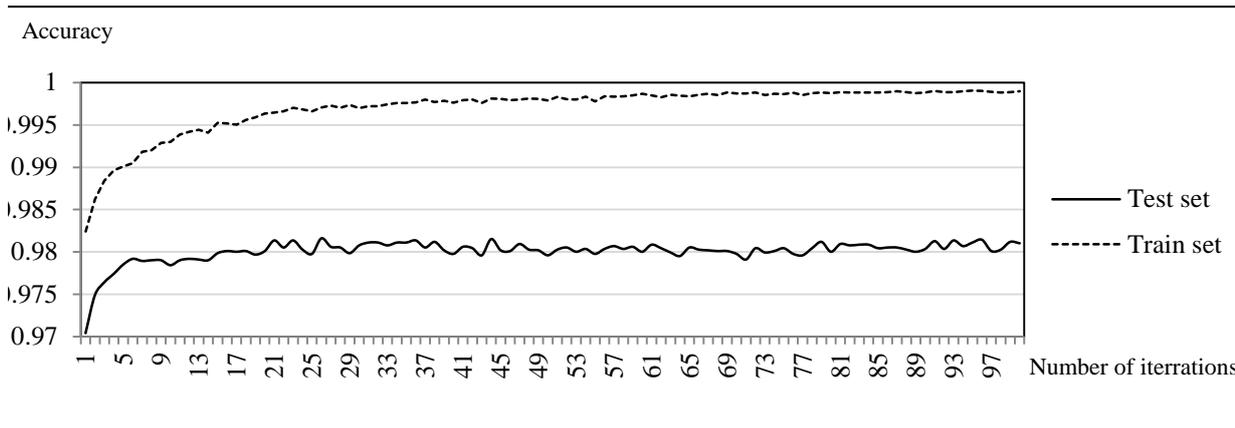

Figure 2 - 130 hidden layer network test and train set tagging accuracy as a function of the number of iterations

The first experiment was designed to determine the trade-off between the run-time speed and the size of the hidden layer. We made a series of experiments disregarding the tagging accuracy.

Hidden size	Time (ms)	Words/sec
50	1530	7816
70	1888	6334
90	2345	5100
110	2781	4300
130	3518	3399
150	5052	2367
170	5466	2188
190	6734	1776
210	7096	1685
230	8332	1435
250	9576	1248
270	10350	1155
290	11080	1079
310	12364	967

Table 1 - Execution time vs. number of neurons on the hidden layer

Because, for a given number of neurons in the hidden layer, the tagging speed is independent on the tagging accuracy, we partially trained (using one iteration and only 1000 training sentences) several network configurations. The first network only had 50 neurons in the hidden layer and for the next networks, we incremented the hidden layer size by 20 neurons until we reached 310 neurons. The total number of tested networks is 14. After this, we measured the time it took to tag the 1984 test corpus (11,960 words) for each individual network, as an average of 3 tagging runs in order to reduce the impact of the operating system load on the tagger (Table 1 shows the figures).

Determining the optimal size of the hidden layer is a very delicate subject and there are no perfect solutions, most of them being based on trial and error: small-sized hidden layers lead to under-fitting, while large hidden layers usually cause over-fitting. Also, because of the trade-off between runtime speed and the size of hidden layers, and if runtime speed is an important factor in a particular NLP application, then hidden layers with smaller number of neurons are preferable, as they surely do not over-fit the data and offer a noticeable speed boost.

hidden layer	Train set accuracy	Cross validation accuracy
50	99.18	97.95
70	99.20	98.02
90	99.27	98.03
110	99.29	98.05
130	99.35	98.12
150	99.35	98.09
170	99.41	98.07
190	99.40	98.10
210	99.40	98.21

Table 2 - Train and test accuracy rates for different hidden layer configurations

As shown in Table 1, the runtime speed of our system shows a constant decay when we increase the hidden layer size. The same decay can be seen in the training speed, only this time by an order of magnitude larger. Because training a single network takes a lot of time, this experiment was designed to estimate the size of the hidden layer which offers good performance in tagging. To do this, we individually trained a number of networks in 30 iterations, using various hidden layer configurations (50, 70, 90,

110, 130, 150, 170, 190, and 210 neurons) and 5 initial random initializations of the weights. For each configuration, we stored the accuracy of reproducing the learning data (the tagging of the training corpus) and the accuracy on the unseen data (test sets). The results are shown in Table 2. Although a hidden layer of 210 neurons did not seem to over-fit the data, we stopped the experiment, as the training time got significantly longer.

The next experiment was designed to see how the number of training iterations influences the tagging performance of networks with different hidden layer configurations. Intuitively, the training process must be stopped when the network begins to over-fit the data (i.e. the train set accuracy increases, but the test set accuracy drops). Our experiments indicate that this is not always the case, as in some situations the continuation of the training process leads to better results on the cross-validation data (as shown in Figure 2). So, the problem comes to determining which is the most stable configuration of the neural network (i.e. which hidden unit size will be most likely to return good results on the test set) and establish the number of iterations it takes for the system to be trained. To do this, we ran the training procedure for 100 iterations and for each training iteration, we computed the accuracy rate of every individual network on the cross-validation set (see Table 3 for the averaged values). As shown, the network configuration using 130 neurons on the hidden layer is most likely to produce better results on the cross-validation set regardless of the number of iterations.

Although, some other configurations provided better figures for the maximum accuracy, their average accuracy is lower than that of the 130 hidden unit network. Other good candidates are the 90 and 110 hidden unit networks, but not the larger valued ones, which display a lower average accuracy and also significantly slower tagging speeds.

The most suitable network configuration for a given task depends on the language, MSD encoding size, speed and accuracy requirements. In our own daily applications we use the 130 hidden unit network. After observing the behavior of the various networks on the cross-validation set we determined that a good choice is to stop the training procedure after 40 iterations.

Hidden units	Avg. acc.	Max. acc.	St. dev.
50	97.94	98.31	0.127002
70	98.03	98.31	0.12197
50	97.94	98.37	0.139762
70	98.03	98.43	0.124996
90	98.07	98.39	0.134487
110	98.08	98.45	0.127109
130	98.14	98.44	0.136072
150	98.01	98.36	0.143324
170	97.94	98.36	0.122834

Table 3 - Average and maximum accuracy for various hidden layer configuration calculated over 100 training iterations on the test set

To obtain the accuracy of the system, in our last experiment we used the 130 hidden unit network and we performed the training/testing procedure on the 1984 corpus, using 10-fold validation and 30 random initializations. The final accuracy was computed as an average between all the accuracy figures measured at the end of the training process (after 40 iterations). The first 1/10 of the 1984 corpus on which we tuned the hyperparameters was not included in the test data, but was used for training. The mean accuracy of the system (98.41%) was measured as an average of 270 values.

#### 4 Comparison to other methods

In his work, Ceașu (2006) presents a different approach to MSD tagging using the Maximum Entropy framework. He presents his results on the same corpus we used for training and testing (the 1984 corpus) and he compares his method (98.45% accuracy) with the Tiered Tagging methodology (97.50%) (Tufiş and Dragomirescu, 2004).

Our Neural Network approach obtained similar (slightly lower) results (98.41%), although it is arguable that our split/train procedure is not identical to the one used in his work (no details were given as how the 1/10 of the training corpus was selected). Also, our POS tagger detected cases where the annotation in the Gold Standard was erroneous. One such example is in “lame de ras” (English “razor blades”) where “lame” (English “blades”) is a noun, “de” (“for”) is a preposition and “ras” (“shaving”) is a supine verb (with a past participle form) which was incorrectly annotated as a noun.

## 5 Network pattern analysis

Using feed-forward neural networks gives the ability to outline what input features contribute to the selection of various MSD attribute values in the output layer which might help in reducing the tagset and thus, redesigning the network topology with beneficial effects both on the speed and accuracy.

To determine what input features contribute to the selection of certain MSD attribute values, one can analyze the weights inside the neural network and extract the input  $\rightarrow$  output links that are formed during training. We used the network with 130 units on the hidden layer, which was previously trained for 100 iterations. Based on the input encoding, we divided the features into 5 groups (one group for each MSD inside the local context – two previous MSDs, current and following two possible MSDs). For a target attribute value (noun, gender feminine, gender masculine, etc.) and for each input group, we selected the top 3 input values which support the decision of assigning the target value to the attribute (features that increase the output value) and the top 3 features which discourage this decision (features that decrease the output value). For clarity, we will use the following notations for the groups:

- $G_{-2}$ : group one – the assigned MSD for the word at position  $i-2$
- $G_{-1}$ : group two – the assigned MSD for the word at position  $i-1$
- $G_0$ : group three – the possible MSDs for the word at position  $i$
- $G_1$ : group four – the possible MSDs for the word at position  $i+1$
- $G_2$ : group five – the possible MSDs for the word at position  $i+2$

where  $i$  corresponds to the position of the word which is currently being tagged. Also, we classify the attribute values into two categories (C): (P) *want to see* (support the decision) and (N) *don't want to see* (discourage the decision).

Table 4 shows partial ( $G_{-1}$   $G_0$   $G_1$ ) examples of two target attribute values (cat=Noun and gender=Feminine) and their corresponding input features used for discrimination.

Target value	Group	C	Attribute values
Noun	$G_{-1}$	P	main (of a verb), <b>article</b> , masculine (gender of a noun/adjective)

		N	particle, conjunctive particle, auxiliary (of a verb), demonstrative (of a pronoun)
		$G_0$	P
	N		adverb, pronoun, numeral, interrogative/relative (of a pronoun)
	$G_1$	P	<b>genitive/dative (of a noun/adjective)</b> , particle, punctuation
N		conjunctive particle, strong (of a pronoun), non-definite (of a noun/adjective), exclamation mark	
Fem.	$G_{-1}$	P	main (of a verb), preposition, <b>feminine (of a noun/adjective)</b>
		N	auxiliary (of a verb), particle, demonstrative (of a pronoun)
	$G_0$	P	<b>feminine (of a noun/adjective)</b> , nominative/accusative (of a noun/adjective), past (of a verb)
		N	masculine (of a noun/adjective), auxiliary (of a verb), interrogative/relative (of a pronoun), adverb
	$G_1$	P	dative/genitive (of a noun/adjective), indicative (of a verb), <b>feminine (of a noun/adjective)</b>
		N	conjunctive particle, future particle, nominative/accusative (of a noun/adjective)

Table 4 – P/N features for various attribute values.

For instance, when deciding on whether to give a noun (N) label to current position ( $G_0$ ), we can see that the neural network has learned some interesting dependencies: at position  $G_{-1}$  we find an article (which frequently determines a noun) and at the current position it is very important for the word being tagged to actually be a common or proper noun (either by lexicon lookup or by suffix guessing) and not be an adverb, pronoun or numeral (POSeS that cannot be found in the typical ambiguity class of a noun). At the next position of the target ( $G_1$ ) we also find a noun in genitive or dative, corresponding to a frequent construction in Romanian, e.g. “mașina băiatului” being a sequence of two nouns, the second at genitive/dative.

If the neural network outputs the feminine gender to its current MSD, one may see that it

has actually learned the agreement rules (at least locally): the feminine gender is present both before ( $G_{-1}$ ) the target word as well as after it ( $G_1$ ).

## 6 Conclusions and future work

We presented a new approach for large tagset part-of-speech tagging using neural networks. An advantage of using this methodology is that it does not require extensive knowledge about the grammar of the target language. When building a new MSD tagger for a new language one is only required to provide the training data and create an appropriate MSD encoding system and as shown, the MSD encoding algorithm is fairly simple and our proposed version works for any other MSD compatible encoding, regardless of the language.

Observing which features do not participate in any decision helps design custom topologies for the Neural Network, and provides enhancements in both speed and accuracy. The configurable nature of our system allows users to provide their own MSD encodings, which permits them to mask certain features that are not useful for a given NLP application.

If one wants to process a large amount of text and is interested only in assigning grammatical categories to words, he can use a MSD encoding in which he strips off all unnecessary features. Thus, the number of necessary neurons would decrease, which assures faster training and tagging. This is of course possible in any other tagging approaches, but our framework supports this by masking attributes inside the MSD encoding configuration file, without having to change anything else in the training corpus. During testing the system only verifies if the MSD encodings are identical and the displayed accuracy directly reflects the performance of the system on the simplified tagging schema.

We also proposed a methodology for selecting a network configurations (i.e. number of hidden units), which best suites the application requirements. In our daily applications we use a network with 130 hidden units, as it provides an optimal speed/accuracy trade-off (approx. 3400 words per second with very good average accuracy).

The tagger is implemented as part of a larger application that is primarily intended for text-to-speech (TTS) synthesis. The system is free for non-commercial use and we provide both web and desktop user-interfaces. It is part of the

METASHARE platform and available online<sup>2</sup>. Our primary goal was to keep the system language independent, thus all our design choices are based on the necessity to avoid using language specific knowledge, when possible. The application supports various NLP related tasks such as lexical stress prediction, syllabification, letter-to-sound conversion, lemmatization, diacritic restoration, prosody prediction from text and the speech synthesizer uses unit-selection.

From the tagging perspective, our future plans include testing the system on other highly inflectional languages such as Czech and Slovene and investigating different methods for automatically determining a more suitable custom network topology, such as genetic algorithms.

# Learning to lemmatise Polish noun phrases

Adam Radziszewski

Institute of Informatics, Wrocław University of Technology

Wybrzeże Wyspiańskiego 27

Wrocław, Poland

adam.radziszewski@pwr.wroc.pl

## Abstract

We present a novel approach to noun phrase lemmatisation where the main phase is cast as a tagging problem. The idea draws on the observation that the lemmatisation of almost all Polish noun phrases may be decomposed into transformation of singular words (tokens) that make up each phrase. We perform evaluation, which shows results similar to those obtained earlier by a rule-based system, while our approach allows to separate chunking from lemmatisation.

## 1 Introduction

Lemmatisation of word forms is the task of finding base forms (lemmas) for each token in running text. Typically, it is performed along POS tagging and is considered crucial for many NLP applications. Similar task may be defined for whole noun phrases (Degórski, 2011). By lemmatisation of noun phrases (NPs) we will understand assigning each NP a grammatically correct NP corresponding to the same phrase that could stand as a dictionary entry.

The task of NP lemmatisation is rarely considered, although it carries great practical value. For instance, any keyword extraction system that works for a morphologically rich language must deal with lemmatisation of NPs. This is because keywords are often longer phrases (Turney, 2000), while the user would be confused to see inflected forms as system output. Similar situation happens when attempting at terminology extraction from domain corpora: it is usually assumed that domain terms are subclass of NPs (Marciniak and Mykowiecka, 2013).

In (1) we give an example Polish noun phrase (*‘the main city of the municipality’*). Throughout the paper we assume the usage of the tagset

of the National Corpus of Polish (Przepiórkowski, 2009), henceforth called NCP in short. The orthographic form (1a) appears in instrumental case, singular. Phrase lemma is given as (1b). Lemmatisation of this phrase consists in reverting case value of the main noun (*miasto*) as well as its adjective modifier (*główne*) to nominative (nom). Each form in the example is in singular number (sg), *miasto* has neuter gender (n), *gmina* is feminine (f).

- (1) a. *głównym miastem gminy*  
main city municipality  
inst:sg:n inst:sg:n gen:sg:f
- b. *główne miasto gminy*  
main city municipality  
nom:sg:n nom:sg:n gen:sg:f

According to the lemmatisation principles accompanying the NCP tagset, adjectives are lemmatised as masculine forms (*główny*), hence it is not sufficient to take word-level lemma nor the orthographic form to obtain phrase lemmatisation. Degórski (2011) discusses some similar cases. He also notes that this is not an easy task and lemma of a whole NP is rarely a concatenation of lemmas of phrase components. It is worth stressing that even the task of word-level lemmatisation is non-trivial for inflectional languages due to a large number of inflected forms and even larger number of syncretisms. According to Przepiórkowski (2007), “a typical Polish adjective may have 11 textually different forms (...) but as many as 70 different tags (2 numbers  $\times$  7 cases  $\times$  5 genders)”, which indicates the scale of the problem. What is more, several syntactic phenomena typical for Polish complicate NP lemmatisation further. E.g., adjectives may both precede and follow nouns they modify; many English prepositional phrases are realised in Polish using oblique case without any proposition (e.g., there is no standard Polish coun-

terpart for the preposition *of* as genitive case is used for this purpose).

In this paper we present a novel approach to noun phrase lemmatisation where the main phase is cast as a tagging problem and tackled using a method devised for such problems, namely Conditional Random Fields (CRF).

## 2 Related works

NP lemmatisation received very little attention. This situation may be attributed to prevalence of works targeted at English, where the problem is next to trivial due to weak inflection in the language.

The only work that contains a complete description and evaluation of an approach to this task we were able to find is the work of Degórski (2011). The approach consists in incorporating phrase lemmatisation rules into a shallow grammar developed for Polish. This is implemented by extending the Spejdl shallow parsing framework (Buczyński and Przepiórkowski, 2009) with a rule action that is able to generate phrase lemmas. Degórski assumes that lemma of each NP may be obtained by concatenating each token’s orthographic form, lemma or ‘half-lemmatised’ form (e.g. grammatical case normalised to nominative, while leaving feminine gender). The other assumption is to neglect letter case: all phrases are converted to lower case and this is not penalised during evaluation. For development and evaluation, two subsets of NCP were chosen and manually annotated with NP lemmas: development set (112 phrases) and evaluation set (224 phrases). Degórski notes that the selection was not entirely random: two types of NPs were deliberately omitted, namely foreign names and “a few groups for which the proper lemmatisation seemed very unclear”. The final evaluation was performed in two ways. First, it is shown that the output of the entire system intersects only with 58.5% of the test set. The high error rate is attributed to problems with identifying NP boundaries correctly (29.5% of test set was not recognised correctly with respect to phrase boundaries). The other experiment was to limit the evaluation to those NPs whose boundaries were recognised correctly by the grammar (70.5%). This resulted in 82.9% success rate.

The task of phrase lemmatisation bears a close resemblance to a more popular task, namely lemmatisation of named entities. Depending on the

type of named entities considered, those two may be solved using similar or significantly different methodologies. One approach, which is especially suitable for person names, assumes that nominative forms may be found in the same source as the inflected forms. Hence, the main challenge is to define a similarity metric between named entities (Piskorski et al., 2009; Kocoń and Piasecki, 2012), which can be used to match different mentions of the same names. Other named entity types may be realised as arbitrary noun phrases. This calls for more robust lemmatisation strategies.

Piskorski (2005) handles the problem of lemmatisation of Polish named entities of various types by combining specialised gazetteers with lemmatisation rules added to a hand-written grammar. As he notes, organisation names are often built of noun phrases, hence it is important to understand their internal structure. Another interesting observation is that such organisation names are often structurally ambiguous, which is exemplified with the phrase (2a), being a string of items in genitive case (*‘of the main library of the Higher School of Economics’*). Such cases are easier to solve when having access to a collocation dictionary — it may be inferred that there are two collocations here: *Biblioteka Główna* and *Wyższa Szkoła Handlowa*.

- (2) a. *Biblioteki Głównej Wyższej*

While the paper reports detailed figures on named entity recognition performance, the quality of lemmatisation is assessed only for all entity types collectively: “79.6 of the detected NEs were lemmatised correctly” (Piskorski, 2005).

## 3 Phrase lemmatisation as a tagging problem

The idea presented here is directly inspired by Degórski’s observations. First, we will also assume

that lemma of any NP may be obtained by concatenating simple transformations of word forms that make up the phrase. As we will show in Sec. 4, this assumption is virtually always satisfied. We will argue that there is a small finite set of inflectional transformations that are sufficient to lemmatise nearly every Polish NP.

Consider example (1) again. Correct lemmatisation of the phrase may be obtained by applying a series of simple inflectional transformations to each of its words. The first two words need to be turned into nominative forms, the last one is already lemmatised. This is depicted in (3a). To show the real setting, this time we give full NCP tags and word-level lemmas assigned as a result of tagging. In the NCP tagset, the first part of each tag denotes grammatical class (*adj* stands for adjective, *subst* for noun). Adjectives are also specified for degree (*pos* — positive degree).

- (3) a. *głównym*  
*główny*  
*adj:sg:inst:n:pos*  
*miastem*                      *gminy*  
*miasto*                        *gmina*  
*subst:sg:inst:n*    *subst:sg:gen:f*
- b. *główne*                      *miasto*  
*adj:sg:nom:n:pos*    *subst:sg:nom:n*  
*cas=nom*                      *cas=nom*  
*gminy*  
*subst:sg:gen:f*  
 =

Example (3b) consists of three rows: the lemmatised phrase, the desired tags (tags that would be attached to tokens of the lemmatised phrase) and the transformations needed to obtain lemma from orthographic forms. The notation *cas=nom* means that to obtain the desired form (e.g. *główne*) you need to find an entry in a morphological dictionary that bears the same word-level lemma as the inflected form (*główny*) and a tag that results from taking the tag of the inflected form (*adj:sg:inst:n:pos*) and setting the value of the tagset attribute *cas* (grammatical case) to the value *nom* (nominative). The transformation labelled = means that the inflected form is already equal to the desired part of the lemma, hence no transformation is needed.

A tagset note is in order. In the NCP tagset each tag may be decomposed into grammatical class and attribute values, where the choice

of applicable attributes depends on the grammatical class. For instance, nouns are specified for number, gender and case. This assumption is important for our approach to be able to use simple tag transformations in the form *replace the value of attribute A with the new value V (A=V)*. This is not a serious limitation, since the same assumption holds for most tagsets developed for inflectional languages, e.g., the whole MULTEXT-East family (Erjavec, 2012), Czech tagset (Jakubiček et al., 2011).

Our idea is simple: by expressing phrase lemmatisation in terms of word-level transformations we can reduce the task to tagging problem and apply well known Machine Learning techniques that have been devised for solving such problems (e.g. CRF). An important advantage is that this allows to rely not only on the information contained within the phrase to be lemmatised, but also on tokens belonging to its local neighbourhood.

Assuming that we have already trained a statistical model, we need to perform the following steps to obtain lemmatisation of a new text:

1. POS tagging,
2. NP chunking,
3. tagging with transformations by applying the trained model,
4. application of transformations to obtain NP lemmas (using a morphological dictionary to generate forms).

To train the statistical model, we need training data labelled with such transformations. Probably the most reliable way to obtain such data would be to let annotators manually encode a training corpus with such transformations. However, the task would be extremely tedious and the annotators would probably have to undergo special training (to be able to think in terms of transformations). We decided for a simpler solution. The annotators were given a simpler task of assigning each NP instance a lemma and a heuristic procedure was used to induce transformations by matching the manually annotated lemmas to phrases' orthographic forms using a morphological dictionary. The details of this procedure are given in the next section.

We decided to perform the experiments using the data from *Polish Corpus of Wrocław Univer-*

sity of Technology<sup>1</sup> (Broda et al., 2012). The corpus (abbreviated to *KPWr* from now on) contains manual shallow syntactic annotation which includes NP chunks and their syntactic heads. The main motivation to use this corpus was its very permissive licence (Creative Commons Attribution), which will not constrain any further use of the tools developed. What is more, it allowed us to release the data annotated manually with phrase lemmas and under the same licence<sup>2</sup>.

One of the assumptions of *KPWr* annotation is that actual noun phrases and prepositional phrases are labelled collectively as NP chunks. To obtain real noun phrases, phrase-initial prepositions must be stripped off<sup>3</sup>. For practical reasons we decided to include automatic recognition of phrase-initial prepositions into our model: we introduced a special transformation for such cases (labelled *p*), having the interpretation that the token belongs to a phrase-initial preposition and should be discarded when generating phrase lemma. Prepositions are usually contained in single tokens. There are some cases of multi-word units which we treat as prepositions (*secondary prepositions*), e.g. *ze względu na* (*with respect to*). This solution allows to use our lemmatiser directly against chunker output to obtain NP lemmas from both NPs and PPs. For instance, the phrase *o przenoszeniu bakterii drogą płciową* (*about sexual transmission of bacteria*) should be lemmatised to *przenoszenie bakterii drogą płciową* (*sexual transmission of bacteria*).

#### 4 Preparation of training data

First, simple lemmatisation guidelines were developed. The default strategy is to normalise the case to nominative and the number to singular. If the phrase was in fact prepositional, phrase-initial preposition should be removed first. If changing the number would alter semantics of the phrase, it should be left plural (e.g., *warunki* ‘conditions’ as in *terms and conditions*). Some additional exceptions concern pronouns, fixed expressions and

<sup>1</sup>We used version 1.1 downloaded from <http://www.nlp.pwr.wroc.pl/kpwr>.

<sup>2</sup>The whole dataset described in this paper is available at <http://nlp.pwr.wroc.pl/en/static/kpwr-lemma>.

<sup>3</sup>Note that if we decided to use the data from NCP, we would still have to face this issue. Although an explicit distinction is made between NPs and PPs, NPs are not annotated as separate chunks when belonging to a PP chunk (an assumption which is typical for shallow parsing).

proper names. They were introduced to obtain lemmas that are practically most useful.

A subset of documents from *KPWr* corpus was drawn randomly. Each NP/PP belonging to this subset was annotated manually. Contrary to (DeGórski, 2011), we made no exclusions, so the obtained set contains some foreign names and a number of cases which were hard to lemmatise manually. Among the latter there was one group we found particularly interesting. It consisted of items following the following pattern: NP in plural modified by another NP or PP in plural. For many cases it was hard to decide if both parts were to be reverted to singular, only the main one or perhaps both of them should be left in plural. We present two such cases in (4a) and (4b). For instance, (4b) could be lemmatised as *opis tytułu z Wikipedii* (*description of a Wikipedia title*), but it was not obvious if it was better than leaving the whole phrase as is.

- (4) a. *obawy ze strony autorów*  
‘concerns on the part of the authors’  
b. *opisy tytułów z Wikipedii*  
‘descriptions of the Wikipedia titles’

Altogether, the annotated documents contain 1669 phrases. We used the same implementation of the 2+1 model which was used to annotate morphosyntax in NCP (Przepiórkowski and Szwałkiewicz, 2012): two annotators performed the task independently, after which their decisions were compared and the discrepancies were highlighted. The annotators were given a chance to rethink their decisions concerning the highlighted phrases. Both annotators were only told which phrases were lemmatised differently by the other party but they didn’t know the other decision. The purpose of this stage was to correct obvious mistakes. Their output was finally compared, resulting in 94% phrases labelled identically (90% before reconsidering decisions). The remaining discrepancies were decided by a superannotator. The whole set was divided randomly into the development set (1105 NPs) and evaluation set (564 NPs).

The development set was enhanced with word-level transformations that were induced automatically in the following manner. The procedure assumes the usage of a morphological dictionary extracted from Morfeusz SGJP analyser<sup>4</sup> (Woliński,

<sup>4</sup>[morfeusz-sgjp-src-20110416](http://morfeusz-sgjp-src-20110416) package

2006). The dictionary is stored as a set of (*orthographic form, word-level lemma, tag*). The procedure starts with tokenisation of the manually assigned lemma. Next, a heuristic identification of phrase-initial preposition is performed. The assumption is that, having cut the preposition, all the remaining tokens of the original inflected phrase must be matched 1:1 to corresponding tokens from the human-assigned lemma. If any match problem did occur, an error was reported and such a case was examined manually. The only problems encountered were due to proper names unknown to the dictionary and misspelled phrases (altogether about 10 cases). Those cases were dealt with manually. Also, all the extracted phrase-initial prepositions were examined and no controversy was found.

The input and output to the matching procedure is illustrated in Fig. 1. The core matching happens at token level. The task is to find a suitable transformation for the given inflected form from the original phrase, its tag and word-level lemma, but also given the desired form being part of human-assigned lemma. If the inflected form is identical to the desired human-assigned lemma, the '=' transformation is returned without any tag analysis. For other cases the morphological dictionary is required. For instance, the inflected form *tej* tagged as *adj:sg:loc:f:pos* should be matched to the human-assigned form *ta* (the row label *H lem*). The first subtask is to find all entries in the morphological dictionary with the orthographic form equal to human-assigned lemma (*ta*), the word-level lemma equal to the lemma assigned by the tagger (*ten*) and having a tag with the same grammatical class as the tagger has it (*adj*; we deliberately disallow transformations changing the grammatical class). The result is a set of entries with the given lemma and orthographic form, but with different tags attached. For the example considered, two tags may be obtained: *adj:sg:nom:f:pos* and *adj:sg:voc:f:pos* (the former is in nominative case, the latter — in vocative). Each of the obtained tags is compared to the tag attached to the inflected forms (*adj:sg:loc:f:pos*) and this way candidate transformations are generated (*cas=nom* and *cas=voc* here). The transformations are heuristically ranked. Most importantly,

obtained from <http://sgjp.pl/morfeusz/dopobrania.html>. The package is available under 2-clause BSD licence.

*cas=nom* is always preferred, then *nmb=sg* (enforcing singular number), then transforming the gender to different values, preferably to masculine inanimate (*gnd=m3*). The lowest possible ranking is given to a transformation enforcing case value other than nominative.

Figure 1: Matching of an NP and its lemma. The first row shows the original inflected form. The next three present tagger output: tags (split into two rows) and lemmas. *H lem* stands for the lemma assigned by a human. Last row presents the transformations induced.

We are fully aware of limitations of this approach. This ranking was inspired only by intuition obtained from the lemmatisation guidelines and the transformations selected this way may be wrong in a number of cases. While many transformations may lead to obtaining the same lemma for a given form, many of them will still be accidental. Different syncretisms may apply to different lexemes, which can negatively impact the ability of the model to generalise from one phrase to other. On the other hand, manual inspection of some fragments suggest that the transformations inferred are rarely unjustified.

The frequencies of all transformations induced from the development set are given in Tab. 1. Note that the first five most frequent transformation make up 98.7% of all cases. These findings support our hypothesis that a small finite set of transformations is sufficient to express lemmatisation of nearly every Polish NP.

We have also tested an alternative variant of the matching procedure that included additional transformation 'lem' with the meaning *take the word-level lemma assigned by the tagger as the correct lemmatisation*. This transformation could be induced after an unsuccessful attempt to induce the '=' transformation (i.e., if the correct human-assigned lemmatisation was not identical to orthographic form). This resulted in replacing a number of tag-level transformations (mostly *cas=nom*) with the simple 'lem'. The advantage of this vari-

=	2444	72%

ant is that application of this transformation does not require resorting to the dictionary. The disadvantage is that it is likely to worsen the generalising power of the model.

## 5 CRF and features

The choice of CRF for sequence labelling was mainly influenced by its successful application to chunking of Polish (Radziszewski and Pawlaczek, 2012). The work describes a feature set proposed for this task, which includes word forms in a local window, values of grammatical class, gender, number and case, tests for agreement on number, gender and case, as well as simple tests for letter case.

We took this feature set as a starting point. Then we performed some experiments with feature generation and selection. For this purpose the development set was split into training and testing part. The most obvious, yet most successful change was to introduce features returning the chunk tag assigned to a token. As KPWr also contains information on the location of chunks' syntactic heads and this information is also output by the chunker, we could also use this in our features. Another improvement resulted from completely removing tests for grammatical gender and limiting the employed tests for number to the current token.

The final feature set includes the following

items:

- the word forms (turned lower-case) of tokens occupying a local window  $(-2, \dots, +2)$ ,
- word form bigrams:  $(-1, 0)$  and  $(0, 1)$ ,
- chunk tags (IOB2 tags concatenated with Boolean value denoting whether the syntactic head is placed at the position), for a local window  $(-1, 0, +1)$
- chunk tags (IOB2 tags only) for positions  $-2$  and  $+2$ , and two chunk tag bigrams:  $(-1, 0)$  and  $(0, 1)$ ,
- grammatical class of tokens in the window  $(-2, \dots, +2)$ ,
- grammatical class for the focus token (0) concatenated with the last character of the word-form,
- values of grammatical case for tokens  $(-2, -1, +1, +2)$ ,
- grammatical class of the focus token concatenated with its gender value,
- 2-letter prefix of the word form (lower-cased),
- tests for agreements and letter case as in (Radziszewski and Pawlaczek, 2012).

## 6 Evaluation

The performed evaluation assumed training of the CRF on the whole development set annotated with the induced transformations and then applying the trained model to tag the evaluation part with transformations. Transformations were then applied and the obtained phrase lemmas were compared to the reference annotation. This procedure includes the influence of deficiencies of the morphological dictionary. The version of KPWr used here was tagged automatically using the WCRFT tagger (Radziszewski, 2013), hence tagging errors are also included.

Degórski (2011) reports separate figures for the performance of the entire system (chunker + NP lemmatiser) on the whole test set and performance of the entire system limiting the test set only to those phrases that the system is able to chunk correctly (i.e., to output correct phrase boundaries). Such a choice is reasonable given that his system

is based on rules that intermingle chunking with lemmatisation. We cannot expect the system to lemmatise correctly those groups which it is unable to capture. Our approach assumes two-stage operation, where the chunker stage is partially independent from the lemmatisation. This is why we decided to report performance of the whole system on the whole test set, but also, performance of the lemmatisation module alone on the *whole test set*. This seems more appropriate, since the chunker may be improved or completely replaced independently, while discarding the phrases that are too hard to parse is likely to bias the evaluation of the lemmatisation stage (what is hard to chunk is probably also hard to lemmatise).

For the setting where chunker was used, we used the CRF-based chunker mentioned in the previous section (Radziszewski and Pawlaczek, 2012). The chunker has been trained on the entire KPWr except for the documents that belong to the evaluation set.

Degórski (2011) uses concatenation of word-level base forms assigned by the tagger as a baseline. Observation of the development set suggests that returning the original inflected NPs may be a better baseline. We tested both variants. As detection of phrase-initial prepositions is a part of our task formulation, we had to implement it in the baseline algorithms as well. Otherwise, the comparison would be unfair. We decided to implement both baseline algorithms using the same CRF model but trained on fabricated data. The training data for the ‘take-orthographic-form’ baseline was obtained by leaving the ‘remove-phrase-initial-preposition’ (‘p’) transformation and replacing all others with ‘=’. Similarly, for the ‘take-lemma’ baseline, other transformations were substituted with ‘lem’.

The results of the full evaluation are presented in Tab. 2. The first conclusion is that the figures are disappointingly low, but comparable with the 58.5% success rate reported in (Degórski, 2011). The other observation is that the proposed solution significantly outperforms both baseline, out of which the ‘take-orthographic-form’ (*orth baseline*) performs slightly better. Also, it turns out that the variation of the matching procedure using the ‘lem’ transformation (row labelled *CRF lem*) performs slightly worse than the procedure without this transformation (row *CRF nolem*). This supports the suspicion that relying on word-

level lemmas may reduce the ability to generalise.

Algorithm	Prec.	Recall	F
CRF nolem	55.1%	56.9%	56.0%
CRF lem	53.7%	55.5%	54.6%
orth baseline	38.6%	39.9%	39.2%
lem baseline	36.2%	37.4%	36.8%

Table 2: Performance of NP lemmatisation including chunking errors.

Results corresponding to performance of the lemmatisation module alone are reported in Tab. 3. The test has been performed using chunk boundaries and locations of syntactic heads taken from the reference corpus. In this settings recall and precision have the same interpretation, hence we simply refer to the value as *accuracy* (percentage of chunks that were lemmatised correctly). The figures are considerably higher than those reported in Tab. 2, which shows the huge impact of chunking errors. It is worth noting that the best accuracy achieved is only slightly lower than that achieved by Degórski (82.9%), while our task is harder. As mentioned above, in Degórski’s setting, the phrases that are too hard to parse are excluded from the test set. Those phrases are also likely to be hard cases for lemmatisation. The other important difference stems from phrase definitions used in both corpora; NPs in NCP are generally shorter than the chunks allowed in KPWr. Most notably, KPWr allows the inclusion of PP modifiers within NP chunks (Broda et al., 2012). It seems likely that the proposed algorithm would performed better when trained on data from NCP which assumes simpler NP definition. Note that the complex NP definition in KPWr also explains the huge gap between results of lemmatisation alone and lemmatisation including chunking errors.

Algorithm	Correct lemmas	Accuracy
CRF nolem	455 / 564	80.7%
CRF lem	444 / 564	78.7%
orth baseline	314 / 564	55.7%
lem baseline	290 / 564	51.4%

Table 3: Performance of NP lemmatisation alone.

We also checked the extent to which the entries unknown to the morphological dictionary could lower the performance of lemmatisation. It turned out that only 8 words couldn’t be transformed during evaluation due to lack of the entries that

were sought in the morphological dictionary, out of which 5 were anyway handled correctly in the end by using the simple heuristic to output the ‘=’ transformation when everything else fails.

A rudimentary analysis of lemmatiser output indicates that the most common error is the assignment of the orthographic form as phrase lemma where something else was expected. This seems to concern mostly many NPs that are left in plural, even simple ones (e.g. *audycje telewizyjne* ‘TV programmes’), but there are also some cases of personal pronouns left in oblique case (*was* ‘you-pl-accusative/genitive’). It seems that a part of these cases come from tagging errors (even if the correct transformation is obtained, the results of its application depend on the tag and lemma attached to the inflected form by the tagger). Not surprisingly, proper names are hard cases for the model (e.g. *Pod Napięciem* was lemmatised to *napięcie*, which would be correct weren’t it a title).

## 7 Conclusions and further work

We presented a novel approach to lemmatisation of Polish noun phrases. The main advantage of this solution is that it allows to separate the lemmatisation phrase from the chunking phrase. Degórski’s rule-based approach (Degórski, 2011) was also built on top of an existing parser but, as he notes, to improve the lemmatisation accuracy, the grammar underlying the parser should actually be rewritten with lemmatisation in mind. The other advantage of the approach presented here is that it is able to learn from a corpus containing manually assigned phrase lemmas. Extending existing chunk-annotated corpora with phrase lemmas corresponds to a relatively simple annotation task.

The performance figures obtained by our algorithm are comparable with that of Degórski’s grammar, while the conditions under which our system was evaluated were arguably less favourable. To enable a better comparison it would be desirable to evaluate our approach against the phrases from NCP.

The main disadvantage of the approach lies in the data preparation stage. It requires some semi-manual work to obtain labelling with transformations, which is language- and tagset-dependent. A very interesting alternative has been suggested by an anonymous reviewer: instead of considering tag-level transformations that require an exhaustive morphological dictionary, it would be simpler

to rely entirely on string-to-string transformations that map inflected forms to their expected counterparts. Such transformations may be expressed in terms of simple edit scripts, which has already been successfully applied to word-level lemmatisation of Polish and other languages (Chrupała et al., 2008). This way, the training data labelled with transformations could be obtained automatically. What is more, application of such transformations also does not depend on the dictionary. It is not obvious how this would affect the performance of the module and, hence, needs to be evaluated. We plan this as our further work.

Also, it would be worthwhile to evaluate the presented solution for other Slavic languages.

# Using Conceptual Class Attributes to Characterize Social Media Users

Shane Bergsma and Benjamin Van Durme

Department of Computer Science and Human Language Technology Center of Excellence  
Johns Hopkins University  
Baltimore, MD 21218, USA

## Abstract

We describe a novel approach for automatically predicting the hidden demographic properties of social media users. Building on prior work in common-sense knowledge acquisition from third-person text, we first learn the distinguishing attributes of certain classes of people. For example, we learn that people in the *Female* class tend to have *maiden names* and *engagement rings*. We then show that this knowledge can be used in the analysis of first-person communication; knowledge of distinguishing attributes allows us to both classify users and to bootstrap new training examples. Our novel approach enables substantial improvements on the widely-studied task of user gender prediction, obtaining a 20% relative error reduction over the current state-of-the-art.

## 1 Introduction

There has been growing interest in *characterizing* social media users based on the content they generate; that is, automatically labeling users with demographic categories such as age and gender (Burger and Henderson, 2006; Schler et al., 2006; Rao et al., 2010; Mukherjee and Liu, 2010; Penacchiotti and Popescu, 2011; Burger et al., 2011; Van Durme, 2012). Automatic user characterization has applications in targeted advertising and personalization, and could also lead to finer-grained assessment of public opinion (O'Connor et al., 2010) and health (Paul and Dredze, 2011).

Consider the following tweet and suppose we wish to predict the user's gender:

*Dirac was one of my boyhood heroes. I'm glad I met him once. RT Paul Dirac image by artist Eric Handy: [http:...](#)*

State-of-the-art approaches cast this problem as a classification task and train classifiers using supervised learning (Section 2). The features of the classifier are indicators of specific words in the user-generated text. While a human would assume that someone with *boyhood heroes* is **male**, a standard classifier has no way of exploiting such knowledge unless the phrase occurs in training data. We present an algorithm that improves user characterization by collecting and exploiting such common-sense knowledge.

Our work is inspired by algorithms that process large text corpora in order to discover the attributes of semantic classes, e.g. (Berland and Charniak, 1999; Schubert, 2002; Almuhareb and Poesio, 2004; Tokunaga et al., 2005; Girju et al., 2006; Paşca and Van Durme, 2008; Alfonseca et al., 2010). We learn the distinguishing attributes of different demographic groups (Section 3), and then automatically assign users to these groups whenever they refer to a distinguishing attribute in their writings (Section 4). Our approach obviates the need for expensive annotation efforts, and allows us to rapidly bootstrap training data for new classification tasks.

We validate our approach by advancing the state-of-the-art on the most well-studied user classification task: predicting user gender (Section 5). Our bootstrapped system, trained purely from automatically-annotated Twitter data, significantly reduces error over a state-of-the-art system trained on thousands of gold-standard training examples.

## 2 Supervised User Characterization

The current state-of-the-art in user characterization is to use supervised classifiers trained on annotated data. For each instance to be classified, the output is a decision about a distinct demographic property, such as *Male/Female* or *Over/Under-18*. A variety of classification algorithms have been employed, including SVMs (Rao et al., 2010), de-

cision trees (Pennacchiotti and Popescu, 2011), logistic regression (Van Durme, 2012), and the Winnow algorithm (Burger et al., 2011).

**Content Features: *BoW*** Prior classifiers use a set of features encoding the presence of specific words in the user-generated text. We call these features *BoW* features as they encode the standard Bag-of-Words representation which has been highly effective in text categorization and information retrieval (Sebastiani, 2002).

**User-Profile Features: *U<sub>sr</sub>*** Some researchers have explored features for user-profile meta-information in addition to user content. This may include the user’s communication behavior and network of contacts (Rao et al., 2010), their full name (Burger et al., 2011) and whether they provide a profile picture (Pennacchiotti and Popescu, 2011). We focus on the case where we only have access to the user’s screen-name (a.k.a. username). Using a combination of content and username features “represents a use case common to many different social media sites, such as chat rooms and news article comment streams” (Burger et al., 2011). We refer to features derived from a username as *U<sub>sr</sub>* features in our experiments.

### 3 Learning Class Attributes

We aim to improve the automated classification of users into various demographic categories by learning and applying the distinguishing attributes of those categories, e.g. that *males* have *boyhood heroes*. Our approach builds on lexical-semantic research on the topic of *class-attribute extraction*. In this research, the objective is to discover various *attributes* or *parts* of classes of entities. For example, Berland and Charniak (1999) learn that the class *car* has parts such as *headlight*, *windshield*, *dashboard*, etc. Berland and Charniak extract these attributes by mining a corpus for fillers of patterns such as ‘*car*’s *X*’ or ‘*X* of a *car*’. Note their patterns explicitly include the class itself (*car*). Another approach is to use patterns that are based on *instances* (i.e. hyponyms or sub-classes) of the class. For example, Paşca and Van Durme (2007) learn the attributes of the class *car* via patterns involving instances of cars, e.g. *Chevrolet Corvette*’s *X* and *X* of a *Honda Civic*. For these approaches, lists of instances are typically collected from publicly-available resources such as WordNet or Wikipedia (Paşca and Van Durme, 2007;

Van Durme et al., 2008), acquired automatically from corpora (Paşca and Van Durme, 2008; Alfonso et al., 2010), or simply specified by hand (Schubert, 2002).

**Creation of Instance Lists** We use an instance-based approach; our instances are derived from collections of common nouns that are associated with roles and occupations of people. For the gender task that we study in our experiments, we acquire class instances by filtering the dataset of nouns and their genders created by Bergsma and Lin (2006). This dataset indicates how often a noun is referenced by a male, female, neutral or plural pronoun. We extract prevalent common nouns for males and females by selecting only those nouns that (a) occur more than 200 times in the dataset, (b) mostly occur with male or female pronouns, and (c) occur as lower-case more often than upper-case in a web-scale N-gram corpus (Lin et al., 2010). We then classify a noun as **Male** (resp. **Female**) if the noun is indicated to occur with male (resp. female) pronouns at least 85% of the time. Since the gender data is noisy, we also quickly pruned by hand any instances that were malformed or obviously incorrectly assigned by our automatic process. This results in 652 instances in total. Table 1 provides some examples.

**Male:** bouncer, altar boy, army officer, dictator, assailant, cameraman, drifter, chauffeur, bad guy

**Female:** young lady, lesbian, ballerina, waitress, granny, chairwoman, heiress, soprano, socialite

Table 1: Example instances used for extraction of class attributes for the gender classification task

**Attribute Extraction** We next collect and rank attributes for each class. We first look for fillers of attribute-patterns involving each of the instances. Let *I* represent an instance of one of our classes. We find fillers of the single high-precision pattern:

$$\underbrace{\{\text{word}=I, \text{tag}=NN\}}_{\text{instance}} \underbrace{\{\text{word}='s\}}_{\text{'s}} \underbrace{\{\{\text{word}=. * \}^* \{\text{tag}=N. * \}\}}_{\text{attribute}}$$

(E.g. *dictator*’s [*former mistress*]). The expression “tag=NN” means that *I* must be tagged as a noun. The expression in square brackets is the filler, i.e. the extracted attribute, *A*. The notation “{word=. \*} \* tag=N. \*” means that *A* can be any sequence of tokens ending in a noun. We use an

equivalent pattern when  $I$  is multi-token. The output of this process is a set of  $(I, A)$  pairs.

In attribute extraction, typically one must choose between the precise results of rich patterns (involving punctuation and parts-of-speech) applied to small corpora (Berland and Charniak, 1999) and the high-coverage results of superficial patterns applied to web-scale data, e.g. via the Google API (Almuhareb and Poesio, 2004). We obtain the best of both worlds by matching our precise pattern against a version of the Google N-gram Corpus that includes the part-of-speech tag distributions for every N-gram (Lin et al., 2010). We found that applying this pattern to web-scale data is effective in extracting useful attributes. We acquired around 20,000 attributes in total.

**Finding Distinguishing Attributes** Unlike prior work, we aim to find *distinguishing* properties of each class; that is, the kinds of properties that uniquely distinguish a particular category. Prior work has mostly focused on finding “relevant” attributes (Alfonseca et al., 2010) or “correct” parts (Berland and Charniak, 1999). A *leg* is a relevant and correct part of both a male and a female (and many other living and inanimate objects), but it does not help us distinguish males from females in social media. We therefore rank our attributes for each class by their strength of association with instances of that specific class.<sup>1</sup>

To calculate the association, we first disregard the count of each  $(I, A)$  pair and consider each unique pair to be a single probabilistic event. We then convert the  $(I, A)$  pairs to corresponding  $(C, A)$  pairs by replacing  $I$  with the corresponding class,  $C$ . We then calculate the pointwise mutual information (Church and Hanks, 1990) between each  $C$  and  $A$  over the set of events:

$$\text{PMI}(C, A) = \log \frac{p(C, A)}{p(C)p(A)} \quad (1)$$

If the  $\text{PMI} > 0$ , the observed probability of a class and attribute co-occurring is greater than the probability of co-occurrence that we would expect if  $C$  and  $A$  were independently distributed. For each class, we rank the attributes by their PMI scores.

<sup>1</sup>Reisinger and Paşca (2009) considered the related problem of finding the most appropriate *class* for each *attribute*; they take an existing ontology of concepts (WordNet) as a class hierarchy and use a Bayesian approach to decide “the correct level of abstraction for each attribute.”

**Filtering Attributes** We experimented with two different methods to select a final set of distinguishing attributes for each class: (1) we used a threshold to select the top-ranked attributes for each class, and (2) we manually filtered the attributes. For the gender classification task, we manually filtered the entire set of attributes to select around 1000 attributes that were judged to be discriminative (two thirds of which are female). This filtering took one annotator only a few hours to complete. Because this process was so trivial, we did not invest in developing annotation guidelines or measuring inter-annotator agreement. We make these filter attributes available online as an attachment to this article, available through the ACL Anthology.

Ultimately, we discovered that manual filtering was necessary to avoid certain pathological cases in our Twitter data. For example, our PMI scoring finds *homepage* to be strongly associated with males. In our gold-standard gender data (Section 5), however, *every* user has a homepage [by dataset construction]; we might therefore incorrectly classify every user as **Male**. We agree with Richardson et al. (1998) that “automatic procedures ... provide the only credible prospect for acquiring world knowledge on the scale needed to support common-sense reasoning” but “hand vetting” might be needed to ensure “accuracy and consistency in production level systems.” Since our approach requires manual involvement in the filtering of the attribute list, one might argue that one should simply manually enumerate the most relevant attributes directly. However, the manual generation of conceptual features by a single researcher results in substantial variability both across and within participants (McRae et al., 2005). Psychologists therefore generate such lists by pooling the responses across many participants: future work may compare our “automatically generate, manually prune” approach to soliciting attributes via crowdsourcing.<sup>2</sup>

Table 2 gives examples of our extracted at-

<sup>2</sup>One can also view the work of manually filtering attributes as a kind of “feature labeling.” There is evidence from Zaidan et al. (2007) that a few hours of feature labeling can be more productive than annotating new training examples. In fact, since Zaidan et al. (2007) label features at the token level (e.g., in our case one would highlight “handbag” in a given tweet), while we label features at the type level (e.g., deciding whether to mark the word “handbag” as feminine in general), our process is likely even more efficient. Future work may also wish to consider this connection to so-called “annotator rationales” more deeply.

**Male:** wife, widow, wives, ex-girlfriend, erection, testicles, wet dream, bride, buddies, ex-wife, first-wife, penis, death sentence, manhood

**Female:** vagina, womb, maiden name, dresses, clitoris, wedding dress, uterus, shawl, necklace, ex-husband, ex-boyfriend, dowry, nightgown

Table 2: Example attributes for gender classes, in descending order of class-association score

tributes. Our approach captures many *multi-token* attributes; these are often distinguishing even though the head noun is ambiguous (e.g. *name* is ambiguous, *maiden name* is not). Our attributes also go beyond the traditional meronyms that were the target of earlier work. As we discuss further in Related Work (Section 7), previous researchers have worried about a proper definition of *parts* or *attributes* and relied on human judgments for evaluation (Berland and Charniak, 1999; Girju et al., 2006; Van Durme et al., 2008). For us, whether a property such as *dowry* should be considered an “attribute” of the class **Female** is immaterial; we echo Almuhareb and Poesio (2004) who (on a different task) noted that “while the notion of ‘attribute’ is not completely clear... our results suggest that trying to identify attributes is beneficial.”

#### 4 Applying Class Attributes

To classify users using the extracted attributes, we look for cases where users refer to such attributes in their first-person writings. We performed a preliminary analysis of a two-week sample of tweets from the TREC Tweets2011 Corpus.<sup>3</sup> We found that users most often reveal their attributes in the possessive construction, “my *X*” where *X* is an attribute, quality or event that they possess (in a linguistic sense). For example, we found over 1000 tweets with the phrase “my wife.” In contrast, “I have a wife” occurs only 5 times.<sup>4</sup>

We therefore assign a user to a demographic category as follows: We first part-of-speech tag our data using CRFTagger (Phan, 2006) and then look for “my *X*” patterns where *X* is a sequence of tokens terminating in a noun, analogous to our

<sup>3</sup><http://trec.nist.gov/data/tweets/> This corpus was developed for the TREC Microblog track (Soboroff et al., 2012).

<sup>4</sup>Note that “I am a man” occurs only 20 times. Users also reveal their names in “my name is *X*” patterns in several hundred tweets, but this is small compared to cases of self-distinguishing *attributes*. Exploiting these alternative patterns could nevertheless be a possible future direction.

attribute-extraction pattern (Section 3).<sup>5</sup> When a user uses such a “my *X*” construction, we match the filler *X* against our attribute lists for each class. If the filler is on a list, we call it a *self-distinguishing attribute* of a user. We then apply our knowledge of the self-distinguishing attribute and its corresponding class in one of the following three ways:

##### (1) *ARules*: Using Attribute-Based Rules to Override a Classifier

When human-annotated data is available for training and testing a supervised classifier, we refer to it as *gold standard* data. Our first technique provides a simple way to use our identified self-distinguishing attributes in conjunction with a classifier trained on gold-standard data. If the user has any self-distinguishing attributes, we assign the user to the corresponding class; otherwise, we trust the output of the classifier.

##### (2) *Bootstrapped*: Automatic Labeling of Training Examples

Even without gold standard training data, we can use our self-distinguishing attributes to automatically bootstrap annotations. We collect a large pool of unlabeled users and their tweets, and we apply the *ARules* described above to label those users that have self-distinguishing attributes. Once an example is auto-annotated, we delete the self-distinguishing attributes from the user’s content. This prevents the subsequent learning algorithm from trivially learning the rules with which we auto-annotated the data. Next, the auto-annotated examples are used as training data for a supervised system.<sup>6</sup> Finally, when applying the *Bootstrapped* classifiers, we can still apply the *ARules* as a post-process (although in practice this made little difference in our final results).

##### (3) *BootStacked*: Gold Standard and *Bootstrapped* Combination

Although we show that an accurate classifier can be trained using auto-annotated *Bootstrapped* data alone, we also test whether we can combine this data with any gold-standard training examples to achieve even better performance. We use the following simple but

<sup>5</sup>While we used an “off the shelf” POS tagger in this work, we note that taggers optimized specifically for social media are now available and would likely have resulted in higher tagging accuracy (e.g. Owoputi et al. (2013)).

<sup>6</sup>Note that while our target gender task presents mutually-exclusive output classes, we can still train classifiers for other categories without clear opposites (e.g. for labeling users as *Parents* or *Doctors*) by using the 1-class classification paradigm (Koppel and Schler, 2004).

effective method for combining data from these two sources, inspired by prior techniques used in the domain adaptation literature (Daumé III and Marcu, 2006). We first use the trained *Bootstrapped* system to make predictions on the entire set of gold standard data (gold train, development, and test sets). We then use these predictions as *features* in a classifier trained on the gold standard data. We refer to this system as the *BootStacked* system in our evaluation.

## 5 Twitter Gender Prediction

To test the use of self-distinguishing attributes in user classification, we apply our methods to the task of gender classification on Twitter. This is an important and intensely-studied task within academia and industry. Furthermore, for this task it is possible to semi-automatically acquire large amounts of ground truth (Burger et al., 2011). We can therefore benchmark our approach against state-of-the-art supervised systems trained with plentiful gold-standard data, giving us an idea of how well our *Bootstrapped* system might compare to theoretically top-performing systems on other tasks, domains, and social media platforms where such gold-standard training data is not available.

**Gold Data** Our data is derived from the corpus created by Burger et al. (2011). Burger et al. observed that many Twitter users link their Twitter profile to homepages on popular blogging websites. Since “many of these [sites] have well-structured profile pages [where users] must select gender and other attributes from dropdown menus,” they were able to link these attributes to the Twitter users. Using this process, they created a large multi-lingual corpus of Twitter users and genders.

We filter non-English tweets from this corpus using the LID system of Bergsma et al. (2012) and also tweets containing URLs (since many of these are spam) and re-tweets. We then filter users with <40 tweets and randomly divide the remaining users into 2282 training, 1140 development, and 1141 test examples.

**Classifier Set-up** We train logistic-regression classifiers on this gold standard data via the LIBLINEAR package (Fan et al., 2008). We optimize the classifier’s regularization parameter on development data and report final results on the held-out test examples. We also report the results of

our new attribute-based strategies (Section 4) on the test data. We report *accuracy*: the percentage of examples labeled correctly.

Our classifiers use both *BoW* and *Usr* features (Section 2). To increase the generality of our *BoW* features, we preprocess the text by lower-casing and converting all digits to special ‘#’ symbols. We then create real-valued features that encode the *log*-count of each word in the input. While Burger et al. (2011) found “no appreciable difference in performance” when using either binary presence/absence features or encoding the frequency of the word, we found real-valued features worked better in development experiments. For the *Usr* features, we add special beginning and ending characters to the username, and then create features for all character n-grams of length two-to-four in the modified username string. We include n-gram features with the original capitalization pattern and separate features with the n-grams lower-cased.

**Unlabeled Data** For *Bootstrapped* training, we also use a pool of unlabeled Twitter data. This pool comprises the union of 2.2 billion tweets from 05/2009 to 10/2010 (O’Connor et al., 2010), 1.9 billion tweets collected from 07/2011 to 11/2012, and 80 million tweets collected from the followers of 10-thousand location and language-specific Twitter feeds. We filter this corpus as above, except we do not put any restrictions on the number of tweets needed per user. We also filter any users that overlap with our gold standard data.

**Bootstrapping Analysis** We apply our *Bootstrapped* auto-annotation strategy to this unlabeled data, yielding 789,285 auto-annotated examples of users and their tweets. The decisions of our bootstrapping process reflect the true gender distribution; the auto-annotated data is 60.5% **Female**, remarkably close to the 60.9% proportion in our gold standard test set. Figure 1 shows that a wide range of self-distinguishing attributes are used in the auto-annotation process. This is important because if only a few attributes are used (e.g. *wife/husband* or *penis/vagina*), we might systematically miss a segment of users (e.g. young people that don’t have husbands or wives, or people that don’t frequently talk about their genitalia). Thus a wide range of common-sense knowledge is useful for bootstrapping, which is one reason why automatic approaches are needed to acquire it.

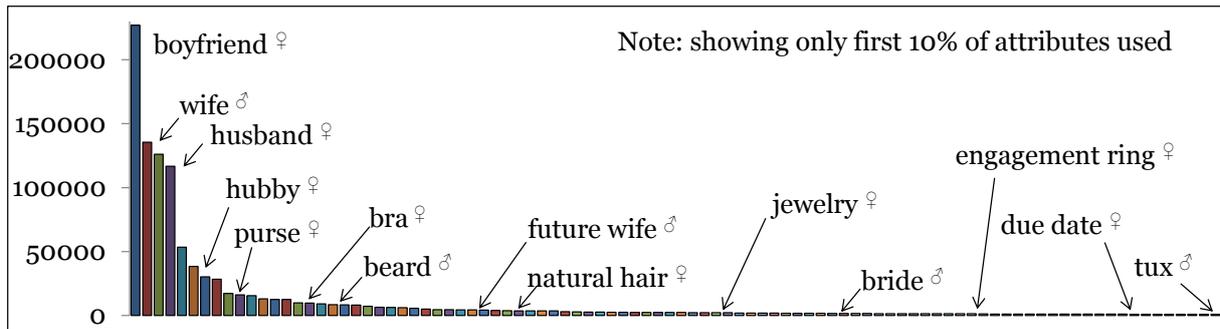

Figure 1: Frequency with which attributes are used to auto-annotate examples in the bootstrapping approach. The plot identifies some attributes and their corresponding class (labeled via gender symbol).

Majority-class baseline	60.9
Supervised on 100 examples	72.0
Supervised on 2282 examples	84.0
Supervised on 100 examples + <i>ARules</i>	74.7
Supervised on 2282 examples + <i>ARules</i>	84.7
<i>Bootstrapped</i>	86.0
<i>BootStacked</i>	<b>87.2</b>

Table 3: Classification accuracy (%) on gold standard test data for user gender prediction on Twitter

## 6 Results

Our main classification results are presented in Table 3. The majority-class baseline for this task is to always choose **Female**; this achieves an accuracy of 60.9%. A standard classifier trained on 100 gold-standard training examples improves over this baseline, to 72.0%, while one with 2282 training examples achieves 84.0%. This latter result represents the current state-of-the-art: a classifier trained on thousands of gold standard examples, making use of both *Usr* and *BoW* features. Our performance compares favourably to Burger et al. (2011), who achieved 81.4% using the same features, but on a very different subset of the data (also including tweets in other languages).<sup>7</sup>

Applying the *ARules* as a post-process significantly improves performance in both cases (McNemar’s,  $p < 0.05$ ). It is also possible to use the *ARules* as a stand-alone system rather than as a post-process, however the coverage is low: we find a distinguishing attribute in 18.3% of the 695 **Female** instances in the test data, and make the cor-

<sup>7</sup>Note that it is possible to achieve even higher performance on gender classification in social media if you have further information about a user, such as their full first and last name (Burger et al., 2011; Bergsma et al., 2013).

rect decision in 96.9% of these cases. We find a distinguishing attribute in 11.4% of the 446 **Male** instances, with 86.3% correct decisions.

The *Bootstrapped* system substantially improves over the state-of-the-art, achieving 86% accuracy and doing so *without using any gold standard training data*. This is important because having thousands of gold standard annotations for every possible user characterization task, in every domain and social media platform, is not realistic. Combining the bootstrapped classifier with the gold standard annotations in the *BootStacked* model results in further gains in performance.<sup>8</sup> These results provide strong validation for both the inherent utility of class-attributes knowledge in user characterization and the effectiveness of our specific strategies for exploiting such knowledge.

Figure 2 shows the learning curve of the *Bootstrapped* classifier. Performance rises consistently across all the auto-annotated training data; this is encouraging because there is theoretically no reason not to vastly increase the amount of auto-annotated data by collecting an even larger collection of tweets. Finally, note that most of the gains of the *Bootstrapped* system appear to derive from the tweet content itself, i.e. the *BoW* features. However, the *Usr* features are also helpful at most training sizes.

We provide some of the top-ranked features of the *Bootstrapped* system in Table 4. We see that a variety of other common-sense knowledge is learned by the system (e.g., the association between males and urinals, boxers, fatherhood, etc.), as well as stylistic clues (e.g. **Female** users using *betcha* and *xox* in their writing). The username

<sup>8</sup>We observed no further gains in accuracy when applying the *ARules* as a post-process on top of these systems.

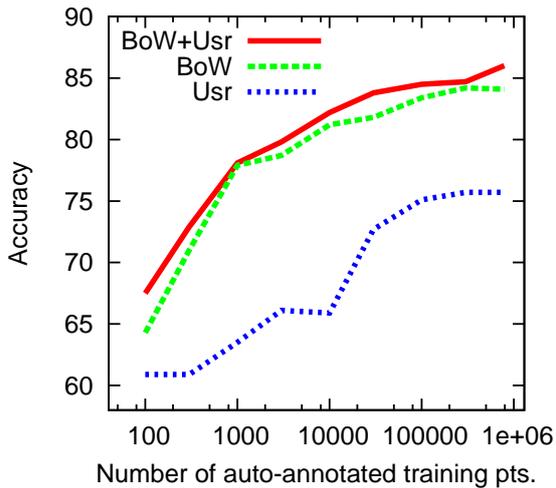

Figure 2: Learning curve for *Bootstrapped* logistic-regression classifier, with automatically-labeled data, for different feature classes.

features capture reasonable associations between gender classes and particular names (such as *mike*, *tony*, *omar*, etc.) and also between gender classes and common nouns (such as *guy*, *dad*, *sir*, etc.).

## 7 Related Work

**User Characterization** The field of sociolinguistics has long been concerned with how various morphological, phonological and stylistic aspects of language can vary with a person’s age, gender, social class, etc. (Fischer, 1968; Labov, 1972). This early work therefore had an emphasis on analyzing the *form* of language, as opposed to its *content*. This emphasis continued into early machine learning approaches, which predicted author properties based on the usage of function words, parts-of-speech, punctuation (Koppel et al., 2002) and spelling/grammatical errors (Koppel et al., 2005).

Recently, researchers have focused less on the sociolinguistic implications and more on the tasks themselves, naturally leading to classifiers with feature representations capturing content in addition to style (Schler et al., 2006; Garera and Yarowsky, 2009; Mukherjee and Liu, 2010). Our work represents a logical next step for content-based classification, a step partly suggested by Schler et al. (2006) who noted that “those who are interested in automatically profiling bloggers for commercial purposes would be well served by considering additional features - which we deliberately ignore in this study - such as author self-identification.”

**Male *BoW* features:** wife, wifey, sucked, shave, boner, boxers, missus, installed, manly, in-laws, brah, urinal, kickoff, golf, comics, ubuntu, homo, nhl, jedi, fatherhood, nigga, movember, algebra

**Male *Usr* features:** boy, mike, ben, guy, mr, dad, jr, kid, tony, dog, lord, sir, omar, dude, man, big

**Female *BoW* features:** hubby, hubs, jewelry, sewing, mascara, fabulous, bf, softball, betcha, motherhood, perky, cozy, zumba, xox, cuddled, belieber, bridesmaid, anorexic, jammies, pad

**Female *Usr* features:** mrs, mom, jen, lady, wife, mary, joy, mama, pink, kim, diva, elle, woma, ms

Table 4: Examples of highly-weighted *BoW* (content) and *Usr* (username) features (in descending order of weight) in the *Bootstrapped* system for predicting user gender in Twitter.

Many recent papers have analyzed the language of social media users, along dimensions such as ethnicity (Eisenstein et al., 2011; Rao et al., 2011; Pennacchiotti and Popescu, 2011; Fink et al., 2012) time zone (Kiciman, 2010), political orientation (Rao et al., 2010; Pennacchiotti and Popescu, 2011) and gender (Rao et al., 2010; Burger et al., 2011; Van Durme, 2012).

**Class-Attribute Extraction** The idea of using simple patterns to extract useful semantic relations goes back to Hearst (1992) who focused on hyponyms. Hearst reports that she “tried applying this technique to meronymy (i.e., the part/whole relation), but without great success.” Berland and Charniak (1999) did have success using Hearst-style patterns for part-whole detection, which they attribute to their “very large corpus and the use of more refined statistical measures for ranking the output.” Girju et al. (2006) devised a supervised classification scheme for part/whole relation discovery that integrates the evidence from multiple patterns. These efforts focused exclusively on the *meronymy* relation as used in WordNet (Miller et al., 1990). Indeed, Berland and Charniak (1999) attempted to filter out attributes that were regarded as *qualities* (like *driveability*) rather than parts (like *steering wheels*) by removing words ending with the suffixes *-ness*, *-ing*, and *-ity*. In our work, such qualities are not filtered and are ultimately valuable in classification; for example, the attributes *peak fertility* and *loveliness* are highly

associated with females.

As subsequent research became more focused on applications, looser definitions of class attributes were adopted. Almuhareb and Poesio (2004) automatically mined class attributes that include parts, qualities, and those with an “agentive” or “telic” role with the class. Their extended set of attributes was shown to enable an improved representation of nouns for the purpose of clustering these nouns into semantic concepts. Tokunaga et al. (2005) define attributes as properties that can serve as focus words in questions about a target class; e.g. *director* is an attribute of a *movie* since one might ask, “Who is the *director* of this *movie*?” Another line of research has been motivated by the observation that much of Internet search consists of people looking for *values* of various class attributes (Bellare et al., 2007; Paşca and Van Durme, 2007; Paşca and Van Durme, 2008; Alfonseca et al., 2010). By knowing the attributes of different classes, search engines can better recognize that queries such as “altitude guadalajara” or “population guadalajara” are seeking *values* for a particular city’s “altitude” and “population” *attributes* (Paşca and Van Durme, 2007). Finally, note that Van Durme et al. (2008) compared instance-based and class-based patterns for broad-definition attribute extraction, and found both to be effective.

Of course, text-mining with custom-designed patterns is not the only way to extract class-attribute information. Experts can manually specify the attributes of entities, as in the WordNet project (Miller et al., 1990). Others have automatically extracted attribute relations from dictionary definitions (Richardson et al., 1998), structured online sources such as Wikipedia infoboxes, (Wu and Weld, 2007) and large-scale collections of high-quality tabular web data (Cafarella et al., 2008). Attribute extraction has also been viewed as a sub-component or special case of the information obtained by general-purpose knowledge extractors (Schubert, 2002; Pantel and Pennacchiotti, 2006).

**NLP Applications of Common-Sense Knowledge** The kind of information derived from class-attribute extraction is sometimes referred to as a type of *common-sense knowledge*. The need for computer programs to represent common-sense knowledge has been recognized since the work of McCarthy (1959). Lenat et al. (1990)

defines common sense as “human consensus reality knowledge: the facts and concepts that you and I know and which we each assume the other knows.”

While we are the first to exploit common-sense knowledge in user characterization, common sense has been applied to a range of other problems in natural language processing. In many ways WordNet can be regarded as a collection of common-sense relationships. WordNet has been applied in a myriad of NLP applications, including in seminal works on semantic-role labeling (Gildea and Jurafsky, 2002), coreference resolution (Soon et al., 2001) and spelling correction (Budanitsky and Hirst, 2006). Also, many approaches to the task of sentiment analysis “begin with a large lexicon of words marked with their prior polarity” (Wilson et al., 2009). Like our class-attribute associations, the common-sense knowledge that the word *cool* is positive while *unethical* is negative can be learned from associations in web-scale data (Turney, 2002). We might also view information about *synonyms* or *conceptually-similar words* as a kind of common-sense knowledge. In this perspective, our work is related to recent work that has extracted distributionally-similar words from web-scale data and applied this knowledge in tasks such as named-entity recognition (Lin and Wu, 2009) and dependency parsing (Täckström et al., 2012).

## 8 Conclusion

We have proposed, developed and successfully evaluated a novel approach to user characterization based on exploiting knowledge of user class attributes. The knowledge is obtained using a new algorithm that discovers *distinguishing* attributes of particular classes. Our approach to discovering distinguishing attributes represents a significant new direction for research in class-attribute extraction, and provides a valuable bridge between the fields of user characterization and lexical knowledge extraction.

We presented three effective techniques for leveraging this knowledge within the framework of supervised user characterization: rule-based post-processing, a learning-by-bootstrapping approach, and a stacking approach that integrates the predictions of the bootstrapped system into a system trained on annotated gold-standard training data. All techniques lead to significant improve-

ments over state-of-the-art supervised systems on the task of Twitter gender classification.

While our technique has advanced the state-of-the-art on this important task, our approach may prove even more useful on other tasks where training on thousands of gold-standard examples is not even an option. Currently we are exploring the prediction of finer-grained user roles, such as *student*, *waitress*, *parent*, and so forth, based on extensions to the process laid out here.

## Abstract

With the increasing amount of user generated reference texts in the web, automatic quality assessment has become a key challenge. However, only a small amount of annotated data is available for training quality assessment systems. Wikipedia contains a large amount of texts annotated with cleanup templates which identify quality flaws. We show that the distribution of these labels is topically biased, since they cannot be applied freely to any arbitrary article. We argue that it is necessary to consider the topical restrictions of each label in order to avoid a sampling bias that results in a skewed classifier and overly optimistic evaluation results. We factor out the topic bias by extracting reliable training instances from the revision history which have a topic distribution similar to the labeled articles. This approach better reflects the situation a classifier would face in a real-life application.

## 1 Introduction

User generated content is the main driving force of the increasingly social web. Blogs, wikis and forums make up a large amount of the daily information consumed by web users. The main properties of user generated content are a low publication threshold and little or no editorial control, which leads to a high variance in quality. In order to navigate through large repositories of information efficiently and safely, users need a way to quickly assess the quality of the content. Automatic quality assessment has therefore become a key application in today's information society. However, there is a lack of training data annotated with fine-grained quality information.

Wikipedia, the largest encyclopedia on the web,

contains so-called cleanup templates, which constitute a sophisticated system of user generated labels that mark quality problems in articles. Recently, these cleanup templates have been used for automatically identifying articles with particular quality flaws in order to support Wikipedia's quality assurance process in Wikipedia. In a shared task (Anderka and Stein, 2012b), several systems have shown that it is possible to identify the ten most frequent quality flaws with high recall and fair precision.

However, quality flaw detection based on cleanup template recognition suffers from a topic bias that is well known from other text classification applications such as authorship attribution or genre identification. We discovered that cleanup templates have implicit topical restrictions, i.e. they cannot be applied to any arbitrary article. As a consequence, corpora of flawed articles based on these templates are biased towards particular topics. We argue that it is therefore not sufficient for evaluating a quality flaw prediction systems to measure how well they can separate (topically restricted) flawed articles from a set of random outliers. It is rather necessary to determine reliable negative instances with a similar topic distribution as the set of positive instances in order to factor out the sampling bias. Related studies (Brooke and Hirst, 2011) have proven that topic bias is a confounding factor that results in misleading cross-validated performance while allowing only near chance performance in practical applications.

We present an approach for factoring out the bias from quality flaw corpora by mining reliable negative instances for each flaw from the article revision history. Furthermore, we employ the article revision history to extract reliable positive training instances by using the version of each article at the time it has first been identified as flawed. This way, we avoid including articles with outdated cleanup templates, a frequent phe-

nomenon that can occur when a template is not removed after fixing a problem in an article. In our experiments, we focus on neutrality and style flaws, since they are of particular high importance within the Wikipedia community (Stvilia et al., 2008; Ferschke et al., 2012a) and are recognized beyond Wikipedia in applications such as uncertainty recognition (Szarvas et al., 2012) and hedge detection (Farkas et al., 2010).

## 2 Related Work

Topic bias is a known problem in text classification. Mikros and Argiri (2007) investigate the topic influence in authorship attribution. They found that even simple stylometric features, such as sentence and token length, readability measures or word length distributions show considerable correlations with topic. They argue that many features that were largely considered to be topic neutral are in fact topic-dependent variables. Consequently, results obtained on multitopic corpora are prone to be biased by the correlation of authors with specific topics. Therefore, several authors introduce topic-controlled corpora for applications such as author identification (Koppel and Schler, 2003; Luyckx and Daelemans, 2005) or genre detection (Finn and Kushmerick, 2006).

Brooke and Hirst (2011) measure the topic bias in the *International Corpus of Learner English* and found that it causes a substantial skew in classifiers for native language detection. In accordance with Mikros et al., the authors found that even non-lexicalized meta features, such as vocabulary size or length statistics, depend on topics and cause cross-validated performance evaluations to be unrealistically high. In a practical setting, these biased classifiers hardly exceed chance performance.

As already noted above, a similar kind of topic bias negatively influences quality flaw detection in Wikipedia. Anderka et al. (2012) automatically identify quality flaws by predicting the cleanup templates in unseen articles with a one-class classification approach. Based on this work, a competition on quality flaw prediction has been established (Anderka and Stein, 2012b). The winning team of the inaugural edition of the task was able to detect the ten most common quality flaws with an average  $F_1$ -Score of 0.81 using a PU learning approach (Ferretti et al., 2012). With a binary classification approach, Ferschke et

al. (2012b) achieved an average  $F_1$ -Score of 0.80, while reaching a higher precision than the winning team.

A closer examination of the aforementioned quality flaw detection systems reveals a systematic sampling bias in the training data, which leads to an overly optimistic performance evaluation and classifiers that are biased towards particular article topics. Our approach factors out the topic bias from the training data by mining topically controlled training instances from the Wikipedia revision history. The results show that flaw detection is a much harder problem in a real-life scenario.

## 3 Quality Flaws and Flaw Recognition in Wikipedia

Quality standards in Wikipedia are mainly defined by the *featured article criteria*<sup>1</sup> and the *Wikipedia Manual of Style*<sup>2</sup>. These policies define the characteristics excellent articles have to exhibit. Other sets of quality criteria are adaptations or relaxations of these standards, such as the *good article criteria* or the quality grading schemes of individual interest groups in Wikipedia.

In this work, we focus on quality flaws regarding neutrality and style problems. We chose these categories due to their high importance within the Wikipedia community (Stvilia et al., 2008; Ferschke et al., 2012a) and due to their relevance to content outside of Wikipedia, such as blogs or online news articles. According to the Wikipedia policies<sup>3</sup>, an article has to be written from a neutral point of view. Thus, authors must avoid stating opinions and seriously contested assertions as facts, avoid presenting uncontested factual assertions as mere opinions, prefer nonjudgmental language and indicate the relative prominence of opposing views. Furthermore, authors have to adhere to the stylistic guidelines defined in the Manual of Style. While this subsumes a broad range of issues such as formatting and article structure, we focus on the style of writing and disregard mere structural properties.

Any articles that violate these criteria can be marked with cleanup templates<sup>4</sup> to indicate their need for improvement. These templates can thus be regarded as proxies for quality flaws in Wikipedia.

	Flaw	Description	Articles	Templates
Neutrality	<b>Advert</b>	The article appears to be written like an advertisement and is thus not neutral	7,332	2
	<b>POV</b>	The neutrality of this article is disputed	5,086	10
	<b>Globalize</b>	The article may not represent a worldwide view of the subject	1,609	1
	<b>Peacock</b>	The article may contain wording that merely promotes the subject without imparting verifiable information	1,195	1
	<b>Weasel</b>	The article contains vague phrasing that often accompanies biased or unverifiable information	704	4
Style	<b>Tone</b>	The tone of the article is not encyclopedic according to the Wikipedia Manual of Style	4,563	6
	<b>In-universe</b>	The article describes a work or element of fiction in a primarily in-universe style <sup>a</sup>	2,227	1
	<b>Copy-edit</b>	The article requires copy editing for grammar, style, cohesion, tone, or spelling	1,954	6
	<b>Trivia</b>	Contains lists of miscellaneous information	1,282	2
	<b>Essay-like</b>	The article is written like a personal reflection or essay	1,244	1
	<b>Confusing</b>	The article may be confusing or unclear to readers	1,084	1
	<b>Technical</b>	The article may be too technical for most readers to understand	690	2

<sup>a</sup> According to the Wikipedia Manual of Style, an in-universe perspective describes the article subject matter from the perspective of characters within a fictional universe as if it were real.

Table 1: Neutrality and style flaw corpora used in this work

**Template Clusters** Since several cleanup templates might represent different manifestations of the same quality flaw, there is a *1 to n* relationship between quality flaws and cleanup templates. For instance, the templates `pov-check`<sup>5</sup>, `pov`<sup>6</sup> and `npov language`<sup>7</sup> can all be mapped to the same flaw concerning the neutral point of view of an article. This aggregation of cleanup templates into flaw-clusters is a subjective task. It is not always clear whether a particular template refers to an existing flaw or should be regarded as a separate class. Too many clusters will cause definition overlaps (i.e. similar cleanup templates are assigned to different clusters), while too few clusters will result in unclear flaw definitions, since each flaw receives a wide range of possible manifestations.

**Template Scope** Another important aspect to be considered is the difference in the scope which cleanup templates can have. *Inline-templates* are placed directly in the text and refer to the sentence or paragraph they are placed in. Templates with a *section* parameter, refer to the section they are placed in. The majority of templates, however, refer to a whole page. The consideration of the template scope is of particular importance for quality flaw recognition problems. For example, the presence of a cleanup template which marks a single section as *not notable* does not entail that the whole article is not notable.

<sup>5</sup>The article has been nominated for a neutrality check

<sup>6</sup>The neutrality of the article is disputed

<sup>7</sup>The article contains a non-neutral style of writing

**Topical Restriction** A final aspect that has not been taken into account by related work is that many cleanup templates have restrictions concerning the pages they may be applied to. A hard restriction is the page type (or namespace) a template might be used in. For example, some templates can only be used in articles while others can only be applied to discussion pages. This is usually enforced by maintenance scripts running on the Wikimedia servers. A soft restriction, on the other hand, are the topics of the articles a template can be used in. Many cleanup templates can only be applied to articles from certain subject areas. An example with a particularly obvious restriction is the template *in-universe* (see Table 1), which should only be applied to articles about fiction. This topical restriction is neither explicitly defined nor automatically enforced, but it plays an important role in the quality flaw recognition task, as the remainder of this paper will show. While flaws merely concerning the structural or linguistic properties of an article are less restricted to individual topics, they are still affected by a certain degree of *topical preference*. Many subject areas in Wikipedia are organized in *WikiProjects*<sup>8</sup>, which have their own ways of reviewing and ensuring quality within their topical scope. Depending on the quality assurance processes established in a WikiProject, different importance is given to individual types of flaws. Thus, the distribution of cleanup templates regarding structural or grammatical flaws is also biased towards certain topics.

<sup>8</sup><http://en.wikipedia.org/wiki/WP:PROJ>

We will henceforth subsume the concept of topical preference under the term topical restriction.

**Quality Flaw Recognition** Based on the above definition of quality flaws, we define the quality flaw recognition task similar to Anderka et al. (2012) as follows: Given a sample of articles in which each article has been tagged with any cleanup template  $\tau_i$  from a specific template cluster  $T_f$  thus marking all articles in the sample with a quality flaw  $f$ , it has to be decided whether or not an unseen article suffers from  $f$ .

#### 4 Data Selection and Corpus Creation

For creating our corpora, we start with selecting all cleanup templates listed under the categories *neutrality* and *style* in the typology of cleanup templates provided by Anderka and Stein (2012a). Each of the selected templates serves as the nucleus of a template cluster that potentially represents a quality flaw. To each cluster, we add all templates that are synonymous to the nucleus. The synonyms are listed in the template description under *redirects* or *shortcuts*. Then we iteratively add all synonyms of the newly added template until no more redirects can be found. Furthermore, we manually inspect the lists of similar templates in the *see also* sections of the template descriptions and include all templates that refer to the same concept as the other templates in the cluster. As mentioned earlier, this is a subjective task and largely depends on the desired granularity of the flaw definitions. We finally merge semantically similar template clusters to avoid too fine grained flaw distinctions.

As a result, we obtain a total number of 94 template clusters representing 60 style flaws and 34 neutrality flaws. From each of these clusters, we remove templates with inline or section scope due to the reasons outlined in Section 3. We also remove all templates that are restricted to pages other than articles (e.g. discussion or user pages).

We use the Java Wikipedia Library (Zesch et al., 2008) to extract all articles marked with the selected templates. We only regard flaws with at least 500 affected articles in the snapshot of the English Wikipedia from January 4, 2012. Table 1 lists the final sets of flaws used in this work. For each flaw, the nucleus of the template cluster is provided along with a description, the number of affected articles, and the cluster size. We make the corpora freely available for down-

Flaw	$\kappa$	$F_1$
Advert	.60	.80
Confusing	.60	.80
Copy-edit	.00	.50
Essay-like	.60	.80
Globalize:	.60	.80
In-universe	.80	.90
Peacock	.70	.84
POV	.60	.80
Technical	.90	.95
Tone	.40	.70
Trivia	.20	.60
Weasel	.50	.74

Table 2: Agreement of human annotator with gold standard

load under <http://www.ukp.tu-darmstadt.de/data/wiki-flaws/>.

#### Agreement with Human Rater

Quality flaw detection in Wikipedia is based on the assumption that cleanup templates are valid markers of quality flaws. In order to test the reliability of these user assigned templates as quality flaw markers, we carried out an annotation study in which a human annotator was asked to perform the binary flaw detection task manually. Even though the human performance does not necessarily provide an upper boundary for the automatic classification task, it gives insights into potentially problematic cases and ill-defined annotations. The annotator was provided with the template definitions from the respective template information page as instructions. For each of the 12 article scope flaws, we extracted the plain text of 10 random flawed articles and 10 random untagged articles. The annotator had to decide for each flaw individually whether a given text belonged to a flawed article or not. She was not informed about the ratio of flawed to untagged articles.

Table 2 lists the chance corrected agreement (Cohen’s  $\kappa$ ) along with the  $F_1$  performance of the human annotations against the gold standard corpus. The templates *copy-edit* and *trivia* yielded the lowest performance in the study. Even though *copy-edit* templates are assigned to whole articles, they refer to grammatical and stylistic problems of relatively small portions of the text. This increases the risk of overlooking a problematic span of text, especially in longer articles. The *trivia* template, on the other hand, designates sections that contain miscellaneous information that are not well integrated in the article. Upon manual inspection, we found a wide range of possible manifestations of

this flaw ranging from an agglomeration of incoherent factoids to well-structured sections that did not exactly match the focus of the article, which is the main reason for the low agreement.

## 5 Selection of Reliable Training Instances

Independent from the classification approach used to identify flawed articles, reliable training data is the most important prerequisite for good predictions. On the one hand, we need a set of examples that reliably represent a particular flaw, while on the other hand, we need counterexamples which reliably represent articles that do not suffer from the same flaw. The latter aspect is most important for discriminative classification approaches, since they rely on negative instances for training the classifier. However, reliable negative instances are also important for one-class classification approaches, since it is only for the counterexamples (or outliers) that the performance of one-class classifiers can be sufficiently evaluated. It is furthermore important that the positive and the negative instances do not differ *systematically* in any respect other than the presence or absence of the respective flaws, since any systematic difference will bias the classifier. In this context, the topical restrictions of cleanup templates have to be taken into account. In the following, we describe our approach to extracting reliable training instances from the quality flaw corpora.

### 5.1 Reliable Positives

In previous work, the latest available versions of flawed articles have been used as positive training instances. However, we found upon manual inspection of the data that a substantial number of articles has been significantly edited between the time  $t_\tau$ , at which the template was first assigned, and the time  $t_e$ , at which the articles have been extracted. Using the latest version at time  $t_e$  can thus include articles in which the respective flaw has already been fixed without removing the cleanup template. Therefore, we use the revision of the article at time  $t_\tau$  to assure that the flaw is still present in the training instance.

We use the Wikipedia Revision Toolkit (Ferschke et al., 2011), an enhancement of the Java Wikipedia Library, to gain access to the revision history of each article. For every article in the corpus of positive examples for flaw  $f$  that is marked

with template  $\tau \in T_f$ , we backtrack the revision history chronologically, until we find the first revision  $r_{t_{\tau-1}}$  that is not tagged with  $\tau$ . We then add the succeeding revision  $r_{t_\tau}$  to the corpus of reliable positives for flaw  $f$ . In Section 6, we show that the classification performance improves for most flaws when using reliable positives instead of the latest available article versions.

### 5.2 Reliable Negatives and Topical Restriction

A central problem of the quality flaw recognition approach is the fact that there are no articles available that are tagged to not contain a particular quality problem. So far, two solutions to this issue have been proposed in related work. Anderka et al. (2012) tackle the problem with a one-class classifier that is trained on the positive instances alone thus eradicating the need for negative instances in the training phase. However, in order to evaluate the classifier, a set of outliers is needed. The authors circumvent this issue by evaluating their classifiers on a set of random untagged instances and a set of featured articles and argue that the actual performance of predicting the quality flaws lies between the two.

Ferretti et al. (2012) follow a two step classification approach (PU learning) that first uses a Naive Bayes classifier trained on positive instances and random untagged articles to pre-classify the data. In a second phase, they use the negatives identified by the Naive Bayes classifier to train a Support Vector Machine that produces the final predictions. Even though the Naive Bayes classifier was supposed to identify reliable negatives, the authors found no significant improvement over a random selection of negative instances, which effectively renders the PU learning approach redundant.

None of the above approaches consider the issue of topical restriction mentioned in Section 3, which introduces a systematic bias to the data. Both approaches sample random negative instances  $A_{rnd}$  for any given set of flawed articles  $A_f$  from a set of untagged articles  $A_u$  (see Fig. 1a). In order to factor out the article topics as a major characteristic for distinguishing flawed articles from the set of outliers, reliable negative instances  $A_{rel}$  have to be sampled from the restricted topic set  $A_{topic}$  that contains articles with a topic distribution similar to the flawed articles in  $A_f$  (see Fig. 1b). This will avoid the systematic bias and

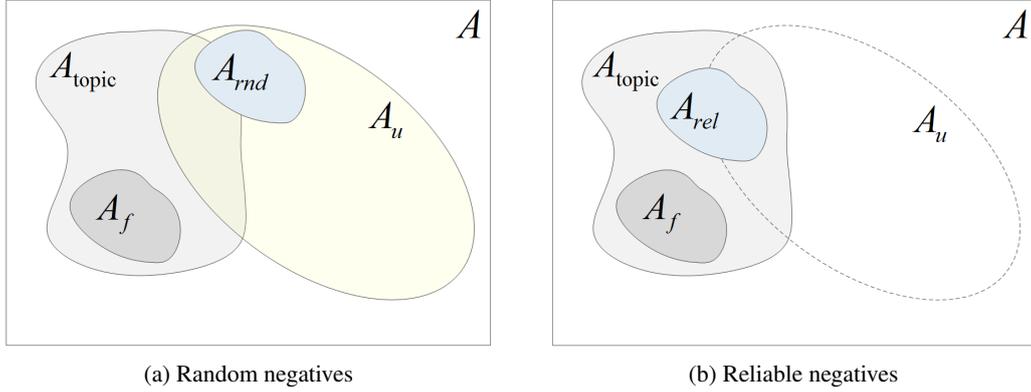

Figure 1: Sampling of negative instances for a given set of flawed articles ( $A_f$ ). Random negatives ( $A_{rnd}$ ) are sampled from articles without any cleanup templates ( $A_u$ ). Reliable negatives ( $A_{rel}$ ) are sampled from the set of articles ( $A_{topic}$ ) with the same topic distribution as  $A_f$

result in a more realistic performance evaluation.

In the following, we present our approach to extracting reliable negative training instances that conform with the topical restrictions of the cleanup templates. Without loss of generality, we assume that an article, from which a cleanup template  $\tau \in T_f$  is deleted at a point in time  $d_\tau$ , the article no longer suffers from flaw  $f$  at that point in time. Thus, the revision  $r_{d_\tau}$  is a reliable *negative instance* for the flaw  $f$ . Additionally, since the article was once tagged with  $\tau \in T_f$ , it belongs to the the same restricted topic set  $A_{topic}$  as the positive instances for flaw  $f$ .

We use the *Apache Hadoop*<sup>9</sup> framework and *WikiHadoop*<sup>10</sup>, an input format for Wikipedia XML dumps, for crawling the whole revision history of the English Wikipedia on a compute cluster. WikiHadoop allows each Hadoop mapper to receive adjacent revision pairs, which makes it possible to compare the changes made from one revision to the next. For every template  $\tau \in T_f$ , we extract all adjacent revision pairs  $(r_{d_\tau-1}, r_{d_\tau})$ , in which the first revision contains  $\tau$  and the second does not contain  $\tau$ . Since there are occasions in which a template is replaced by another template from the same cluster, we ensure that  $r_{d_\tau}$  does also not contain any other template from cluster  $T_f$  before we finally add the revision to the set of reliable negatives for flaw  $f$ .

In the remainder of this section, we evaluate the topical similarity between the positive and the negative set of articles for each flaw using both our method and the original approach. In Wikipedia,

the topic of an article is captured by the categories assigned to it. In order to compare two sets of articles with respect to their topical similarity, we represent each article set as a category frequency vector. Formally, we calculate for each set the vector  $\vec{C} = (w_{c_1}, w_{c_2}, \dots, w_{c_n})$  with  $w_{c_i}$  being the weight of category  $c_i$ , i.e. the number of times it occurs in the set, and  $n$  being the total number of categories in Wikipedia. We can then estimate the topical similarity of two article sets by calculating the cosine similarity of their category frequency vectors  $\vec{C}_1 := A$  and  $\vec{C}_2 := B$  as

$$\text{sim}(A, B) = \frac{A \cdot B}{\|A\| \|B\|} = \frac{\sum_{i=1}^n A_i \times B_i}{\sqrt{\sum_{i=1}^n (A_i)^2} \times \sqrt{\sum_{i=1}^n (B_i)^2}}$$

Table 3 gives an overview of the similarity scores between each positive training set and the corresponding reliable negative set as well as between each positive set and a random set of untagged articles. We can see that the topics of articles in the positive training sets are highly similar to the topics of the corresponding reliable negative articles while they show little similarity to the articles in the random set. This implies that the systematic bias introduced by the topical restriction has largely been eradicated by our approach.

Individual flaws have differently strong topical restrictions. The strength of this restriction depends on the size of  $A_{topic}$ . That is, a flaw such as *in-universe* is restricted to a very narrow selection of articles, while a flaw such as *copy edit* can be applied to most articles and rather shows a topical preference due to reasons outlined in Section 3. It

is therefore to be expected that that flaws with a small  $A_{topic}$  are more prone to the topic bias.

## 6 Experiments

In the following, we describe our system architecture and the setup of our experiments. Our system for quality flaw detection follows the approach by Ferschke et al. (2012b), since it has been particularly designed as a modular system based on the Unstructured Information Management Architecture<sup>11</sup>, which makes it easy to extend. Instead of using *Mallet* (McCallum, 2002) as a machine learning toolkit, we employ the *Weka Data Mining Software* (Hall et al., 2009) for classification, since it offers a wider range of state-of-the-art machine learning algorithms. For each of the 12 quality flaws, we employ three different dataset configurations. The BASE configuration uses the newest version of each flawed article as positive instances and a random set of untagged articles as negative instances. The RELP configuration uses reliable positives, as described in Section 5.1, in combination with random outliers. Finally, the RELALL configuration employs reliable positives in combination with the respective reliable negatives as described in Section 5.2.

### Features

An extensive survey of features for quality flaw recognition has been provided by Anderka et al. (2012). We selected a subset of these features for our experiments and grouped them into four feature sets in order to determine how well different combinations of features perform in the task.

Table 4: Feature sets used in the experiments

Table 4 lists all feature types used in our experiments.

Since the feature space becomes large due to the ngram features, we prune it in two steps. First, we filter the ngrams according to their document frequency in the training corpus. We discard all ngrams that occur in less than  $x\%$  and more than  $y\%$  of all documents. Several values for  $x$  and  $y$  have been evaluated in parameter tuning experiments. The best results have been achieved with  $x=2$  and  $y=90$ . In a second step, we apply the Information Gain feature selection approach (Mitchell, 1997) to the remaining set to determine the most useful features.

### Learning Algorithms

We evaluated several learning algorithms from the Weka toolkit with respect to their performance on

Algorithm	Average $F_1$
<b>SVM RBF Kernel</b>	<b>0.82</b>
AdaBoost (decision stumps)	0.80
SVM Poly Kernel	0.79

Naive Bayes	0.72
MultiBoostAB (decision stumps)	0.71
Logistic Regression	0.60
LibSVM One Class	0.67

Table 5: Average  $F_1$ -scores over all flaws on RELP using all features

the quality flaw recognition task. Table 5 shows the average  $F_1$ -score of each algorithm on the RELP dataset using all features. The performance has been evaluated with 10-fold cross validation on 2,000 documents split equally into positive and negative instances. One class classifiers are trained on the positive instances alone. We determined the best parameters for each algorithms in a parameter optimization run and list the results of the best configuration.

Overall, Support Vector Machines with RBF kernels yielded the best average results and outperformed the other algorithms on every flaw. We used a sequential minimal optimization (SMO) algorithm (Platt, 1998) to train the SVMs and used different  $\gamma$ -values for the RBF kernel function. In contrast to Ferretti et al. (2012), we did not see significant improvements when optimizing  $\gamma$  for each individual flaw, so we determined one best setting for each dataset. Since SVMs with RBF kernels are a special case of RBF networks that fit a single basis function to the data, we also used general RBF networks that can employ multiple basis functions, but we did not achieve better results with that approach.

One-class classification, as proposed by Anderka et al. (2012), did not perform well within our setup. Even though we used an out-of-the-box one class classifier, we achieve similar results as Anderka et al. in their pessimistic setting, which best resembles our configuration. However, the performance still lacks behind the other approaches in our experiments. The best performing algorithm reported by Ferschke et al. (2012b), AdaBoost with decision stumps as a weak learner, showed the second best results in our experiments.

## 7 Evaluation and Discussion

The SVMs achieve a similar cross-validated performance on all feature sets containing ngrams, showing only minor improvements for individual flaws when adding non-lexical features. This suggests that the classifiers largely depend on the ngrams and that other features do not contribute significantly to the classification performance. While structural quality flaws can be well captured by special purpose features or intentional modeling, as related work has shown, more subtle content flaws such as the neutrality and style flaws are mainly captured by the wording itself. Textual features beyond the ngram level, such as syntactic and semantic qualities of the text, could further improve the classification performance of these flaws and should be addressed in future work. Table 6 shows the performance of the SVMs with RBF kernel<sup>12</sup> on each dataset using the *NGRAM* feature set. The average performance based on *NOWIKI* is slightly lower while using *ALL* features results in slightly higher average  $F_1$ -scores. However, the differences are not statistically significant and thus omitted. Classifiers using the *NONGRAM* feature set achieved average  $F_1$ -scores below 0.50 on all datasets. The results have been obtained by 10-fold cross validation on 2,000 documents per flaw.

The classifiers trained on reliable positives and random untagged articles (RELP) outperform the respective classifiers based on the BASE dataset for most flaws. This confirms our original hypothesis that using the appropriate revision of each tagged article is superior to using the latest available version from the dump. The performance on the RELALL dataset, in which the topic bias has been factored out, yields lower  $F_1$ -scores than the two other approaches. Flaws that are restricted to a very narrow set of topics (i.e.  $A_{topic}$  in Fig. 1b is small), such as the *in-universe* flaw, show the biggest drop in performance. Since the topic bias plays a major role in the quality flaw detection task, as we have shown earlier, the topic-controlled classifier cannot take advantage of the topic information, while the classifiers trained on the other corpora can make use of these characteristic as the most discriminative features. In the RELALL setting, however, the differences between the positive and negative instances are largely determined by the flaws alone. Classifiers trained on

<sup>12</sup> $\gamma=0.01$  for BASE,RELp and  $\gamma=0.001$  for RELALL

such a dataset therefore come closer to recognizing the actual quality flaws, which makes them more useful in a practical setting despite lower cross-validated scores.

In addition to cross-validation, we performed a cross-corpus evaluation of the classifiers for each flaw. Therefore, we evaluated the performance of the unbiased classifiers (trained on RELALL) on the biased data (RELP) and vice versa. Hereby, the positive training and test instances remain the same in both settings, while the unbiased data contains negative instances sampled from  $A_{rel}$  and the unbiased data from  $A_{rnd}$  (see Figure 1). With the *NGRAM* feature set, the reliable classifiers outperformed the unreliable classifiers on all flaws that can be well identified with lexical cues, such as *Advert* or *Technical*. In the biased case, we found both topic related and flaw specific ngrams among the most highly ranked ngram features. In the unbiased case, most of the informative ngrams were flaw specific expressions. Consequently, biased classifiers fail on the unbiased dataset in which the positive and negative class are sampled from the same topics, which renders the highly ranked topic ngrams unusable. Flaws that do not largely rely on lexical cues, however, cannot be predicted more reliably with the unbiased classifier. This means that additional features are needed to describe these flaw. We tested this hypothesis by using the full feature set *ALL* and saw a substantial improvement on the side of the unbiased classifier, while the performance of the biased classifier remained unchanged.

A direct comparison of our results to related work is difficult, since neutrality and style flaws have not been targeted before in a similar manner. However, the *Advert* flaw was also part of the ten flaw types in the PAN Quality Flaw Recognition Task (Anderka and Stein, 2012b). The best system achieved an  $F_1$  score of 0.839, which is just below the results of our system on the BASE dataset, which is similar to the PAN setup.

## 8 Conclusions

We showed that text classification based on Wikipedia cleanup templates is prone to a topic bias which causes skewed classifiers and overly optimistic cross-validated evaluation results. This bias is known from other text classification applications, such as authorship attribution, genre detection and native language detection. We demon-

strated how to avoid the topic bias when creating quality flaw corpora. Unbiased corpora are not only necessary for training unbiased classifiers, they are also invaluable resources for gaining a deeper understanding of the linguistic properties of the flaws. Unbiased classifiers reflect much better the performance of quality flaw recognition “in the wild”, because they detect actual flawed articles rather than identifying the articles that are prone to certain quality due to their topic or subject matter. In our experiments, we presented a system for identifying Wikipedia articles with style and neutrality flaws, a novel category of quality problems that is of particular importance within and outside of Wikipedia. We showed that selecting a reliable set of positive training instances mined from the revision history improves the classification performance. In future work, we aim to extend our quality flaw detection system to not only find articles that contain a particular flaw, but also to identify the flaws within the articles, which can be achieved by leveraging the positional information of in-line cleanup templates.

## Abstract

We address the problem of informal word recognition in Chinese microblogs. A key problem is the lack of word delimiters in Chinese. We exploit this reliance as an opportunity: recognizing the relation between informal word recognition and Chinese word segmentation, we propose to model the two tasks jointly. Our joint inference method significantly outperforms baseline systems that conduct the tasks individually or sequentially.

## 1 Introduction

User generated content (UGC) – including microblogs, comments, SMS, chat and instant messaging – collectively referred to as *microtext* by Gouwset *et al.* (2011) or *network informal language* by Xia *et al.* (2005), is the hallmark of the participatory Web.

While a rich source that many applications are interested in mining for knowledge, microtext processing is difficult to process. One key reason for this difficulty is the ubiquitous presence of informal words – anomalous terms that manifest as *ad hoc* abbreviations, neologisms, unconventional spellings and phonetic substitutions. Such informality is often present in oral conversation, and user-generated microblogs reflect this informality. Natural language processing (NLP) tools largely fail to work properly on microtext, as they have largely been trained on formally written text (i.e., newswire). Recent work has started to address these shortcomings (Xia and Wong, 2006; Kobus *et al.*, 2008; Han and Baldwin, 2011). Informal words and their usage in microtext evolves quickly, following social trends and news events.

\*This research is supported by the Singapore National Research Foundation under its International Research Centre @ Singapore Funding Initiative and administered by the IDM Programme Office.

These characteristics make it difficult for lexicographers to compile lexica to keep with the pace of language change.

We focus on this problem in the Chinese language. Through our analysis of a gathered Chinese microblog corpus, we observe that Chinese informal words originate from three primary sources, as given in Table 1.

But unlike noisy words in English, Chinese informal words are more difficult to mechanically recognize for two critical reasons: first, Chinese does not employ word delimiters; second, Chinese informal words combine numbers, alphabetic letters and Chinese characters. Techniques for English informal word detection that rely on word boundaries and informal word orthography need to be adapted for Chinese. Consider the microtext “不要剧透了” (meaning “Don’t tell me the spoilers (to a movie or joke)”, also in Table 1). If “不要” (“don’t”) and “了” (past tense marker) are correctly recognized as two words, we may predict the previously unseen characters “剧透” (“tell spoilers”) as an informal word, based on the learned Chinese language patterns. However, state-of-the-art Chinese segmenters<sup>1</sup> incorrectly yield “不要\_剧\_透了”, preferring to chunk “透了” (“thoroughly”) as a word, as they do not consider the possibility that “剧透” (“spoiler”) could be an informal word. This example illustrates the mutual dependency between Chinese word segmentation (henceforth, CWS) and informal word recognition (IWR) that should be solved jointly.

Hence, rather than pipeline the two processes serially as previous work, we formulate it as a two-layer sequential labeling problem. We employ factorial conditional random field (FCRF) to solve both CWS and IWR jointly. To our best knowledge, this is the first work that shows how Chinese microtext can be analyzed from raw text to

<sup>1</sup><http://www.ictclas.org/index.html>

Table 1: Our classification of Chinese informal words as originating from three primary sources. For **Phonetic Substitutions**, pronunciation is indicated by the phonetic Pinyin transcription system.

	Informal Word	Formal Word	Example Sentence	English Translation
1) Phonetic Substitutions	木有(mu4 you3)	没有(me1 you3)	开发区木有出租车	No taxi in the development area
	孩纸们(hai2 zhi3 men)	孩子们(hai2 zi men)	起床了孩纸们	Get up kids
2) Abbreviation	bs	鄙视(bi shi)	我bs你	I despise you
	桌游	桌面游戏	来桌游吧	Let's play board games
3) Neologisms	剧透	剧情透露	不要剧透了	Don't tell (me) the spoilers
	给力	很棒	真给力啊	So awesome!
	秒杀	迅速购买	速度秒杀它	Quickly purchase it

derive joint solutions for both problems of CWS and IWR. We also propose novel features for input to the joint inference. Our techniques significantly outperform both research and commercial state-of-the-art for these problems, including two-step linear CRF baselines which perform the two tasks sequentially.

We detail our methods in Section 2. In Section 3, we first describe the details of our dataset and baseline systems, followed by demonstrating two sets of experiments for CWS and IWR, respectively. Section 4 offers the discussion on error analysis and limitations. We discuss related work in Section 5, before concluding our paper.

## 2 Methodology

Given an input Chinese microblog post, our method simultaneously segments the sentences into words (the Chinese Word Segmentation, CWS, task), and marks the component words as informal or formal ones (the Informal Word Recognition, IWR, task).

### 2.1 Problem Formalization

The two tasks are simple to formalize. The IWR task labels each Chinese character with either an **F** (part of a formal word) or **IF** (informal word). For the CWS task, we follow the widely-used **BIES** coding scheme (Low et al., 2005; Hai et al., 2006), where **B**, **I**, **E** and **S** stand for *beginning of a word*, *inside a word*, *end of a word* and *single-character word*, respectively. As a result, we have two (hidden) labels to associate with each (observable) character. Figure 1 illustrates an example microblog post graphically, where the labels are in circles and the observations are in squares. The two informal words in the example post are “木有” (normalized form: “没有”; English gloss: “no”) and “rp” (“人品值”; “luck”).

### 2.2 Conditional Random Field Models

Given the general performance and discriminative framework, Conditional Random Fields (CRFs) (Lafferty et al., 2001) is a suitable framework for tackling sequence labeling problems. Other alternative frameworks such as Markov Logic Networks (MLNs) and Integer Linear Programming (ILP) could also be considered. However, we feel that for this task, formulating efficient global formulas (constraints) for MLN (ILP) is comparatively less straightforward than in other tasks (e.g. compared to Semantic Role Labeling, where the rules may come directly from grammatical constraints). CRFs represent a basic, simple and well-understood framework for sequence labeling, making it a suitable framework for adapting to perform joint inference.

#### 2.2.1 Linear-Chain CRF

A linear-chain CRF (LCRF; Figure 2a) predicts the output label based on feature functions provided by the scientist on the input. In fact, the LCRF has been used for the exact problem of CWS (Sun and Xu, 2011), garnering state-of-the-art performance, and as such, validate it as a strong baseline for comparison.

#### 2.2.2 Factorial CRF

To properly model the interplay between the two sub-problems, we employ the factorial CRF (FCRF) model, which is based on the dynamic CRF (DCRF) (Sutton et al., 2007). By introducing a pairwise factor between different variables at each position, the FCRF model results as a special case of the DCRF. A FCRF captures the joint distribution among various layers and jointly predicts across layers. Figure 2 illustrates both the LCRF and FCRF models, where cliques include within-chain edges (e.g.,  $y_t, y_{t+1}$ ) in both LCRF and FCRF models, and the between-chain edges (e.g.,  $y_t, z_t$ ) only in the FCRF.

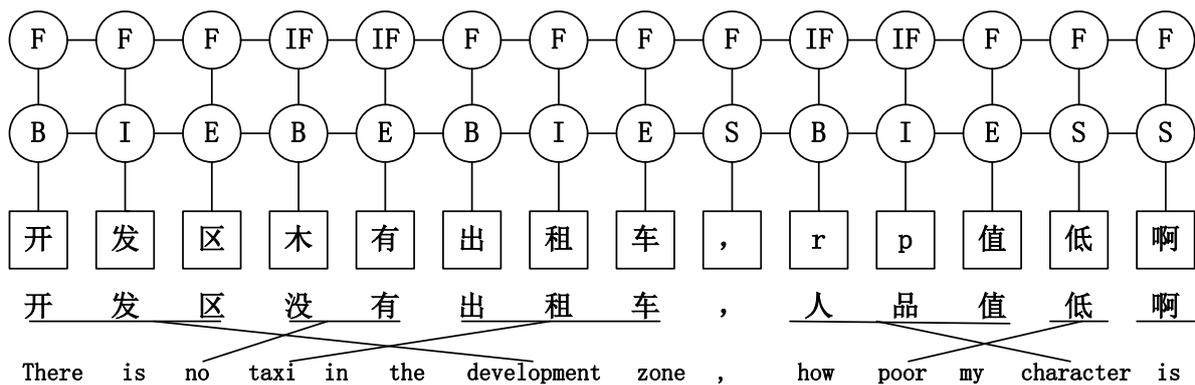

Figure 1: A Chinese microtext (bottom layer) with annotations for IWR (top layer) and CWS (middle layer). The bottom three lines give the normalized Chinese form, its pronunciation in Pinyin and aligned English translation.

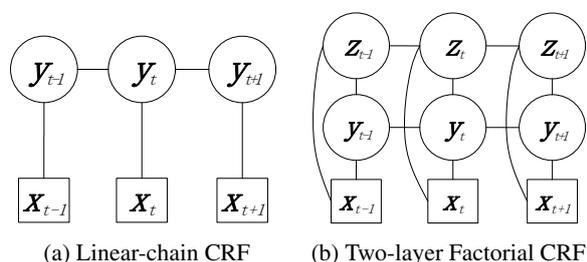

Figure 2: Graphical representations of the two types of CRFs used in this work.  $y_t$  denotes the 1<sup>st</sup> layer label,  $z_t$  denotes the 2<sup>nd</sup> layer label, and  $x_t$  denotes the observation sequence.

Although the FCRF can be collapsed into a LCRF whose state space is the cross-product of the outcomes of the state variables (i.e., 8 labels in this case), Sutton *et al.* (2007) noted that such a LCRF requires not only more parameters in the number of variables, but also more training data to achieve equivalent performance with an FCRF. Given the limited scale of the state space and training data, we follow the FCRF model, using exact Junction Tree (Jensen, 1996) inference and decoding algorithm to perform prediction.

### 2.3 CRF Features

We use three broad feature classes – lexical, dictionary-based and statistical features – aiming to distinguish the output classes for the CWS and IRW problems. Character-based sequence labeling is employed for word segmentation due to its simplicity and robustness to the unknown word problem (Xue, 2003).

A key contribution of our work is also to propose novel features for joint inference. We

propose new features for the dictionary-based and statistical feature classes, which we have marked in the discussion below with “(\*)”. We later examine their efficacy in Section 3.

**Lexical Features.** As a foundation, we employ lexical (n-gram) features informed by the previous state-of-the-art for CWS (Sun and Xu, 2011; Low *et al.*, 2005). These features are listed below<sup>2</sup>:

- Character 1-gram:  $C_k(i - 4 < k < i + 4)$
- Character 2-gram:  $C_k C_{k+1}(i - 4 < k < i + 3)$
- Character 3-gram:  $C_k C_{k+1} C_{k+2}(i - 3 < k < i + 2)$
- Character lexicon:  $C_{-1} C_1$   
This feature is used to capture the common indicators in Chinese interrogative sentences. (e.g., “是不是” (“whether or not”), “好不好” (“OK or not”))
- Whether  $C_k$  and  $C_{k+1}$  are identical, for  $i - 4 < k < i + 3$ .  
This feature is used to capture the words of employing character doubling in Chinese. (e.g., “拜拜” (“see you”), “天天” (“every day”))

**Dictionary-based Features.** We use features that indicate whether the input character sequence

<sup>2</sup>For notational convenience, we denote a candidate character token  $C_i$  as having a context  $\dots C_{i-1} C_i C_{i+1} \dots$ . We use  $C_{m:n}$  to express a subsequence starting at the position  $m$  and ending at  $n$ .  $len$  stands for the length of the subsequence, and  $offset$  denotes the position offset of  $C_{m:n}$  from the current character  $C_i$ . We use  $b$  (beginning),  $m$  (middle) and  $e$  (ending) to indicate the position of  $C_k$  ( $m \leq k \leq n$ ) within the string  $C_{m:n}$ .

matches entries in certain lexica. We use the on-line dictionary from Peking University as the formal lexicon and the compiled informal word list from our training instances as the informal lexicon. In addition, we employ additional online word lists<sup>3</sup> to distinguish named entities and function words from potential informal words.

As shown in Table 1, alphabetic sequences in microblogs may refer to Chinese Pinyin or Pinyin abbreviations, rather than English (e.g., “*bs*” for *bi shi*; “to despise”). Hence, we added dictionary-based features to indicate the presence of Pinyin initials, finals and standard Pinyin expansions, using a UK English word list<sup>4</sup>. The final list of dictionary-based features employed are:

- If  $C_k (i - 4 < k < i + 4)$  is a surname:  
*Surname@k*
- (\*) If  $C_k (i - 4 < k < i + 4)$  is a stop word:  
*StopW@k*
- (\*) If  $C_k (i - 4 < k < i + 4)$  is a noun-suffix:  
*NSuffix@k*
- (\*) If  $C_k (i - 4 < k < i + 4)$  is a Pinyin Initial: *Initial@k*
- (\*) If  $C_k (i - 4 < k < i + 4)$  is a Pinyin Final: *Final@k*
- If  $C_k (i - 4 < k < i + 4)$  is a English letter:  
*En@k*
- If  $C_{m:n} (i - 4 < m < n < i + 4, 0 < n - m < 5)$  matches one entry in the Peking University dictionary:  
*FW@m:n; len@offset; FW-C\_k@b-offset, FW-C\_k@n-offset or FW-C\_k@e-offset*
- (\*) If  $C_{m:n} (i - 4 < m < n < i + 4, 0 < n - m < 5)$  matches one entry in the informal word list:  
*IFW@m:n; len@offset; IFW-C\_k@b-offset, IFW-C\_k@n-offset or IFW-C\_k@e-offset*
- (\*) If  $C_{m:n} (i - 4 < m < n < i + 4, 0 < n - m < 5)$  matches one entry in the valid Pinyin list:  
*PY@m:n; len@offset; PY-C\_k@b-offset, PY-C\_k@n-offset or PY-C\_k@e-offset*

**Statistical Features.** We use pointwise mutual information (PMI) variant (Church and Hanks,

<sup>3</sup>Resources are available at <http://www.sogou.com/labs/resources.html>

<sup>4</sup><http://www.bckelk.uklinux.net/menu.html>

1990) to account for global, corpus-wide information. This measures the difference between the observed probability of an event (i.e., several characters combined as an informal word) and its expectation, based on the probabilities of the individual events (i.e., the probability of the individual characters occurring in the corpus). Compared with other standard association measures such as MI, PMI tends to assign rare events higher scores. This makes it a useful signal for IWR, as it is sensitive to informal words which often have low frequency. However, the word frequency alone is not reliable enough to distinguish informal words from uncommon but formal words.

In response to these difficulties in differentiating linguistic registers, we compute two different PMI scores for character-based bigrams from two large corpora representing news and microblogs as features. We also use the difference between the two PMI scores as a differential feature. In addition, we also convert all the character-based bigrams into Pinyin-based bigrams (ignoring tones<sup>5</sup>) and compute the Pinyin-level PMI in the same way. These features capture inconsistent use of the bigram across the two domains, which assists to distinguish informal words. Note that we eschew smoothing in our computation of PMI, as it is important to capture the inconsistent character bigrams usage between the two domains. For example, the word “*rp*” appears in the microblog domain, but not in news. If smoothing is conducted, the character bigram “*rp*” will be given a non-zero probability in both domains, not reflective of actual use. For each character  $C_i$ , we incorporate the PMI of the character bigrams as follows:

- (\*) If  $C_k C_{k+1} (i - 4 < k < i + 4)$  is not a Chinese word recorded in dictionaries:  
*CPMI-N@k+i; CPMI-M@k+i; CDiff@k+i; PYPMI-N@k+i; PYPMI-M@k+i; PYDiff@k+i*

### 3 Experiment

We discuss the dataset, baseline systems and experiments results in detail in the following.

#### 3.1 Data Preparation

We utilize the Chinese social media archive, PrEV (Cui et al., 2012), to obtain Chinese mi-

<sup>5</sup>The informal word may have the same Pinyin transcription as its formal counterpart without considering the differences in tones.

croblog posts from the public timeline of Sina Weibo<sup>6</sup>. Sina Weibo is the largest microblogging in China, where over 100 million Chinese microblog posts are posted daily (Cao, 2012), likely the largest public source of informal and daily Chinese language use. Our dataset has a total of 6,678,021 messages, covering two months from June to July of 2011. To annotate the corpus, we employ *Zhubajie*<sup>7</sup>, one of China mainland’s largest crowdsourcing (Wang et al., 2010) platforms to obtain informal word annotations. In total, we spent US\$110 on assembling a subset of 5,500 posts (12,446 sentences) in which 1,658 unique informal words are annotated within five weeks via *Zhubajie*. Each post was annotated by three annotators with moderate (0.57) inter-annotator agreement measured by Fleiss’  $\kappa$  (Joseph, 1971), and conflicts were resolved by majority voting.

We divided the annotated corpus, taking 4,000 posts for training, and the remainder (1,500) for testing. Through inspection, we note that 79.8% of the informal words annotated in the testing set are not covered by the training set. We also follow Wang et al. (2012)’s conventions and apply rule-sets to preprocess the corpus’ *URLs*, *emoticons*, “*@usernames*” and *Hashtags* as pre-segmented words, before input to CWS and IWR. For the CWS task, the first author manually labelled the same corpus following the segmentation guidelines published with the *SIGHAN-5*<sup>8</sup> MSR dataset.

### 3.2 Baseline Systems

We implemented several baseline systems to compare with proposed FCRF joint inference method.

**Existing Systems.** We re-implemented Xia and Wong (2008)’s extended Support Vector Machine (SVM) based microtext IWR system to compare with our method. Their system only does IWR, using the CWS and POS tagging output of the ICTCLAS segmenter (Zhang et al., 2003) as input. To compare our joint inference versus other learning models, we also employed a decision tree (DT) learner, equipped with the same feature set as our FCRF. Both the SVM and DT models are provided by the Weka3 (Hall et al., 2009) toolkit, using its default configuration.

To evaluate CWS performance, we compare with two recent segmenters. Sun and Xu (2011)’s

work achieves state-of-the-art performance and is publicly available. They employ a LCRF taking as input both lexical and statistical features derived from unlabeled data. As a second baseline, we also evaluate against a widely-used, commercially-available alternative, the recently released 2011 ICTCLAS segmenter<sup>9</sup>.

**Two-stage Sequential Systems.** To benchmark the improvement that the factorial CRF model has by doing the two tasks jointly, we compare with a LCRF solution that chains these two tasks together. For completeness, we test pipelining in both directions – CWS feeding features for IWR ( $LCRF_{cws} \succ LCRF_{iwr}$ ), and the reverse ( $LCRF_{iwr} \succ LCRF_{cws}$ ). We modify the open-source Mallet GRMM package (Sutton, 2006) to implement both this sequential LCRF model and our proposed FCRF model. Both models take the whole feature set described in Section 2.3.

**Upper Bound Systems.** To measure the upper-bound achievable with perfect support from the complementary task, we also provided gold standard labels of one task (e.g., IWR) as an input feature to the other task (e.g., CWS). These systems (hereafter denoted as LCRF $\succ$ LCRF-UB and FCRF-UB) are meant for reference only, as they have access to answers for the opposing tasks.

**Adapted SVM for Joint Classification.** For completeness, we also compared our work against the standard SVM classification model that performs both tasks by predicting the cross-product of the CWS and IWR individual classes (in total, 8 classes). We train the SVM classifier on the same set of features as the FCRF, by providing the cross-product of two layer labels as gold labels. This system (hereafter denoted as SVM-JC) was implemented using the LibSVM package (Chang and Lin, 2011).

### 3.3 Evaluation Metrics

We use the standard metrics of precision, recall and  $F_1$  for the IWR task. Only words that exactly match the manually-annotated labels are considered correct. For example given the sentence “怎么介么好吃呢” (“怎么这么好吃呢”; “How delicious it is”), if the IWR component identifies “介么” as an informal word, it will be considered correct, whereas both “介么好” and “介” are deemed incorrect. For CWS evaluation, we employ the conventional scoring script provided in *SIGHAN-*

<sup>6</sup><http://open.weibo.com>

<sup>7</sup><http://www.zhubajie.com>

<sup>8</sup><http://www.sighan.org>

<sup>9</sup><http://www.ictclas.org/index.html>

5, which also provides out-of-vocabulary recall (OOVR).

To determine statistical significance of the improvements, we also compute paired, one-tailed  $t$  tests. As pointed out by Yeh and Alexander (2000), the randomization method is more reliable in measuring the significance of  $F_1$  through handling non-linear functions of random variables. Thus we employ Padó (2006)’s implementation of randomization algorithm to measure the significance of  $F_1$ .

### 3.4 Experimental Results

The goal of our experiments is to answer the following research questions:

- RQ1 Do the two tasks of CWS and IWR benefit from each other?
- RQ2 Is jointly modeling both tasks more efficient than conducting each task separately or sequentially?
- RQ3 What is the upper bound improvement that can be achieved with perfect support from the opposing task?
- RQ4 Are the features we designed for the joint inference method effective?
- RQ5 Is there a significant difference between the performance of the joint inference of a cross-product SVM and our proposed FCRF?

#### 3.4.1 CWS Performance

Table 2: Performance comparison on the CWS task. The two bottom-most rows show upper bound performance. ‘ $\ddagger$ ’(‘\*’) in the top four lines indicates statistical significance at  $p < 0.001$  (0.05) when compared with the previous row. Symbols in the bottom two lines indicate significant difference between upper bound systems and their corresponding counterparts.

	Pre	Rec	$F_1$	OOVR
ICTCLAS (2003)	0.640	0.767	0.698	0.551
Sun and Xu (2011)	0.661 $\ddagger$	0.691 $\ddagger$	0.675	0.572 $\ddagger$
LCRF <sub>iwr</sub> > LCRF <sub>cws</sub>	0.741 $\ddagger$	0.775 $\ddagger$	0.758*	0.607*
FCRF	<b>0.757<math>\ddagger</math></b>	<b>0.801<math>\ddagger</math></b>	<b>0.778*</b>	<b>0.633*</b>
LCRF <sub>iwr</sub> > LCRF <sub>cws</sub> -UB	0.807 $\ddagger$	0.815 $\ddagger$	0.811*	0.731 $\ddagger$
FCRF-UB	0.820 $\ddagger$	0.833 $\ddagger$	0.826*	0.758 $\ddagger$

In general, our FCRF yields the best performance among all systems (top portion of Table 2),

answering RQ1. Given microblog posts as test data, the  $F_1$  of ICTCLAS drops from 0.985<sup>10</sup> to 0.698, clearly showing the difficulty of processing microtext. The sequential LCRF model and FCRF model both outperform the baselines, which means with the novel features shared by the two tasks, CWS benefits significantly from the results of IWR. Hence our segmenter outperforms the existing segmenters by tackling one of the bottlenecks of recognizing informal words in Chinese microtext.

To illustrate, the sequence “...有木有人...” (“...有没有人...”; “...is there anyone...”), is correctly labeled as **BIES** by our FCRF model but mislabeled by baseline systems as **SSBE**. This is likely due to the ignorance of the informal word “有木有”, leading baseline systems to keep the formal word “有人” (“someone”) as a segment.

More importantly, by jointly optimizing the probabilities of labels on both layers, the FCRF model slightly but significantly improves over the sequential LCRF method, answering RQ2. Thus we conclude that jointly modeling both tasks is more effective than performing the tasks sequentially.

For RQ3, the last two rows presents the upper-bound systems that have access to gold standard labels for IWR. Both upper-bound systems statistically outperform their counterparts, indicating that there is still room to improve CWS performance with better IWR as input. This also validates our assumption that CWS can benefit from joint consideration of IWR. Taking the best previous work as our lower bound (0.69  $F_1$ ), we see that our FCRF methodology (0.77) makes significant progress towards the upper bound (0.82).

#### 3.4.2 IWR Performance

For RQ1 and RQ2, Table 3 compares the performance of our method with the baseline systems on the IWR task. Overall, the FCRF method again outperforms all the baseline systems. We note that the CRF based models achieve much higher precision score than baseline systems, which means that the CRF based models can make accurate predictions without enlarging the scope of prospective informal words. Compared with the CRF based models, the SVM and DT both over-predict informal words, incurring a larger precision penalty. Studying this phe-

<sup>10</sup>Self-declared segmentation accuracy on formal text. <http://www.ictclas.org/>

Table 3: Performance comparison on the IWR task. ‘‡’ or ‘\*’ in the top four rows indicates statistical significance at  $p < 0.001$  or  $< 0.05$  compared with the previous row. Symbols in the bottom two rows indicate differences between upper bound systems and their counterparts.

	Pre	Rec	F <sub>1</sub>
<b>SVM</b>	0.382	0.621	0.473
<b>DT</b>	0.402*	0.714*	0.514*
<b>LCRF<sub>cws</sub> &gt; LCRF<sub>iwr</sub></b>	0.858‡	0.591‡	0.699*
<b>FCRF</b>	<b>0.877*</b>	<b>0.655*</b>	<b>0.750*</b>
<b>LCRF<sub>cws</sub> &gt; LCRF<sub>iwr</sub>-UB</b>	0.840	0.726*	0.779*
<b>FCRF-UB</b>	0.878	0.752*	0.810*

nomenon more closely, we find it is difficult for the baseline systems to classify segments mixed with formal and informal characters. Taking the microblog “怎么介么好吃呢” (“怎么这么好吃呢”; “how delicious it is”) as an example, without considering the possible word boundaries suggested by the contextual formal words – i.e., “怎么” (“how”) and “好吃” (“delicious”) – the baselines chunk the informal words (i.e., “介么”) together with adjacent characters mistakenly as “介么好” or “么介么”.

As indicated by the bold figures in Table 3, the FCRF performs slightly better than the sequential LCRF ( $p < 0.05$ ) – a weaker trend when compared with the CWS case. As an example, the sequential LCRF method fails to recognize “爱疯” (“iPhone”) as an informal word in the sentence “我的爱疯好玩” (“my iPhone is fun”), where the FCRF succeeds. Inspecting the output, the LCRF segmenter mislabels “爱疯” as **SS**. By jointly considering the probabilities of the two layers, the FCRF model infers better quality segmentation labels, which in turn enhances the FCRF’s capability to recognize the sequence of two characters as an informal word. This is further validated by the significant performance gulf between the upper bound and the basic system shown in the lower half of the table.

For RQ3, interestingly, the difference in performance between the LCRF and FCRF upper-bound systems is not significant. However, these are upper bounds, and we expect on real-world data that CWS performance will not be perfect. As such, we still recommend using the FCRF model, as the joint process is more robust to noisy input from one channel.

Table 4: F<sub>1</sub> comparison between FCRF and FCRF<sub>-new</sub>. (“\*”) indicates statistical significance at  $p < 0.05$  when compared with the previous row.

	CWS	IWR
<b>FCRF<sub>-new</sub></b>	0.690	0.552
<b>FCRF</b>	0.778*	0.750*

### 3.4.3 Feature set evaluation

For RQ4, to evaluate the effectiveness of our newly-introduced feature sets (those marked with “\*” in Section 2.3), we also test a FCRF (FCRF<sub>-new</sub>) without our new features. According to Table 4, performance drops by a significant amount: 0.088 F<sub>1</sub> on CWS and 0.198 F<sub>1</sub> on IWR. FCRF<sub>-new</sub> makes many mistakes identical to the baselines: segmenting informal words into several single-character words and chunking adjacent characters from informal and formal words together.

### 3.4.4 Adapted SVM-JC vs. FCRF

Table 5: F<sub>1</sub> comparison between SVM, SVM-JC and FCRF. ‘‡’ (“\*”) indicates statistical significance at  $p < 0.001$  (0.05) when compared with the previous row.

	CWS	IWR
<b>SVM</b>	—	0.473
<b>SVM-JC</b>	0.741	0.624‡
<b>FCRF</b>	0.778*	0.750*

For RQ5, according to Table 5, our SVM trained to predict the cross-product CWS/IWR classification (SVM-JC) performs quite well on its own. Unsurprisingly, it does not outperform our proposed FCRF, which has access to more structural correlation among the CWS and IWR labels. SVM-JC significantly ( $p < 0.001$ ) outperforms the baseline SVM system by 0.151 in the IWR task, which we think is partially explained by its good performance (0.761) on the CWS task. The over-prediction tendency of the individual SVM is largely solved by simultaneously modeling the CWS task, whereas FCRF turns out to be more effective in solving joint inference problem, although in a weaker trend in terms of the statistical significance ( $p < 0.05$ ).

We conclude that the use of the FCRF model and the addition of our new features are both essential for the high performance of our system.

## 4 Discussion

We wish to understand the causes of errors in our models so that we may better understand its weaknesses. Manually inspecting the errors of our system, we found three major categories of errors which we dissect here.

For IWR, the major source of error, accounting for more than 60% of all errors, is caused by what we term the *partially observed informal word* phenomenon. This refers to informal words containing multiple characters, where some of its components have appeared in the training data as informal words individually. For instance, the single-character informal word, “狠” (“很”; “very”) appears in training multiple times, thus the unseen informal word “狠久” (“很久”; “long time”) is a *partially observed* informal word. In this case, the model incorrectly labels the known, single character “狠” with **IF.S** as an informal word, instead of labeling the unseen sequence “狠久” with correct labels **IF.B IF.E**. Errors then result in both tasks.

This observation motivates the use of the relation between the known informal word and its formal counterpart in order to inform the model to better predict in cases of partial observations. Following the same example, given that “狠” is an informal word, if the model also considers the probability of normalizing “狠” to “很”, while considering the higher probability that the character sequence “很久” could be a formal word, there would be a higher likelihood of correctly predicting the sequence “狠久” as an informal word. So informal word normalization is also an intrinsic component of IWR and CWS, and we believe it is an interesting direction for future work.

Another source of error is a side effect of microtext being extremely short. For example, in the sentence “肥家! 太累了。。。 ” (“回家! 太累了。。。”; “Go home! Exhausted.”), the unseen informal word “肥家” itself forms a short sentence. Although it has a subsequent sentence “太累了。。。 ” (“Exhausted”) as context, and the two are pragmatically related, (i.e., “I am exhausted! [And as a result,] I want to go home.”), the lexical relationship between the sentences is weak; i.e., “太累了。。。 ” appears frequently as the context of various sentences, making the context difficult to utilize. These phenomena makes it difficult to recognize “肥家” as an informal word.

A possible solution could factor in proximity, similar to density-based matching, as in Tellex *et*

Table 6: Sample Chinese freestyle named entities that are usernames.

Freestyle Named Entity	Explanation
“榴莲雪媚娘”	“榴莲” (“durian”), “雪” (“snow”), “媚娘” (“charming lady”)
“棉宝”	It is short for the cartoon name “海绵宝宝”.
“dj文祥”, “徐pp”	Usernames mixed of Chinese and alphabetic characters

*al.* (2003). We can assign a higher weight to features related to characters closer to the current target character. In particular, for this example, given the current target character “肥”, we can assign higher weight to features generated from features from the proximal context “肥家”, and lower weight to features extracted from distal contexts.

Another major group of errors come from what we term *freestyle named entities* as exemplified in Table 6; i.e., person names in the form of user IDs and nicknames, that have less constraint on form in terms of length, canonical structure (not surnames with given names; as is standard in Chinese names) and may mix alphabetic characters. Most of these belong to the category of *Person Name* (PER), as defined in CoNLL-2003<sup>11</sup> Named Entity Recognition shared task. Such freestyle entities are often misrecognized as informal words, as they share some of the same stylistic markings, and are not marked by features used to recognize previous Chinese named entity recognition methods (Gao et al., 2005; Zhao and Kit, 2008) that work on news or general domain text. We recognize this as a challenge in Chinese microtext, but beyond the scope of our current work.

## 5 Related Work

In English, IWR has typically been investigated alongside normalization. Several recent works (Han and Baldwin, 2011; Gouws et al., 2011; Han et al., 2012) aim to produce informal/formal word lexicons and mappings. These works are based on distributional similarity and string similarity that address concerns of lexical variation and spelling. These methods propose two-step unsupervised approaches to first detect and then normalize detected informal words using dictionaries.

In processing Chinese informal language, work conducted by Xia and Wong address the problem

<sup>11</sup><http://www.cnts.ua.ac.be/conll2003/ner/>

of in bulletin board system (BBS) chats. They employ pattern matching and SVM-based classification to recognize Chinese informal sentences (not individual words) chat (Xia et al., 2005). Both methods had their advantages: the learning-based method did better on recall, while the pattern matching performed better on precision. To obtain consistent performance on new unseen data, they further employed an error-driven method which performed more consistently over time-varying data (Xia and Wong, 2006). In contrast, our work identifies individual informal words, a finer-grained (and more difficult) task.

While seminal, we feel that the difference in scope (informal sentence detection rather than word detection) shows the limitation of their work for microblog IWR. Their chats cover only 651 unique informal words, as opposed to our study covering almost triple the word types (1,658). Our corpus demonstrates a higher ratio of informal word use (a new informal word appears in  $\frac{1,658}{12,446} = 13\%$  of sentences, as opposed to  $\frac{651}{22,400} = 2\%$  in their BBS corpus). Further analysis of their corpus reveals that phonetic substitution is the primary origin of informal words in their corpus – 99.2% as reported in (Wong and Xia, 2008). In contrast, the origin for informal words in microblogs is more varied, where phonetic substitutions abbreviations and neologisms, account for 53.1%, 21.4% and 18.7% of the informal word types, respectively. Their method is best suited for phonetic substitution, thus performing well on their corpus but poorly on ours.

More closely related, Li and Yarowsky (2008) tackle Chinese IWR. They bootstrap 500 informal/formal word pairs by using manually-tuned queries to find definition sentences on the Web. The resulting noisy list is further re-ranked based on n-gram co-occurrence. However, their method makes a basic assumption that informal/formal word pairs co-occur within a definition sentence (i.e., “<informal word> means <formal word>”) may not hold in microblog data, as microbloggers largely do not define the words they use.

Closely related to our work is the task of Chinese new word detection, normally treated as a separate process from word segmentation in most previous works (Chen and Bai, 1998; Wu and Jiang, 2000; Chen and Ma, 2002; Gao et al., 2005). Aiming to improve both tasks, work by Peng *et al.* (2004) and Sun *et al.* (2012) conduct

segmentation and detection sequentially, but in an iterative manner rather than joint. This is a weakness as their linear CRF model requires re-training. Their method also requires thresholds to be set through heuristic tuning, as to whether the segmented words are indeed new words. We note that the task of new word detection refers to out-of-vocabulary (OOV) detection, and is distinctly different from IWR (new words could be both formal or informal words).

## 6 Conclusion

There is a close dependency between Chinese word segmentation (CWS) and informal word recognition (IWR). To leverage this, we employ a factorial conditional random field to perform both tasks of CWS and IWR jointly.

We propose novel features including statistical and lexical features that improve the performance of the inference process. We evaluate our method on a manually-constructed data set and compare it with multiple research and industrial baselines that perform CWS and IWR individually or sequentially. Our experimental results show our joint inference model yields significantly better  $F_1$  for both tasks. For analysis, we also construct upper bound systems to assess the potential maximal improvement, by feeding one task with the gold standard labels from the complementary task. These experiments further verify the necessity and effectiveness of modeling the two tasks jointly, and point to the possibility of even better performance with improved per-task performance.

Analyzing the classes of errors made by our system, we identify a promising future work topic to handle errors arising from *partially observed informal words* – where parts of a multi-character informal word have been observed before. We believe incorporating informal word normalization into the inference process may help address this important source of error.

## Acknowledgments

We would like to thank the anonymous reviewers for their valuable comments. We also appreciate the proofreading effort made by Tao Chen, Xiangan He, Ning Fang, Yushi Wang and Haochen Zhan from WING. This work also benefits from the discussion with Yang Liu, associate professor from Tsinghua University.

## Abstract

We introduce the novel task of automatically generating questions that are relevant to a text but do not appear in it. One motivating example of its application is for increasing user engagement around news articles by suggesting relevant comparable questions, such as “*is Beyonce a better singer than Madonna?*”, for the user to answer. We present the first algorithm for the task, which consists of: (a) offline construction of a comparable question template database; (b) ranking of relevant templates to a given article; and (c) instantiation of templates only with entities in the article whose comparison under the template’s relation makes sense. We tested the suggestions generated by our algorithm via a Mechanical Turk experiment, which showed a significant improvement over the strongest baseline of more than 45% in all metrics.

## 1 Introduction

For companies whose revenues are mainly ad-based, *e.g.* Facebook, Google and Yahoo, increasing user engagement is an important goal, leading to more time spent on site and consequently to increased exposure to ads. Examples for typical engaging content include other articles for the user to read, updates from the user’s social neighborhood and votes or comments on videos, blogs etc.

In this paper we propose a new way to increase user engagement around news articles, namely suggesting questions for the user to answer, which are related to the viewed article. Our motivation is that there are questions that are “irresistible” because they are fun, involve emotional reaction and expect simple answers. These are comparative questions, such as “*is Beyonce a better singer than*

*Madonna?*”, “*who is better looking, Brad Pitt or George Clooney?*”, “*who is faster: Superman or Flash?*” and “*which camera brand do you prefer: Canon or Nikon?*” Furthermore, such questions are social in nature since users would be interested in reading the opinions of other users, similar to viewing other comments (Schuth et al., 2007). Hence, a user that provided an answer may return to view other answers, further increasing her engagement with the site.

One approach for generating comparable questions would be to employ traditional question generation, which syntactically transform assertions in a given text into questions (Mitkov et al., 2006; Heilman and Smith, 2010; Rus et al., 2010). Sadly, fun and engaging comparative questions are typically not found within the text of news articles. A different approach would be to find concrete relevant questions within external collections of manually generated comparable questions. Such collections include Community-based Question Answering (CQA) sites such as Yahoo! Answers and Baidu Zhidao and sites that are specialized in polls, such as Toluna. However, it is highly unlikely that such sources will contain enough relevant questions for any news article due to typical sparseness issues as well as differences in interests between askers in CQA sites and news reporters. To better address the motivating application above, we propose the novel task of automatically suggesting comparative questions that are relevant to a given input news article but do not appear in it.

To achieve broad coverage for our task, we present an algorithm that generates synthetic concrete questions from *question templates*, such as “*Who is a better actor: #1 or #2?*”. Our algorithm consists of two parts. An offline part constructs a database of comparative question templates that appear in a large question corpus. For a given news article, an online part chooses relevant tem-

## Who's Hollywood's Hottest Dad?

In honor of Father's Day, Us Weekly wants to know -- who do you think is the hottest dad in Hollywood?

**David Beckham**, 36 -- who's expecting baby No. 4 with wife **Victoria** -- is already father to sons Brooklyn, 12, Romeo, 8, and Cruz, 6; **Brad Pitt**, 47, co-parents six children with **Angelina Jolie** (Maddox, 9, Pax, 7, Zahara, 6, Shiloh, 5, and twins Knox and Vivienne, 2); **Will Smith** helped pave the way for his superstar children Jaden, 12, and Willow, 10; and **Matthew McConaughey**, 41, is the proud father of cuties Levi, 2, and Vida, 1.

Tell Us: Who's the hottest dad in Hollywood?

Figure 1: An example news article from OMG!

plates for the article by matching between the article content and typical template contexts. The algorithm then instantiates each relevant template with two entities that appear in the article. Yet, for a given template, only some of the entities are plausible slot fillers. For example, ‘*Madonna*’ is not a reasonable filler for “*Who is a better dad, #1 or #2?*”. Thus, our algorithm employs entity filtering to exclude candidate instantiations that do not make sense.

To test the performance of our algorithm, we conducted a Mechanical Turk experiment that assessed the quality of suggested questions for news articles on celebrities. We compared our algorithm to a random baseline and to a partial version of our algorithm that includes a template relevance component but lacks filtering of candidate instantiations. The results show that the full algorithm provided 45% more correct instantiations, but surprisingly also 46% more relevant suggestions compared to the stronger baseline. These results point at the importance of both picking relevant templates and smart instantiation selection to the quality of generated questions. In addition, they indicate that user perception of relevance is affected by the correctness of the question.

## 2 Motivation and Algorithmic Overview

Before we detail our algorithm, we provide some motivations and insights to the design choices we took in our algorithm, which also indicate the difficulties inherent in the task.

### 2.1 Motivation

Given a news article, our algorithm generates a set of comparable questions for the article from question templates, e.g. “*who is faster #1 or #2?*”. Though the template words typically do not appear in the article, they need to be *relevant* to its content, that is they should correspond to one of the main themes in the article or to one of the pub-

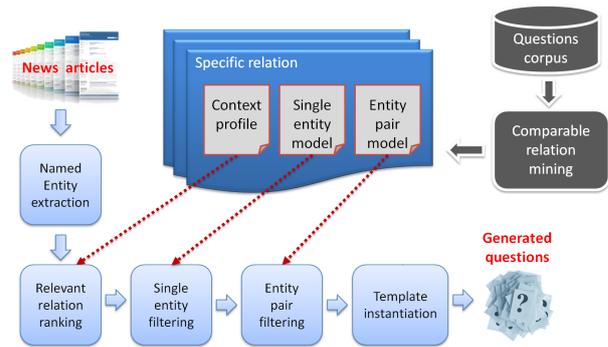

Figure 2: A high-level overview of the comparable question generation algorithm. The offline part is colored dark grey and the online part is colored light blue.

lic interests of the compared entities. For example, “*who is a better dad #1 or #2?*” is relevant to the article in Figure 1, while “*who is faster #1 or #2?*” is not relevant. Therefore, we need to model the typical contents to which each template is relevant.

Looking at the structure of comparable questions, we observed that a specific *comparable relation*, such as ‘*better dad*’ and ‘*faster*’, can usually be combined with named entities in several syntactic ways to construct a concrete question. We encode this information in *generic comparable templates*, e.g. “*who is a RE: #1 or #2?*” and “*is #1 a RE than #2?*”, where *RE* is a slot for a comparable relation and *#1* and *#2* are slots for entities. Using the above generic templates, ‘*Jet Li*’ and ‘*Jackie Chan*’ can be combined with the comparable relation ‘*better fighter*’ to generate “*who is a better fighter: Jackie Chan or Jet Li?*” and “*is Jackie Chan a better fighter than Jet Li?*” respectively. Following, our algorithm separately maintains comparable relations and generic templates.

In this paper we constrain ourselves to generate comparable questions between entities that appear in the article. Yet, not all entities can be compared to each other under a specific template, adding substantial complexity to the generation of questions. Looking at Figure 1, the generated question “*who is faster, Angelina Jolie or David Beckham?*” makes sense with respect to *David Beckham*, but not with respect to *Angelina Jolie*, since the typical reader is rarely interested in her running skills. Our algorithm thus needs to assess whether an instantiation is *correct*, that is whether the comparison between the two entities makes sense under the specific template.

Further delving into question correctness, the above example shows the need to assess each entity by itself. However, even if both entities are independently valid for the template, their comparison may not make sense. For example, “*who is better looking: Will Smith or Angelina Jolie?*” doesn’t feel right, even though each entity by itself fits the template. This is because when comparing looks, we expect a same sex comparison.

## 2.2 Algorithmic Overview

The above observations led us to the design of the automatic generation algorithm depicted in Figure 2. The algorithm’s offline part constructs, from a large collection of questions, a database of comparable relations, together with their typical contexts. It also extracts generic templates and the mapping to the relations that may instantiate them. From this database, we learn: (a) a *context profile* per template for relevance matching; (b) a *single entity model* per template slot that identify valid instantiations; and (c) an *entity pair model* that detects pairs of entities that can be compared together under the template. In the online part, these three models are applied to rank relevant templates for a given article and to generate only correct questions with respect to template instantiation.

The next two sections detail the template extraction component and the model training and application component in our algorithm.

## 3 Comparable Question Mining

To suggest comparable questions our algorithm needs a database of question templates. As discussed previously, a good source for mining such templates are CQA sites. Specifically, in this study we utilize all questions submitted to Yahoo! Answers in 2011 as our corpus. We next describe how comparable relations and generic comparable templates are extracted from this corpus.

### 3.1 Comparable Relation Extraction

An important observation for the task of comparable relation extraction is that many relations are complex multiword expressions, and thus their automatic detection is not trivial. Examples for such relations are marked in the questions “*Who is the best rapper alive, Eminem or Jay-z?*” and “*Who is the most beautiful woman in the world, Adriana Lima or Jessica Alba?*”. Therefore, we decided to employ a Conditional Random Fields (CRF) tag-

ger (Lafferty et al., 2001) to the task, since CRF was shown to be state-of-the-art for sequential relation extraction (Mooney and Bunescu, 2005; Culotta et al., 2006; Jindal and Liu, 2006).

As a pre-processing step for detecting comparable relations, our extraction algorithm identifies all the named entities of interest in our corpus, keeping only questions that contain at least two entities. In each of remaining questions, we then substitute the entity names with the variable slots #*i* in the order of their appearance. For example, “*Nnamdi Asomugha vs. Darrelle Revis? Who is the better cornerback?*” turned into “*#1 vs. #2? Who is the better cornerback?*”. This transformation helps us to design a simpler CRF than that of (Jindal and Liu, 2006), since our CRF utilizes the known positions of the target entities in the text.

To train the CRF model, the authors manually tagged all comparable relation words in approximately 300 transformed questions in the filtered corpus. The local and global features for the CRF, which we induce from each question word, are specified in Figures 3 and 4 respectively. Though there are many questions in Yahoo! Answers containing two named entities, e.g. “*Is #1 dating #2?*”, our CRF tagger is trained to detect only comparable relations like “*Who is prettier #1 or #2?*”. This is due to the labeled training set, which contains only this kind of relations, and to our features, which capture aspects of this specific linguistic structure.

The trained model was then applied to all other questions in the filtered corpus. This tagging process resulted in 60,000 identified question relation occurrences. From this output we constructed a database consisting of all occurring relations; each relation is accompanied by its *supporting questions*, those questions in which the relation occurrences were found. To achieve a highly accurate database, we filtered out relations with less than 50 supporting questions, ending with 295 relations in our database<sup>1</sup>. The authors conducted a manual evaluation of the CRF tagger performance, which showed 80% precision per occurrence. Yet, our filtering above of relations with low support left us with virtually 100% precision per relation and per occurrence.

<sup>1</sup>We intend to make this database publicly available under Yahoo! Webscope™ (<http://webscope.sandbox.yahoo.com>).

<sup>2</sup><http://nlp.stanford.edu/software/>

- (a) The word itself
- (b) Whether the word is capitalized
- (c) The word's suffixes of length 1,2, and 3, which helps in detecting comparative adjectives that ends 'est' or 'er'
- (d) The word's position in the sentence
- (e) The word's Part of speech (POS) tag, based on the Stanford POS tagger<sup>2</sup>
- (f) The words in a window of  $\pm 3$  around the current one
- (g) The adjective before the word, if exists, which helps detecting comparative noun phrases, e.g. 'better driver' and 'best singer'
- (h) The shortest word distance between the word and one of the  $\#i$  variables.
- (i) The shortest word distance of the word to one of the following connectives: 'between', 'out', ':', ',', '?'

- (b) The average word distance between all  $\#i$  variables in the question
- (c) The conjunction tokens appearing between the  $\#i$  variables, such as *or, vs, and*

Figure 4: CRF global features for each word

### 3.2 Comparable Template Extraction

Our second mining task is to extract generic comparable templates that appear in our corpus, as well as identifying which comparable relation can instantiate which generic template.

To this end, we replace each recognized relation sequence with a variable  $RE$  in the support questions annotated with  $\#i$  variables. For example, "who is the best rapper alive,  $\#1$  or  $\#2$ ?" is transformed to "who is  $RE$ ,  $\#1$  or  $\#2$ ?". We next count the occurrences of each templated question. While some questions contain many details besides the comparable generic template, others are simpler and contain only the generic template. Through this counting, frequently occurring generic templates are revealed, such as "is  $\#1$  a  $RE$  than  $\#2$ ?". We retain only generic templates which appeared more than 50 times.

Finally, for each comparable relation we mark as applicable only generic templates that occur at least once in the supporting questions of this relation. For example, the template "who is  $RE$ :  $\#1$  or  $\#2$ ?" was found applicable for 'funnier', and thus could be used to generate the concrete question "who is funnier: Jennifer Aniston or Courteney Cox?". On average, each relation was associated with 3 generic templates.

## 4 Online Question Generation

The online part of our automatic generation algorithm takes as input a news article and generates concrete comparable questions for it. Its high level description is presented in Algorithm 1. The algorithm starts with identifying the comparable relations in our database that are relevant to the article. For each relevant relation, we then generate concrete questions by picking generic templates that are applicable for this relation and instantiating them with pairs of named entities appearing in the article. Yet, as discussed before, only for some entity pairs the comparison under the specific relation makes sense, a quality which we refer to as instantiation correctness (see Section 2). To this end, we utilize two supervised models to filter incorrect instantiations. We next detail the two aspects of the online part: ranking relevant relations and correctly instantiating relations.

### 4.1 Ranking relevant relations

To assess how relevant a given comparable relation is to an article, we model the relation's typical context as a distribution over latent semantic topics. Specifically, we utilize Latent Dirichlet Allocation (LDA) (Blei et al., 2003) to infer latent topics in texts.

To train an LDA model, we constructed for each comparable relation a pseudo-document consisting of all questions that contain this relation in our corpus (the supporting questions). We then

trained a model of 200 topics over these pseudo-documents, resulting in a model over a lexicon of 107,835 words. An additional product of the LDA training process is a topic distribution for each relation’s pseudo-document, which we consider as the relation’s *context profile*. We note that, unless otherwise specified, different model parameters were chosen based on a small held out collection of articles and questions, manually annotated by the authors. This collection was used to validate that the chosen parameter values indeed “make sense” for the task.

Given a news article, a distribution over LDA topics is inferred from the article’s text using the trained model. Then, a cosine similarity between this distribution and the context profile of each comparable relation in our database is computed and taken as the relevance score for this relation. Finally, we rank all relations according to their relevance score and pick the top  $M$  as candidates for instantiation ( $M=3$  in our experiment).

## 4.2 Correctly instantiating relations

To generate useful questions from relevant comparable relations, we need to retain only correct instantiations of these relations. To this end, we utilize two complementing types of filters, one for each entity by itself, and one for pairs, since each filter considers different attributes of the entities at hand. For example, for the relation ‘*is faster*’, the single entity filter looks for athletes of all kinds, for whom this comparison is of interest to the reader. The pair filter, on the other hand, attempts to pass only same sex and same profession comparisons, *e.g.* male football players or female baseball players for this relation.

We next describe the various features we extract for every entity and the supervised models that given this feature vector representation assess the correctness of an instantiation.

### 4.2.1 Entity Features

We want to represent each entity as a vector of features that capture different aspects of entity characterization. To this end, we utilize two different broad-scale sources of information about named entities. The first is DBPedia<sup>3</sup>, which contains structured information on entries in Wikipedia, many of them are named entities that appear in news articles. The second source is the corpus of

<sup>3</sup><http://wiki.dbpedia.org/About>

CQA questions, which in our study was harvested from Yahoo! Answers (see Section 3).

For named entities with a DBPedia entry, we extract all the DBPedia properties of classes *subject* and *type* as indicator features. Some example features for *Brad Pitt* include *Actors\_from\_Oklahoma*, *AmericanAtheists*, *Artist* and *American\_film\_producers*.

One property that is currently missing from DBPedia is *gender*, a feature that was found to be very useful in our experiments. We automatically induce this feature from the Wikipedia abstract in each DBPedia entry. Specifically, we construct a histogram of male and female pronouns: *he* and *his* vs. *she* and *her*. The majority pronoun sex is then chosen to be the gender of the named entity, or none if the histogram is empty.

One way to utilize the CQA question corpus could be to extract co-occurring words with each target entity as relevant contexts. Yet, since our questions come from Yahoo! Answers, we decided to use another attribute of the questions, the category to which the question is assigned, within a hierarchy of 1,669 categories (*e.g.* ‘*Sports>Baseball*’ and ‘*Pets>Dogs*’). For each named entity, we construct a histogram of the number of questions containing it that are assigned to each category. This histogram is normalized into a probability distribution with Laplace smoothing of 0.03, to incorporate the uncertainty that lies in named entities that appear only very few times. The categories and their probabilities are added as features, providing a high level representation of relevant contexts for the entity.

### 4.2.2 Single entity filtering

We view the task of single entity filtering as a classification task. To this end, we trained a classifier per relation, constructing a different labeled training set for each relation. Positive examples are the entities that instantiate this relation in our CQA corpus. As negative examples, we take named entities that were never seen instantiating the relation in the corpus, but still occurred in some questions. We note that our named entity tagger could recognize more than 200,000 named entities, and most of them are negative for a given relation.

For each relation we select negative examples by sampling uniformly from its negative entity list, assuming that the probability of hitting false negatives is low for such a long list. It is known that better classification performance is typically

achieved for a balanced training set (Provost, 2000). In our case, we over sample to help the classifier explore the large space of negative examples. Specifically, we sample 2,000 negative examples and duplicate the positive set to reach a similar number.

We utilize the Support Vector Machines (SVM) implementation of LIBSVM (Chang and Lin, 2011) with a linear kernel as our classifier. The feature vector of each named entity was induced as described in Section 4.2.1. We split the labeled dataset into 70% training set and 30% validation set. Feature selection using information gain was performed on the training set to throw out non-significant features (Mitchell, 1997). The average accuracy of the single classifiers, measured over the validation sets, was 91%.

### 4.2.3 Entity pair filtering

Similar to single entity filtering, we view the task of filtering entity pairs as a classification task, training a separate classifier for each relation. Entity pairs that instantiate the given relation in the question corpus are considered positive examples. Yet, the space of all the pairs that never instantiated the relation is huge, and the set of positive examples is relatively much smaller compared to the situation in the single entity classifier. In our study, uniform negative example sampling turned the training into a trivial task, preventing from the classifier to choose an useful discriminative boundary. Therefore, we generate negative examples by sampling only from pairs of named entities that both pass the single entity filter for this relation. The risk here is that we may sample false negative examples. Still, this sampling scheme enabled the classifier to identify better discriminative features.

To generate features for a candidate pair, we take the two feature vectors of the two entities and induce families of pair features by comparing between the two vectors. Figure 5 describes the various features we generate. We utilize LIBSVM with an RBF kernel for this task, splitting the examples into 70% training set and 30% validation set. We over sampled the positive examples to reach up to 100 examples.

The average accuracy of the pair classifiers on the validation set was 83%. For example, named entities that pass the single entity filtering for “*be funny*”, include Jay Leno, David Letterman (American TV hosts), Jim Carrey, and Steve Mar-

- (a) All shared DBPedia indicator features in the two vectors:  $f_a^{DBPedia} \cap f_b^{DBPedia}$ , indicating them as shared, e.g. ‘*FilmMaker\_s*’
  - (b) All DBPedia features that appear only in one of the vectors, termed *one-side features*:  $f_a^{DBPedia} \setminus f_b^{DBPedia}$  and  $f_b^{DBPedia} \setminus f_a^{DBPedia}$ , indicating them as such, e.g. ‘*FilmMaker\_o*’
  - (c) Wikipedia categories that are ancestors of at least two one-side features that appear in the training set. For example, a common ancestor of ‘*Spanish\_actors*’ and ‘*Russian\_actors*’ is ‘*European\_actors*’. These features provide a high level perspective on one-side features
  - (d) The Yahoo! Answers categories in which both named entities appear
  - (e) Hellinger distance (Pollard, 2001) between the probability distributions over categories of the two entities
  - (f) Three indicator gender features: whether both named entities are males, both are females or are different

tin (actors). The pair classifier assigned positive scores only to {*Jay Leno, David Letterman*} (TV hosts) and {*Jim Carrey, Steve Martin*} (actors) but not to other pairings of these entities.

## 5 Evaluation

### 5.1 Experimental Settings

To evaluate our algorithm’s performance, we designed a Mechanical Turk (MTurk) experiment in which human annotators assess the quality of the questions that our algorithm generates for a sample of news articles. As the source of test articles, we chose the OMG! website<sup>4</sup>, which contains news articles on celebrities.

Test articles were selected by first randomly sampling 5,000 news article from those that were posted on OMG! in 2011. We then filtered out articles that are longer than 4,000 characters, which were found to be tiresome for annotators to read, and those that are shorter than 300 characters, which consist mainly of video and photos. We were left with a pool of 1,016 articles from which we randomly sampled 100 as the test set.

For each test article our algorithm obtained the top three relevant comparable relations, and for each relation selected the best instantiation (if exists). We used two baselines for performance comparison. The first *random baseline* chooses a relation randomly out of all possible relations in the database and then instantiates it with a random pair of entities that appear in the article. The second *relevance baseline* chooses the most relevant

<sup>4</sup><http://www.omg.com/>

	Relevance	Correctness
Random baseline	29%	43%
Relevance baseline	37%	53%
Full algorithm	54%	77%

Table 1: Relevance and correctness percentage by tested algorithm

relation to the article based on our algorithm, but still instantiates it with a random pair. For each test article, we presented to the evaluators the questions generated by the three tested algorithms in a random order to avoid any bias. We note that our second baseline enabled us to measure the stand-alone contribution of the LDA-based relevance model. In addition, it enabled us to measure the relative contribution of the instantiation models on top of relevance model.

Each article was evaluated by 10 MTurk workers, which were asked to mark for each displayed question whether it is relevant and whether it is correct (see Section 2 for relevance and correctness definitions). The workers were given precise instructions along with examples before they started the test. A control story was used to filter out dishonest or incapable workers<sup>5</sup>.

## 5.2 Results

For each tested algorithm, we separately counted the percentage of annotations that marked each question as relevant and the percentage of annotations that marked each question as instantiated correctly, denoted *relevance score* and *correctness score*. We then averaged these scores over all questions that were displayed for the test articles. The results are presented in Table 1. The differences between the full algorithm and the baselines are statistically significant at  $p < 0.01$  and between baselines the differences are statistically significant at  $p < 0.05$  using the Wilcoxon double-sided signed-ranks test (Wilcoxon, 1945).

Our main result is that our full algorithm substantially outperforms the stronger relevance baseline. It improves the correctness score by 45%, which points at the effectiveness of our two step filtering of incorrect instantiations. It’s performance is just under 80%, showing high quality entity pair selection for relations. Yet, we did not expect to see an increase of 46% in the relevance

<sup>5</sup>We intend to make the tested articles, the instructions to annotators and their annotations publicly available under Yahoo! Webscope™ (<http://webscope.sandbox.yahoo.com>).

metric, since both the full algorithm and the relevance baseline use the same relevance component to rank relations by. One explanation for this is that sometimes the instantiation filter eliminates all possible entity pairs for some relation that is incorrectly considered relevant by the algorithm. Thus, the filtering of entities provides also an additional filtering perspective on relevance. In addition, it may be that humans tend to be more permissive when assessing the relevance of a correctly instantiated question.

To illustrate the differences between baselines and the full algorithm, Table 2 presents an example article together with the suggested generated questions by each algorithm. The random baseline picked an irrelevant relation, and while the relevance baseline selected a relevant relation, “*a better president*”, it was instantiated incorrectly. The full algorithm, on the other hand, both chose relevant relations for all three questions and instantiated them correctly. Especially, the incorrectly instantiated relation in the relevance baseline is now correctly instantiated with plausible presidential candidates.

Comparing between baselines, the relevance baseline beats the random baseline by 28% in terms of relevance. This is not surprising, since this was the focus of this baseline. Yet, it also improved correctness by 23% over the random baseline. This is an unexpected result that indicates that when users view relevant relations, they may be more forgiving in their perception of unreasonable instantiations.

For each article, our full algorithm attempts to generate three questions, one for each of the top three relevant questions. It is possible that for some articles not all three questions will be generated, due to instantiation filtering. We found that for 85% of the articles all three questions were generated. For the remaining 15% at least one question was always generated, and for  $\frac{1}{3}$  of them two questions were composed. Furthermore, we found that the relevance and correctness scores were not affected by the position of the question. In the case of instantiation correctness, since the best pair was picked for each relation and this component is quite accurate, this is somewhat expected. In the case of relevance, this indicates that there are usually several relations in our database that are relevant to the article.

Ron Livingston is teaming up with Tom Hanks and HBO again after their successful 2001 collaboration on Band of Brothers. The actor has been cast in HBO's upcoming film Game Change that centers on the 2008 presidential campaign, Deadline reports. He joins Ed Harris, Julianne Moore and Woody Harrelson. The Jay Roach-directed movie follows John McCain (Harris) as he selects Alaska Gov. Sarah Palin (Moore) as his running mate, throughout the campaign and to their ultimate defeat to Barack Obama. Livingston will play Mark Wallace, one of the campaign's senior advisors and the man who prepped Palin for her debate. Harrelson will play campaign strategist Steve Schmidt. . .

Algorithm	Question
Random baseline	Who is a better singer, Sarah Palin or Barack Obama ?
Relevance baseline	Would Ron Livingston be a better president than Julianne Moore ?
Full algorithm	Who has the best movies Tom Hanks or Julianne Moore ?
Full algorithm	Is John Mccain a better leader than Barack Obama ?
Full algorithm	Would Sarah Palin be a better president than John Mccain ?

Table 2: Automatically generated questions by the baselines and the full algorithm to an example article

### 5.3 Error Analysis

To better understand the performance of our algorithm, we looked at some low quality questions that were generated, either due to incorrect instantiation or due to irrelevance to the article.

Starting with relevance, one of the repeating mistakes was promoting relations that are related to a list of named entities in the article, but not to its main theme. For example, the relation ‘*who is a better actor*’ was incorrectly ranked high for an article about Ricky Gervais claiming that he has been asked to host Globes again after he offended Angelina Jolie, Johnny Depp, Robert Downey Jr. and Charlie Sheen, among others during last Globes ceremony. The reason for this mistake is that many named entities appear as frequent terms in LDA topics, and thus mentioning many names that belong to a single topic drives LDA to assign this topic a high probability. Yet, unlike other cases, here entity filtering does not help ignoring such errors, since the same entities that triggered the ranking of the relation are also valid instantiations for it.

Analyzing incorrect instantiations, many mistakes are due to mismatches between the two compared entities that were too fine grained for our algorithm to catch. For example, “*who’s the better guitarist: Paul McCartney or Ringo Starr?*” was generated since our algorithm failed to identify that *Ringo Starr* is a drummer rather than a guitarist, though both participants in the relation are musicians. In other cases, strong co-occurrence of the two celebs in our question corpus convinced the classifiers that they can be matched. For example, “*who is a better dancer Michael Jackson or Debbie Rowe?*” was incorrectly generated, since Debbie Rowe is not a dancer. Yet, she was Michael Jackson’s wife and they appear together

in a lot of questions in our corpus.

## 6 Related Work

Traditionally, question generation focuses on converting assertions in a text into question forms (Brown et al., 2005; Mitkov et al., 2006; Myller, 2007; Heilman and Smith, 2010; Rus et al., 2010; Agarwal et al., 2011; Olney et al., 2012). To the best of our knowledge, there is no prior work on our task, which is to generate relevant synthetic questions whose content, except for the arguments, might not appear in the text.

Our extraction of comparable relations falls within the field of Relation Extraction, in which CRF is a state-of-the-art method (Mooney and Bunescu, 2005; Culotta et al., 2006). We note that in the works of Jindal and Liu (2006) and Li et. al. (2010) comparative questions are identified as an intermediate step for the task of extracting compared entities, which are unknown in their setting. We, on the other hand, detect the compared entities in a pre-processing step, and our target is the extraction of the comparable relations given known candidate entities.

Our algorithm ranks relevant templates based on the similarity between an article’s content and the typical context of each relation. Prior work rank relevant concrete questions to a given input question, focusing on strong lexical similarities (Jeon et al., 2005; Cai et al., 2011; Hao and Agichtein, 2012). We, however, do not expect to find direct lexical similarities between candidate relations and the article. Instead, we are interested in a higher level topical similarity to the input article, for which LDA topics were shown to help (Celikyilmaz et al., 2010).

Finally, several works present unsupervised methods for ranking proper template instantia-

tions, mainly as selectional preferences (Light and Greiff, 2002; Erk, 2007; Ritter et al., 2010). However, we eventually choose instantiation candidates, and thus preferred supervised methods that enable filtering and not just ranking. Furthermore, we target a more subtle discrimination between entities than prior work, *e.g.* between quarterbacks, singers and actors. Machine learning naturally incorporates the many features that capture different aspects of entity characterization.

## 7 Conclusions

We introduced the novel task of automatically generating synthetic comparable questions that are relevant to a given news article but do not necessarily appear in it. To this end, we proposed an algorithm that consists of two parts. The offline part identifies comparable relations in a large collection of questions. Its output is a database of comparable relations together with a context profile for each relation and models that detect correct instantiations of this relation, all learned from the question corpus. In the online part, given a news article, the algorithm identifies relevant comparable relations based on the similarity between the article content and each relation’s context profile. Then, relevant relations are instantiated only with pairs of named entities from the article whose comparison makes sense by applying the instantiation correctness models to candidate pairs.

We assessed the performance of our algorithm via a Mechanical Turk experiment. A partial version of our algorithm, without instantiation filtering, was our strongest baseline. The full algorithm outperformed this baseline by 45% on question correctness, but surprisingly also by 46% on question relevance. These results show that our supervised filtering methods are successful in keeping only correct pairs, but they also serve as an additional filtering for relevant relations, on top of context matching.

In future work, we want to generate more diverse and intriguing questions by selecting relevant named entities for template instantiation that do not appear in the article. Another direction would be take a supervised approach, training classifiers over a labeled dataset for filtering irrelevant templates and incorrect instantiations. Finally, it would be interesting to see how our algorithm performs on other news domains.

## Abstract

Punctuations are not available in automatic speech recognition outputs, which could create barriers to many subsequent text processing tasks. This paper proposes a novel method to predict punctuation symbols for the stream of words in transcribed speech texts. Our method jointly performs parsing and punctuation prediction by integrating a rich set of syntactic features when processing words from left to right. It can exploit a global view to capture long-range dependencies for punctuation prediction with linear complexity. The experimental results on the test data sets of IWSLT and TDT4 show that our method can achieve high-level performance in punctuation prediction over the stream of words in transcribed speech text.

## 1 Introduction

Standard automatic speech recognizers output unstructured streams of words. They neither perform a proper segmentation of the output into sentences, nor predict punctuation symbols. The unavailable punctuations and sentence boundaries in transcribed speech texts create barriers to many subsequent processing tasks, such as summarization, information extraction, question answering and machine translation. Thus, the segmentation of long texts is necessary in many real applications. For example, in speech-to-speech translation, continuously transcribed speech texts need to be segmented before being fed into subsequent machine translation systems (Takezawa et al., 1998; Nakamura, 2009). This is because current machine translation (MT) systems perform the translation at the sentence level, where various models used in MT are trained over segmented sentences and many algorithms inside MT have an exponential complexity with regard to the length of inputs.

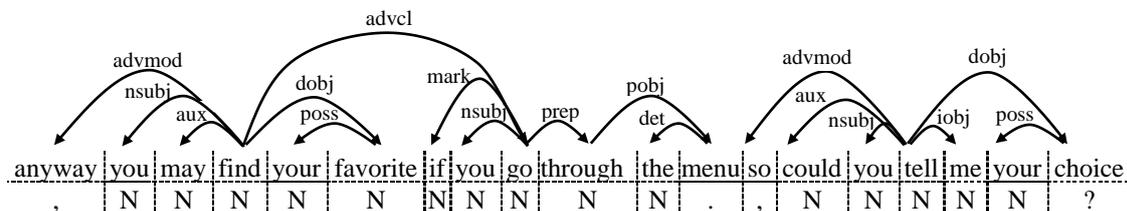

The punctuation prediction problem has attracted research interest in both the speech pro-

cessing community and the natural language processing community. Most previous work primarily exploits local features in their statistical models such as lexicons, prosodic cues and hidden event language model (HELM) (Liu et al., 2005; Matusov et al., 2006; Huang and Zweig, 2002; Stolcke and Shriberg, 1996). The word-level models integrating local features have narrow views about the input and could not achieve satisfied performance due to the limited context information access (Favre et al., 2008). Naturally, global contexts are required to model the punctuation prediction, especially for long-range dependencies. For instance, in English question sentences, the ending question mark is long-range dependent on the initial phrases (Lu and Ng, 2010), such as “*could you*” in Figure 1. There has been some work trying to incorporate syntactic features to broaden the view of hypotheses in the punctuation prediction models (Roark et al., 2006; Favre et al., 2008). In their methods, the punctuation prediction is treated as a separated post-procedure of parsing, which may suffer from the problem of error propagation. In addition, these approaches are not able to incrementally process inputs and are not efficient for very long inputs, especially in the cases of long transcribed speech texts from presentations where the number of streaming words could be larger than hundreds or thousands.

In this paper, we propose jointly performing punctuation prediction and transition-based dependency parsing over transcribed speech text. When the transition-based parsing consumes the stream of words left to right with the shift-reduce decoding algorithm, punctuation symbols are predicted for each word based on the contexts of the parsing tree. Two models are proposed to cause the punctuation prediction to interact with the transition actions in parsing. One is to conduct transition actions of parsing followed by punctuation predictions in a cascaded way. The other is to associate the conventional transition actions of parsing with punctuation predictions, so that predicted punctuations are directly inferred from the

Figure 1. An example of punctuation prediction.

parsing tree. Our models have linear complexity and are capable of handling streams of words with any length. In addition, the computation of models use a rich set of syntactic features, which can improve the complicated punctuation predictions from a global view, especially for the long range dependencies.

Figure 1 shows an example of how parsing helps punctuation prediction over the transcribed speech text. As illustrated in Figure 1(b), two commas are predicted when their preceding words act as the adverbial modifiers (*advmod*) during parsing. The period after the word “*menu*” is predicted when the parsing of an adverbial clause modifier (*advcl*) is completed. The question mark at the end of the input is determined when a direct object modifier (*dobj*) is identified, together with the long range clue that the auxiliary word occurs before the nominal subject (*nsubj*). Eventually, two segmentations are formed according to the punctuation prediction results, shown in Figure 1(c).

The training data used for our models is adapted from Treebank data by excluding all punctuations but keeping the punctuation contexts, so that it can simulate the unavailable annotated transcribed speech texts. In decoding, beam search is used to get optimal punctuation prediction results. We conduct experiments on both IWSLT data and TDT4 test data sets. The experimental results show that our method can achieve higher performance than the CRF-based baseline method.

The paper is structured as follows: Section 2 conducts a survey of related work. The transition-based dependency parsing is introduced in Section

3. We explain our approach to predicting punctuations for transcribed speech texts in Section 4. Section 5 gives the results of our experiment. The conclusion and future work are given in Section 6.

## 2 Related Work

Sentence boundary detection and punctuation prediction have been extensively studied in the speech processing field and have attracted research interest in the natural language processing field as well. Most previous work exploits local features for the task. Kim and Woodland (2001), Huang and Zweig (2002), Christensen et al. (2001), and Liu et al. (2005) integrate both prosodic features (pitch, pause duration, etc.) and lexical features (words, n-grams, etc.) to predict punctuation symbols during speech recognition, where Huang and Zweig (2002) uses a maximum entropy model, Christensen et al. (2001) focus on finite state and multi-layer perceptron methods, and Liu et al. (2005) uses conditional random fields. However, in some scenarios the prosodic cues are not available due to inaccessible original raw speech waveforms. Matusov et al. (2006) integrate segmentation features into the log-linear model in the statistical machine translation (SMT) framework to improve the translation performance when translating transcribed speech texts. Lu and Ng (2010) uses dynamic conditional random fields to perform both sentence boundary and sentence type prediction. They achieved promising results on both English and Chinese transcribed speech texts. The above work only ex-

exploits local features, so they were limited to capturing long range dependencies for punctuation prediction.

It is natural to incorporate global knowledge, such as syntactic information, to improve punctuation prediction performance. Roark et al. (2006) use a rich set of non-local features including parser scores to re-rank full segmentations. Favre et al. (2008) integrate syntactic information from a PCFG parser into a log-linear and combine it with local features for sentence segmentation. The punctuation prediction in these works is performed as a post-procedure step of parsing, where a parse tree needs to be built in advance. As their parsing over the stream of words in transcribed speech text is exponentially complex, their approaches are only feasible for short input processing. Unlike these works, we incorporate punctuation prediction into the parsing which process left to right input without length limitations.

Numerous dependency parsing algorithms have been proposed in the natural language processing community, including transition-based and graph-based dependency parsing. Compared to graph-based parsing, transition-based parsing can offer linear time complexity and easily leverage non-local features in the models (Yamada and Matsumoto, 2003; Nivre et al., 2006b; Zhang and Clark, 2008; Huang and Sagae, 2010). Starting with the work from (Zhang and Nivre, 2011), in this paper we extend transition-based dependency parsing from the sentence-level to the stream of words and integrate the parsing with punctuation prediction.

Joint POS tagging and transition-based dependency parsing are studied in (Hatori et al., 2011; Bohnet and Nivre, 2012). The improvements are reported with the joint model compared to the pipeline model for Chinese and other richly inflected languages, which shows that it also makes sense to jointly perform punctuation prediction and parsing, although these two tasks of POS tagging and punctuation prediction are different in two ways: 1). The former usually works on a well-formed single sentence while the latter needs to process multiple sentences that are very lengthy. 2). POS tags are must-have features to parsing while punctuations are not. The parsing quality in the former is more sensitive to the performance of the entire task than in the latter.

### 3 Transition-based dependency parsing

In a typical transition-based dependency parsing process, the shift-reduce decoding algorithm is

applied and a queue and stack are maintained (Zhang and Nivre, 2011). The queue stores the stream of transcribed speech words, the front of which is indexed as the current word. The stack stores the unfinished words which may be linked with the current word or a future word in the queue. When words in the queue are consumed from left to right, a set of transition actions is applied to build a parse tree. There are four kinds of transition actions conducted in the parsing process (Zhang and Nivre, 2011), as described in Table 1.

Action	Description
<i>Shift</i>	Fetches the current word from the queue and pushes it to the stack
<i>Reduce</i>	Pops the stack
<i>LeftArc</i>	Adds a dependency link from the current word to the stack top, and pops the stack
<i>RightArc</i>	Adds a dependency link from the stack top to the current word, takes away the current word from the queue and pushes it to the stack

Table 1. Action types in transition-based parsing

The choice of each transition action during the parsing is scored by a linear model that can be trained over a rich set of non-local features extracted from the contexts of the stack, the queue and the set of dependency labels. As described in (Zhang and Nivre, 2011), the feature templates could be defined over the lexicons, POS-tags and the combinations with syntactic information.

In parsing, beam search is performed to search the optimal sequence of transition actions, from which a parse tree is formed (Zhang and Clark, 2008). As each word must be pushed to the stack once and popped off once, the number of actions needed to parse a sentence is always  $2n$ , where  $n$  is the length of the sentence. Thus, transition-based parsing has a linear complexity with the length of input and naturally it can be extended to process the stream of words.

## 4 Our method

### 4.1 Model

In the task of punctuation prediction, we are given a stream of words from an automatic transcription of speech text, denoted by  $w_1^n := w_1, w_2, \dots, w_n$ . We are asked to output a sequence of punctuation symbols  $S_1^n := s_1, s_2, \dots, s_n$  where  $s_i$  is attached to  $w_i$  to form a sentence like Figure 1(c). If there are no ambiguities,  $S_1^n$  is also abbreviated as  $S$ ,

similarly for  $w_1^n$  as  $w$ . We model the search of the best sequence of predicted punctuation symbols  $S^*$  as:

$$S^* = \operatorname{argmax}_S P(S_1^n | w_1^n) \quad (1)$$

We introduce the transition-based parsing tree  $T$  to guide the punctuation prediction in Model (2), where parsing trees are constructed over the transcribed text while containing no punctuations.

$$S^* = \operatorname{argmax}_S \sum_T P(T | w_1^n) \times P(S_1^n | T, w_1^n) \quad (2)$$

Rather than enumerate all possible parsing trees, we jointly optimize the punctuation prediction model and the transition-based parsing model with the form:

$$(S^*, T^*) = \operatorname{argmax}_{(S,T)} P(T | w_1^n) \times P(S_1^n | T, w_1^n) \quad (3)$$

Let  $T_1^i$  be the constructed partial tree when  $w_1^i$  is consumed from the queue. We decompose the Model (3) into:

$$(S^*, T^*) = \operatorname{argmax}_{(S,T)} \prod_{i=1}^n P(T_1^i | T_1^{i-1}, w_1^i) \times P(s_i | T_1^i, w_1^i) \quad (4)$$

It is noted that a partial parsing tree uniquely corresponds to a sequence of transition actions, and vice versa. Suppose  $T_1^i$  corresponds to the action sequence  $A_1^i$  and let  $a_i$  denote the last action in  $A_1^i$ . As the current word  $w_i$  can only be consumed from the queue by either *Shift* or *RightArc* according to Table 1, we have  $a_i \in \{\textit{Shift}, \textit{RightArc}\}$ . Thus, we synchronize the punctuation prediction with the application of *Shift* and *RightArc* during the parsing, which is explained by Model (5).

$$(S^*, T^*) = \operatorname{argmax}_{(S,T)} \prod_{i=1}^n P(T_1^i, A_1^i | T_1^{i-1}, w_1^i) \times P(s_i | a_i, T_1^i, w_1^i) \quad (5)$$

The model is further refined by reducing the computation scope. When a full-stop punctuation is determined (i.e., a segmentation is formed), we discard the previous contexts and restart a new

procedure for both parsing and punctuation prediction over the rest of words in the stream. In this way we are theoretically able to handle the unlimited stream of words without needing to always keep the entire context history of streaming words. Let  $b_i$  be the position index of last full-stop punctuation<sup>1</sup> before  $i$ ,  $T_{b_i}^i$  and  $A_{b_i}^i$  the partial tree and corresponding action sequence over the words  $w_{b_i}^i$ , Model (5) can be rewritten by:

$$(S^*, T^*) = \operatorname{argmax}_{(S,T)} \prod_{i=1}^n P(T_{b_i}^i, A_{b_i}^i | T_{b_i}^{i-1}, w_{b_i}^i) \times P(s_i | a_i, T_{b_i}^i, w_{b_i}^i) \quad (6)$$

With different computation of Model (6), we induce two joint models for punctuation prediction: the cascaded punctuation prediction model and the unified punctuation prediction model.

## 4.2 Cascaded punctuation prediction model (CPP)

In Model (6), the computation of two sub-models is independent. The first sub-model is computed based on the context of words and partial trees without any punctuation knowledge, while the computation of the second sub-model is conditional on the context from the partially built parsing tree  $T_{b_i}^i$  and the transition action. As the words in the stream are consumed, each computation of transition actions is followed by a computation of punctuation prediction. Thus, the two sub-models are computed in a cascaded way, until the optimal parsing tree and optimal punctuation symbols are generated. We call this model the *cascaded punctuation prediction model (CPP)*.

## 4.3 Unified punctuation prediction model (UPP)

In Model (6), if the punctuation symbols can be deterministically inferred from the partial tree,  $P(s_i | a_i, T_{b_i}^i, w_{b_i}^i)$  can be omitted because it is always 1. Similar to the idea of joint POS tagging and parsing (Hatori et al., 2011; Bohnet and Nivre, 2012), we propose attaching the punctuation prediction onto the parsing tree by embedding  $s_i$  into  $a_i$ . Thus, we extend the conventional transition actions illustrated in Table 1 to a new set of transition actions for the parsing, denoted by  $\hat{A}$ :

<sup>1</sup> Specially,  $b_i$  is equal to 1 if there are no previous full-stop punctuations.

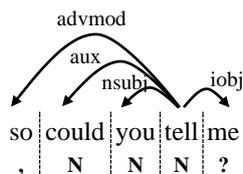

$$\hat{A} = \{LeftArc, Reduce\} \cup \{Shift(s) | s \in Q\} \\ \cup \{RightArc(s) | s \in Q\}$$

where  $Q$  is the set of punctuation symbols to be predicted,  $s$  is a punctuation symbol belonging to  $Q$ ,  $Shift(s)$  is an action that attaches  $s$  to the current word on the basis of original  $Shift$  action in parsing,  $RightArc(s)$  attaches  $s$  to the current word on the basis of original  $RightArc$  action.

With the redefined transition action set  $\hat{A}$ , the computation of Model (6) is reformulated as:

$$(S^*, T^*) = \operatorname{argmax}_{(S, T)} \prod_{i=1}^n P \left( T_{b_i}^i, \hat{A}_{b_i}^i \mid T_{b_i}^{i-1}, \hat{A}_{b_i}^{i-1}, w_{b_i}^i \right) \quad (7)$$

Here, the computation of parsing tree and punctuation prediction is unified into one model where the sequence of transition action outputs uniquely determines the punctuations attached to the words. We refer to it as the **unified punctuation prediction model (UPP)**.

(a). Parsing tree and attached punctuation symbols

$Shift(,)$ ,  $Shift(N)$ ,  $Shift(N)$ ,  $LeftArc$ ,  $LeftArc$ ,  $LeftArc$ ,  $Shift(N)$ ,  $RightArc(?)$ ,  $Reduce$ ,  $Reduce$

(b). The corresponding sequence of transition actions

Figure 2. An example of punctuation prediction using the UPP model, where N is a null type punctuation symbol denoting no need to attach any punctuation to the word.

Figure 2 illustrates an example how the UPP model works. Given an input “so could you tell me”, the optimal sequence of transition actions in Figure 2(b) is calculated based on the UPP model to produce the parsing tree in Figure 2(a). According to the sequence of actions, we can determine the sequence of predicted punctuation symbols like “,NNN?” that have been attached to the words shown in Figure 2(a). The final segmentation with the predicted punctuation insertion could be “so, could you tell me?”.

#### 4.4 Model training and decoding

In practice, the sub-models in Model (6) and (7) with the form of  $P(Y|X)$  is computed with a linear model  $Score(Y, X)$  as

$$Score(Y, X) = \Phi(Y, X) \cdot \vec{\lambda}$$

where  $\Phi(Y, X)$  is the feature vector extracted from the output  $Y$  and the context  $X$ , and  $\vec{\lambda}$  is the weight vector. For the features of the models, we incorporate the bag of words and POS tags as well as tree-based features shown in Table 2, which are the same as those defined in (Zhang and Nivre, 2011).

(a)	$w_s; w_0; w_1; w_2; p_s; p_0; p_1; p_2; w_s p_s; w_0 p_0; w_1 p_1; w_2 p_2; w_s p_s w_0 p_0; w_s p_s w_0; w_s p_s p_0; w_s w_0 p_0; p_s w_0 p_0; w_s w_0; p_s p_0; p_0 p_1; p_s p_0 p_1; p_0 p_1 p_2;$
(b)	$p_{sh} p_s p_0; p_s p_{sl} p_0; p_s p_{sr} p_0; p_s p_0 p_0; w_s d; p_s d; w_0 d; p_0 d; w_s w_0 d; p_s p_0 d; w_s v_l; p_s v_l; w_s v_r; p_s v_r; w_0 v_l; p_0 v_l; w_{sh}; p_{sh}; t_s; w_0 l; p_0 l; t_0 l; w_0 r; p_0 r; t_0 r; w_1 l; p_1 l; t_1 l; w_{sh2}; p_{sh2}; t_{sh}; w_{sl2}; p_{sl2}; t_{sl2}; w_{sr2}; p_{sr2}; t_{sr2}; w_0 l2; p_0 l2; t_0 l2; p_s p_{sl} p_{sl2}; p_s p_{sr} p_{sr2}; p_s p_{sh} p_{sh2}; p_0 p_0 p_0 l2; w_s T_l; p_s T_l; w_s T_r; p_s T_r; w_0 T_l; p_0 T_l;$

Table 2. (a) Features of the bag of words and POS tags. (b). Tree-based features.  $w$ —word;  $p$ —POS tag;  $d$ —distance between  $w_s$  and  $w_0$ ;  $v$ —number of modifiers;  $t$ —dependency label;  $T$ —set of dependency labels;  $s, 0, 1$  and  $2$  index the stack top and three front items in the queue respectively;  $h$ —head;  $l$ —left/leftmost;  $r$ —right/rightmost;  $h2$ —head of a head;  $l2$ —second leftmost;  $r2$ —second rightmost.

The training data for both the CPP and UPP models need to contain parsing trees and punctuation information. Due to the absence of annotation over transcribed speech data, we adapt the Treebank data for the purpose of model training. To do this, we remove all types of syntactic information related to punctuation symbols from the raw Treebank data, but record what punctuation symbols are attached to the words. We normalize various punctuation symbols into two types: Middle-paused punctuation (M) and Full-stop punctuation (F). Plus null type (N), there are three kinds of punctuation symbols attached to the words. Table 3 illustrates the normalizations of punctuation symbols. In the experiments, we did not further distinguish the type among full-stop punctuation because the question mark and the exclamation mark have very low frequency in Treebank data.

But our CPP and UPP models are both independent regarding the number of punctuation types to be predicted.

Punctuations	Normalization
Period, question mark, exclamation mark	Full-stop punctuation (F)
Comma, Colon, semi-colon	Middle-paused punctuation (M)
Multiple Punctuations (e.g., !!!!?)	Full-stop punctuation (F)
Quotations, brackets, etc.	Null (N)

Table 3. Punctuation normalization in training data

As the feature templates are the same for the model training of both CPP and UPP, the training instances of CPP and UPP have the same contexts but with different outputs. Similar to work in (Zhang and Clark, 2008; Zhang and Nivre, 2011), we train CPP and UPP by generalized perceptron (Collins, 2002).

In decoding, beam search is performed to get the optimal sequence of transition actions in CPP and UPP, and the optimal punctuation symbols in CPP. To ensure each segment decided by a full-stop punctuation corresponds to a single parsing tree, two constraints are applied in decoding for the pruning of deficient search paths.

- (1) Proceeding-constraint: If the partial parsing result is not a single tree, the full-stop punctuation prediction in CPP cannot be performed. In UPP, if *Shift(F)* or *RightArc(F)* fail to result in a single parsing tree, they cannot be performed as well.
- (2) Succeeding-constraint: If the full-stop punctuation is predicted in CPP, or *Shift(F)* and *RightArc(F)* are performed in UPP, the following transition actions must be a sequence of *Reduce* actions until the stack becomes empty.

## 5 Experiments

### 5.1 Experimental setup

Our training data of transition-based dependency trees are converted from phrasal structure trees in English Web Treebank (LDC2012T13) and the English portion of OntoNotes 4.0 (LDC2011T03) by the Stanford Conversion toolkit (Marneffe et al., 2006). It contains around 1.5M words in total and consist of various genres including weblogs, web texts, newsgroups, email, reviews, question-

answer sessions, newswires, broadcast news and broadcast conversations. To simulate the transcribed speech text, all words in dependency trees are lowercased and punctuations are excluded before model training. In addition, every ten dependency trees are concatenated sequentially to simulate a parsing result of a stream of words in the model training.

There are two test data sets used in our experiments. One is the English corpus of the IWSLT09 evaluation campaign (Paul, 2009) that is the conversational speech text. The other is a subset of the TDT4 English data (LDC2005T16) which consists of 200 hours of closed-captioned broadcast news.

In the decoding, the beam size of both the transition-based parsing and punctuation prediction is set to 5. The part-of-speech tagger is our re-implementation of the work in (Collins, 2002).

The evaluation metrics of our experiments are precision (*prec.*), recall (*rec.*) and F1-measure ( $F_1$ ).

For the comparison, we also implement a baseline method based on the CRF model. It incorporates the features of bag of words and POS tags shown in Table 2(a), which are commonly used in previous related work.

### 5.2 Experimental results

We test the performance of our method on both the correctly recognized texts and automatically recognized texts. The former data is used to evaluate the capability of punctuation prediction of our algorithm regardless of the noises from speech data, as our model training data come from formal text instead of transcribed speech data. The usage of the latter test data set aims to evaluate the effectiveness of our method in real applications where lots of substantial recognition errors could be contained. In addition, we also evaluate the quality of our transition-based parsing, as its performance could have a big influence on the quality of punctuation prediction.

#### 5.2.1 Performance on correctly recognized text

The evaluation of our method on correctly recognized text uses 10% of IWSLT09 training set, which consists of 19,972 sentences from BTEC (Basic Travel Expression Corpus) and 10,061 sentences from CT (Challenge Task). The average input length is about 10 words and each input contains 1.3 sentences on average. The evaluation results are presented in Table 4.

	Measure	Middle-Paused	Full-stop	Mixed
Baseline (CRF)	<i>prec.</i>	33.2%	81.5%	78.8%
	<i>rec.</i>	25.9%	83.8%	80.7%
	$F_1$	29.1%	82.6%	79.8%
CPP	<i>prec.</i>	51%	89%	89.6%
	<i>rec.</i>	50.3%	93.1%	92.7%
	$F_1$	50.6%	91%	91.1%
UPP	<i>prec.</i>	52.6%	93.2%	92%
	<i>rec.</i>	59.7%	91.3%	92.3%
	$F_1$	55.9%	92.2%	92.2%

Table 4. Punctuation prediction performance on correctly recognized text

We achieved good performance on full-stop punctuation compared to the baseline, which shows our method can efficiently process sentence segmentation because each segment is decided by the structure of a single parsing tree. In addition, the global syntactic knowledge used in our work help capture long range dependencies of punctuations. The performance of middle-paused punctuation prediction is fairly low between all methods, which shows predicting middle-paused punctuations is a difficult task. This is because the usage of middle-paused punctuations is very flexible, especially in conversational data. The last column in Table 4 presents the performance of the pure segmentation task where the middle-paused and full-stop punctuations are mixed and not distinguished. The performance of our method is much higher than that of the baseline, which shows our method is good at segmentation. We also note that UPP yields slightly better performance than CPP on full-stop and mixed punctuation prediction, and much better performance on middle-paused punctuation prediction. This could be because the interaction of parsing and punctuation prediction is closer together in UPP than in CPP.

### 5.2.2 Performance on automatically recognized text

Table 5 shows the experimental results of punctuation prediction on automatically recognized text from TDT4 data that is recognized using SRI’s English broadcast news ASR system where the word error rate is estimated to be 18%. As the annotation of middle-paused punctuations in TDT4 is not available, we can only evaluate the performance of full-stop punctuation prediction (i.e., detecting sentence boundaries). Thus, we merge every three sentences into one single input before

performing full-stop prediction. The average input length is about 43 words.

	Measure	Full-stop
Baseline (CRF)	<i>prec.</i>	37.7%
	<i>rec.</i>	60.7%
	$F_1$	46.5%
CPP	<i>prec.</i>	63%
	<i>rec.</i>	58.6%
	$F_1$	60.2%
UPP	<i>prec.</i>	73.9%
	<i>rec.</i>	51.6%
	$F_1$	60.7%

Table 5. Punctuation prediction performance on automatically recognized text

Generally, the performance shown in Table 5 is not as high as that in Table 4. This is because the speech recognition error from ASR systems degrades the capability of model prediction. Another reason might be that the domain and style of our training data mismatch those of TDT4 data. The baseline gets a little higher recall than our method, which shows the baseline method tends to make aggressive segmentation decisions. However, both precision and  $F_1$  score of our method are much higher than the baseline. CPP has higher recall than UPP, but with lower precision and  $F_1$  score. This is in line with Table 4, which consistently illustrates CPP can get higher recall on full-stop punctuation prediction for both correctly recognized and automatically recognized texts.

### 5.2.3 Performance of transition-based parsing

Performance of parsing affects the quality of punctuation prediction in our work. In this section, we separately evaluate the performance of our transition-based parser over various domains including the Wall Street Journal (WSJ), weblogs, newsgroups, answers, email messages and reviews. We divided annotated Treebank data into three data sets: 90% for model training, 5% for the development set and 5% for the test set. The accuracy of our POS-tagger achieves 96.71%. The beam size in the decoding of both our POS-tagging and parsing is set to 5. Table 6 presents the results of our experiments on the measures of UAS and LAS, where the overall accuracy is obtained from a general model which is trained over the combination of the training data from all domains.

We first evaluate the performance of our transition-based parsing over texts containing punctuations (TCP). The evaluation results show that our transition-based parser achieves state-of-the-art performance levels, referring to the best dependency parsing results reported in the shared task of SANCL 2012 workshop<sup>2</sup>, although they cannot be compared directly due to the different training data and test data sets used in the experiments. Secondly, we evaluate our parsing model in CPP over the texts without punctuations (TOP). Surprisingly, the performance over TOP is better than that over TCP. The reason could be that we cleaned out data noises caused by punctuations when preparing TOP data. These results illustrate that the performance of transition-based parsing in our method does not degrade after being integrated with punctuation prediction. As a by-product of the punctuation prediction task, the outputs of parsing trees can benefit the subsequent text processing tasks.

	Data sets	UAS	LAS
Texts containing punctuations (TCP)	WSJ	92.6%	90.3%
	Weblogs	90.7%	88.2%
	Answers	89.4%	85.7%
	Newsgroups	90.1%	87.6%
	Reviews	90.9%	88.4%
	Email Messages	89.6%	87.1%
	Overall	90.5%	88%
Texts without punctuations (TOP)	WSJ	92.6%	91.1%
	Weblogs	92.5%	91.1%
	Answers	95%	94%
	Newsgroups	92.6%	91.2%
	Reviews	92.6%	91.2%
	Email Messages	92.9%	91.7%
	Overall	92.6%	91.2%

Table 6. The performance of our transition-based parser on written texts. UAS=unlabeled attachment score; LAS=labeled attachment score

## 6 Conclusion and Future Work

In this paper, we proposed a novel method for punctuation prediction of transcribed speech texts. Our approach jointly performs parsing and punctuation prediction by integrating a rich set of syntactic features. It can not only yield parse trees, but also determine sentence boundaries and predict punctuation symbols from a global view of the in-

puts. The proposed algorithm has linear complexity in the size of input, which can efficiently process the stream of words from a purely text processing perspective without the dependences on either the ASR systems or subsequent tasks. The experimental results show that our approach outperforms the CRF-based method on both the correctly recognized and automatically recognized texts. In addition, the performance of the parsing over the stream of transcribed words is state-of-the-art, which can benefit many subsequent text processing tasks.

In future work, we will try our method on other languages such as Chinese and Japanese, where Treebank data is available. We would also like to test the MT performance over transcribed speech texts with punctuation symbols inserted based on our method proposed in this paper.

## Abstract

Structural information in web text provides natural annotations for NLP problems such as word segmentation and parsing. In this paper we propose a discriminative learning algorithm to take advantage of the linguistic knowledge in large amounts of natural annotations on the Internet. It utilizes the Internet as an external corpus with massive (although slight and sparse) natural annotations, and enables a classifier to evolve on the large-scaled and real-time updated web text. With Chinese word segmentation as a case study, experiments show that the segmenter enhanced with the Chinese wikipedia achieves significant improvement on a series of testing sets from different domains, even with a single classifier and local features.

## 1 Introduction

Problems related to information retrieval, machine translation and social computing need fast and accurate text processing, for example, word segmentation and parsing. Taking Chinese word segmentation for example, the state-of-the-art models (Xue and Shen, 2003; Ng and Low, 2004; Gao et al., 2005; Nakagawa and Uchimoto, 2007; Zhao and Kit, 2008; Jiang et al., 2009; Zhang and Clark, 2010; Sun, 2011b; Li, 2011) are usually trained on human-annotated corpora such as the Penn Chinese Treebank (CTB) (Xue et al., 2005), and perform quite well on corresponding test sets. Since the text used for corpus annotating are usually drawn from specific fields (e.g. newswire or finance), and the annotated corpora are limited in

(c) Knowledge for dependency parsing

Figure 1: Natural annotations for word segmentation and dependency parsing.

size (e.g. tens of thousands), the performance of word segmentation tends to degrade sharply when applied to new domains.

Internet provides large amounts of raw text, and statistics collected from it have been used to improve parsing performance (Nakov and Hearst, 2005; Pitler et al., 2010; Bansal and Klein, 2011; Zhou et al., 2011). The Internet also gives massive (although slight and sparse) natural annotations in the forms of structural information including hyperlinks, fonts, colors and layouts (Sun, 2011a). These annotations usually imply valuable knowledge for problems such as word segmentation and parsing, based on the hypothesis that the subsequences marked by structural information are meaningful fragments in sentences. Figure 1 shows an example. The hyperlink indicates

a Chinese phrase (meaning NLP), and it probably corresponds to a connected sub-graph for dependency parsing. Creators of web text give valuable annotations during editing, the whole Internet can be treated as a wide-covered and real-time updated corpus.

Different from the dense and accurate annotations in human-annotated corpora, natural annotations in web text are sparse and slight, it makes direct training of NLP models impracticable. In this work we take for example a most important problem, word segmentation, and propose a novel discriminative learning algorithm to leverage the knowledge in massive natural annotations of web text. Character classification models for word segmentation usually factorize the whole prediction into atomic predictions on characters (Xue and Shen, 2003; Ng and Low, 2004). Natural annotations in web text can be used to get rid of implausible predication candidates for related characters, knowledge in the natural annotations is therefore introduced in the manner of searching space pruning. Since constraint decoding in the pruned searching space integrates the knowledge of the baseline model and natural annotations, it gives predictions not worse than the normal decoding does. Annotation differences between the outputs of constraint decoding and normal decoding are used to train the enhanced classifier. This strategy makes the usage of natural annotations simple and universal, which facilitates the utilization of massive web text and the extension to other NLP problems.

Although there are lots of choices, we choose the Chinese wikipedia as the knowledge source due to its high quality. Structural information, including hyperlinks, fonts and colors are used to determine the boundaries of meaningful fragments. Experimental results show that, the knowledge implied in the natural annotations can significantly improve the performance of a baseline segmenter trained on CTB 5.0, an F-measure increment of 0.93 points on CTB test set, and an average increment of 1.53 points on 7 other domains. It is an effective and inexpensive strategy to build word segmenters adaptive to different domains. We hope to extend this strategy to other NLP problems such as named entity recognition and parsing.

In the rest of the paper, we first briefly introduce the problems of Chinese word segmentation and the character classification model in section

2, then describe the representation of the knowledge in natural annotations of web text in section 3, and finally detail the strategy of discriminative learning on natural annotations in section 4. After giving the experimental results and analysis in section 5, we briefly introduce the previous related work and then give the conclusion and the expectation of future research.

## 2 Character Classification Model

Character classification models for word segmentation factorize the whole prediction into atomic predictions on single characters (Xue and Shen, 2003; Ng and Low, 2004). Although natural annotations in web text do not directly support the discriminative training of segmentation models, they do get rid of the implausible candidates for predictions of related characters.

Given a sentence as a sequence of  $n$  characters, word segmentation splits the sequence into  $m(\leq n)$  subsequences, each of which indicates a meaningful word. Word segmentation can be formalized as a character classification problem (Xue and Shen, 2003), where each character in the sentence is given a boundary tag representing its position in a word. We adopt the boundary tags of Ng and Low (2004),  $b$ ,  $m$ ,  $e$  and  $s$ , where  $b$ ,  $m$  and  $e$  mean the beginning, the middle and the end of a word, and  $s$  indicates a single-character word. the decoding procedure searches for the labeled character sequence  $y$  that maximizes the score func-

- 

tion:

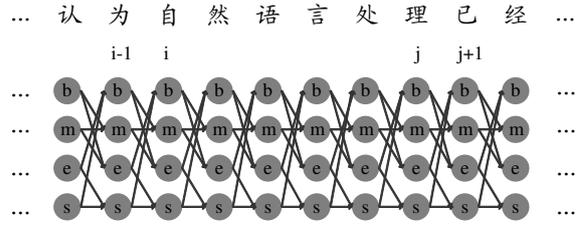

$$\begin{aligned} f(x) &= \arg \max_y S(y | \vec{\alpha}, \Phi, x) \\ &= \arg \max_y \Phi(x, y) \cdot \vec{\alpha} \\ &= \arg \max_y \sum_{(i,t) \in y} \Phi(i, t, x, y) \cdot \vec{\alpha} \end{aligned} \quad (1)$$

The score of the whole sequence  $y$  is accumulated across all its character-label pairs,  $(i, t) \in y$  (s.t.  $1 \leq i \leq n$  and  $t \in \{b, m, e, s\}$ ). The feature function  $\Phi$  maps a labeled sequence or a character-label pair into a feature vector,  $\vec{\alpha}$  is the parameter vector and  $\Phi(x, y) \cdot \vec{\alpha}$  is the inner product of  $\Phi(x, y)$  and  $\vec{\alpha}$ .

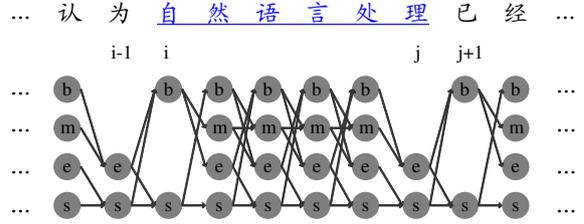

Analogous to other sequence labeling problems, word segmentation can be solved through a viterbi-style decoding procedure. We omit the decoding algorithm in this paper due to its simplicity and popularity.

The feature templates for the classifier is shown in Table 1.  $C_0$  denotes the current character, while  $C_{-k}/C_k$  denote the  $k$ th character to the left/right of  $C_0$ . The function  $Pu(\cdot)$  returns *true* for a punctuation character and *false* for others, the function  $T(\cdot)$  classifies a character into four types, 1, 2, 3 and 4, representing *number*, *date*, *English letter* and *others*, respectively.

The classifier can be trained with online learning algorithms such as perceptron, or offline learning models such as support vector machines. We choose the perceptron algorithm (Collins, 2002) to train the classifier for the character classification-based word segmentation model. It learns a discriminative model mapping from the inputs  $x \in X$  to the outputs  $\tilde{y} \in Y$ , where  $X$  is the set of sentences in the training corpus and  $Y$  is the set of corresponding labeled results. Algorithm 1 shows the perceptron algorithm for tuning the parameter  $\vec{\alpha}$ . The ‘‘averaged parameters’’ technology (Collins, 2002) is used for better performance.

(b) Shrunk searching space

Figure 2: Shrink of searching space for the character classification-based word segmentation model.

### 3 Knowledge in Natural Annotations

Web text gives massive natural annotations in the form of structural informations, including hyperlinks, fonts, colors and layouts (Sun, 2011a). Although slight and sparse, these annotations imply valuable knowledge for problems such as word segmentation and parsing.

As shown in Figure 1, the subsequence  $P = i..j$  of sentence  $S$  is composed of bolded characters determined by a hyperlink. Such natural annotations do not clearly give each character a boundary tag, or define the head-modifier relationship between two words. However, they do help to shrink the set of plausible predication candidates for each character or word. For word segmentation, it implies that characters  $i - 1$  and  $j$  are the rightmost characters of words, while characters  $i$  and  $j + 1$  are the leftmost characters of words. For  $i - 1$  or  $j$ , the plausible predication set  $\Psi$  becomes  $\{e, s\}$ ; For  $i$  and  $j + 1$ , it becomes  $\{b, s\}$ ; For other characters  $c$  except the two at sentence boundaries,  $\Psi(c)$  is still  $\{b, m, e, s\}$ . For dependency parsing, the subsequence  $P$  tends to form a connected dependency graph if it contains more than one word. Here we use  $\Psi$  to denote the set of plausible head of a word (modifier). There must be a single word  $w \in P$  as the root of subsequence  $P$ , whose plausible heads fall out of  $P$ , that is,  $\Psi(w) = \{x | x \in S - P\}$ . For the words in  $P$  except the root, the plausible heads for each

```

---

word  $w$  are the words in  $P$  except  $w$  itself, that is,  $\Psi(w) = \{x | x \in P - \{w\}\}$ .

Creators of web text give valuable structural annotations during editing, these annotations reduce the predication uncertainty for atomic characters or words, although not exactly defining which predication is. Figure 2 shows an example for word segmentation, depicting the shrink of searching space for the character classification-based model. Since the decrement of uncertainty indicates the increment of knowledge, the whole Internet can be treated as a wide-covered and real-time updated corpus. We choose the Chinese wikipedia as the external knowledge source, and structural information including hyperlinks, fonts and colors are used in the current work due to their explicitness of representation.

#### 4 Learning with Natural Annotations

Different from the dense and accurate annotations in human-annotated corpora, natural annotations are sparse and slight, which makes direct training of NLP models impracticable. Annotations implied by structural information do not give an exact predication to a character, however, they help to get rid of the implausible predication candidates for related characters, as described in the previous section.

Previous work on constituency parsing or machine translation usually resort to some kinds of heuristic tricks, such as punctuation restrictions, to eliminate some implausible candidates during decoding. Here the natural annotations also bring knowledge in the manner of searching space pruning. Conditioned on the completeness of the decoding algorithm, a model trained on an existing corpus probably gives better or at least not worse predications, by constraint decoding in the pruned searching space. The constraint decoding procedure integrates the knowledge of the baseline

---

**Algorithm 3** Online version of perceptron learning with natural annotations.

```
1:  $\vec{\alpha} \leftarrow \text{TRAIN}(\mathcal{C})$ 
2: for  $x$  with natural annotations do
3:    $y \leftarrow \text{DECODE}(x, \vec{\alpha})$ 
4:    $\tilde{y} \leftarrow \text{CONSTRAINTDECODE}(x, \vec{\alpha}, \Psi)$ 
5:   if  $y \neq \tilde{y}$  then
6:      $\vec{\alpha} \leftarrow \vec{\alpha} + \Phi(x, \tilde{y}) - \Phi(x, y)$ 
7:   output  $\vec{\alpha}$  at regular time
```

---

model and natural annotations, the predication differences between the outputs of constraint decoding and normal decoding can be used to train the enhanced classifier.

Restrictions of the searching space according to natural annotations can be easily incorporated into the decoder. If the completeness of the searching algorithm can be guaranteed, the constraint decoding in the pruned searching space will give predications not worse than those given by the normal decoding. If a predication of constraint decoding differs from that of normal decoding, it indicates that the annotation precision is higher than the latter. Furthermore, the degree of difference between the two predications represents the amount of new knowledge introduced by the natural annotations over the baseline.

The baseline model  $\vec{\alpha}$  is trained on an existing human-annotated corpus. A set of sentences  $\mathcal{F}$  with natural annotations are extracted from the Chinese wikipedia, and we reserve the ones for which constraint decoding and normal decoding give different predications. The predictions of reserved sentences by constraint decoding are used as additional training data for the enhanced classifier. The overall training pipeline is analogous to self-training (McClosky et al., 2006), Algorithm 2 shows the pseudo-codes. Considering the *online* characteristic of the perceptron algorithm, if we are able to leverage much more (than the Chinese wikipedia) data with natural annotations, an online version of learning procedure shown in Algorithm 3 would be a better choice. The technology of “averaged parameters” (Collins, 2002) is easily to be adapted here for better performance.

When constraint decoding and normal decoding give different predications, we only know that the former is probably better than the latter. Although there is no explicit evidence for us to measure how much difference in accuracy between the

Partition	Sections	# of word
<b>CTB</b>		
Training	1 – 270	0.47M
	400 – 931	
	1001 – 1151	
Developing	301 – 325	6.66K
Testing	271 – 300	7.82K

Table 2: Data partitioning for CTB 5.0.

two predications, we can approximate how much new knowledge that a naturally annotated sentence brings. For a sentence  $x$ , given the predications of constraint decoding and normal decoding,  $\tilde{y}$  and  $y$ , the difference of their scores  $\delta = S(y) - S(\tilde{y})$  indicates the degree to which the current model mistakes. This indicator helps us to select more valuable training examples.

The strategy of learning with natural annotations can be adapted to other situations. For example, if we have a list of words or phrases (especially in a specific domain such as medicine and chemical), we can generate annotated sentences automatically by string matching in a large amount of raw text. It probably provides a simple and effective domain adaptation strategy for already trained models.

## 5 Experiments

We use the Penn Chinese Treebank 5.0 (CTB) (Xue et al., 2005) as the existing annotated corpus for Chinese word segmentation. For convenient of comparison with other work in word segmentation, the whole corpus is split into three partitions as follows: chapters 271-300 for testing, chapters 301-325 for developing, and others for training. We choose the Chinese wikipedia<sup>1</sup> (version 20120812) as the external knowledge source, because it has high quality in contents and it is much better than usual web text. Structural informations, including hyperlinks, fonts and colors are used to derive the annotation information.

To further evaluate the improvement brought by the fuzzy knowledge in Chinese wikipedia, a series of testing sets from different domains are adopted. The four testing sets from SIGHAN Bakeoff 2010 (Zhao and Liu, 2010) are used, they are drawn from the domains of literature, finance, computer science and medicine. Although the reference sets are annotated according to a different

<sup>1</sup><http://download.wikimedia.org/backup-index.html>.

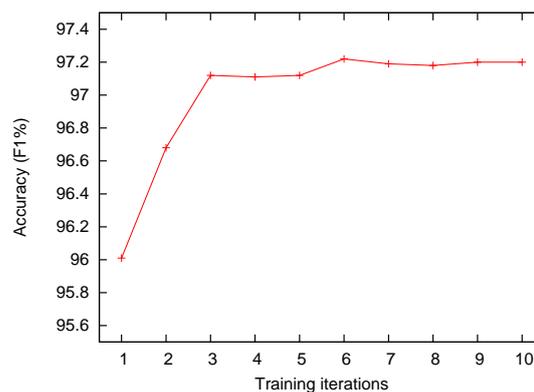

Figure 3: Learning curve of the averaged perceptron classifier on the CTB developing set.

word segmentation standard (Yu et al., 2001), the quantity of accuracy improvement is still illustrative since there are no vast diversities between the two segmentation standards. We also annotated another three testing sets<sup>2</sup>, their texts are drawn from the domains of chemistry, physics and machinery, and each contains 500 sentences.

### 5.1 Baseline Classifier for Word Segmentation

We train the baseline perceptron classifier for word segmentation on the training set of CTB 5.0, using the developing set to determine the best training iterations. The performance measurement for word segmentation is balanced F-measure,  $F = 2PR/(P + R)$ , a function of precision  $P$  and recall  $R$ , where  $P$  is the percentage of words in segmentation results that are segmented correctly, and  $R$  is the percentage of correctly segmented words in the gold standard words.

Figure 3 shows the learning curve of the averaged perceptron on the developing set. The second column of Table 3 lists the performance of the baseline classifier on eight testing sets, where newswire denotes the testing set of the CTB itself. The classifier performs much worse on the domains of chemistry, physics and machinery, it indicates the importance of domain adaptation for word segmentation (Gao et al., 2004; Ma and Way, 2009; Gao et al., 2010). The accuracy on the testing sets from SIGHAN Bakeoff 2010 is even lower due to the difference in both domains and word segmentation standards.

<sup>2</sup>They are available at <http://nlp.ict.ac.cn/jiangwenbin/>.

Table 3: Performance of the baseline classifier and the classifier enhanced with natural annotations in Chinese wikipedia.

## 5.2 Classifier Enhanced with Natural Annotations

The Chinese wikipedia contains about 0.5 million items. From their description text, about 3.9 millions of sentences with natural annotations are extracted. With the CTB training set as the existing corpus  $\mathcal{C}$ , about 0.8 million sentences are reserved according to Algorithm 2, the segmentations given by constraint decoding are used as additional training data for the enhanced classifier.

According to the previous description, the difference of the scores of constraint decoding and normal decoding,  $\delta = S(y) - S(\tilde{y})$ , indicates the importance of a constraint segmentation to the improvement of the baseline classifier. The constraint segmentations of the reserved sentences are sorted in descending order according to the difference of the scores of constraint decoding and normal decoding, as described previously. From the beginning of the sorted list, different amounts of segmented sentences are used as the additional training data for the enhanced character classifier. Figure 4 shows the performance curve of the enhanced classifiers on the developing set of CTB. We found that the highest accuracy was achieved when 160,000 sentences were used, while more additional training data did not give continuous improvement. A recent related work about self-training for segmentation (Liu and Zhang, 2012) also reported a very similar trend, that only a moderate amount of raw data gave the most obvious improvements.

The performance of the enhanced classifier is listed in the third column of Table 3. On the CTB testing set, training data from the Chinese

(Sun, 2011b)	98.17
<b>Our Work</b>	<b>98.28</b>

Table 4: Comparison with state-of-the-art work in Chinese word segmentation.

wikipedia brings an F-measure increment of 0.93 points. On out-of-domain testing sets, the improvements are much larger, an average increment of 1.53 points is achieved on seven domains. It is probably because the distribution of the knowledge in the CTB training data is concentrated in the domain of newswire, while the contents of the Chinese wikipedia cover a broad range of domains, it provides knowledge complementary to that of CTB.

Table 4 shows the comparison with other work in Chinese word segmentation. Our model achieves an accuracy higher than that of the state-of-the-art models trained on CTB only, although using a single classifier with only local features. From the viewpoint of resource utilization, the comparison between our system and previous work without using additional training data is unfair. However, we believe this work shows another interesting way to improve Chinese word segmentation, it focuses on the utilization of fuzzy and sparse knowledge on the Internet rather than making full use of a specific human-annotated corpus. On the other hand, since only a single classifier and local features are used in our method, better performance could be achieved

resorting to complicated features, system combination and other semi-supervised technologies. What is more, since the text on Internet is wide-covered and real-time updated, our strategy also helps a word segmenter be more domain adaptive and up to date.

## 6 Related Work

Li and Sun (2009) extracted character classification instances from raw text for Chinese word segmentation, resorting to the indication of punctuation marks between characters. Sun and Xu (Sun and Xu, 2011) utilized the features derived from large-scaled unlabeled text to improve Chinese word segmentation. Although the two work also made use of large-scaled raw text, our method is essentially different from theirs in the aspects of both the source of knowledge and the learning strategy.

Lots of efforts have been devoted to semi-supervised methods in sequence labeling and word segmentation (Xu et al., 2008; Suzuki and Isozaki, 2008; Haffari and Sarkar, 2008; Tomanek and Hahn, 2009; Wang et al., 2011). A semi-supervised method tries to find an optimal hyper-plane of both annotated data and raw data, thus to result in a model with better coverage and higher accuracy. Researchers have also investigated unsupervised methods in word segmentation (Zhao and Kit, 2008; Johnson and Goldwater, 2009; Mochihashi et al., 2009; Hewlett and Cohen, 2011). An unsupervised method mines the latent distribution regularity in the raw text, and automatically induces word segmentation knowledge from it. Our method also needs large amounts of external data, but it aims to leverage the knowledge in the fuzzy and sparse annotations. It is fundamentally different from semi-supervised and unsupervised methods in that we aimed to excavate a totally different kind of knowledge, the natural annotations implied by the structural information in web text.

In recent years, much work has been devoted to the improvement of word segmentation in a variety of ways. Typical approaches include the introduction of global training or complicated features (Zhang and Clark, 2007; Zhang and Clark, 2010), the investigation of word internal structures (Zhao, 2009; Li, 2011), the adjustment or adaptation of word segmentation standards (Wu, 2003; Gao et al., 2004; Jiang et al., 2009), the integrated

solution of segmentation and related tasks such as part-of-speech tagging and parsing (Zhou and Su, 2003; Zhang et al., 2003; Fung et al., 2004; Goldberg and Tsarfaty, 2008), and the strategies of hybrid or stacked modeling (Nakagawa and Uchimoto, 2007; Kruengkrai et al., 2009; Wang et al., 2010; Sun, 2011b).

In parsing, Pereira and Schabes (1992) proposed an extended inside-outside algorithm that infers the parameters of a stochastic CFG from a partially parsed treebank. It uses partial bracketing information to improve parsing performance, but it is specific to constituency parsing, and its computational complexity makes it impractical for massive natural annotations in web text. There are also work making use of word co-occurrence statistics collected in raw text or Internet n-grams to improve parsing performance (Nakov and Hearst, 2005; Pitler et al., 2010; Zhou et al., 2011; Bansal and Klein, 2011). When enriching the related work during writing, we found a work on dependency parsing (Spitkovsky et al., 2010) who utilized parsing constraints derived from hypertext annotations to improve the unsupervised dependency grammar induction. Compared with their method, the strategy we proposed is formal and universal, the discriminative learning strategy and the quantitative measurement of fuzzy knowledge enable more effective utilization of the natural annotation on the Internet when adapted to parsing.

## 7 Conclusion and Future Work

This work presents a novel discriminative learning algorithm to utilize the knowledge in the massive natural annotations on the Internet. Natural annotations implied by structural information are used to decrease the searching space of the classifier, then the constraint decoding in the pruned searching space gives predictions not worse than the normal decoding does. Annotation differences between the outputs of constraint decoding and normal decoding are used to train the enhanced classifier, linguistic knowledge in the human-annotated corpus and the natural annotations of web text are thus integrated together. Experiments on Chinese word segmentation show that, the enhanced word segmenter achieves significant improvement on testing sets of different domains, although using a single classifier with only local features.

Since the contents of web text cover a broad range of domains, it provides knowledge comple-

mentary to that of human-annotated corpora with concentrated distribution of domains. The content on the Internet is large-scaled and real-time updated, it compensates for the drawback of expensive building and updating of corpora. Our strategy, therefore, enables us to build a classifier more domain adaptive and up to date. In the future, we will compare this method with self-training to better illustrate the importance of boundary information, and give error analysis on what types of errors are reduced by the method to make this investigation more complete. We will also investigate more efficient algorithms to leverage more massive web text with natural annotations, and further extend the strategy to other NLP problems such as named entity recognition and parsing.

## Abstract

This paper introduces a graph-based semi-supervised joint model of Chinese word segmentation and part-of-speech tagging. The proposed approach is based on a graph-based label propagation technique. One constructs a nearest-neighbor similarity graph over all trigrams of labeled and unlabeled data for propagating syntactic information, i.e., label distributions. The derived label distributions are regarded as virtual evidences to regularize the learning of linear conditional random fields (CRFs) on unlabeled data. An inductive character-based joint model is obtained eventually. Empirical results on Chinese tree bank (CTB-7) and Microsoft Research corpora (MSR) reveal that the proposed model can yield better results than the supervised baselines and other competitive semi-supervised CRFs in this task.

## 1 Introduction

Word segmentation and part-of-speech (POS) tagging are two critical and necessary initial procedures with respect to the majority of high-level Chinese language processing tasks such as syntax parsing, information extraction and machine translation. The traditional way of segmentation and tagging is performed in a pipeline approach, first segmenting a sentence into words, and then assigning each word a POS tag. The pipeline approach is very simple to implement, but frequently causes error propagation, given that wrong segmentations in the earlier stage harm the subsequent POS tagging (Ng and Low, 2004). The joint approaches of word segmentation and POS tagging (joint S&T) are proposed to resolve these two tasks simultaneously. They effectively alleviate the error propagation, because segmentation

and tagging have strong interaction, given that most segmentation ambiguities cannot be resolved without considering the surrounding grammatical constructions encoded in a POS sequence (Qian and Liu, 2012).

In the past years, several proposed supervised joint models (Ng and Low, 2004; Zhang and Clark, 2008; Jiang et al., 2009; Zhang and Clark, 2010) achieved reasonably accurate results, but the outstanding problem among these models is that they rely heavily on a large amount of labeled data, i.e., segmented texts with POS tags. However, the production of such labeled data is extremely time-consuming and expensive (Jiao et al., 2006; Jiang et al., 2009). Therefore, semi-supervised joint S&T appears to be a natural solution for easily incorporating accessible unlabeled data to improve the joint S&T model. This study focuses on using a graph-based label propagation method to build a semi-supervised joint S&T model. Graph-based label propagation methods have recently shown they can outperform the state-of-the-art in several natural language processing (NLP) tasks, e.g., POS tagging (Subramanya et al., 2010), knowledge acquisition (Talukdar et al., 2008), shallow semantic parsing for unknown predicate (Das and Smith, 2011). As far as we know, however, these methods have not yet been applied to resolve the problem of joint Chinese word segmentation (CWS) and POS tagging.

Motivated by the works in (Subramanya et al., 2010; Das and Smith, 2011), for structured problems, graph-based label propagation can be employed to infer valuable syntactic information (n-gram-level label distributions) from labeled data to unlabeled data. This study extends this intuition to construct a similarity graph for propagating trigram-level label distributions. The derived label distributions are regarded as prior knowledge to regularize the learning of a sequential model, conditional random fields (CRFs) in this case, on both

labeled and unlabeled data to achieve the semi-supervised learning. The approach performs the incorporation of the derived labeled distributions by manipulating a “virtual evidence” function as described in (Li, 2009). Experiments on the data from the Chinese tree bank (CTB-7) and Microsoft Research (MSR) show that the proposed model results in significant improvement over other comparative candidates in terms of F-score and out-of-vocabulary (OOV) recall.

This paper is structured as follows: Section 2 points out the main differences with the related work of this study. Section 3 reviews the background, including supervised character-based joint S&T model based on CRFs and graph-based label propagation. Section 4 presents the details of the proposed approach. Section 5 reports the experiment results. The conclusion is drawn in Section 6.

## 2 Related Work

Prior supervised joint S&T models present approximate 0.2% - 1.3% improvement in F-score over supervised pipeline ones. The state-of-the-art joint models include reranking approaches (Shi and Wang, 2007), hybrid approaches (Nakagawa and Uchimoto, 2007; Jiang et al., 2008; Sun, 2011), and single-model approaches (Ng and Low, 2004; Zhang and Clark, 2008; Kruengkrai et al., 2009; Zhang and Clark, 2010). The proposed approach in this paper belongs to the single-model type.

There are few explorations of semi-supervised approaches for CWS or POS tagging in previous works. Xu et al. (2008) described a Bayesian semi-supervised CWS model by considering the segmentation as the hidden variable in machine translation. Unlike this model, the proposed approach is targeted at a general model, instead of one oriented to machine translation task. Sun and Xu (2011) enhanced a CWS model by interpolating statistical features of unlabeled data into the CRFs model. Wang et al. (2011) proposed a semi-supervised pipeline S&T model by incorporating  $n$ -gram and lexicon features derived from unlabeled data. Different from their concern, our emphasis is to learn the semi-supervised model by injecting the label information from a similarity graph constructed from labeled and unlabeled data.

The induction method of the proposed approach

also differs from other semi-supervised CRFs algorithms. Jiao et al. (2006), extended by Mann and McCallum (2007), reported a semi-supervised CRFs model which aims to guide the learning by minimizing the conditional entropy of unlabeled data. The proposed approach regularizes the CRFs by the graph information. Subramanya et al. (2010) proposed a graph-based self-train style semi-supervised CRFs algorithm. In the proposed approach, an analogous way of graph construction intuition is applied. But overall, our approach differs in three important aspects: first, novel feature templates are defined for measuring the similarity between vertices. Second, the critical property, i.e., sparsity, is considered among label propagation. And third, the derived label information from the graph is smoothed into the model by optimizing a modified objective function.

## 3 Background

### 3.1 Supervised Character-based Model

The character-based joint S&T approach is operated as a sequence labeling fashion that each Chinese character, i.e., *hanzi*, in the sequence is assigned with a tag. To perform segmentation and tagging simultaneously in a uniform framework, according to Ng and Low (2004), the tag is composed of a word boundary part, and a POS part, e.g., “B\_NN” refers to the first character in a word with POS tag “NN”. In this paper, 4 word boundary tags are employed: B (beginning of a word), M (middle part of a word), E (end of a word) and S (single character). As for the POS tag, we shall use the 33 tags in the Chinese tree bank. Thus, the potential composite tags of joint S&T consist of 132 ( $4 \times 33$ ) classes.

The first-order CRFs model (Lafferty et al., 2001) has been the most common one in this task. Given a set of labeled examples  $\mathcal{D}_l = \{(x_i, y_i)\}_{i=1}^l$ , where  $x_i = x_i^1 x_i^2 \dots x_i^N$  is the sequence of characters in the  $i$ th sentence, and  $y_i = y_i^1 y_i^2 \dots y_i^N$  is the corresponding label sequence. The goal is to learn a CRFs model in the form,

$$p(y_i|x_i; \Lambda) = \frac{1}{Z(x_i; \Lambda)} \exp\left\{\sum_{j=1}^N \sum_{k=1}^K \lambda_k f_k(y_i^{j-1}, y_i^j, x_i, j)\right\} \quad (1)$$

where  $Z(x_i; \Lambda)$  is the partition function that normalizes the exponential form to be a probability distribution, and  $f_k(y_i^{j-1}, y_i^j, x_i, j)$ . In this study,

the baseline feature templates of joint S&T are the ones used in (Ng and Low, 2004; Jiang et al., 2008), as shown in Table 1.  $\Lambda = \{\lambda_1 \lambda_2 \dots \lambda_K\} \in \mathbb{R}^K$  are the weight parameters to be learned. In supervised training, the aim is to estimate the  $\Lambda$  that maximizes the conditional likelihood of the training data while regularizing model parameters:

$$\mathcal{L}(\Lambda) = \sum_{i=1}^l \log p(y_i|x_i; \Lambda) - R(\Lambda) \quad (2)$$

$R(\Lambda)$  can be any standard regularizer on parameters, e.g.,  $R(\Lambda) = \|\Lambda\| / 2\delta^2$ , to limit overfitting on rare features and avoid degeneracy in the case of correlated features. This objective function can be optimized by the stochastic gradient method or other numerical optimization methods.

Type	Font Size
Unigram	$C_n(n = -2, -1, 0, 1, 2)$
Bigram	$C_n C_{n+1}(n = -2, -1, 0, 1)$
Date, Digit and Alphabetic Letter	$T(C_{-2})T(C_{-1})T(C_0)$ $T(C_1)T(C_2)$

Table 1: The feature templates of joint S&T.

### 3.2 Graph-based Label Propagation

Graph-based label propagation, a critical subclass of semi-supervised learning (SSL), has been widely used and shown to outperform other SSL methods (Chapelle et al., 2006). Most of these algorithms are transductive in nature, so they cannot be used to predict an unseen test example in the future (Belkin et al., 2006). Typically, graph-based label propagation algorithms are run in two main steps: graph construction and label propagation. The graph construction provides a natural way to represent data in a variety of target domains. One constructs a graph whose vertices consist of labeled and unlabeled examples. Pairs of vertices are connected by weighted edges which encode the degree to which they are expected to have the same label (Zhu et al., 2003). Popular graph construction methods include  $k$ -nearest neighbors ( $k$ -NN) (Bentley, 1980; Beygelzimer et al., 2006),  $b$ -matching (Jebara et al., 2009) and local reconstruction (Daitch et al., 2009). Label propagation operates on the constructed graph. The primary objective is to propagate labels from a few labeled vertices to the entire graph by optimizing a loss function based on the constraints or

properties derived from the graph, e.g., smoothness (Zhu et al., 2003; Subramanya et al., 2010; Talukdar et al., 2008), or sparsity (Das and Smith, 2012). State-of-the-art label propagation algorithms include LP-ZGL (Zhu et al., 2003), Adsorption (Baluja et al., 2008), MAD (Talukdar and Crammer, 2009) and Sparse Inducing Penalties (Das and Smith, 2012).

## 4 Method

The emphasis of this work is on building a joint S&T model based on two different kinds of data sources, labeled and unlabeled data. In essence, this learning problem can be treated as incorporating certain gainful information, e.g., prior knowledge or label constraints, of unlabeled data into the supervised model. The proposed approach employs a transductive graph-based label propagation method to acquire such gainful information, i.e., label distributions from a similarity graph constructed over labeled and unlabeled data. Then, the derived label distributions are injected as virtual evidences for guiding the learning of CRFs.

### Algorithm 1 semi-supervised joint S&T induction

#### Input:

$$\mathcal{D}_l = \{(x_i, y_i)\}_{i=1}^l \text{ labeled sentences}$$

$$\mathcal{D}_u = \{(x_i)\}_{i=l+1}^{l+u} \text{ unlabeled sentences}$$

#### Output:

$\Lambda$ : a set of feature weights

- 1: **Begin**
- 2:  $\{\mathcal{G}\} = \text{construct\_graph}(\mathcal{D}_l, \mathcal{D}_u)$
- 3:  $\{q_0\} = \text{init\_labelDist}(\{\mathcal{G}\})$
- 4:  $\{q\} = \text{propagate\_label}(\{\mathcal{G}\}, \{q_0\})$
- 5:  $\{\Lambda\} = \text{train\_crf}(\mathcal{D}_l \cup \mathcal{D}_u, \{q\})$
- 6: **End**

The model induction includes the following steps (see Algorithm 1): firstly, given labeled and unlabeled data, i.e.,  $\mathcal{D}_l = \{(x_i, y_i)\}_{i=1}^l$  with  $l$  labeled sentences and  $\mathcal{D}_u = \{(x_i)\}_{i=l+1}^{l+u}$  with  $u$  unlabeled sentences, a specific similarity graph  $\mathcal{G}$  representing  $\mathcal{D}_l$  and  $\mathcal{D}_u$  is constructed (**construct\_graph**). The vertices (Section 4.1) in the constructed graph consist of all *trigrams* that occur in labeled and unlabeled sentences, and edge weights between vertices are computed using the cosine distance between pointwise mutual information (PMI) statistics. Afterwards, the estimated label distributions  $q_0$  of vertices in the graph  $\mathcal{G}$  are randomly initialized (**init\_labelDist**). Subsequently,

the label propagation procedure (**propagate\_label**) is conducted for projecting label distributions  $q$  from labeled vertices to the entire graph, using the algorithm of Sparse-Inducing Penalties (Das and Smith, 2012) (Section 4.2). The final step (**train\_crf**) of the induction is incorporating the inferred trigram-level label distributions  $q$  into CRFs model (Section 4.3).

#### 4.1 Graph Construction

In most graph-based label propagation tasks, the final effect depends heavily on the quality of the graph. Graph construction thus plays a central role in graph-based label propagation (Zhu et al., 2003). For character-based joint S&T, unlike the unstructured learning problem whose vertices are formed directly by labeled and unlabeled instances, the graph construction is non-trivial. Das and Petrov (2011) mentioned that taking individual characters as the vertices would result in various ambiguities, whereas the similarity measurement is still challenging if vertices corresponding to entire sentences.

This study follows the intuitions of graph construction from Subramanya et al. (2010) in which vertices are represented by character trigrams occurring in labeled and unlabeled sentences. Formally, given a set of labeled sentences  $\mathcal{D}_l$ , and unlabeled ones  $\mathcal{D}_u$ , where  $\mathcal{D} \triangleq \{\mathcal{D}_l, \mathcal{D}_u\}$ , the goal is to form an undirected weighted graph  $\mathcal{G} = (V, E)$ , where  $V$  is defined as the set of vertices which covers all trigrams extracted from  $\mathcal{D}_l$  and  $\mathcal{D}_u$ . Here,  $V = V_l \cup V_u$ , where  $V_l$  refers to trigrams that occurs at least once in labeled sentences and  $V_u$  refers to trigrams that occur only in unlabeled sentences. The edges  $E \in V_l \times V_u$ , connect all the vertices. This study makes use of a symmetric  $k$ -NN graph ( $k = 5$ ) and the edge weights are measured by a symmetric similarity function (Equation (3)):

$$w_{i,j} = \begin{cases} \text{sim}(x_i, x_j) & \text{if } j \in \mathcal{K}(i) \text{ or } i \in \mathcal{K}(j) \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

where  $\mathcal{K}(i)$  is the set of the  $k$  nearest neighbors of  $x_i$  ( $|\mathcal{K}(i)| = k, \forall i$ ) and  $\text{sim}(x_i, x_j)$  is a similarity measure between two vertices. The similarity is computed based on the co-occurrence statistics over the features in Table 2. Most features we adopted are selected from those of (Subramanya et al., 2010). Note that a novel feature in the last row encodes the classes of surrounding character-

s, where four types are defined: number, punctuation, alphabetic letter and other. It is especially helpful for the graph to make connections with trigrams that may not have been seen in labeled data but have similar label information. The pointwise mutual information values between the trigrams and each feature instantiation that they have in common are summed to sparse vectors, and their cosine distances are computed as the similarities.

Description	Feature
Trigram + Context	$x_1x_2x_3x_4x_5$
Trigram	$x_2x_3x_4$
Left Context	$x_1x_2$
Right Context	$x_4x_5$
Center Word	$x_3$
Trigram - Center Word	$x_2x_4$
Left Word + Right Context	$x_2x_4x_5$
Right Word + Left Context	$x_1x_2x_3$
Type of Trigram: number, punctuation, alphabetic letter and other	$t(x_2)t(x_3)t(x_4)$

Table 2: Features employed to measure the similarity between two vertices, in a given text “ $x_1x_2x_3x_4x_5$ ”, where the trigram is “ $x_2x_3x_4$ ”.

The nature of the similarity graph enforces that the connected trigrams with high weight appearing in different texts should have similar syntax configurations. Thus, the constructed graph is expected to provide additional information that cannot be expressed directly in a sequence model (Subramanya et al., 2010). One primary benefit of this property is on enriching vocabulary coverage. In other words, the new features of various trigrams only occurring in unlabeled data can be discovered. As the excerpt in Figure 1 shows, the trigram “天津港” (Tianjin port) has no any label information, as it only occurs in unlabeled data, but fortunately its neighborhoods with similar syntax information, e.g., “上海港” (Shanghai port), “广州港” (Guangzhou port), can assist to infer the correct tag “M<sub>NN</sub>”.

#### 4.2 Label Propagation

In order to induce trigram-level label distributions from the graph constructed by the previous step, a label propagation algorithm, Sparsity-Inducing Penalties, proposed by Das and Smith (2012), is employed. This algorithm is used because it captures the property of sparsity that only a few labels

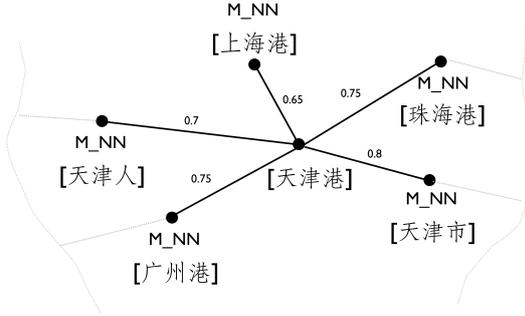

Figure 1: An excerpt from the similarity graph over trigrams on labeled and unlabeled data.

are typically associated with a given instance. In fact, the sparsity is also a common phenomenon among character-based CWS and POS tagging. The following convex objective is optimized on the similarity graph in this case:

$$\begin{aligned} & \operatorname{argmin}_q \sum_{j=1}^l \|q_j - r_j\|^2 \\ & + \mu \sum_{i=1, k \in \mathcal{N}(i)}^{l+u} w_{ik} \|q_i - q_k\|^2 + \lambda \sum_{i=1}^{l+u} \|q_i\|^2 \\ & \text{s.t. } q_i \geq 0, \forall i \in V \end{aligned} \quad (4)$$

where  $r_j$  denotes empirical label distributions of labeled vertices, and  $q_i$  denotes unnormalized estimate measures in every vertex. The  $w_{ik}$  refers to the similarity between the  $i$ th trigram and the  $k$ th trigram, and  $\mathcal{N}(i)$  is a set of neighbors of the  $i$ th trigram.  $\mu$  and  $\lambda$  are two hyperparameters whose values are discussed in Section 5. The squared-loss criterion<sup>1</sup> is used to formulate the objective function. The first term in Equation (4) is the seed match loss which penalizes the estimated label distributions  $q_j$ , if they go too far away from the empirical labeled distributions  $r_j$ . The second term is the edge smoothness loss that requires  $q_i$  should be smooth with respect to the graph, such that two vertices connected by an edge with high weight should be assigned similar labels. The final term is a regularizer to incorporate the prior knowledge, e.g., uniform distributions used in (Talukdar et al., 2008; Das and Smith, 2011). This study applies the squared norm of  $q$  to encourage sparsity per vertex. Note that the estimated label distribution

<sup>1</sup>It can be seen as a multi-class extension of quadratic cost criterion (Bengio et al., 2006) or as a variant of the objective in (Zhu et al., 2003). An entropic distance measure could also be used, e.g., KL-divergence (Subramanya et al., 2010; Das and Smith, 2012).

$q_i$  in Equation (4) is relaxed to be unnormalized, which simplifies the optimization. Thus, the objective function can be optimized by L-BFGS-B (Zhu et al., 1997), a generic quasi-Newton gradient-based optimizer. The partial derivatives of Equation (4) are computed for each parameter of  $q$  and then passed on to the optimizer that updates them such that Equation (4) is maximized.

### 4.3 Semi-Supervised CRFs Training

The trigram-level label distributions inferred in the propagation step can be viewed as a kind of valuable “prior knowledge” to regularize the learning on unlabeled data. The final step of the induction is thus to incorporate such prior knowledge into CRFs. Li (2009) generalizes the use of virtual evidence to undirected graphical models and, in particular, to CRFs for incorporating external knowledge. By extending the similar intuition, as illustrated in Figure 2, we modify the structure of a regular linear-chain CRFs on unlabeled data for smoothing the derived label distributions, where virtual evidences, i.e.,  $q$  in our case, are donated by  $\{v_1, v_2, \dots, v_T\}$ , in parallel with the state variables  $\{y_1, y_2, \dots, y_T\}$ . The modified CRFs model allows us to flexibly define the interaction between estimated state values and virtual evidences by potential functions. Therefore, given labeled and unlabeled data, the learning objective is defined as follows:

$$\mathcal{L}(\Lambda) + \sum_{i=l+1}^{l+u} E_{p(y_i|x_i, v_i; \Lambda^g)} [\log p(y_i, v_i|x_i; \Lambda)] \quad (5)$$

where the conditional probability in the second term is denoted as

$$\begin{aligned} p(y_i, v_i|x_i; \Lambda) = & \frac{1}{Z'(x_i; \Lambda)} \exp\left\{ \sum_{j=1}^N \sum_{k=1}^K \lambda_k f_k(y_i^{j-1}, y_i^j, x_i, j) \right. \\ & \left. + \alpha \sum_{t=1}^N s(y_i^t, v_i^t) \right\} \end{aligned} \quad (6)$$

The first term in Equation (5) is the same as Equation (2), which is the traditional CRFs learning objective function on the labeled data. The second term is the expected conditional likelihood of unlabeled data. It is directed to maximize the conditional likelihood of hidden states with the derived label distributions on unlabeled data, i.e.,  $p(y, v|x)$ , where  $y$  and  $v$  are jointly modeled but

the probability is still conditional on  $x$ . Here,  $Z'(x; \Lambda)$  is the partition function of normalization that is achieved by summing the numerator over both  $y$  and  $v$ . A virtual evidence feature function of  $s(y_i^t, v_i^t)$  with pre-defined weight  $\alpha$  is defined to regularize the conditional distributions of states over the derived label distributions. The learning is impacted by the derived label distributions as Equation (7): firstly, if the trigram  $x_i^{t-1}x_i^tx_i^{t+1}$  at current position does have no corresponding derived label distributions ( $v_i^t = null$ ), the value of zero is assigned to all state hypotheses so that the posteriors would not be affected by the derived information. Secondly, if it does have a derived label distribution, since the virtual evidence in this case is a distribution instead of a specific label, the label probability in the distribution under the current state hypothesis is assigned. This means that the values of state variables are constrained to agree with the derived distributions.

$$s(y_i^t, v_i^t) = \begin{cases} q_{x_i^{t-1}x_i^tx_i^{t+1}}(y_i^t) & \text{if } v_i^t \neq null \\ 0 & \text{else} \end{cases} \quad (7)$$

The second term in Equation (5) can be optimized by using the expectation maximization (EM) algorithm in the same fashion as in the generative approach, following (Li, 2009). One can iteratively optimize the  $Q$  function  $Q(\Lambda) = \sum_y p(y_i|x_i; \Lambda^g) \log p(y_i, v_i|x_i; \Lambda)$ , in which  $\Lambda^g$  is the model estimated from the previous iteration. Here the gradient of the  $Q$  function can be measured by:

$$\frac{\partial Q(\Lambda)}{\partial \Lambda_k} = \sum_t \sum_{y_i^{t-1}, y_i^t} f_k(y_i^{t-1}, y_i^t, x_i, t) \cdot (p(y_i^{t-1}, y_i^t|x_i, v_i; \Lambda) - p(y_i^{t-1}, y_i^t|x_i; \Lambda)) \quad (8)$$

The forward-backward algorithm is used to measure  $p(y_i^{t-1}, y_i^t|x_i, v_i; \Lambda)$  and  $p(y_i^{t-1}, y_i^t|x_i; \Lambda)$ . Thus, the objective function Equation (5) is optimized as follows: for the instances  $i = 1, 2, \dots, l$ , the parameters  $\Lambda$  are learned as the supervised manner; for the instances  $i = l + 1, l + 2, \dots, u + l$ , in the E-step, the expected value of  $Q$  function is computed, based on the current model  $\Lambda^g$ . In the M-step, the posteriors are fixed and updated  $\Lambda$  that maximizes Equation (5).

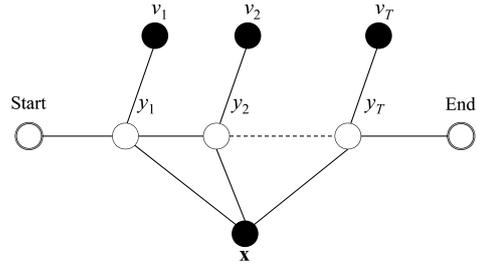

Figure 2: Modified linear-chain CRFs integrating virtual evidences on unlabeled data.

## 5 Experiment

### 5.1 Setting

The experimental data are mainly taken from the Chinese tree bank (CTB-7) and Microsoft Research (MSR)<sup>2</sup>. CTB-7 consists of over one million words of annotated and parsed text from Chinese newswire, magazine news, various broadcast news and broadcast conversation programs, web newsgroups and weblogs. It is a segmented, POS tagged<sup>3</sup> and fully bracketed corpus. The train, development and test sets<sup>4</sup> from CTB-7 and their corresponding statistics are reported in Table 3. To satisfy the characteristic of the semi-supervised learning problem, the train set, i.e., the labeled data, is formed by a relatively small amount of annotated texts sampled from CTB-7. For the unlabeled data in this experiment, a greater amount of texts is extracted from CTB-7 and MSR, which contains 53,108 sentences with 2,418,690 characters.

The performance measurement indicators for word segmentation and POS tagging (joint S&T) are balance F-score,  $F = 2PR/(P+R)$ , the harmonic mean of precision (P) and recall (R), and out-of-vocabulary recall (OOV-R). For segmentation, a token is regarded to be correct if its boundaries match the ones of a word in the gold standard. For the POS tagging, it is correct only if both the boundaries and the POS tags are perfect matches.

The experimental platform is implemented based on two toolkits: Mallet (McCallum and Kachites, 2002) and Junto (Talukdar and Pereira, 2010). Mallet is a java-based package for statistical natural language processing, which includes the CRFs implementation. Junto is a graph-

<sup>2</sup>It can be download at: [www.sighan.org/bakeoff2005](http://www.sighan.org/bakeoff2005).

<sup>3</sup>There is a total of 33 POS tags in CTB-7.

<sup>4</sup>The extracted sentences in train, development and test set were assigned with the composite tags as described in Section 3.1.

based label propagation toolkit that provides several state-of-the-art algorithms.

Data	#Sent	#Word	#Char	#OOV

Test	2,037	65,219	104,502	0.089

Table 3: Training, development and testing data.

## 5.2 Baseline and Proposed Models

In the experiment, the baseline supervised pipeline and joint S&T models are built only on the train data. The proposed model will also be compared with the semi-supervised pipeline S&T model described in (Wang et al., 2011). In addition, two state-of-the-art semi-supervised CRFs algorithms, Jiao’s CRFs (Jiao et al., 2006) and Subramanya’s CRFs (Subramanya et al., 2010), are also used to build joint S&T models. The corresponding settings of the above candidates are listed below:

- **Baseline I:** a supervised CRFs pipeline S&T model. The feature templates are from Zhao et al. (2006) and Wu et al. (2008).
- **Wang’s model:** a semi-supervised CRFs pipeline S&T model. The same feature templates in (Wang et al., 2011) are used, i.e., “+ $n$ -gram+cluster+lexicon”.
- **Baseline II:** a supervised CRFs joint S&T model. The feature templates introduced in Section 3.1 are used.
- **Jiao’s model:** a semi-supervised CRFs joint S&T model trained using the entropy regularization (ER) criteria (Jiao et al., 2006). The optimization method proposed by Mann and McCallum (2007) is applied.
- **Subramanya’s model:** a self-train style semi-supervised CRFs joint S&T model based on the same parameters used in (Subramanya et al., 2010).
- **Our model:** several parameters in our model are needed to tune based on the development set, e.g.,  $\mu$ ,  $\lambda$  and  $\alpha$ .

In all the CRFs models above, the Gaussian regularizer and stochastic gradient descent method are employed.

## 5.3 Main Results

This experiment yielded a similarity graph that consists of 462,962 trigrams from labeled and unlabeled data. The majority (317,677 trigrams) occurred only in unlabeled data. Based on the development data, the hyperparameters of our model were tuned among the following settings: for the graph propagation,  $\mu \in \{0.2, 0.5, 0.8\}$  and  $\lambda \in \{0.1, 0.3, 0.5, 0.8\}$ ; for the CRFs training,  $\alpha \in \{0.1, 0.3, 0.5, 0.7, 0.9\}$ . The best performed joint settings are  $\mu = 0.5$ ,  $\lambda = 0.3$  and  $\alpha = 0.7$ . With the chosen set of hyperparameters, the test data was used to measure the final performance.

Model	Segmentation		POS Tagging	
	F <sub>1</sub>	OOV-R	F <sub>1</sub>	OOV-R
Baseline I	94.27	60.12	91.08	51.72
Wang’s	95.17	63.10	91.64	53.29
Baseline II	95.14	61.52	91.61	52.29
Jiao’s	95.58	63.05	92.11	53.27
Subramanya’s	96.30	67.12	92.46	57.15
Our model	<b>96.85</b>	<b>68.09</b>	<b>92.89</b>	<b>58.36</b>

Table 4: The performance of segmentation and POS tagging on testing data.

Table 4 summarizes the performance of segmentation and POS tagging on the test data, in comparison with the other five models. Firstly, as expected, for the two supervised baselines, the joint model outperforms the pipeline one, especially on segmentation. It obtains 0.92% and 2.32% increase in terms of F-score and OOV-R respectively. This outcome verifies the commonly accepted fact that the joint model can substantially improve the pipeline one, since POS tags provide additional information to word segmentation (Ng and Low, 2004). Secondly, it is also noticed that all four semi-supervised models are able to benefit from unlabeled data and greatly improve the results with respect to the baselines. On the whole, for segmentation, they achieve average improvements of 1.02% and 6.8% in F-score and OOV-R; whereas for POS tagging, the average increments of F-score and OOV-R are 0.87% and 6.45%. An interesting phenomenon is found among the comparisons with baselines that the supervised joint model (Baseline II) is even competitive with semi-supervised pipeline one (Wang et al., 2011). This illustrates the effects of error propagation in the pipeline approach. Thirdly, in what concerns the semi-supervised approaches, the three joint S&T models, i.e., Jiao’s, Subramanya’s and our model, are superior to the pipeline model, i.e., Wang’s

model. Moreover, the two graph-based approaches, i.e., Subramanya’s and our model, outperform the others. Most importantly, the boldface numbers in the last row illustrate that our model does achieve the best performance. Overall, for word segmentation, it obtains average improvements of 1.43% and 8.09% in F-score and OOV-R over others; for POS tagging, it achieves average improvements of 1.09% and 7.73%.

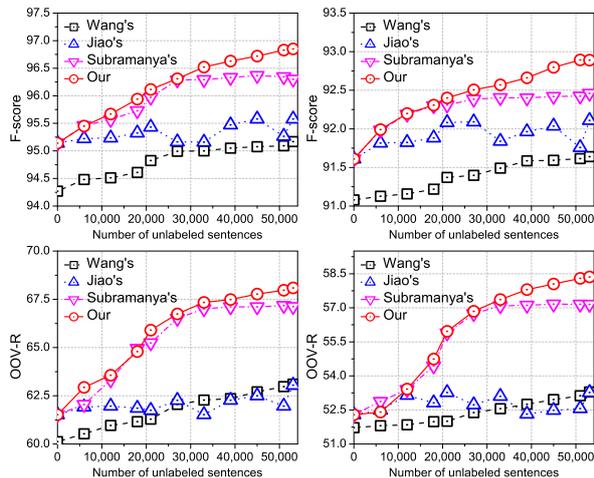

Figure 3: The learning curves of semi-supervised models on unlabeled data, where left graphs are segmentation and the right ones are tagging.

#### 5.4 Learning Curve

An additional experiment was conducted to investigate the impact of unlabeled data for the four semi-supervised models. Figure 3 illustrates the curves of F-score and OOV-R for segmentation and tagging respectively, as the unlabeled data size is progressively increased in steps of 6,000 sentences. It can be clearly observed that all curves of our model are able to mount up steadily and achieve better gains over others consistently. The most competitive performance of the other three candidates is achieved by Subramanya’s model. This strongly reveals that the knowledge derived from the similarity graph does effectively strengthen the model. But in Subramanya’s model, when the unlabeled size ascends to approximately 30,000 sentences the curves become nearly asymptotic. The semi-supervised pipeline model, Wang’s model, presents a much slower growth on all curves over the others and also begins to overfit with large unlabeled data sizes (>25,000 sentences). The figure also shows an erratic fluctuation of Jiao’s model. Since this approach aims

at minimizing conditional entropy over unlabeled data and encourages finding putative labelings for unlabeled data, it results in a data-sensitive model (Li et al., 2009).

#### 5.5 Analysis & Discussion

A statistical analysis of the segmentation and tagging results of the supervised joint model (Baseline II) and our model is carried out to comprehend the influence of the graph-based semi-supervised behavior. For word segmentation, the most significant improvement of our model is mainly concentrated on two kinds of words which are known for their difficulties in terms of CWS: a) named entities (NE), e.g., “天津港” (Tianjin port) and “保税区” (free tax zone); and b) Chinese numbers (CN), e.g., “八点五亿” (eight hundred and fifty million) and “百分之七十二” (seventy two percent). Very often, these words do not exist in the labeled data, so the supervised model is hard to learn their features. Part of these words, however, may occur in the unlabeled data. The proposed semi-supervised approach is able to discover their label information with the help of a similarity graph. Specifically, it learns the label distributions from similar words (neighborhoods), e.g., “上海港” (Shanghai port), “保护区” (protection zone), “九点七亿” (nine hundred and seventy million). The statistics in Table 5 demonstrate significant error reductions of 50.44% and 48.74% on test data, corresponding to NE and CN respectively.

Type	#word	#baErr	#gbErr	ErrDec%
NE	471	226	112	50.44
CN	181	119	61	48.74

Table 5: The statistics of segmentation error for named entities (NE) and Chinese numbers (CN) in test data. #baErr and #gbErr denote the count of segmentations by Baseline II and our model; ErrDec% denotes the error reduction.

On the other hand, to better understand the tagging results, we summarize the increase and decrease of the top five common tagging error patterns of our model over Baseline II for the correctly segmented words, as shown in Table 6. The error pattern is defined by “A→B” that refers the true tag of “A” is annotated by a tag of “B”. The obvious improvement brought by our model occurs with the tags “NN”, “CD”, “NR”, “JJ” and “NR”, where errors are reduced 60.74% on aver-

Pattern	#baErr	↓	Pattern	#baErr	↑
NN→VV	58	38	NN→NR	13	6
CD→NN	41	27	IJ→ON	9	5
NR→VV	29	17	VV→NN	4	3
JJ→NN	18	11	NR→NN	1	3
NR→VA	19	10	JJ→AD	1	2

Table 6: The statistics of POS tagging error patterns in test data. #baErr denote the count of tagging error by Baseline II, while ↓ and ↑ denotes the number of error reduced or increased by our model.

age. More impressively, there is a large portion of fixed error pattern instances stemming from OOV words. Meanwhile, it is also observed that the disambiguation of error patterns in the right portion of the table slightly suffers from our approach. In reality, it is impossible and unrealistic to request a model to be “no harms but only benefits” under whatever circumstances.

## 6 Conclusion

This study introduces a novel semi-supervised approach for joint Chinese word segmentation and POS tagging. The approach performs the semi-supervised learning in the way that the trigram-level distributions inferred from a similarity graph are used to regularize the learning of CRFs model on labeled and unlabeled data. The empirical results indicate that the similarity graph information and the incorporation manner of virtual evidences present a positive effect to the model induction.

## Abstract

Modern phrase-based machine translation systems make extensive use of word-based translation models for inducing alignments from parallel corpora. This is problematic, as the systems are incapable of accurately modelling many translation phenomena that do not decompose into word-for-word translation. This paper presents a novel method for inducing phrase-based translation units directly from parallel data, which we frame as learning an inverse transduction grammar (ITG) using a recursive Bayesian prior. Overall this leads to a model which learns translations of entire sentences, while also learning their decomposition into smaller units (phrase-pairs) recursively, terminating at word translations. Our experiments on Arabic, Urdu and Farsi to English demonstrate improvements over competitive baseline systems.

## 1 Introduction

The phrase-based approach (Koehn et al., 2003) to machine translation (MT) has transformed MT from a narrow research topic into a truly useful technology to end users. Leading translation systems (Chiang, 2007; Koehn et al., 2007; Marcu et al., 2006) all use some kind of multi-word translation unit, which allows translations to be produced from large canned units of text from the training corpus. Larger phrases allow for the lexical context to be considered in choosing the translation, and also limit the number of reordering decisions required to produce a full translation.

Word-based translation models (Brown et al., 1993) remain central to phrase-based model training, where they are used to infer word-level alignments from sentence aligned parallel data, from

which phrasal translation units are extracted using a heuristic. Although this approach demonstrably works, it suffers from a number of shortcomings. Firstly, many phrase-based phenomena which do not decompose into word translations (e.g., idioms) will be missed, as the underlying word-based alignment model is unlikely to propose the correct alignments. Secondly, the relationship between different phrase-pairs is not considered, such as between single word translations and larger multi-word phrase-pairs or where one large phrase-pair subsumes another.

This paper develops a phrase-based translation model which aims to address the above shortcomings of the phrase-based translation pipeline. Specifically, we formulate translation using inverse transduction grammar (ITG), and seek to learn an ITG from parallel corpora. The novelty of our approach is that we develop a Bayesian prior over the grammar, such that a nonterminal becomes a ‘cache’ learning each production *and* its complete yield, which in turn is recursively composed of its child constituents. This is closely related to adaptor grammars (Johnson et al., 2007a), which also generate full tree rewrites in a monolingual setting. Our model learns translations of entire sentences while also learning their decomposition into smaller units (phrase-pairs) recursively, terminating at word translations. The model is richly parameterised, such that it can describe phrase-based phenomena while also explicitly modelling the relationships between phrase-pairs and their component expansions, thus ameliorating the disconnect between the treatment of words versus phrases in the current MT pipeline. We develop a Bayesian approach using a Pitman-Yor process prior, which is capable of modelling a diverse range of geometrically decaying distributions over infinite event spaces (here translation phrase-pairs), an approach shown to be state of the art for language modelling (Teh, 2006).

We are not the first to consider this idea; Neubig et al. (2011) developed a similar approach for learning an ITG using a form of Pitman-Yor adaptor grammar. However Neubig et al.’s work was flawed in a number of respects, most notably in terms of their heuristic beam sampling algorithm which does not meet either of the Markov Chain Monte Carlo criteria of ergodicity or detailed balance. Consequently their approach does not constitute a valid Bayesian model. In contrast, this paper provides a more rigorous and theoretically sound method. Moreover our approach results in consistent translation improvements across a number of translation tasks compared to Neubig et al.’s method, and a competitive phrase-based baseline.

## 2 Related Work

Inversion transduction grammar (or ITG) (Wu, 1997) is a well studied synchronous grammar formalism. Terminal productions of the form  $X \rightarrow e/f$  generate a word in two languages, and non-terminal productions allow phrasal movement in the translation process. Straight productions, denoted by their non-terminals inside square brackets [...], generate their symbols in the given order in both languages, while inverted productions, indicated by angled brackets  $\langle \dots \rangle$ , generate their symbols in the reverse order in the target language.

In the context of machine translation, ITG has been explored for statistical word alignment in both unsupervised (Zhang and Gildea, 2005; Cherry and Lin, 2007; Zhang et al., 2008; Pauls et al., 2010) and supervised (Haghighi et al., 2009; Cherry and Lin, 2006) settings, and for decoding (Petrov et al., 2008). Our paper fits into the recent line of work for jointly inducing the phrase table and word alignment (DeNero and Klein, 2010; Neubig et al., 2011). The work of DeNero and Klein (2010) presents a *supervised* approach to this problem, whereas our work is *unsupervised* hence more closely related to Neubig et al. (2011) which we describe in detail below.

A number of other approaches have been developed for learning phrase-based models from bilingual data, starting with Marcu and Wong (2002) who developed an extension to IBM model 1 to handle multi-word units. This pioneering approach suffered from intractable inference and moreover, suffers from degenerate solutions (DeNero and Klein, 2010). Our approach is similar to these previous works, except that we impose

additional constraints on how phrase-pairs can be tiled to produce a sentence pair, and moreover, we seek to model the embedding of phrase-pairs in one another, something not considered by this prior work. Another strand of related research is in estimating a broader class of synchronous grammars than ITGs, such as SCFGs (Blunsom et al., 2009b; Levenberg et al., 2012). Conceptually, our work could be readily adapted to general SCFGs using similar techniques.

This work was inspired by adaptor grammars (Johnson et al., 2007a), a monolingual grammar formalism whereby a non-terminal rewrites in a single step as a complete subtree. The model prior allows for trees to be generated as a mixture of a cache and a base adaptor grammar. In our case, we have generalised to a bilingual setting using an ITG. Additionally, we have extended the model to allow recursive nesting of adapted non-terminals, such that we end up with an infinitely recursive formulation where the top-level and base distributions are explicitly linked together.

As mentioned above, ours is not the first work attempting to generalise adaptor grammars for machine translation; (Neubig et al., 2011) also developed a similar approach based around ITG using a Pitman-Yor Process prior. Our approach improves upon theirs in terms of the model and inference, and critically, this is borne out in our experiments where we show uniform improvements in translation quality over a baseline system, as compared to their almost entirely negative results. We believe that their approach had a number of flaws: For inference they use a beam-search, which may speed up processing but means that they are no longer sampling from the true distribution, nor a distribution with the same support as the posterior. Moreover they include a Metropolis-Hastings correction step, which is required to correct the samples to account for repeated substructures which will be otherwise underrepresented. Consequently their approach does not constitute a Markov Chain Monte Carlo sampler, but rather a complex heuristic.

The other respect in which this work differs from Neubig et al. (2011) is in terms of model formulation. They develop an ITG which generates phrase-pairs as terminals, while we employ a more restrictive word-based model which forces the decomposition of every phrase-pair. This is an important restriction as it means that we jointly learn

a word and phrase based model, such that word based phenomena can affect the phrasal structures. Finally our approach models separately the three different types of ITG production (monotone, swap and lexical emission), allowing for a richer parameterisation which the model exploits by learning different hyper-parameter values.

### 3 Model

The generative process of the model follows that of ITG with the following simple grammar

$$\begin{aligned} X &\rightarrow [X X] \mid \langle X X \rangle \\ X &\rightarrow e/f \mid e/\perp \mid \perp/f, \end{aligned}$$

where  $[\cdot]$  denotes monotone ordering and  $\langle \cdot \rangle$  denotes a swap in one language. The symbol  $\perp$  denotes the empty string. This corresponds to a simple generative story, with each stage being a non-terminal rewrite starting with  $X$  and terminating when there are no frontier non-terminals.

A popular variant is a *phrasal ITG*, where the leaves of the ITG tree are phrase-pairs and the training seeks to learn a segmentation of the source and target which yields good phrases. We would not expect this model to do very well as it cannot consider overlapping phrases, but instead is forced into selecting between many competing – and often equally viable – options. Our approach improves over the phrasal model by recursively generating complete phrases. This way we don't insist on a single tiling of phrases for a sentence pair, but explicitly model the set of hierarchically nested phrases as defined by an ITG derivation. This approach is closer in spirit to the phrase-extraction heuristic, which defines a set of 'atomic' terminal phrase-pairs and then extracts every combination of these atomic phase-pairs which is contiguous in the source and target.<sup>1</sup>

The generative process is that we draw a complete ITG tree,  $t \sim P_2(\cdot)$ , as follows:

1. choose the rule type,  $r \sim R$ , where  $r \in \{\text{mono}, \text{swap}, \text{emit}\}$
2. for  $r = \text{mono}$ 
  - (a) draw the complete subtree expansion,  $t = X \rightarrow [\dots] \sim T_M$
3. for  $r = \text{swap}$ 
  - (a) draw the complete subtree expansion,  $t = X \rightarrow \langle \dots \rangle \sim T_S$

<sup>1</sup>Our technique considers the subset of phrase-pairs which are consistent with the ITG tree.

4. for  $r = \text{emit}$ 
  - (a) draw a pair of strings,  $(e, f) \sim E$
  - (b) set  $t = X \rightarrow e/f$

Note that we split the problem of drawing a tree into two steps: first choosing the top-level rule type and then drawing a rule of that type. This gives us greater control than simply drawing a tree of any type from one distribution, due to our parameterisation of the priors over the model parameters  $T_M$ ,  $T_S$  and  $E$ .

To complete the generative story, we need to specify the prior distributions for  $T_M$ ,  $T_S$  and  $E$ . First, we deal with the emission distribution,  $E$  which we draw from a Dirichlet Process prior  $E \sim \text{DP}(b_E, P_0)$ . We restrict the emission rules to generate word pairs rather than phrase pairs.<sup>2</sup> For the base distribution,  $P_0$ , we use a simple uniform distribution over word pairs,

$$P_0(e, f) = \begin{cases} \eta^2 \frac{1}{\sqrt{E} \sqrt{F}} & e \neq \perp, f \neq \perp \\ \eta(1-\eta) \frac{1}{\sqrt{F}} & e = \perp, f \neq \perp \\ \eta(1-\eta) \frac{1}{\sqrt{E}} & e \neq \perp, f = \perp \end{cases},$$

where the constant  $\eta$  denotes the binomial probability of a word being aligned.<sup>3</sup>

We use Pitman-Yor Process priors for the  $T_M$  and  $T_S$  parameters

$$\begin{aligned} T_M &\sim \text{PYP}(a_M, b_M, P_1(\cdot | r = \text{mono})) \\ T_S &\sim \text{PYP}(a_S, b_S, P_1(\cdot | r = \text{swap})) \end{aligned}$$

where  $P_1(t_1, t_2 | r)$  is a distribution over a pair of trees (the left and right children of a monotone or swap production).  $P_1$  is defined as follows:

1. choose the complete left subtree  $t_1 \sim P_2$ ,
2. choose the complete right subtree  $t_2 \sim P_2$ ,
3. set  $t = X \rightarrow [t_1 t_2]$  or  $t = X \rightarrow \langle t_1 t_2 \rangle$  depending on  $r$

This generative process is mutually recursive:  $P_2$  makes draws from  $P_1$  and  $P_1$  makes draws from  $P_2$ . The recursion is terminated when the rule type  $r = \text{emit}$  is drawn.

Following standard practice in Bayesian models, we integrate out  $R$ ,  $T_M$ ,  $T_S$  and  $E$ . This means draws from  $P_2$  (or  $P_1$ ) are no longer *iid*: for any non-trivial tree, computing its probability under this model is complicated by the fact

<sup>2</sup>Note that we could allow phrases here, but given the model can already reason over phrases by way of its hierarchical formulation, this is an unnecessary complication.

<sup>3</sup>We also experimented with using word translation probabilities from IBM model 1, based on the prior used by Levenberg et al. (2012), however we found little empirical difference compared with this simpler uniform model.

that the probability of its two subtrees are interdependent. This is best understood in terms of the Chinese Restaurant Franchise (CRF; Teh et al. (2006)), which describes the posterior distribution after integrating out the model parameters. In our case we can consider the process of drawing a tree from  $P_2$  as a customer entering a restaurant and choosing where to sit, from an infinite set of tables. The seating decision is based on the number of other customers at each table, such that popular tables are more likely to be joined than unpopular or empty ones. If the customer chooses an occupied table, the identity of the tree is then set to be the same as for the other customers also seated there. For empty tables the tree must be sampled from the base distribution  $P_1$ . In the standard CRF analogy, this leads to another customer entering the restaurant one step up in the hierarchy, and this process can be chained many times. In our case, however, every new table leads to new customers reentering the original restaurant – these correspond to the left and right child trees of a monotone or swap rule. The recursion terminates when a table is shared, or a new table is labelled with a emit rule.

### 3.1 Inference

The probability of a tree (i.e., a draw from  $P_2$ ) under the model is

$$P_2(t) = P(r)P_2(t|r) \quad (1)$$

where  $r$  is the rule type, one of `mono`, `swap` or `emit`. The distribution over types,  $P(r)$ , is defined as

$$P(r) = \frac{n_r^{T,-} + b_T \frac{1}{3}}{n^{T,-} + b_T}$$

where  $n^{T,-}$  are the counts over rules of types.<sup>4</sup>

The second component in (1),  $P_2(t|r)$ , is defined separately for each rule type. For  $r = \text{mono}$  or  $r = \text{swap}$  rules, it is defined as

$$P_2(t|r) = \frac{n_{t,r}^- - K_{t,r}^- a_r}{n_r^- + b_r} + \frac{K_r^- a_r + b_r}{n_r^- + b_r} P_1(t_1, t_2|r), \quad (2)$$

where  $n_{t,r}^-$  is the count for tree  $t$  in the other training sentences,  $K_{t,r}^-$  is the table count for  $t$  and  $n_r^-$

<sup>4</sup>The conditioning on event and table counts,  $n^-$ ,  $K^-$  is omitted for clarity.

and  $K_r^-$  are the total count of trees and tables, respectively. Finally, the probability for  $r = \text{emit}$  is given by

$$P_2(t|r = \text{emit}) = \frac{n_{t,E}^- + b_E P_0(e, f)}{n_r^- + b_r},$$

where  $t = X \rightarrow e/f$ .

To complete the derivation we still need to define  $P_1$ , which is formulated as

$$P_1(t_1, t_2) = P_2(t_1)P_2(t_2|t_1),$$

where the conditioning of the second recursive call to  $P_2$  reflects that the counts  $n^-$  and  $K^-$  may be affected by the first draw from  $P_2$ . Although these two draws are assumed *iid* in the prior, after marginalising out  $T$  they are no longer independent. For this reason, evaluating  $P_2(t)$  is computationally expensive, requiring tracking of repeated substructures in descendent sub-trees of  $t$ , which may affect other descendants. This results in an asymptotic complexity exponential in the number of nodes in the tree. For this reason we consider trees annotated with binary values denoting their table assignment, namely whether they share a table or are seated alone. Given this, the calculation is greatly simplified, and has linear complexity.<sup>5</sup>

We construct an approximating ITG following the technique used for sampling trees from monolingual tree-substitution grammars (Cohn et al., 2010). To do so we encode the first term from (2) separately from the second term (corresponding to draws from  $P_1$ ). Summing together these two alternate paths – i.e., during inside inference – we recover  $P_2$  as shown in (2). The full grammar transform for inside inference is shown in Table 1.

The sampling algorithm closely follows the process for sampling derivations from Bayesian PCFGs (Johnson et al., 2007b). For each sentence-pair, we first decrement the counts associated with its current tree, and then sample a new derivation. This involves first constructing the inside lattice using the productions in Table 1, and then performing a top-down sampling pass. After sampling each derivation from the approximating grammar, we then convert this into its corresponding ITG tree, which we then score with the full model and accept or reject the sample using the

<sup>5</sup>To support this computation, we track explicit table assignments for every training tree and their component subtrees. We also sample trees labelled with seating indicator variables.

Type	$X \rightarrow M$	$P(r = \text{mono})$
	$X \rightarrow S$	$P(r = \text{swap})$
	$X \rightarrow E$	$P(r = \text{emit})$
Base	$M \rightarrow [XX]$	$\frac{K_M^- a_M + b_M}{n_M^- + b_M}$
	$S \rightarrow \langle XX \rangle$	$\frac{K_S^- a_S + b_S}{n_S^- + b_S}$
Count	For every tree, $t$ , of type $r = \text{mono}$ , with $n_{t,M} > 0$ :	
	$M \rightarrow \text{sig}(t)$	$\frac{n_{t,M}^- - K_{t,M}^- a_r}{n_M^- + b_M}$
	$\text{sig}(t) \rightarrow \text{yield}(t)$	1
	For every tree, $t$ , of type $r = \text{swap}$ , with $n_{t,S} > 0$ :	
$S \rightarrow \text{sig}(t)$	$\frac{n_{t,S}^- - K_{t,S}^- a_S}{n_S^- + b_S}$	
$\text{sig}(t) \rightarrow \text{yield}(t)$	1	
Emit	For every word pair, $e/f$ in sentence pair, where one of $e, f$ can be $\perp$ :	
	$E \rightarrow e/f$	$P_2(t)$

Table 1: Grammar transformation rules for MAP inside inference. The function  $\text{sig}(t)$  returns a unique identifier for the complete tree  $t$ , and the function  $\text{yield}(t)$  returns the pair of terminal strings from the yield of  $t$ .

Metropolis-Hastings algorithm.<sup>6</sup> Accepted samples then replace the old tree (otherwise the old tree is retained) and the model counts are incremented. This process is then repeated for each sentence pair in the corpus in a random order.

## 4 Experiments

**Datasets** We train our model across three language pairs: Urdu→English (UR-EN), Farsi→English (FA-EN), and Arabic→English (AR-EN). The corpora statistics of these translation tasks are summarised in Table 2. The UR-EN corpus comes from NIST 2009 translation evaluation.<sup>7</sup> The AR-EN training data consists of the eTIRR corpus (LDC2004E72), the Arabic news corpus (LDC2004T17), the Ummah corpus (LDC2004T18), and the sentences with confidence  $c > 0.995$  in the ISI automatically extracted web parallel corpus (LDC2006T02). For FA-EN, we use TEP<sup>8</sup> Tehran English-Persian Parallel corpus (Pilevar and Faili, 2011), which consists of conversational/informal text extracted

<sup>6</sup>The full model differs from the approximating grammar in that it accounts for inter-dependencies between subtrees by recursively tracking the changes in the customer and table counts while scoring the tree. Around 98% of samples were accepted in our experiments.

FA-EN	4.7M	4.4M	498K
AR-EN	1.94M	2.08M	113K

Table 2: Corpora statistics showing numbers of parallel sentences and source and target words for the training sets.

from 1600 movie subtitles. We tokenized this corpus, removed noisy single-word sentences, randomly selected the development and test sets, and used the rest of the corpus as the training set. We discard sentences with length above 30 from the datasets for all experiments.<sup>9</sup>

**Sampler configuration** Samplers are initialised with trees created from GIZA++ alignments constructed using a SCFG factorisation method (Blunsom et al., 2009a). This algorithm represents the translation of a sentence as a large SCFG rule, which it then factorises into lower rank SCFG rules, a process akin to rule binarisation commonly used in SCFG decoding. Rules that cannot be reduced to a rank-2 SCFG are simplified by dropping alignment edges until they can be factorised, the net result being an ITG derivation largely respecting the alignments.<sup>10</sup>

The blocked sampler was run 1000 iterations for UR-EN, 100 iterations for FA-EN and AR-EN. After each full sampling iteration, we resample all the hyper-parameters using slice-sampling, with the following priors:  $a \sim \text{Beta}(1, 1)$ ,  $b \sim \text{Gamma}(10, 0.1)$ . Figure 1 shows the posterior probability improves with each full sampling iterations. The alignment probability was set to  $\eta = 0.99$ . The sampling was repeated for 5 independent runs, and we present results where we combine the outputs of these runs. This is a form of Monte Carlo integration which allows us to represent the uncertainty in the posterior, while also representing multiple modes, if present.

The time complexity of our inference algorithm is  $O(n^6)$ , which can be prohibitive for large scale machine translation tasks. We reduce the complexity by constraining the *inside* inference to consider only derivations which are compatible

<sup>9</sup>Hence the BLEU scores we get for the baselines may appear lower than what reported in the literature.

<sup>10</sup>Using the factorised alignments directly in a translation system resulted in a slight loss in BLEU versus using the un-factorised alignments. Our baseline system uses the latter.

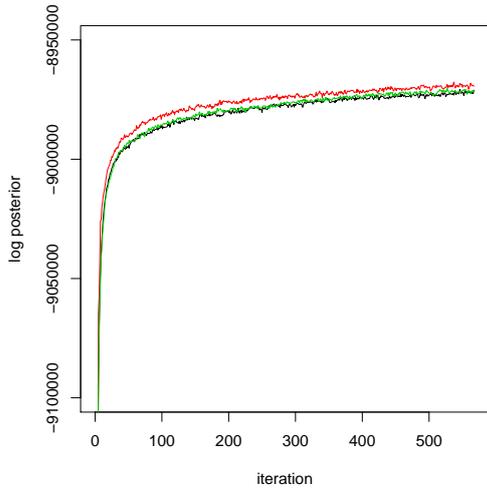

Figure 1: Training progress on the UR-EN corpus, showing the posterior probability improving with each full sampling iteration. Different colours denote independent sampling runs.

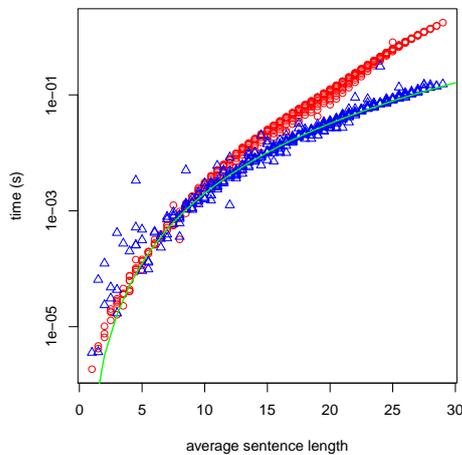

Figure 2: The runtime cost of bottom-up inside inference and top-down sampling as a function of sentence length (UR-EN), with time shown on a logarithmic scale. Full ITG inference is shown with red circles, and restricted inference using the intersection constraints with blue triangles. The average time complexity for the latter is roughly  $O(l^4)$ , as plotted in green  $t = 2 \times 10^{-7}l^4$ .

with high confidence alignments from GIZA++.<sup>11</sup> Figure 2 shows the sampling time with respect to the average sentence length, showing that our alignment-constrained sampling algorithm is better than the unconstrained algorithm with empirical complexity of  $n^4$ . However, the time complexity is still high, so we set the maximum sentence length to 30 to keep our experiments practicable. Presumably other means of inference may be more efficient, such as Gibbs sampling (Levenberg et al., 2012) or auxiliary variable sampling (Blunsom and Cohn, 2010); we leave these extensions to future work.

**Baselines.** Following (Levenberg et al., 2012; Neubig et al., 2011), we evaluate our model by using its output word alignments to construct a phrase table. As a baseline, we train a phrase-based model using the Moses toolkit<sup>12</sup> based on the word alignments obtained using GIZA++ in both directions and symmetrized using the growdiag-final-and heuristic<sup>13</sup> (Koehn et al., 2003). This alignment is used as input to the rule factorisation algorithm, producing the ITG trees with which we initialise our sampler. To put our results in the context of the previous work, we also compare against *pialign* (Neubig et al., 2011), an ITG algorithm using a Pitman-Yor process prior, as described in Section 2.<sup>14</sup>

In the end-to-end MT pipeline we use a standard set of features: relative-frequency and lexical translation model probabilities in both directions; distance-based distortion model; language model and word count. We set the distortion limit to 6 and max-phrase-length to 7 in all experiments. We train 3-gram language models using modified Kneser-Ney smoothing. For AR-EN experiments the language model is trained on English data as (Blunsom et al., 2009a), and for FA-EN and UR-EN the English data are the target sides of the bilingual training data. We use minimum error rate training (Och, 2003) with nbest list size 100 to optimize the feature weights for maximum development BLEU.

<sup>11</sup>These are taken from the final model 4 word alignments, using the intersection of the source-target and target-source models. These alignments are very high precision (but have low recall), and therefore are unlikely to harm the model.

<sup>12</sup><http://www.statmt.org/moses>

<sup>13</sup>We use the default parameter settings in both Moses and GIZA++.

<sup>14</sup><http://www.phontron.com/pialign>

Table 3: The BLEU scores for the translation tasks of three language pairs. The individual column show the average and 95% confidence intervals for 5 independent runs, whereas the combination column show the results for combining the phrase tables of all these runs. The baselines are GIZA++ alignments and those generated by the pialign (Neubig et al., 2011) **bold**: the best result.

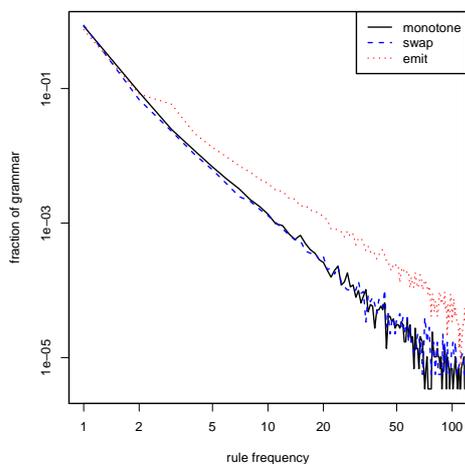

Figure 3: Fraction of rules with a given frequency, using a single sample grammar (UR-EN).

#### 4.1 Results

Table 3 shows the BLEU scores for the three translation tasks UR/AR/FA→EN based on our method against the baselines. For our models, we report the average BLEU score of the 5 independent runs as well as that of the *aggregate* phrase table generated by these 5 independent runs. There are a number of interesting observations in Table 3. Firstly, combining the phrase tables from independent runs results in increased BLEU scores, possibly due to the representation of uncertainty in the outputs, and the representation of different modes captured by the individual models. We believe this type of Monte Carlo model averaging should be considered in general when sampling techniques are employed for grammatical inference, e.g. in parsing and translation. Secondly, our approach consistently improves over the Giza++ baseline often by a large margin, whereas *pialign* under-

performs the GIZA++ baseline in many cases. Thirdly, our model consistently outperforms *pialign* (except in AR-EN MT08 which is very close). This highlights the modeling and inference differences between our method and the *pialign*.

## 5 Analysis

In this section, we present some insights about the learned grammar and the model hyper-parameters. Firstly, we start by presenting various statistics about different learned grammars. Figure 3 shows the fraction of rules with a given frequency for each of the three rule types. The three types of rule exhibit differing amounts of high versus low frequency rules, and all roughly follow power laws. As expected, there is a higher tendency to reuse high-frequency emissions (or single-word translation) compared to other rule types, which are the basic building blocks to compose larger rules (or phrases). Table 4 lists the high frequency monotone and swap rules in the learned grammar. We observe the high frequency swap rules capture reordering in verb clusters, preposition-noun inversions and adjective-noun reordering. Similar patterns are seen in the monotone rules, along with some common canned phrases. Note that “in Iraq” appears twice, once as an inversion in UR-EN and another time in monotone order for AR-EN.

Secondly, we analyse the values learned for the model hyper-parameters; Figure 4.(a) shows the posterior distribution over the hyper-parameter values. There is very little spread in the inferred values, suggesting the sampling chains may have converged. Furthermore, there is a large difference between the learned hyper-parameters for the monotone rules versus the swap rules. For the Pitman-Yor Process prior, the values of the hyper-

parameters affects the rate at which the number of types grows compared to the number of tokens. Specifically, as the discount  $a$  or the concentration  $b$  parameters increases we expect for a relative increase in the number of types. If the number of observed monotone and swap rules were equal, then there would be a higher chance in reusing the monotone rules. However, the number of observed monotone and swap rules are not equal, as plotted in Figure 4.(b). Similar results were observed for the other language pairs (figures omitted for space reasons).

Thirdly, we performed a manual evaluation for the quality of the phrase-pairs learned exclusively by our method vs *pialign*. For each method, we considered the top-100 high frequency phrase-pairs which are specific to that method. Then we asked a bilingual human expert to identify reasonably well phrase-pairs among these top-100 phrase-pairs. The results are summarized in Table 5, and show that we learn roughly twice as many reasonably good phrase-pairs for AR-EN and FA-EN compared to *pialign*.

## Conclusions

We have presented a novel method for learning a phrase-based model of translation directly from parallel data which we have framed as learning an inverse transduction grammar (ITG) using a recursive Bayesian prior. This has led to a model which learns translations of entire sentences, while also learning their decomposition into smaller units (phrase-pairs) recursively, terminating at word translations. We have presented a Metropolis-Hastings sampling algorithm for blocked inference in our non-parametric ITG. Our experiments on Urdu-English, Arabic-English, and Farsi-English translation tasks all demonstrate improvements over competitive baseline systems.

## Abstract

Most statistical machine translation (SMT) systems are modeled using a log-linear framework. Although the log-linear model achieves success in SMT, it still suffers from some limitations: (1) the features are required to be linear with respect to the model itself; (2) features cannot be further interpreted to reach their potential. A neural network is a reasonable method to address these pitfalls. However, modeling SMT with a neural network is not trivial, especially when taking the decoding efficiency into consideration. In this paper, we propose a variant of a neural network, i.e. additive neural networks, for SMT to go beyond the log-linear translation model. In addition, word embedding is employed as the input to the neural network, which encodes each word as a feature vector. Our model outperforms the log-linear translation models with/without embedding features on Chinese-to-English and Japanese-to-English translation tasks.

## 1 Introduction

Recently, great progress has been achieved in SMT, especially since Och and Ney (2002) proposed the log-linear model: almost all the state-of-the-art SMT systems are based on the log-linear model. Its most important advantage is that arbitrary features can be added to the model. Thus, it casts complex translation between a pair of languages as feature engineering, which facilitates research and development for SMT.

Regardless of how successful the log-linear model is in SMT, it still has some shortcomings.

---

This joint work was done while the first author visited NICT.

On the one hand, features are required to be linear with respect to the objective of the translation model (Nguyen et al., 2007), but it is not guaranteed that the potential features be linear with the model. This induces modeling inadequacy (Duh and Kirchhoff, 2008), in which the translation performance may not improve, or may even decrease, after one integrates additional features into the model. On the other hand, it cannot deeply interpret its surface features, and thus can not efficiently develop the potential of these features. What may happen is that a feature  $p$  does initially not improve the translation performance, but after a nonlinear operation, e.g.  $\log(p)$ , it does. The reason is not because this feature is useless but the model does not efficiently interpret and represent it. Situations such as this confuse explanations for feature designing, since it is unclear whether such a feature contributes to a translation or not.

A neural network (Bishop, 1995) is a reasonable method to overcome the above shortcomings. However, it should take constraints, e.g. the decoding efficiency, into account in SMT. Decoding in SMT is considered as the expansion of translation states and it is handled by a heuristic search (Koehn, 2004a). In the search procedure, frequent computation of the model score is needed for the search heuristic function, which will be challenged by the decoding efficiency for the neural network based translation model. Further, decoding with non-local (or state-dependent) features, such as a language model, is also a problem. Actually, even for the (log-) linear model, efficient decoding with the language model is not trivial (Chiang, 2007).

In this paper, we propose a variant of neural networks, i.e. additive neural networks (see Section 3 for details), for SMT. It consists of two components: a linear component which captures non-local (or state dependent) features and a non-linear component (i.e., neural network) which encodes lo-

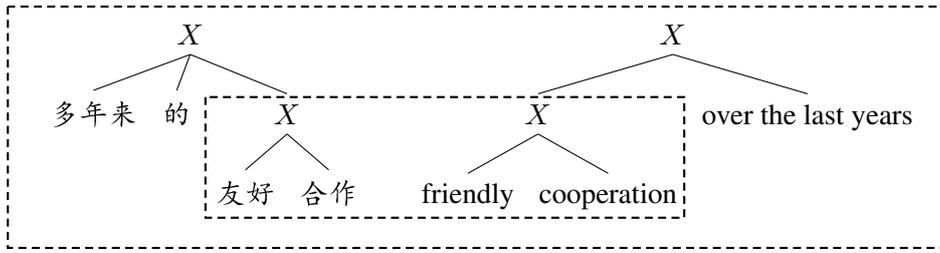

Figure 1: A bilingual tree with two synchronous rules,  $r_1 : X \rightarrow \langle \text{友好 合作}; \text{friendly cooperation} \rangle$  and  $r_2 : X \rightarrow \langle \text{多年来的 } X; X \text{ over the last years} \rangle$ . The inside rectangle denotes the partial derivation  $d_1 = \{r_1\}$  with the partial translation  $e_1 = \text{“friendly cooperation”}$ , and the outside rectangle denotes the derivation  $d_2 = \{r_1, r_2\}$  with the translation  $e_2 = \text{“friendly cooperation over the last years”}$ .

cal (or state independent) features. Compared with the log-linear model, it has more powerful expressive abilities and can deeply interpret and represent features with hidden units in neural networks. Moreover, our method is simple to implement and its decoding efficiency is comparable to that of the log-linear model. We also integrate word embedding into the model by representing each word as a feature vector (Collobert and Weston, 2008). Because of the thousands of parameters and the non-convex objective in our model, efficient training is not simple. We propose an efficient training methodology: we apply the mini-batch conjugate sub-gradient algorithm (Le et al., 2011) to accelerate the training; we also propose pre-training and post-training methods to avoid poor local minima. The biggest contribution of this paper is that it goes beyond the log-linear model and proposes a non-linear translation model instead of re-ranking model (Duh and Kirchhoff, 2008; Sokolov et al., 2012).

On both Chinese-to-English and Japanese-to-English translation tasks, experiment results show that our model can leverage the shortcomings suffered by the log-linear model, and thus achieves significant improvements over the log-linear based translation.

## 2 Log-linear Model, Revisited

### 2.1 Log-linear Translation Model

Och and Ney (2002) proposed the log-linear translation model, which can be formalized as follows:

$$\mathbf{P}(e, d|f; W) = \frac{\exp \{W^\top \cdot h(f, e, d)\}}{\sum_{e', d'} \exp \{W^\top \cdot h(f, e', d')\}}, \quad (1)$$

where  $f$  denotes the source sentence, and  $e(e')$  denotes its translation candidate;  $d(d')$  is a derivation over the pair  $\langle f, e \rangle$ , i.e.,

a collection of synchronous rules for Hiero grammar (Chiang, 2005), or phrase pairs in Moses (Koehn et al., 2007);  $h(f, e, d) = (h_1(f, e, d), h_2(f, e, d), \dots, h_K(f, e, d))^\top$  is a  $K$ -dimensional feature vector defined on the tuple  $\langle f, e, d \rangle$ ;  $W = (w_1, w_2, \dots, w_K)^\top$  is a  $K$ -dimensional weight vector of  $h$ , i.e., the parameters of the model, and it can be tuned by the toolkit MERT (Och, 2003). Different from Brown’s generative model (Brown et al., 1993), the log-linear model does not assume strong independency holds, and allows arbitrary features to be integrated into the model easily. In other words, it can transform complex language translation into feature engineering: it can achieve high translation performance if reasonable features are chosen and appropriate parameters are assigned for the weight vector.

### 2.2 Decoding By Search

Given a source sentence  $f$  and a weight  $W$ , decoding finds the best translation candidate  $\hat{e}$  via the programming problem:

$$\begin{aligned} \langle \hat{e}, \hat{d} \rangle &= \arg \max_{e, d} \mathbf{P}(e, d|f; W) \\ &= \arg \max_{e, d} \{W^\top \cdot h(f, e, d)\}. \end{aligned} \quad (2)$$

Since the range of  $\langle e, d \rangle$  is exponential with respect to the size of  $f$ , the exact decoding is intractable and an inexact strategy such as beam search is used instead in practice.

The idea of search for decoding can be shown in **Figure 1**: it encodes each search state as a partial translation together with its derivation, e.g.  $\langle e_1, d_1 \rangle$ ; it consequently expands the states from the initial (*empty*) state to the end state  $\langle e_2, d_2 \rangle$  according to the translation rules  $r_1$  and  $r_2$ . During the state expansion process, the score  $w_i \cdot$

$h_i(f, e, d)$  for a partial translation is calculated repeatedly. In the log-linear model, if  $h_i(f, e, d)$  is a local feature, the calculation of its score  $w_i \cdot h_i(f, e, d)$  has a substructure, and thus it can be calculated with dynamic programming which accelerates its decoding. For the non-local features such as the language model, Chiang (2007) proposed a cube-pruning method for efficient decoding. The main reason why cube-pruning works is that the translation model is linear and the model score for the language model is approximately monotonic (Chiang, 2007).

### 3 Additive Neural Networks

#### 3.1 Motivation

Although the log-linear model has achieved great progress for SMT, it still suffers from some pitfalls: it requires features be linear with the model and it can not interpret and represent features deeply. The neural network model is a reasonable method to overcome these pitfalls. However, the neural network based machine translation is far from easy.

As mentioned in Section 2, the decoding procedure performs an expansion of translation states. Firstly, let us consider a simple case in neural network based translation where all the features in the translation model are independent of the translation state, i.e. all the components of the vector  $h(f, e, d)$  are local features. In this way, we can easily define the following translation model with a single-layer neural network:

$$\mathbf{S}(f, e, d; W, M, B) = W^\top \cdot \sigma(M \cdot h(f, e, d) + B), \quad (3)$$

where  $M \in \mathbb{R}^{u \times K}$  is a matrix, and  $B \in \mathbb{R}^u$  is a vector, i.e. bias;  $\sigma$  is a single-layer neural network with  $u$  hidden units, i.e. an element wise sigmoid function  $\text{sigmoid}(x) = 1/(1 + \exp(-x))$ . For consistent description in the rest, we also represent Eq. (3) as a function of a feature vector  $h$ , i.e.  $\mathbf{S}(h; W, M, B) = W^\top \cdot \sigma(M \cdot h + B)$ .

Now let us consider the search procedure with the model in Eq. (3) using **Figure 1** as our example. Suppose the current translation state is encoded as  $\langle e_1, d_1 \rangle$ , which is expanded into  $\langle e_2, d_2 \rangle$  using the rule  $r_2$  ( $d_2 = d_1 \cup \{r_2\}$ ). Since  $h$  is state-independent,  $h(f, e_2, d_2) = h(f, e_1, d_1) + h(r_2)$ . However, since  $S(f, e, d; W, M, B)$  is non-decomposable as a linear model, there is no substructure for calculating  $S(f, e_2, d_2; W, M, B)$ ,

and one has to re-calculate it via Eq. (3) even if the score of  $S(f, e_1, d_1; W, M, B)$  for its previous state  $\langle e_1, d_1 \rangle$  is available. When the size of the parameter  $(W, M, B)$  is relatively large, it will be a challenge for the decoding efficiency.

In order to keep the substructure property,  $S(f, e_2, d_2; W, M, B)$  should be represented as  $F(S(f, e_1, d_1; W, M, B); S(h(r_2); M, B))$  by a function  $F$ . For simplicity, we suppose that the additive property holds in  $F$ , and then we can obtain a new translation model via the following recursive equation:

$$S(f, e_2, d_2; W, M, B) = S(f, e_1, d_1; W, M, B) + S(h(r_2); W, M, B). \quad (4)$$

Since the above model is defined only on local features, it ignores the contributions from non-local features. Actually, existing works empirically show that some non-local features, especially language model, contribute greatly to machine translation.

Scoring for non-local features such as a  $n$ -gram language model is not easily done. In log-linear translation model, Chiang (2007) proposed a cube-pruning method for scoring the language model. The premise of cube-pruning is that the language model score is approximately monotonic (Chiang, 2007). However, if scoring the language model with a neural network, this premise is difficult to hold. Therefore, one of the solutions is to preserve a linear model for scoring the language model directly.

#### 3.2 Definition

According to the above analysis, we propose a variant of a neural network model for machine translation, and we call it **Additive Neural Networks** or **AdNN** for short.

The AdNN model is a combination of a linear model and a neural network: non-local features, e.g. LM, are linearly modeled for the cube-pruning strategy, and local features are modeled by the neural network for deep interpretation and representation. Formally, the AdNN based translation model is discriminative but non-probabilistic, and it can be defined as follows:

$$S(f, e, d; \theta) = W^\top \cdot h(f, e, d) + \sum_{r \in d} W'^\top \cdot \sigma(M \cdot h'(r) + B), \quad (5)$$

where  $h$  and  $h'$  are feature vectors with dimension  $K$  and  $K'$  respectively, and each component of  $h'$  is a local feature which can be defined on a rule  $r : X \rightarrow \langle \alpha, \gamma \rangle$ ;  $\theta = (W, W', M, B)$  is the model parameters with  $M \in \mathbb{R}^{u \times K'}$ . In this paper, we focus on a single-layer neural network for its simplicity, and one can similarly define  $\sigma$  as a multi-layer neural network.

Again for the example shown in **Figure 1**, the model score defined in Eq. (5) for the pair  $\langle e_2, d_2 \rangle$  can be represented as follows:

$$S(f, e_2, d_2; \theta) = W^\top \cdot h(f, e_2, d_2) + W'^\top \cdot \sigma(M \cdot h'(r_1) + B) + W'^\top \cdot \sigma(M \cdot h'(r_2) + B).$$

Eq. (5) is similar to both additive models (Buja et al., 1989) and generalized additive neural networks (Potts, 1999): it consists of many additive terms, and each term is either a linear or a non-linear (a neural network) model. That is the reason why our model is called “additive neural networks”. Of course, our model still has some differences from both of them. Firstly, our model is decomposable with respect to rules instead of the component variables. Secondly, some of its additive terms share the same parameters  $(M, B)$ .

There are also strong relationships between AdNN and the log-linear model. If we consider the parameters  $(M, B)$  as constant and  $\sigma(M \cdot h'(r) + B)$  as a new feature vector, then AdNN is reduced to a log-linear model. Since both  $(M, B)$  and  $(W, W')$  are parameters in AdNN, our model can jointly learn the feature  $\sigma(M \cdot h'(r) + B)$  and tune the weight  $(W, W')$  of the log-linear model together. That is different from most works under the log-linear translation framework, which firstly learn features or sub-models and then tune the log-linear model including the learned features in two separate steps. By joint training, AdNN can learn the features towards the translation evaluation metric, which is the main advantage of our model over the log-linear model.

In this paper, we apply our AdNN model to hierarchical phrase based translation, and it can be similarly applied to phrase-based or syntax-based translation. Similar to Hiero (Chiang, 2005), the feature vector  $h$  in Eq. (5) includes 8 default features, which consist of translation probabilities, lexical translation probabilities, word penalty, glue rule penalty, synchronous rule penalty and language model. These default features are included

because they empirically perform well in the log-linear model. For the local feature vector  $h'$  in Eq (5), we employ word embedding features as described in the following subsection.

### 3.3 Word Embedding features for AdNN

Word embedding can relax the sparsity introduced by the lexicalization in NLP, and it improves the systems for many tasks such as language model, named entity recognition, and parsing (Collobert and Weston, 2008; Turian et al., 2010; Collobert, 2011). Here, we propose embedding features for rules in SMT by combining word embeddings.

Firstly, we will define the embedding for the source side  $\alpha$  of a rule  $r : X \rightarrow \langle \alpha, \gamma \rangle$ . Let  $\mathcal{V}_S$  be the vocabulary in the source language with size  $|\mathcal{V}_S|$ ;  $\mathbb{R}^{n \times |\mathcal{V}_S|}$  be the word embedding matrix, each column of which is the word embedding ( $n$ -dimensional vector) for the corresponding word in  $\mathcal{V}_S$ ; and  $maxSource$  be the maximal length of  $\alpha$  for all rules. We further assume that the  $\alpha$  for all rules share the same length as  $maxSource$ ; otherwise, we add  $maxSource - |\alpha|$  words “NULL” to the end of  $\alpha$  to obtain a new  $\alpha$ . We define the embedding of  $\alpha$  as the concatenation of the word embedding of each word in  $\alpha$ . In particular, for the non-terminal in  $\alpha$ , we define its word embedding as the vector whose components are 0.1; and we define the word embedding of “NULL” as  $\mathbf{0}$ . Then, we similarly define the embedding for the target side of a rule, given an embedding matrix for the target vocabulary. Finally, we define the embedding of a rule as the concatenation of the embedding of its source and target sides.

In this paper, we apply the word embedding matrices from the RNNLM toolkit (Mikolov et al., 2010) with the default settings: we train two RNN language models on the source and target sides of training corpus, respectively, and then we obtain two matrices as their by-products<sup>1</sup>. It would be potentially better to train the word embedding matrix from a much larger corpus as (Collobert and Weston, 2008), and we will leave this as a future task.

### 3.4 Decoding

Substituting the  $\mathbf{P}(e, d|f; W)$  in Eq. (2) with  $S(f, e, d; \theta)$  in Eq. (5), we can obtain its corre-

<sup>1</sup>In the RNNLM toolkit, the default dimension for word embedding is  $n = 30$ . In our experiments, the maximal length of  $\alpha$  and  $\gamma$  are 5 and 12 respectively. Thus the dimension for  $h'$  is  $K' = 30 \times (5 + 12) = 510$ .

sponding decoding formula:

$$\langle \hat{e}, \hat{d} \rangle = \arg \max_{e,d} S(f, e, d; \theta).$$

Given the model parameter  $\theta = (W, W', M, B)$ , if we consider  $(M, B)$  as constant and  $\sigma(M \cdot h'(r) + B)$  as an additional feature vector besides  $h$ , then Eq. (5) goes back to being a log-linear model with parameter  $(W, W')$ . In this way, the decoding for AdNN can share the same search strategy and cube pruning method as the log-linear model.

## 4 Training Method

### 4.1 Training Objective

For the log-linear model, there are various tuning methods, e.g. MERT (Och, 2003), MIRA (Watanabe et al., 2007; Chiang et al., 2008), PRO (Hopkins and May, 2011) and so on, which iteratively optimize a weight such that, after re-ranking a k-best list of a given development set with this weight, the loss of the resulting 1-best list is minimal. In the extreme, if the k-best list consists only of a pair of translations  $\langle \langle e^*, d^* \rangle, \langle e', d' \rangle \rangle$ , the desirable weight should satisfy the assertion: if the BLEU score of  $e^*$  is greater than that of  $e'$ , then the model score of  $\langle e^*, d^* \rangle$  with this weight will be also greater than that of  $\langle e', d' \rangle$ . In this paper, a pair  $\langle e^*, e' \rangle$  for a source sentence  $f$  is called as a preference pair for  $f$ . Following PRO, we define the following objective function under the max-margin framework to optimize the AdNN model:

$$\frac{1}{2} \|\theta\|^2 + \frac{\lambda}{N} \sum_f \sum_{e^*, d^*, e', d'} \delta(f, e^*, d^*, e', d'; \theta), \quad (6)$$

with

$$\delta(\cdot) = \max \{S(f, e', d'; \theta) - S(f, e^*, d^*; \theta) + 1, 0\}$$

where  $f$  is a source sentence in a given development set, and  $\langle \langle e^*, d^* \rangle, \langle e', d' \rangle \rangle$  is a preference pair for  $f$ ;  $N$  is the number of all preference pairs;  $\lambda > 0$  is a regularizer.

### 4.2 Optimization Algorithm

Since there are thousands of parameters in Eq. (6) and the tuning in SMT will minimize Eq. (6) repeatedly, efficient and scalable optimization methods are required. Following Le et al. (2011), we apply the mini-batch Conjugate Sub-Gradient (mini-batch CSG) method to minimize Eq. (6).

Compared with the sub-gradient descent, mini-batch CSG has some advantages: (1) it can accelerate the calculation of the sub-gradient since it calculates the sub-gradient on a subset of preference pairs (i.e. mini-batch) instead of all of the preference pairs; (2) it reduces the number of iterations since it employs the conjugate information besides the sub-gradient. Algorithm 1 shows the procedure to minimize Eq. (6).

---

#### Algorithm 1 Mini-batch conjugate subgradient

---

**Input:**  $\theta^1, T, CGIter, batch-size, k-best-list$

- 1: **for all**  $t$  such that  $1 \leq t \leq T$  **do**
- 2: Sample mini-batch preference pairs with size  $batch-size$  from  $k-best-list$
- 3: Calculate some quantities for CG, e.g. training objective  $Obj$ , subgradient  $\Delta$ , according to Eq. (6) defined over the sampled preference pairs
- 4:  $\theta^{t+1} = CG(\theta^t, Obj, \Delta, CGIter)$
- 5: **end for**

**Output:**  $\theta^{T+1}$

---

In detail, line 2 in Algorithm 1 firstly follows PRO to sample a set of preference pairs from  $k-best-list$ , and then uniformly samples  $batch-size$  pairs from the preference pair set. Line 3 calculates some quantities for CG, and Line 4 calls a CG optimizer<sup>2</sup> and obtains  $\theta^{t+1}$ . At the end of the algorithm, it returns the result  $\theta^{T+1}$ . In this work, we set the maximum number of CG iterations,  $CGIter$ , to a small number, which means  $\theta^{t+1}$  will be returned within  $CGIter$  iterations before the CG converges, for faster learning.

### 4.3 Pre-Training and Post-Training

Since Eq. (6) is non-linear, there are many local minimal solutions. Actually, this problem is inherent and is one many works based on the neural network for other NLP tasks such as language model and parsing, also suffer from. And these works empirically show that some pre-training methods, which provide a reasonable initial solution, can improve the performance. Observing the structure of Eq. (5) and the relationships between our model and a log-linear model, we propose the following simple pre-training method.

---

<sup>2</sup>In implementation, we call the CG toolkit (Hager and Zhang, 2006), which requires overloading objective and sub-gradient functions. For easier description, we substitute overloading functions and transform the value of functions in the pseudo-code.

If we set  $W' = 0$ , the model defined in Eq. (5) can be regarded as a log-linear model with features  $h$ . Therefore, we pre-train  $W$  using MERT or PRO by holding  $W' = 0$ , and use  $(W, W' = 0, M, B)$  as an initializer<sup>3</sup> for Algorithm 1.

Although the above pre-training would provide a reasonable solution, Algorithm 1 may still fall into local minima. We also propose a post-training method: after obtaining a solution with Algorithm 1, we modify this solution slightly to get a new solution. The idea of the post-training method is similar to that of the pre-training method. Suppose  $\theta = (W, W', M, B)$  be the solution obtained from Algorithm 1. If we consider both M and B to be constant, the Eq. (5) goes back to the log-linear model whose features are  $(h, \sigma(M \cdot h' + B))$  and parameters are  $(W, W')$ . Again, we train the parameters  $(W, W')$  with MERT or PRO and get the new parameters  $(\bar{W}, \bar{W}')$ . Therefore, we can set  $\theta = (\bar{W}, \bar{W}', M, B)$  as the final solution for Eq. (6). The advantage of post-training is that it optimizes a convex programming derived from the original nonlinear (non-convex) programming in Eq. (6), and thus it may decrease the risk of poor local optima.

#### 4.4 Training Algorithm

---

##### Algorithm 2 Training Algorithm

---

**Input:**  $MaxIter$ , a dev set, parameters (e.g.  $\lambda$ ) for Algorithm 1

- 1: Pre-train to obtain  $\theta_1 = (W, W' = 0, M, B)$  as the initial parameter
- 2: **for all**  $i$  such that  $1 \leq i \leq MaxIter$  **do**
- 3: Decode with  $\theta_i$  on the dev set and merge all k-best-lists
- 4: Run Algorithm 1 based on the merged k-best-list to obtain  $\theta_{i+1}$
- 5: **end for**
- 6: Post-train based on  $\theta_{MaxIter+1}$  to obtain  $\theta$

**Output:**  $\theta$

---

The whole training for the AdNN model is summarized in Algorithm 2. Given a development set, we first run pre-training to obtain an initial parameter  $\theta_1$  for Algorithm 1 in line 1. Secondly, it iteratively performs decoding and optimization for  $MaxIter$  times in the loop from line 2 to line 5: it decodes with the parameter  $\theta_i$  and merges all the

<sup>3</sup>To avoid the symmetry in the solution, we sample a very small  $(M, B)$  from the gaussian distribution in practice instead of setting  $(M, B) = 0$ .

k-best-lists in line 3; and it then runs Algorithm 1 to optimize  $\theta_{i+1}$ . Thirdly, it runs the post-training to get the result  $\theta$  based on  $\theta_{MaxIter+1}$ .

Of course, we can run post-training after running Algorithm 1 at each iteration  $i$ . However, since each pass of post-training (e.g. PRO) takes several hours because of multiple decoding times, we run it only once, at the end of the iterations instead.

## 5 Experiments and Results

### 5.1 Experimental Setting

We conduct our experiments on the Chinese-to-English and Japanese-to-English translation tasks. For the Chinese-to-English task, the training data is the FBIS corpus (news domain) with about 240k sentence pairs; the development set is the NIST02 evaluation data; the development test set is NIST05; and the test datasets are NIST06, and NIST08. For the Japanese-to-English task, the training data with 300k sentence pairs is from the NTCIR-patent task (Fujii et al., 2010); the development set, development test set, and two test sets are averagely extracted from a given development set with 4000 sentences, and these four datasets are called test1, test2, test3 and test4, respectively.

We run GIZA++ (Och and Ney, 2000) on the training corpus in both directions (Koehn et al., 2003) to obtain the word alignment for each sentence pair. Using the SRILM Toolkits (Stolcke, 2002) with modified Kneser-Ney smoothing, we train a 4-gram language model for the Chinese-to-English task on the Xinhua portion of the English Gigaword corpus and a 4-gram language model for the Japanese-to-English task on the target side of its training data. In our experiments, the translation performances are measured by case-sensitive BLEU4 metric<sup>4</sup> (Papineni et al., 2002). The significance testing is performed by paired bootstrap re-sampling (Koehn, 2004b).

We use an in-house developed hierarchical phrase-based translation (Chiang, 2005) for our baseline system, which shares the similar setting as Hiero (Chiang, 2005), e.g. beam-size=100, k-best-size=100, and is denoted as **L-Hiero** to emphasize its log-linear model. We tune L-Hiero with two methods MERT and PRO implemented in the Moses toolkit. On the same experiment settings, the performance of L-Hiero is comparable

<sup>4</sup>We use mteval-v13a.pl as the evaluation tool(Ref. <http://www.itl.nist.gov/iad/mig/tests/mt/2008/scoring.html>).

	Seconds/Sent
L-Hiero	1.77
AdNN-Hiero-E	1.88

Table 1: The decoding time comparison on NIST05 between L-Hiero and AdNN-Hiero-E.

to that of Moses: on the NIST05 test set, L-Hiero achieves 25.1 BLEU scores and Moses achieves 24.8. Further, we integrate the embedding features (See Section 3.3) into the log-linear model along with the default features as L-Hiero, which is called **L-Hiero-E**. Since L-Hiero-E has hundreds of features, we use PRO as its tuning toolkit.

**AdNN-Hiero-E** is our implementation of the AdNN model with embedding features, as discussed in Section 3, and it shares the same codebase and settings as L-Hiero. We adopt the following setting for training AdNN-Hiero-E:  $u=10$ ;  $batch-size=1000$  and  $CGiter=3$ , as referred in (Le et al., 2011), and  $T=200$  in Algorithm 1; the pre-training and post-training methods as PRO; the regularizer  $\lambda$  in Eq. (6) as 10 and 30, and  $MaxIter$  as 16 and 20 in Algorithm 2, for Chinese-to-English and Japanese-to-English tasks, respectively. Although there are several parameters in AdNN which may limit its practicality, according to many of our internal studies, most parameters are insensitive to AdNN except  $\lambda$  and  $MaxIter$ , which are common in other tuning toolkits such as MIRA and can be tuned<sup>5</sup> on a development test dataset.

Since both MERT and PRO tuning toolkits involve randomness in their implementations, all BLEU scores reported in the experiments are the average of five tuning runs, as suggested by Clark et al. (2011) for fairer comparisons. For AdNN, we report the averaged scores of five post-training runs, but both pre-training and training are performed only once.

## 5.2 Results and Analysis

As discussed in Section 3, our AdNN-Hiero-E shares the same decoding strategy and pruning method as L-Hiero. When compared with L-Hiero, decoding for AdNN-Hiero-E only needs additional computational times for the features in the hidden units, i.e.  $\sigma(M \cdot h'(r) + B)$ . Since

<sup>5</sup>For easier tuning, we tuned these two parameters on a given development test set without post-training in Algorithm 2.

Chinese-to-English				
		NIST05	NIST06	NIST08
L-Hiero	MERT	25.10 <sup>+</sup>	24.46 <sup>+</sup>	17.42 <sup>+</sup>
	PRO	25.57 <sup>+</sup>	25.27 <sup>+</sup>	18.33 <sup>+</sup>
L-Hiero-E	PRO	24.80 <sup>+</sup>	24.46 <sup>+</sup>	18.20 <sup>+</sup>
AdNN-Hiero-E		26.37	25.93	19.42
Japanese-to-English				
		test2	test3	test4
L-Hiero	MERT	24.35 <sup>+</sup>	25.62 <sup>+</sup>	23.68 <sup>+</sup>
	PRO	24.38 <sup>+</sup>	25.55 <sup>+</sup>	23.66 <sup>+</sup>
L-Hiero-E	PRO	24.47 <sup>+</sup>	25.86 <sup>+</sup>	24.03 <sup>+</sup>
AdNN-Hiero-E		25.14	26.32	24.45

Table 2: The BLEU comparisons between AdNN-Hiero-E and Log-linear translation models on the Chinese-to-English and Japanese-to-English tasks. + means the comparison is significant over AdNN-Hiero-E with  $p < 0.05$ .

these features are not dependent on the translation states, they are computed and saved to memory when loading the translation model. During decoding, we just look up these scores instead of re-calculating them on the fly. Therefore, the decoding efficiency of AdNN-Hiero-E is almost the same as that of L-Hiero. As shown in Table 1 the average decoding time for L-Hiero is 1.77 seconds/sentence while that for AdNN-Hiero-E is 1.88 seconds/sentence on the NIST05 test set.

Word embedding features can improve the performance on other NLP tasks (Turian et al., 2010), but its effect on log-linear based SMT is not as expected. As shown in Table 2, L-Hiero-E gains little over L-Hiero for the Japanese-to-English task, and even decreases the performance over L-Hiero for the Chinese-to-English task. These results further prove our claim in Section 1, i.e. the log-linear model requires the features to be linear with the model and thus limits its expressive abilities. However, after the single-layer non-linear operator (sigmoid functions) on the embedding features for deep interpretation and representation, AdNN-Hiero-E gains improvements over both L-Hiero and L-Hiero-E, as depicted in Table 2. In detail, for the Chinese-to-English task, AdNN-Hiero-E improves more than 0.6 BLEU scores over L-Hiero on both test sets: the gains over L-Hiero tuned with PRO are 0.66 and 1.09 on NIST06 and NIST08, respectively, and the gains over L-Hiero tuned with MERT are even more. Similar results are achieved on the Japanese-to-English task. AdNN-Hiero-E gains about 0.7 BLEU scores on

Chinese-to-English

AdNN-Hiero-D	24.42	25.46	23.73

Table 3: The effect of different feature setting on AdNN model. + means the comparison is significant over AdNN-Hiero-D with  $p < 0.05$ .

both test sets.

In addition, to investigate the effect of different feature settings on AdNN, we alternatively design another setting for  $h'$  in Eq. (5): we use the default features for both  $h'$  and  $h$ . In particular, the language model of a rule for  $h'$  is locally calculated without the contexts out of the rule as described in (Chiang, 2007). We call the AdNN model with this setting **AdNN-Hiero-D**<sup>6</sup>. Although there are serious overlaps between  $h$  and  $h'$  for AdNN-Hiero-D which may limit its generalization abilities, as shown in Table 3, it is still comparable to L-Hiero on the Japanese-to-English task, and significantly outperforms L-Hiero on the Chinese-to-English translation task. To investigate the reason why the gains for AdNN-Hiero-D on the two different translation tasks differ, we calculate the perplexities between the target side of training data and test datasets on both translation tasks. We find that the perplexity of the 4-gram language model for the Chinese-to-English task is 321.73, but that for the Japanese-to-English task is only 81.48. Based on these similarity statistics, we conjecture that the log-linear model does not fit well for difficult translation tasks (e.g. translation task on the news domain). The problem seems to be resolved by simply alternating feature representations through non-linear models, i.e. AdNN-Hiero-D, even with single-layer networks.

## 6 Related Work

Neural networks have achieved widespread attentions in many NLP tasks, e.g. the language

<sup>6</sup>All its parameters are shared with AdNN-Hiero-E except  $\lambda$  and  $MaxIter$ , which are tuned on the development test datasets.

model (Bengio et al., 2003); POS, Chunking, NER, and SRL (Collobert and Weston, 2008); Parsing (Collobert and Weston, 2008; Socher et al., 2011); and Machine transliteration (Deselaers et al., 2009). Our work is, of course, highly motivated by these works. Unlike these works, we propose a variant neural network, i.e. additive neural networks, starting from SMT itself and taking both of the model definition and its inference (decoding) together into account.

Our variant of neural network, AdNN, is highly related to both additive models (Buja et al., 1989) and generalized additive neural networks (Potts, 1999; Waal and Toit, 2007), in which an additive term is either a linear model or a neural network. Unlike additive models and generalized additive neural networks, our model is decomposable with respect to translation rules rather than its component variables considering the decoding efficiency of machine translation; and it allows its additive terms of neural networks to share the same parameters for a compact structure to avoid sparsity.

The idea of the neural network in machine translation has already been pioneered in previous works. Castaño et al. (1997) introduced a neural network for example-based machine translation. In particular, Son et al. (2012) and Schwenk (2012) employed a neural network to model the phrase translation probability on the rule level  $\langle \alpha, \gamma \rangle$  instead of the bilingual sentence level  $\langle f, e \rangle$  as in Eq. (5), and thus they did not go beyond the log-linear model for SMT.

There are also works which exploit non-linear models in SMT. Duh and Kirchhoff (2008) proposed a boosting re-ranking algorithm using MERT as a weak learner to improve the model’s expressive abilities; Sokolov et al. (2012) similarly proposed a boosting re-ranking method from the ranking perspective rather than the classification perspective. Instead of considering the re-ranking task in SMT, Xiao et al. (2010) employed a boosting method for the system combination in SMT. Unlike their post-processing models (either a re-ranking or a system combination model) in SMT, we propose a non-linear translation model which can be easily incorporated into the existing SMT framework.

## 7 Conclusion and Future Work

In this paper, we go beyond the log-linear model for SMT and propose a novel AdNN based trans-

lation model. Our model overcomes some of the shortcomings suffered by the log-linear model: linearity and the lack of deep interpretation and representation in features. One advantage of our model is that it jointly learns features and tunes the translation model and thus learns features towards the translation evaluation metric. Additionally, the decoding of our model is as efficient as that of the log-linear model. For Chinese-to-English and Japanese-to-English translation tasks, our model significantly outperforms the log-linear model, with the help of word embedding.

We plan to explore more work on the additive neural networks in the future. For example, we will train word embedding matrices for source and target languages from a larger corpus, and take into consideration the bilingual information, for instance, word alignment; the multi-layer neural network within the additive neural networks will be also investigated in addition to the single-layer neural network; and we will test our method on other translation tasks with larger training data as well.

## Acknowledgments

We would like to thank our colleagues in both HIT and NICT for insightful discussions, Tomas Mikolov for the helpful discussion about the word embedding in RNNLM, and three anonymous reviewers for many invaluable comments and suggestions to improve our paper. ## Abstract

Typical statistical machine translation systems are batch trained with a given training data and their performances are largely influenced by the amount of data. With the growth of the available data across different domains, it is computationally demanding to perform batch training every time when new data comes. In face of the problem, we propose an efficient phrase table combination method. In particular, we train a Bayesian phrasal inversion transduction grammars for each domain separately. The learned phrase tables are hierarchically combined as if they are drawn from a hierarchical Pitman-Yor process. The performance measured by BLEU is at least as comparable to the traditional batch training method. Furthermore, each phrase table is trained separately in each domain, and while computational overhead is significantly reduced by training them in parallel.

## 1 Introduction

Statistical machine translation (SMT) systems usually achieve 'crowd-sourced' improvements with batch training. Phrase pair extraction, the key step to discover translation knowledge, heavily relies on the scale of training data. Typically, the more parallel corpora used, the more phrase pairs and more accurate parameters will be learned, which can obviously be beneficial to improving translation performances. Today, more parallel sentences are drawn from divergent domains, and the size keeps growing. Consequently, how to effectively use those data and improve translation performance becomes a challenging issue.

This joint work was done while the first author visited NICT.

Batch retraining is not acceptable for this case, since it demands serious computational overhead when training on a large data set, and it requires us to re-train every time new training data is available. Even if we can handle the large computation cost, improvement is not guaranteed every time we perform batch tuning on the newly updated training data obtained from divergent domains. Traditional domain adaption methods for SMT are also not adequate in this scenario. Most of them have been proposed in order to make translation systems perform better for resource-scarce domains when most training data comes from resource-rich domains, and ignore performance on a more generic domain without domain bias (Wang et al., 2012). As an alternative, incremental learning may resolve the gap by incrementally adding data sentence-by-sentence into the training data. Since SMT systems trend to employ very large scale training data for translation knowledge extraction, updating several sentence pairs each time will be annihilated in the existing corpus.

This paper proposes a new phrase table combination method. First, phrase pairs are extracted from each domain without interfering with other domains. In particular, we employ the non-parametric Bayesian phrasal inversion transduction grammar (ITG) of Neubig et al. (2011) to perform phrase table extraction. Second, extracted phrase tables are combined as if they are drawn from a hierarchical Pitman-Yor process, in which the phrase tables represented as tables in the Chinese restaurant process (CRP) are hierarchically chained by treating each of the previously learned phrase tables as prior to the current one. Thus, we can easily update the chain of phrase tables by appending the newly extracted phrase table and by treating the chain of the previous ones as its prior.

Experiment results indicate that our method can achieve better translation performance when there exists a large divergence in domains, and can

achieve at least comparable results to batch training methods, with a significantly less computational overhead.

The rest of the paper is organized as follows. In Section 2, we introduce related work. In section 3, we briefly describe the translation model with phrasal ITGs and Pitman-Yor process. In section 4, we explain our hierarchical combination approach and give experiment results in section 5. We conclude the paper in the last section.

## 2 Related Work

Bilingual phrases are cornerstones for phrase-based SMT systems (Och and Ney, 2004; Koehn et al., 2003; Chiang, 2005) and existing translation systems often get ‘crowd-sourced’ improvements (Levenberg et al., 2010). A number of approaches have been proposed to make use of the full potential of the available parallel sentences from various domains, such as domain adaptation and incremental learning for SMT.

The translation model and language model are primary components in SMT. Previous work proved successful in the use of large-scale data for language models from diverse domains (Brants et al., 2007; Schwenk and Koehn, 2008). Alternatively, the language model is incrementally updated by using a succinct data structure with a interpolation technique (Levenberg and Osborne, 2009; Levenberg et al., 2011).

In the case of the previous work on translation modeling, mixed methods have been investigated for domain adaptation in SMT by adding domain information as additional labels to the original phrase table (Foster and Kuhn, 2007). Under this framework, the training data is first divided into several parts, and phrase pairs are extracted with some sub-domain features. Then all the phrase pairs and features are tuned together with different weights during decoding. As a way to choose the right domain for the domain adaptation, a classifier-based method and a feature-based method have been proposed. Classification-based methods must at least add an explicit label to indicate which domain the current phrase pair comes from. This is traditionally done with an automatic domain classifier, and each input sentence is classified into its corresponding domain (Xu et al., 2007). As an alternative to the classification-based approach, Wang et al. (2012) employed a feature-based approach, in which phrase pairs are enriched

by a feature set to potentially reflect the domain information. The similarity calculated by a information retrieval system between the training subset and the test set is used as a feature for each parallel sentence (Lu et al., 2007). Monolingual topic information is taken as a new feature for a domain adaptive translation model and tuned on the development set (Su et al., 2012). Regardless of underlying methods, either classifier-based or feature-based method, the performance of current domain adaptive phrase extraction methods is more sensitive to the development set selection. Usually the domain similar to a given development data is usually assigned higher weights.

Incremental learning in which new parallel sentences are incrementally updated to the training data is employed for SMT. Compared to traditional frequent batch oriented methods, an online EM algorithm and active learning are applied to phrase pair extraction and achieves almost comparable translation performance with less computational overhead (Levenberg et al., 2010; González-Rubio et al., 2011). However, their methods usually require numbers of hyperparameters, such as mini-batch size, step size, or human judgment to determine the quality of phrases, and still rely on a heuristic phrase extraction method in each phrase table update.

## 3 Phrase Pair Extraction with Unsupervised Phrasal ITGs

Recently, phrase alignment with ITGs (Cherry and Lin, 2007; Zhang et al., 2008; Blunsom et al., 2008) and parameter estimation with Gibbs sampling (DeNero and Klein, 2008; Blunsom and Cohn, 2010) are popular. Here, we employ a method proposed by Neubig et al. (2011), which uses parametric Bayesian inference with the phrasal ITGs (Wu, 1997). It can achieve comparable translation accuracy with a much smaller phrase table than the traditional GIZA++ and heuristic phrase extraction methods. It has also been proved successful in adjusting the phrase length granularity by applying character-based SMT with more sophisticated inference (Neubig et al., 2012).

ITG is a synchronous grammar formalism which analyzes bilingual text by introducing inverted rules, and each ITG derivation corresponds to the alignment of a sentence pair (Wu, 1997). Translation probabilities of ITG phrasal align-

ments can be estimated in polynomial time by slightly limiting word reordering (DeNero and Klein, 2008).

More formally,  $P(\langle e, f \rangle; \theta_x, \theta_t)$  are the probability of phrase pairs  $\langle e, f \rangle$ , which is parameterized by a phrase pair distribution  $\theta_t$  and a symbol distribution  $\theta_x$ .  $\theta_x$  is a Dirichlet prior, and  $\theta_t$  is estimated with the Pitman-Yor process (Pitman and Yor, 1997; Teh, 2006), which is expressed as

$$\theta_t \sim PY(d, s, P_{dac}) \quad (1)$$

where  $d$  is the discount parameter,  $s$  is the strength parameter, and  $P_{dac}$  is a prior probability which acts as a fallback probability when a phrase pair is not in the model.

Under this model, the probability for a phrase pair found in a bilingual corpus  $\langle E, F \rangle$  can be represented by the following equation using the Chinese restaurant process (Teh, 2006):

$$P(\langle e_i, f_i \rangle; \langle E, F \rangle) = \frac{1}{C + s}(c_i - d \times t_i) + \frac{1}{C + s}(s + d \times T) \times P_{dac}(\langle e_i, f_i \rangle) \quad (2)$$

where

1.  $c_i$  and  $t_i$  are the customer and table count of the  $i$ th phrase pair  $\langle e_i, f_i \rangle$  found in a bilingual corpus  $\langle E, F \rangle$ ;
2.  $C$  and  $T$  are the total customer and table count in corpus  $\langle E, F \rangle$ ;
3.  $d$  and  $s$  are the discount and strengthen hyper-parameters.

The prior probability  $P_{dac}$  is recursively defined by breaking a longer phrase pair into two through the recursive ITG's generative story as follows (Neubig et al., 2011):

1. Generate symbol  $x$  from  $P_x(x; \theta_x)$  with three possible values: *Base*, *REG*, or *INV*.
2. Depending on the value of  $x$  take the following actions.
  - a. If  $x = \textit{Base}$ , generate a new phrase pair directly from  $P_{base}$ .
  - b. If  $x = \textit{REG}$ , generate  $\langle e_1, f_1 \rangle$  and  $\langle e_2, f_2 \rangle$  from  $P(\langle e, f \rangle; \theta_x, \theta_t)$ , and concatenate them into a single phrase pair  $\langle e_1 e_2, f_1 f_2 \rangle$ .

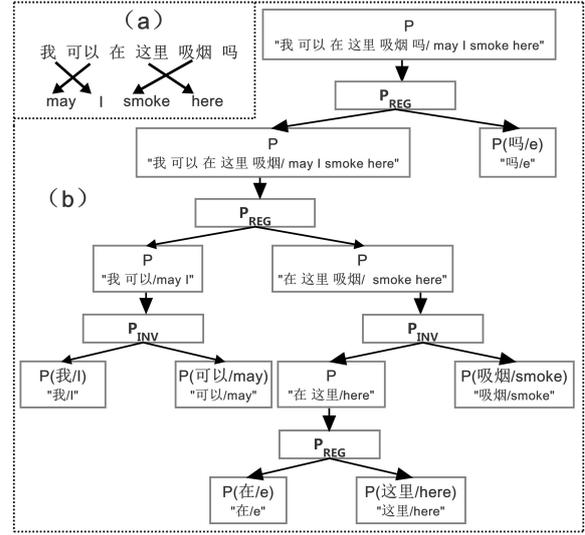

Figure 1: A word alignment (a), and its hierarchical derivation (b).

- c. If  $x = \textit{INV}$ , follow a similar process as b, but concatenate  $f_1$  and  $f_2$  in reverse order  $\langle e_1 e_2, f_2 f_1 \rangle$ .

Note that the  $P_{dac}$  is recursively defined through the binary branched  $P$ , which in turns employs  $P_{dac}$  as a prior probability.  $P_{base}$  is a base measure defined as a combination of the IBM Models in two directions and the unigram language models in both sides. Inference is carried out by a heuristic beam search based block sampling with an efficient look ahead for a faster convergence (Neubig et al., 2012).

Compared to GIZA++ with heuristic phrase extraction, the Bayesian phrasal ITG can achieve competitive accuracy under a smaller phrase table size. Further, the fallback model can incorporate phrases of all granularity by following the ITG's recursive definition. Figure 1 (b) illustrates an example of the phrasal ITG derivation for word alignment in Figure 1 (a) in which a bilingual sentence pair is recursively divided into two through the recursively defined generative story.

## 4 Hierarchical Phrase Table Combination

We propose a new phrase table combination method, in which individually learned phrase table are hierarchically chained through a hierarchical Pitman-Yor process.

Firstly, we assume that the whole training data  $\langle E, F \rangle$  can be split into  $J$  domains,  $\{\langle E^1, F^1 \rangle, \dots, \langle E^J, F^J \rangle\}$ . Then phrase pairs are

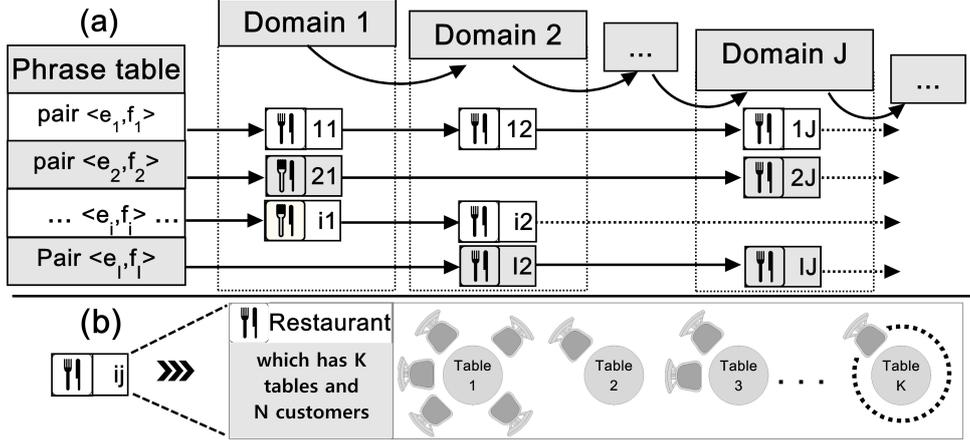

Figure 2: A hierarchical phrase table combination (a), and a basic unit of a Chinese restaurant process with  $K$  tables and  $N$  customers.

extracted from each domain  $j$  ( $1 \leq j \leq J$ ) separately with the method introduced in Section 3. In traditional domain adaptation approaches, phrase pairs are extracted together with their probabilities and/or frequencies so that the extracted phrase pairs are merged uniformly or after scaling.

In this work, we extract the table counts for each phrase pair under the Chinese restaurant process given in Section 3. In Figure 2 (b), a CRP is illustrated which has  $K$  tables and  $N$  customers with each chair representing a customer. Meanwhile there are two parameters, discount and strength for each domain similar to the ones in Equation (1).

Our proposed hierarchical phrase table combination can be formally expressed as following:

$$\begin{aligned}
 \theta^1 &\sim PY(d^1, s^1, P^2) \\
 \dots &\dots \\
 \theta^j &\sim PY(d^j, s^j, P^{j+1}) \\
 \dots &\dots \\
 \theta^J &\sim PY(d^J, s^J, P_{base}^J) \quad (3)
 \end{aligned}$$

Here the  $(j + 1)$ th layer hierarchical Pitman-Yor process is employed as a base measure for the  $j$ th layer hierarchical Pitman-Yor process. The hierarchical chain is terminated by the base measure from the  $J$ th domain  $P_{base}^J$ . The hierarchical structure is illustrated in Figure 2 (a) in which the solid lines implies a fall back using the table counts from the subsequent domains, and the dotted lines means the final fallback to the base measure  $P_{base}^J$ . When we query a probability of a phrase pair  $\langle e, f \rangle$ , we first query the probability of the first layer  $P^1(\langle e, f \rangle)$ . If  $\langle e, f \rangle$  is not in the model, we will fallback to the next level of

$P^2(\langle e, f \rangle)$ . This process continues until we reach the  $J_{th}$  base measure of  $P^J(\langle e, f \rangle)$ . Each fallback can be viewed as a translation knowledge integration process between subsequent domains.

For example in Figure 2 (a), the  $i$ th phrase pair  $\langle e_i, f_i \rangle$  appears only in the domain 1 and domain 2, so its translation probability can be calculated by substituting Equation (3) with Equation (2):

$$\begin{aligned}
 P(\langle e_i, f_i \rangle; \langle E, F \rangle) &= \frac{1}{C^1 + s^1} (c_i^1 - d^1 \times t_i^1) \\
 &+ \frac{s^1 + d^1 \times T^1}{(C^1 + s^1) \times (C^2 + s^2)} (c_i^2 - d^2 \times t_i^2) \\
 &+ \prod_{j=1}^J \left( \frac{s^j + d^j \times T^j}{C^j + s^j} \right) \times P_{base}^J(\langle e_i, f_i \rangle) \quad (4)
 \end{aligned}$$

where the superscript indicates the domain for the corresponding counts, i.e.  $c_i^j$  for the customer count in the  $j$ th domain. The first term in Equation (4) is the phrase probability from the first domain, and the second one comes from the second domain, but weighted by the fallback weight of the 1st domain. Since  $\langle e_i, f_i \rangle$  does not appear in the rest of the layers, the last term is taken from all the fallback weight from the second layer to the  $J$ th layer with the final  $P_{base}^J$ . All the parameters  $\theta^j$  and hyperparameters  $d^j$  and  $s^j$ , are obtained by learning on the  $j$ th domain. Returning the hyperparameters again when cascading another domain may improve the performance of the combination weight, but we will leave it for future work. The hierarchical process can be viewed as an instance of adapted integration of translation knowledge from each sub-domain.

**Algorithm 1 Translation Probabilities Estimation****Input:**  $c_i^j, t_i^j, P_{base}^j, C^j, T^j, d^j$  and  $s^j$ **Output:** The translation probabilities for each pair

```

1: for all phrase pair  $\langle e_i, f_i \rangle$  do
2:   Initialize the  $P(\langle e_i, f_i \rangle) = 0$  and  $w_i = 1$ 
3:   for all domain  $\langle E_j, F_j \rangle$  such that  $1 \leq j \leq J - 1$  do
4:     if  $\langle e_i, f_i \rangle \in \langle E_j, F_j \rangle$  then
5:        $P(\langle e_i, f_i \rangle) += w_i \times (C_i^j - d^j \times t_i^j) / (C^j + s^j)$ 
6:     end if
7:      $w_i = w_i \times (s^j + d^j \times T^j) / (C^j + s^j)$ 
8:   end for
9:    $P(\langle e_i, f_i \rangle) += w_i \times (C_i^J - d^J \times t_i^J + (s^J + d^J \times T^J) \times P_{base}^J(\langle e_i, f_i \rangle)) / (C^J + s^J)$ 
10: end for

```

Our approach has several advantages. First, each phrase pair extraction can concentrate on a small portion of domain-specific data without interfering with other domains. Since no tuning stage is involved in the hierarchical combination, we can easily include a new phrase table from a new domain by simply chaining them together. Second, phrase pair phrase extraction in each domain is completely independent, so it is easy to parallelize in a situation where the training data is too large to fit into a small amount of memory. Finally, new domains can be integrated incrementally. When we encounter a new domain, and if a phrase pair is completely new in terms of the model, the phrase pair is simply appended to the current model, and computed without the fallback probabilities, since otherwise, the phrase pair would be boosted by the fallback probabilities. Pitman-Yor process is also employed in n-gram language models which are hierarchically represented through the hierarchical Pitman-Yor process with switch priors to integrate different domains in all the levels (Wood and Teh, 2009). Our work incrementally combines the models from different domains by directly employing the hierarchical process through the base measures.

## 5 Experiment

We evaluate the proposed approach on the Chinese-to-English translation task with three data sets with different scales.

Data set	Corpus	#sent. pairs
IWSLT	HIT	52,603
	BTEC	19,975
FBIS	Domain 1	47,993
	Domain 2	30,272
	Domain 3	49,509
	Domain 4	38,228
	Domain 5	55,913
LDC	News	221,915
	News	95,593
	Magazine	98,335
	Magazine	254,488
	Finance	86,112

Table 1: The sentence pairs used in each data set.

### 5.1 Experiment Setup

The first data set comes from the IWSLT2012 OLYMPICS task consisting of two training sets: the HIT corpus, which is closely related to the Beijing 2008 Olympic Games, and the BTEC corpus, which is a multilingual speech corpus containing tourism-related sentences. The second data set, the FBIS corpus, is a collection of news articles and does not have domain information itself, so a Latent Dirichlet Allocation (LDA) tool, PLDA<sup>1</sup>, is used to divide the whole corpus into 5 different sub-domains according to the concatenation of the source side and target side as a single sentence (Liu et al., 2011). The third data set is composed of 5 corpora<sup>2</sup> from LDC with various domains, including news, magazine, and finance. The details are shown in Table 1.

In order to evaluate our approach, four phrase pair extraction methods are performed:

1. GIZA-linear: Phrase pairs are extracted in each domain by GIZA++ (Och and Ney, 2003) and the "grow-diag-final-and" method with a maximum length 7. The phrase tables from various domains are linearly combined by averaging the feature values.
2. Pialign-linear: Similar to GIZA-linear, but we employed the phrasal ITG method described in Section 3 using the pialign toolkit<sup>3</sup> (Neubig et

<sup>1</sup><http://code.google.com/p/plda/><sup>2</sup>In particular, they come from LDC catalog number: LDC2002E18, LDC2002E58, LDC2003E14, LDC2005E47, LDC2006E26, in this order.<sup>3</sup><http://www.phontron.com/pialign/>

Methods	IWSLT		FBIS		LDC	
	BLEU	Size	BLEU	Size	BLEU	Size
GIZA-linear	19.222	1,200,877	29.342	15,369,028	30.67	77,927,347
Pialign-linear	19.534	876,059	29.858	7,235,342	31.12	28,877,149
GIZA-batch	19.616	1,185,255	<b>31.38</b>	13,737,258	<b>32.06</b>	63,606,056
Pialign-batch	19.506	841,931	31.104	6,459,200		
Pialign-adaptive	19.624	841,931	30.926	6,459,200		
Hier-combin	<b>20.32</b>	876,059	31.29	7,235,342	32.03	28,877,149

Table 2: BLEU scores and phrase table size by alignment method and probabilities estimation method. Pialign was run with five samples. Because of computational overhead, the baseline Pialign-batch and Pialign-adaptive were not run on the largest data set.

- al., 2011). Extracted phrase pairs are linearly combined by averaging the feature values.
3. GIZA-batch: Instead of splitting into each domain, the data set is merged as a single corpus and then a heuristic GZA-based phrase extraction is performed, similar as GIZA-linear.
  4. Pialign-batch: Similar to the GIZA-batch, a single model is estimated from a single, merged corpus. Since pialign cannot handle large data, we did not experiment on the largest LDC data set.
  5. Pialign-adaptive: Alignment and phrase pairs extraction are same to Pialign-batch, while translation probabilities are estimated by the adaptive method with monolingual topic information (Su et al., 2012). The method established the relationship between the out-of-domain bilingual corpus and in-domain monolingual corpora via topic distribution to estimate the translation probability.

$$\begin{aligned}
\phi(\tilde{e}|\tilde{f}) &= \sum_{t_f} \phi(\tilde{e}, t_f|\tilde{f}) \\
&= \sum_{t_f} \phi(\tilde{e}|t_f, \tilde{f}) \cdot P(t_f|\tilde{f})
\end{aligned} \tag{5}$$

where  $\phi(\tilde{e}|t_f, \tilde{f})$  is the probability of translating  $\tilde{f}$  into  $\tilde{e}$  given the source-side topic  $\tilde{f}$ ,  $P(t_f|\tilde{f})$  is the phrase-topic distribution of  $\tilde{f}$ .

The method we proposed is named Hier-combin. It extracts phrase pairs in the same way as the Pialign-linear. In the phrase table combination process, the translation probability of each phrase pair is estimated by the Hier-combin and the other features are also linearly combined by averaging

the feature values. Pialign is used with default parameters. The parameter 'samps' is set to 5, which indicates 5 samples are generated for a sentence pair.

The IWSLT data consists of roughly 2,000 sentences and 3,000 sentences each from the HIT and BTEC for development purposes, and the test data consists of 1,000 sentences. For the FBIS and LDC task, we used NIST MT 2002 and 2004 for development and testing purposes, consisting of 878 and 1,788 sentences respectively. We employ Moses, an open-source toolkit for our experiment (Koehn et al., 2007). SRILM Toolkit (Stolcke, 2002) is employed to train 4-gram language models on the Xinhua portion of Gigaword corpus, while for the IWSLT2012 data set, only its training set is used. We use batch-MIRA (Cherry and Foster, 2012) to tune the weight for each feature and translation quality is evaluated by the case-insensitive BLEU-4 metric (Papineni et al., 2002). The BLEU scores reported in this paper are the average of 5 independent runs of independent batch-MIRA weight training, as suggested by (Clark et al., 2011).

## 5.2 Result and Analysis

### 5.2.1 Performances of various extraction methods

We carry out a series of experiments to evaluate translation performance. The results are listed in Table 2. Our method significantly outperforms the baseline Pialign-linear. Except for the translation probabilities, the phrase pairs of two methods are exactly same, so the number of phrase pairs are equal in the two methods. Further more, the performance of the baseline Pialign-adaptive is also higher than the baseline Pialign-linear's and lower than ours. This proves that the adaptive method

Methods	Task	Time(minute)
Batch	Retraining	536.9
Hierarchical Combination	Parallel Extraction	122.55
	Integrating	1.5
	Total	124.05

Table 3: Minutes used for alignment and phrase pair extraction in the FBIS data set.

with monolingual topic information is useful in the tasks, but our approach with the hierarchical Pitman-Yor process can estimate more accurate translation probabilities based on all the data from various domains.

Compared with the GIZA-batch, our approach achieves competitive performance with a much smaller phrase table. The number of phrase pairs generated by our method is only 73.9%, 52.7%, and 45.4% of the GIZA-batch’s respectively. In the IWSLT2012 data set, there is a huge difference gap between the HIT corpus and the BTEC corpus, and our method gains 0.814 BLEU improvement. While the FBIS data set is artificially divided and no clear human assigned differences among sub-domains, our method loses 0.09 BLEU.

In the framework we proposed, phrase pairs are extracted from each domain completely independent of each other, so those tasks can be executed on different machines, at different times, and of course in parallel when we assume that the domains are not incrementally added in the training data. The runtime of our approach and the batch-based ITGs sampling method in the FBIS data set is listed in Table 3 measured on a 2.7 GHz E5-2680 CPU and 128 Gigabyte memory. When comparing the hier-combin with the pialign-batch, the BLEU scores are a little higher while the time spent for training is much lower, almost one quarter of the pialign-batch.

Even the performance of the pialign-linear is better than the Baseline GIZA-linear’s, which means that phrase pair extraction with hierarchical phrasal ITGs and sampling is more suitable for domain adaptation tasks than the combination GIZA++ and a heuristic method.

Generally, the hierarchical combination method exploits the nature of a hierarchical Pitman-Yor process and gains the advantage of its smoothing effect, and our approach can incrementally generate a succinct phrase table based on all the data from various domains with more accurate prob-

abilities. Traditional SMT phrase pair extraction is batch-based, while our method has no obvious shortcomings in translation accuracy, not to mention efficiency.

### 5.2.2 Effect of Integration Order

Here, we evaluate whether our hierarchical combination is sensitive to the order of the domains when forming a hierarchical structure. Through Equation (3), in our experiments, we chained the domains in the order listed in Table 1, which is in almost chronological order. Table 4 shows the BLEU scores for the three data sets, in which the order of combining phrase tables from each domain is alternated in the ascending and descending of the similarity to the test data. The similarity between the data from each domain and the test data is calculated using the perplexity measure with 5-gram language model. The model learned from the domain more similar to the test data is placed in the front so that it can largely influence the parameter computation with less backoff effects. There is a big difference between the two opposite order in IWSLT 2012 data set, in which more than one point of decline in BLEU score when taking the BTEC corpus as the first layer. Note that the perplexity of BTEC was 344.589 while that of HIT was 107.788. The result may indicate that our hierarchical phrase combination method is sensitive to the integration order when the training data is small and there exists large gap in the similarity. However, if most domains are similar (FBIS data set) or if there are enough parallel sentence pairs (NIST data set) in each domain, then the translation performances are almost similar even with the opposite integrating orders.

	IWSLT	FBIS	LDC
Descending	20.154	30.491	31.268
Ascending	19.066	30.388	31.254
Difference	<b>1.088</b>	<b>0.103</b>	<b>0.014</b>

Table 4: BLEU scores for the hierarchical model with different integrating orders. Here Pialign was run without multi-samples.

## 6 Conclusion and Future Work

In this paper, we present a novel hierarchical phrase table combination method for SMT, which can exploit more of the potential from all of data coming from various fields and generate a suc-

cinct phrase table with more accurate translation probabilities. The method assumes that a combined model is derived from a hierarchical Pitman-Yor process with each prior learned separately in each domain, and achieves BLEU scores competitive with traditional batch-based ones. Meanwhile, the framework has natural characteristics for parallel and incremental phrase pair extraction. The experiment results on three different data sets indicate the effectiveness of our approach.

In future work, we will also introduce incremental learning for phrase pair extraction inside a domain, which means using the current translation probabilities already obtained as the base measure of sampling parameters for the upcoming domain. Furthermore, we will investigate any tradeoffs between the accuracy of the probability estimation and the coverage of phrase pairs.

## Acknowledgments

We would like to thank our colleagues in both HIT and NICT for insightful discussions, and three anonymous reviewers for many invaluable comments and suggestions to improve our paper. This work is supported by National Natural Science Foundation of China (61100093, 61173073, 61073130, 61272384), and the Key Project of the National High Technology Research and Development Program of China (2011AA01A207).

# Shallow Local Multi Bottom-up Tree Transducers in Statistical Machine Translation

Fabienne Braune and Nina Seemann and Daniel Quernheim and Andreas Maletti

Institute for Natural Language Processing, University of Stuttgart

Pfaffenwaldring 5b, 70569 Stuttgart, Germany

{braunefe, seemanna, daniel, maletti}@ims.uni-stuttgart.de

## Abstract

We present a new translation model integrating the shallow local multi bottom-up tree transducer. We perform a large-scale empirical evaluation of our obtained system, which demonstrates that we significantly beat a realistic tree-to-tree baseline on the WMT 2009 English  $\rightarrow$  German translation task. As an additional contribution we make the developed software and complete tool-chain publicly available for further experimentation.

## 1 Introduction

Besides phrase-based machine translation systems (Koehn et al., 2003), syntax-based systems have become widely used because of their ability to handle non-local reordering. Those systems use synchronous context-free grammars (Chiang, 2007), synchronous tree substitution grammars (Eisner, 2003) or even more powerful formalisms like synchronous tree-sequence substitution grammars (Sun et al., 2009). However, those systems use linguistic syntactic annotation at different levels. For example, the systems proposed by Wu (1997) and Chiang (2007) use no linguistic information and are syntactic in a structural sense only. Huang et al. (2006) and Liu et al. (2006) use syntactic annotations on the source language side and show significant improvements in translation quality. Using syntax exclusively on the target language side has also been successfully tried by Galley et al. (2004) and Galley et al. (2006). Nowadays, open-source toolkits such as Moses (Koehn et al., 2007) offer syntax-based components (Hoang et al., 2009), which allow experiments without expert knowledge. The improvements observed for systems using syntactic annotation on either the source or the target language side naturally led to experiments with models that use syntactic annotations on *both* sides.

However, as noted by Lavie et al. (2008), Liu et al. (2009), and Chiang (2010), the integration of syntactic information on both sides tends to decrease translation quality because the systems become too restrictive. Several strategies such as (i) using parse forests instead of single parses (Liu et al., 2009) or (ii) soft syntactic constraints (Chiang, 2010) have been developed to alleviate this problem. Another successful approach has been to switch to more powerful formalisms, which allow the extraction of more general rules. A particularly powerful model is the non-contiguous version of synchronous tree-sequence substitution grammars (STSSG) of Zhang et al. (2008a), Zhang et al. (2008b), and Sun et al. (2009), which allows sequences of trees on both sides of the rules [see also (Raoult, 1997)]. The multi bottom-up tree transducer (MBOT) of Arnold and Dauchet (1982) and Lilin (1978) offers a middle ground between traditional syntax-based models and STSSG. Roughly speaking, an MBOT is an STSSG, in which all the discontinuities must occur on the target language side (Maletti, 2011). This restriction yields many algorithmic advantages over both the traditional models as well as STSSG as demonstrated by Maletti (2010). Formally, they are expressive enough to express all sensible translations (Maletti, 2012)<sup>1</sup>. Figure 2 displays sample rules of the MBOT variant, called  $\ell$ MBOT, that we use (in a graphical representation of the trees and the alignment).

In this contribution, we report on our novel statistical machine translation system that uses an  $\ell$ MBOT-based translation model. The theoretical foundations of  $\ell$ MBOT and their integration into our translation model are presented in Sections 2 and 3. In order to empirically evaluate the  $\ell$ MBOT model, we implemented a machine trans-

<sup>1</sup>A translation is sensible if it is of linear size increase and can be computed by some (potentially copying) top-down tree transducer.

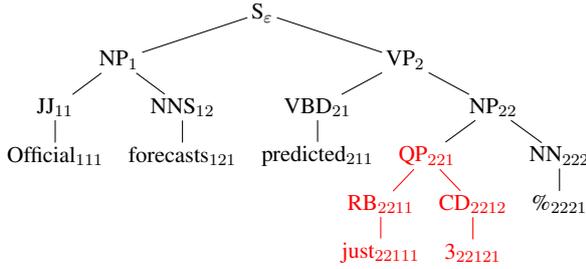

Figure 1: Example tree  $t$  with indicated positions. We have  $t(21) = \text{VBD}$  and  $t|_{221}$  is the subtree marked in red.

lation system that we are going to make available to the public. We implemented  $\ell\text{MBOT}$  inside the syntax-based component of the Moses open source toolkit. Section 4 presents the most important algorithms of our  $\ell\text{MBOT}$  decoder. We evaluate our new system on the WMT 2009 shared translation task English  $\rightarrow$  German. The translation quality is automatically measured using BLEU scores, and we confirm the findings by providing linguistic evidence (see Section 5). Note that in contrast to several previous approaches, we perform large scale experiments by training systems with approx. 1.5 million parallel sentences.

## 2 Theoretical Model

In this section, we present the theoretical generative model used in our approach to syntax-based machine translation. Essentially, it is the local multi bottom-up tree transducer of Maletti (2011) with the restriction that all rules must be shallow, which means that the left-hand side of each rule has height at most 2 (see Figure 2 for shallow rules and Figure 4 for rules including non-shallow rules). The rules extracted from the training example of Figure 3 are displayed in Figure 4. Those extracted rules are forcibly made shallow by removing internal nodes. The application of those rules is illustrated in Figures 5 and 6.

For those that want to understand the inner workings, we recall the principal model in full detail in the rest of this section. Since we utilize syntactic parse trees, let us introduce trees first. Given an alphabet  $\Sigma$  of labels, the set  $T_\Sigma$  of all  $\Sigma$ -trees is the smallest set  $T$  such that  $\sigma(t_1, \dots, t_k) \in T$  for all  $\sigma \in \Sigma$ , integer  $k \geq 0$ , and  $t_1, \dots, t_k \in T$ . Intuitively, a tree  $t$  consists of a labeled root node  $\sigma$  followed by a sequence  $t_1, \dots, t_k$  of its children. A tree  $t \in T_\Sigma$  is *shallow* if  $t = \sigma(t_1, \dots, t_k)$  with  $\sigma \in \Sigma$  and  $t_1, \dots, t_k \in \Sigma$ .

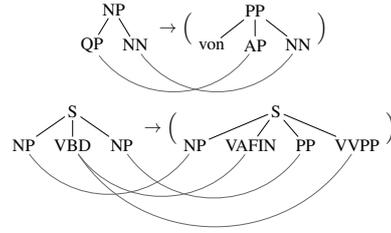

Figure 2: Sample  $\ell\text{MBOT}$  rules.

To address a node inside a tree, we use its position, which is a word consisting of positive integers. Roughly speaking, the root of a tree is addressed with the position  $\varepsilon$  (the empty word). The position  $iw$  with  $i \in \mathbb{N}$  addresses the position  $w$  in the  $i^{\text{th}}$  direct child of the root. In this way, each node in the tree is assigned a unique position. We illustrate this notion in Figure 1. Formally, the *positions*  $\text{pos}(t) \subseteq \mathbb{N}^*$  of a tree  $t = \sigma(t_1, \dots, t_k)$  are inductively defined by  $\text{pos}(t) = \{\varepsilon\} \cup \text{pos}^{(k)}(t_1, \dots, t_k)$ , where

$$\text{pos}^{(k)}(t_1, \dots, t_k) = \bigcup_{1 \leq i \leq k} \{iw \mid w \in \text{pos}(t_i)\} .$$

Let  $t \in T_\Sigma$  and  $w \in \text{pos}(t)$ . The label of  $t$  at position  $w$  is  $t(w)$ , and the subtree rooted at position  $w$  is  $t|_w$ . These notions are also illustrated in Figure 1. A position  $w \in \text{pos}(t)$  is a *leaf* (in  $t$ ) if  $w1 \notin \text{pos}(t)$ . In other words, leaves do not have any children. Given a subset  $N \subseteq \Sigma$ , we let

$$\text{leaf}_N(t) = \{w \in \text{pos}(t) \mid t(w) \in N, w \text{ leaf in } t\}$$

be the set of all leaves labeled by elements of  $N$ . When  $N$  is the set of nonterminals, we call them *leaf nonterminals*. We extend this notion to sequences  $t_1, \dots, t_k \in T_\Sigma$  by

$$\text{leaf}_N^{(k)}(t_1, \dots, t_k) = \bigcup_{1 \leq i \leq k} \{iw \mid w \in \text{leaf}_N(t_i)\} .$$

Let  $w_1, \dots, w_n \in \text{pos}(t)$  be (pairwise prefix-incomparable) positions and  $t_1, \dots, t_n \in T_\Sigma$ . Then  $t[w_i \leftarrow t_i]_{1 \leq i \leq n}$  denotes the tree that is obtained from  $t$  by replacing (in parallel) the subtrees at  $w_i$  by  $t_i$  for every  $1 \leq i \leq n$ .

Now we are ready to introduce our model, which is a minor variation of the local multi bottom-up tree transducer of Maletti (2011). Let  $\Sigma$  and  $\Delta$  be the input and output symbols, respectively, and let  $N \subseteq \Sigma \cup \Delta$  be the set of nonterminal symbols. Essentially, the model works on pairs  $\langle t, (u_1, \dots, u_k) \rangle$  consisting of an input tree  $t \in T_\Sigma$

and a sequence  $u_1, \dots, u_k \in T_\Delta$  of output trees. Such pairs are *pre-translations* of rank  $k$ . The pre-translation  $\langle t, (u_1, \dots, u_k) \rangle$  is *shallow* if all trees  $t, u_1, \dots, u_k$  in it are shallow.

Together with a pre-translation we typically have to store an alignment. Given a pre-translation  $\langle t, (u_1, \dots, u_k) \rangle$  of rank  $k$  and  $1 \leq i \leq k$ , we call  $u_i$  the  $i^{\text{th}}$  translation of  $t$ . An *alignment* for this pre-translation is an injective mapping  $\psi: \text{leaf}_N^{(k)}(u_1, \dots, u_k) \rightarrow \text{leaf}_N(t) \times \mathbb{N}$  such that if  $(w, j) \in \text{ran}(\psi)$ , then also  $(w, i) \in \text{ran}(\psi)$  for all  $1 \leq j \leq i$ .<sup>2</sup> In other words, if an alignment requests the  $i^{\text{th}}$  translation, then it should also request all previous translations.

**Definition 1** A shallow local multi bottom-up tree transducer (*lMBOT*) is a finite set  $R$  of rules together with a mapping  $c: R \rightarrow \mathbb{R}$  such that every rule, written  $t \rightarrow_\psi (u_1, \dots, u_k)$ , contains a shallow pre-translation  $\langle t, (u_1, \dots, u_k) \rangle$  and an alignment  $\psi$  for it.

The components  $t, (u_1, \dots, u_k), \psi$ , and  $c(\rho)$  are called the *left-hand side*, the *right-hand side*, the *alignment*, and the *weight* of the rule  $\rho = t \rightarrow_\psi (u_1, \dots, u_k)$ . Figure 2 shows two example *lMBOT* rules (without weights). Overall, the rules of an *lMBOT* are similar to the rules of an SCFG (synchronous context-free grammar), but our right-hand sides contain a sequence of trees instead of just a single tree. In addition, the alignments in an SCFG rule are bijective between leaf nonterminals, whereas our model permits multiple alignments to a single leaf nonterminal in the left-hand side (see Figure 2).

Our *lMBOT* rules are obtained automatically from data like that in Figure 3. Thus, we (word) align the bilingual text and parse it in both the source and the target language. In this manner we obtain sentence pairs like the one shown in Figure 3. To these sentence pairs we apply the rule extraction method of Maletti (2011). The rules extracted from the sentence pair of Figure 3 are shown in Figure 4. Note that these rules are not necessarily shallow (the last two rules are not). Thus, we post-process the extracted rules and make them shallow. The shallow rules corresponding to the non-shallow rules of Figure 4 are shown in Figure 2.

Next, we define how to combine rules to form derivations. In contrast to most other models, we

<sup>2</sup> $\text{ran}(f)$  for a mapping  $f: A \rightarrow B$  denotes the range of  $f$ , which is  $\{f(a) \mid a \in A\}$ .

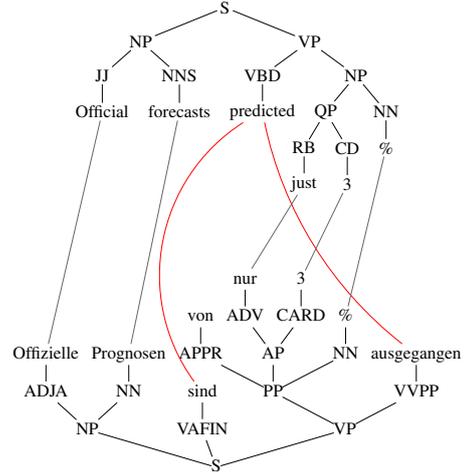

Figure 3: Aligned parsed sentences.

only introduce a derivation semantics that does not collapse multiple derivations for the same input-output pair.<sup>3</sup> We need one final notion. Let  $\rho = t \rightarrow_\psi (u_1, \dots, u_k)$  be a rule and  $w \in \text{leaf}_N(t)$  be a leaf nonterminal (occurrence) in the left-hand side. The  $w$ -rank  $\text{rk}(\rho, w)$  of the rule  $\rho$  is

$$\text{rk}(\rho, w) = \max \{i \in \mathbb{N} \mid (w, i) \in \text{ran}(\psi)\} .$$

For example, for the lower rule  $\rho$  in Figure 2 we have  $\text{rk}(\rho, 1) = 1$ ,  $\text{rk}(\rho, 2) = 2$ , and  $\text{rk}(\rho, 3) = 1$ .

**Definition 2** The set  $\tau(R, c)$  of weighted pre-translations of an *lMBOT*  $(R, c)$  is the smallest set  $T$  subject to the following restriction: If there exist

- a rule  $\rho = t \rightarrow_\psi (u_1, \dots, u_k) \in R$ ,
- a weighted pre-translation

$$\langle t_w, c_w, (u_1^w, \dots, u_k^w) \rangle \in T$$

for every  $w \in \text{leaf}_N(t)$  with

- $\text{rk}(\rho, w) = k_w$ ,<sup>4</sup>
- $t(w) = t_w(\varepsilon)$ ,<sup>5</sup> and
- for every  $iw' \in \text{leaf}_N^{(k)}(u_1, \dots, u_k)$ ,<sup>6</sup>

$$u_i(w') = u_j^v(\varepsilon) \text{ with } \psi(iw') = (v, j),$$

then  $\langle t', c', (u'_1, \dots, u'_k) \rangle \in T$  is a weighted pre-translation, where

- $t' = t[w \leftarrow t_w \mid w \in \text{leaf}_N(t)]$ ,

<sup>3</sup>A standard semantics is presented, for example, in (Maletti, 2011).

<sup>4</sup>If  $w$  has  $n$  alignments, then the pre-translation selected for it has to have suitably many output trees.

<sup>5</sup>The labels have to coincide for the input tree.

<sup>6</sup>Also the labels for the output trees have to coincide.

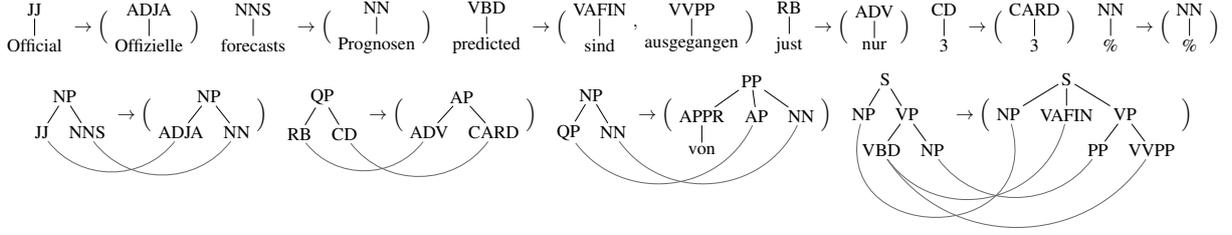

Figure 4: Extracted (even non-shallow) rules. We obtain our rules by making those rules shallow.

- $c' = c(\rho) \cdot \prod_{w \in \text{leaf}_N(t)} c_w$ , and
- $u'_i = u_i[iw' \leftarrow u'_j \mid \psi(iw') = (v, j)]$  for every  $1 \leq i \leq k$ .

Rules that do not contain any nonterminal leaves are automatically weighted pre-translations with their associated rule weight. Otherwise, each nonterminal leaf  $w$  in the left-hand side of a rule  $\rho$  must be replaced by the input tree  $t_w$  of a pre-translation  $\langle t_w, c_w, (u_1^w, \dots, u_{k_w}^w) \rangle$ , whose root is labeled by the same nonterminal. In addition, the rank  $\text{rk}(\rho, w)$  of the replaced nonterminal should match the number  $k_w$  of components in the selected weighted pre-translation. Finally, the nonterminals in the right-hand side that are aligned to  $w$  should be replaced by the translation that the alignment requests, provided that the nonterminal matches with the root symbol of the requested translation. The weight of the new pre-translation is obtained simply by multiplying the rule weight and the weights of the selected weighted pre-translations. The overall process is illustrated in Figures 5 and 6.

### 3 Translation Model

Given a source language sentence  $e$ , our translation model aims to find the best corresponding target language translation  $\hat{g}$ ;<sup>7</sup> i.e.,

$$\hat{g} = \arg \max_g p(g|e) .$$

We estimate the probability  $p(g|e)$  through a log-linear combination of component models with parameters  $\lambda_m$  scored on the pre-translations  $\langle t, (u) \rangle$  such that the leaves of  $t$  concatenated read  $e$ .<sup>8</sup>

$$p(g|e) \propto \prod_{m=1}^7 h_m(\langle t, (u) \rangle)^{\lambda_m}$$

Our model uses the following features  $h_m(\langle t, (u_1, \dots, u_k) \rangle)$  for a general pre-translation  $\tau = \langle t, (u_1, \dots, u_k) \rangle$ :

<sup>7</sup>Our main translation direction is English to German.

<sup>8</sup>Actually,  $t$  must embed in the parse tree of  $e$ ; see Section 4.

- (1) The forward translation weight using the rule weights as described in Section 2
- (2) The indirect translation weight using the rule weights as described in Section 2
- (3) Lexical translation weight source  $\rightarrow$  target
- (4) Lexical translation weight target  $\rightarrow$  source
- (5) Target side language model
- (6) Number of words in the target sentences
- (7) Number of rules used in the pre-translation
- (8) Number of target side sequences; here  $k$  times the number of sequences used in the pre-translations that constructed  $\tau$  (gap penalty)

The rule weights required for (1) are relative frequencies normalized over all rules with the same left-hand side. In the same fashion the rule weights required for (2) are relative frequencies normalized over all rules with the same right-hand side. Additionally, rules that were extracted at most 10 times are discounted by multiplying the rule weight by  $10^{-2}$ . The lexical weights for (2) and (3) are obtained by multiplying the word translations  $w(g_i|e_j)$  [respectively,  $w(e_j|g_i)$ ] of lexically aligned words  $(g_i, e_j)$  across (possibly discontinuous) target side sequences.<sup>9</sup> Whenever a source word  $e_j$  is aligned to multiple target words, we average over the word translations.<sup>10</sup>

$$\begin{aligned} & h_3(\langle t, (u_1, \dots, u_k) \rangle) \\ &= \prod_{\substack{\text{lexical item} \\ e \text{ occurs in } t}} \text{average} \{w(g|e) \mid g \text{ aligned to } e\} \end{aligned}$$

The computation of the language model estimates for (6) is adapted to score partial translations consisting of discontinuous units. We explain the details in Section 4. Finally, the count  $c$  of target sequences obtained in (7) is actually used as a score  $100^{1-c}$ . This discourages rules with many target sequences.

<sup>9</sup>The lexical alignments are different from the alignments used with a pre-translation.

<sup>10</sup>If the word  $e_j$  has no alignment to a target word, then it is assumed to be aligned to a special NULL word and this alignment is scored.

## 4 Decoding

We implemented our model in the syntax-based component of the Moses open-source toolkit by Koehn et al. (2007) and Hoang et al. (2009). The standard Moses syntax-based decoder only handles SCFG rules; i.e., rules with contiguous components on the source and the target language side. Roughly speaking, SCFG rules are  $\ell$ MBOT rules with exactly one output tree. We thus had to extend the system to support our  $\ell$ MBOT rules, in which arbitrarily many output trees are allowed.

The standard Moses syntax-based decoder uses a CYK+ chart parsing algorithm, in which each source sentence is parsed and contiguous spans are processed in a bottom-up fashion. A rule is applicable<sup>11</sup> if the left-hand side of it matches the non-terminal assigned to the full span by the parser and the (non-)terminal assigned to each subspan.<sup>12</sup> In order to speed up the decoding, cube pruning (Chiang, 2007) is applied to each chart cell in order to select the most likely hypotheses for subspans. The language model (LM) scoring is directly integrated into the cube pruning algorithm. Thus, LM estimates are available for all considered hypotheses. To accommodate  $\ell$ MBOT rules, we had to modify the Moses syntax-based decoder in several ways. First, the rule representation itself is adjusted to allow *sequences* of shallow output trees on the target side. Naturally, we also had to adjust hypothesis expansion and, most importantly, language model scoring inside the cube pruning algorithm. An overview of the modified pruning procedure is given in Algorithm 1.

The most important modifications are hidden in lines 5 and 8. The expansion in Line 5 involves matching all nonterminal leaves in the rule as defined in Definition 2, which includes matching all leaf nonterminals in all (discontiguous) output trees. Because the output trees can remain discontiguous after hypothesis creation, LM scoring has to be done individually over all output trees. Algorithm 2 describes our LM scoring in detail. In it we use  $k$  strings  $w_1, \dots, w_k$  to collect the lexical information from the  $k$  output com-

<sup>11</sup>Note that our notion of applicable rules differs from the default in Moses.

<sup>12</sup>Theoretically, this allows that the decoder ignores unary parser nonterminals, which could also disappear when we make our rules shallow; e.g., the parse tree left in the pre-translation of Figure 5 can be matched by a rule with left-hand side NP(Official, forecasts).

- 

ponents  $(u_1, \dots, u_k)$  of a rule. These strings can later be rearranged in any order, so we LM-score all of them separately. Roughly speaking, we obtain  $w_i$  by traversing  $u_i$  depth-first left-to-right. If we meet a lexical element (terminal), then we add it to the end of  $w_i$ . On the other hand, if we meet a nonterminal, then we have to consult the best pre-translation  $\tau' = \langle t', (u'_1, \dots, u'_{k'}) \rangle$ , which will contribute the subtree at this position. Suppose that  $u'_j$  will be substituted into the nonterminal in question. Then we first LM-score the pre-translation  $\tau'$  to obtain the string  $w'_j$  corresponding to  $u'_j$ . This string  $w'_j$  is then appended to  $w_i$ . Once all the strings are built, we score them using our 4-gram LM. The overall LM score for the pre-translation is obtained by multiplying the scores for  $w_1, \dots, w_k$ . Clearly, this treats  $w_1, \dots, w_k$  as  $k$  separate strings, although they eventually will be combined into a single string. Whenever such a concatenation happens, our LM scoring will automatically compute  $n$ -gram LM scores based on the concatenation, which in particular means that the LM scores get more accurate for larger spans. Finally, in the final rule only one component is allowed, which yields that the LM indeed scores the complete output sentence.

Figure 7 illustrates our LM scoring for a pre-translation involving a rule with two (discontiguous) target sequences (the construction of the pre-translation is illustrated in Figure 6). When processing the rule rooted at S, an LM estimate is computed by expanding all nonterminal leaves. In our case, these are NP, VAFIN, PP, and VVPP. However, the nodes VAFIN and VVPP are assembled from a (discontiguous) tree sequence. This means that those units have been considered as in-

---

**Algorithm 2** LM scoring

9:   score = score  $\cdot$  LM( $w_i$ )
```

---

dependent until now. So far, the LM scorer could only score their associated unigrams. However, we also have their associated strings  $w'_1$  and  $w'_2$ , which can now be used. Since VAFIN and VVPP now become parts of a single tree, we can perform LM scoring normally. Assembling the string we obtain

*Offizielle Prognosen sind von nur 3 %  
ausgegangen*

which is scored by the LM. Thus, we first score the 4-grams “Offizielle Prognosen sind von”, then “Prognosen sind von nur”, etc.

## 5 Experiments

### 5.1 Setup

The baseline system for our experiments is the syntax-based component of the Moses open-source toolkit of Koehn et al. (2007) and Hoang et al. (2009). We use linguistic syntactic annotation on both the source and the target language side (tree-to-tree). Our contrastive system is the  $\ell$ MBOT-based translation system presented here. We provide the system with a set of SCFG as well as  $\ell$ MBOT rules. We do not impose any maximal span restriction on either system.

The compared systems are evaluated on the English-to-German<sup>13</sup> news translation task of WMT 2009 (Callison-Burch et al., 2009). For both systems, the used training data is from the 4th version of the *Europarl Corpus* (Koehn, 2005) and the *News Commentary* corpus. Both translation models were trained with approximately 1.5 million bilingual sentences after length-ratio filtering. The word alignments were generated by GIZA++ (Och and Ney, 2003) with the grow-diag-final-and heuristic (Koehn et al., 2005). The

---

<sup>13</sup>Note that our  $\ell$ MBOT-based system can be applied to any language pair as it involves no language-specific engineering.

System	BLEU

$\ell$ <b>MBOT</b>	*13.06
Moses t-to-s	12.72

Table 1: Evaluation results. The starred results are statistically significant improvements over the Baseline (at confidence  $p < 0.05$ ).

English side of the bilingual data was parsed using the Charniak parser of Charniak and Johnson (2005), and the German side was parsed using BitPar (Schmid, 2004) without the function and morphological annotations. Our German 4-gram language model was trained on the German sentences in the training data augmented by the Stuttgart SdeWaC corpus (Web-as-Corpus Consortium, 2008), whose generation is detailed in (Baroni et al., 2009). The weights  $\lambda_m$  in the log-linear model were trained using minimum error rate training (Och, 2003) with the News 2009 development set. Both systems use glue-rules, which allow them to concatenate partial translations without performing any reordering.

### 5.2 Results

We measured the overall translation quality with the help of 4-gram BLEU (Papineni et al., 2002), which was computed on tokenized and lower-cased data for both systems. The results of our evaluation are reported in Table 1. For comparison, we also report the results obtained by a system that utilizes parses only on the source side (Moses tree-to-string) with its standard features.

We can observe from Table 1 that our  $\ell$ MBOT-based system outperforms the baseline. We obtain a BLEU score of 13.06, which is a gain of 0.46 BLEU points over the baseline. This improvement is statistically significant at confidence  $p < 0.05$ , which we computed using the pairwise bootstrap resampling technique of Koehn (2004). Our system is also better than the Moses tree-to-string system. However this improvement (0.34) is not statistically significant. In the next section, we confirm the result of the automatic evaluation through a manual examination of some translations generated by our system and the baseline.

In Table 2, we report the number of  $\ell$ MBOT rules used by our system when decoding the test set. By *lex* we denote rules containing only lexical

	lex	non-term	total
contiguous	23,175	18,355	41,530
discontiguous	315	2,516	2,831

Table 2: Number of rules used in decoding test (lex: only lexical items; non-term: at least one nonterminal).

2-dis	3-dis	4-dis
2,480	323	28

Table 3: Number of  $k$ -discontiguous rules.

items. The label *non-term* stands for rules containing at least one leaf nonterminal. The results show that approx. 6% of all rules used by our  $\ell$ MBOT-system have discontiguous target sides. Furthermore, the reported numbers show that the system also uses rules in which lexical items are combined with nonterminals. Finally, Table 3 presents the number of rules with  $k$  target side components used during decoding.

### 5.3 Linguistic Analysis

In this section we present linguistic evidence supporting the fact that the  $\ell$ MBOT-based system significantly outperforms the baseline. All examples are taken from the translation of the test set used for automatic evaluation. We show that when our system generates better translations, this is directly related to the use of  $\ell$ MBOT rules.

Figures 8 and 9 show the ability of our system to correctly reorder multiple segments in the source sentence where the baseline translates those segments sequentially. An analysis of the generated derivations shows that our system produces the correct translation by taking advantage of rules with discontiguous units on target language side. The rules used in the presented derivations are displayed in Figures 10 and 11. In the first example (Figure 8), we begin by translating “((smuggle)<sub>VB</sub> (eight projectiles)<sub>NP</sub> (into the kingdom)<sub>PP</sub>)<sub>VP</sub>” into the discontiguous sequence composed of (i) “(acht geschosse)<sub>NP</sub>”; (ii) “(in das königreich)<sub>PP</sub>” and (iii) “(schmuggeln)<sub>VP</sub>”. In a second step we assemble all sequences in a rule with contiguous target language side and, at the same time, insert the word “(zu)<sub>PTKZU</sub>” between “(in das königreich)<sub>PP</sub>” and “(schmuggeln)<sub>VP</sub>”.

The second example (Figure 9) illustrates a more complex reordering. First, we trans-

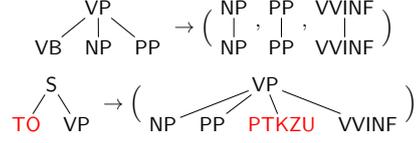

Figure 10: Used  $\ell$ MBOT rules for verbal reordering

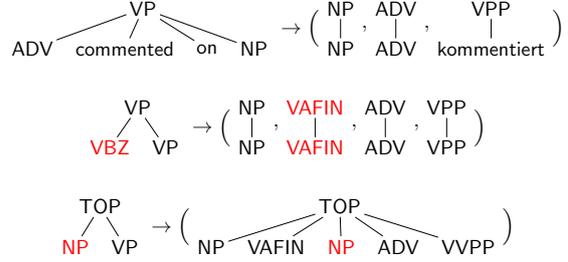

Figure 11: Used  $\ell$ MBOT rules for verbal reordering

late “((again)<sub>ADV</sub> commented on (the problem of global warming)<sub>NP</sub>)<sub>VP</sub>” into the discontiguous sequence composed of (i) “(das problem der globalen erwärmung)<sub>NP</sub>”; (ii) “(wieder)<sub>ADV</sub>” and (iii) “(kommentiert)<sub>VPP</sub>”. In a second step, we translate the auxiliary “(has)<sub>VBZ</sub>” by inserting “(hat)<sub>VAFIN</sub>” into the sequence. We thus obtain, for the input segment “((has)<sub>VBZ</sub> (again)<sub>ADV</sub> commented on (the problem of global warming)<sub>NP</sub>)<sub>VP</sub>”, the sequence (i) “(das problem der globalen erwärmung)<sub>NP</sub>”; (ii) “(hat)<sub>VAFIN</sub>”; (iii) “(wieder)<sub>ADV</sub>”; (iv) “(kommentiert)<sub>VVPP</sub>”. In a last step, the constituent “(president václav klaus)<sub>NP</sub>” is inserted between the discontiguous units “(hat)<sub>VAFIN</sub>” and “(wieder)<sub>ADV</sub>” to form the contiguous sequence “((das problem der globalen erwärmung)<sub>NP</sub> (hat)<sub>VAFIN</sub> (präsident václav klaus)<sub>NP</sub> (wieder)<sub>ADV</sub> (kommentiert)<sub>VVPP</sub>)<sub>TOP</sub>”.

Figures 12 and 13 show examples where our system generates complex words in the target language out of a simple source language word. Again, an analysis of the generated derivation shows that  $\ell$ MBOT takes advantage of rules having several target side components. Examples of such rules are given in Figure 14. Through its ability to use these discontiguous rules, our system correctly translates into reflexive or particle verbs such as “konzentriert sich” (for the English “focuses”) or “besteht darauf” (for the English “insist”). Another phenomenon well handled by our system are relative pronouns. Pronouns such as “that” or “whose” are systematically translated

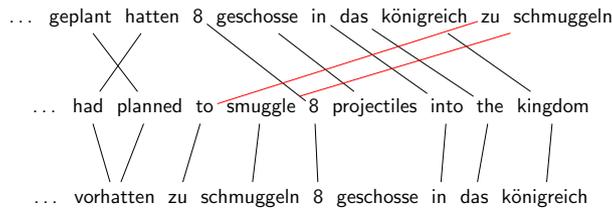

Figure 8: Verbal Reordering (top: our system, bottom: baseline)

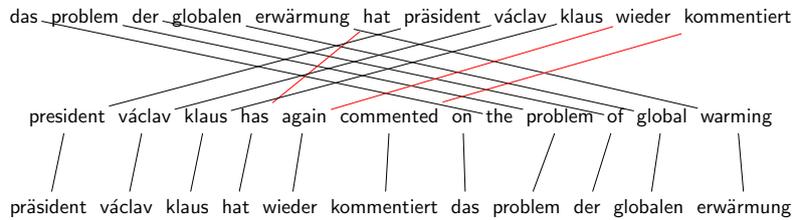

Figure 9: Verbal Reordering (top: our system, bottom: baseline)

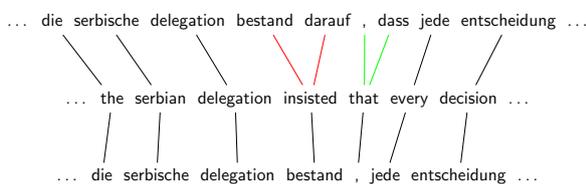

Figure 12: Relative Clause (top: our system, bottom: baseline)

Figure 13: Reflexive Pronoun (top: our system, bottom: baseline)

into both both, “,” and “*dass*” or “,” and “*deren*” (Figure 12).

## 6 Conclusion and Future Work

We demonstrated that our  $\ell$ MBOT-based machine translation system beats a standard tree-to-tree system (Moses tree-to-tree) on the WMT 2009 translation task English  $\rightarrow$  German. To achieve this we implemented the formal model as described in Section 2 inside the Moses machine translation toolkit. Several modifications were necessary to obtain a working system. We publicly release all our developed software and our complete tool-chain to allow independent experiments and evaluation. This includes our  $\ell$ MBOT decoder

Figure 14:  $\ell$ MBOT rules generating a relative clause/reflexive pronoun

presented in Section 4 and a separate C++ module that we use for rule extraction (see Section 3).

Besides the automatic evaluation, we also performed a small manual analysis of obtained translations and show-cased some examples (see Section 5.3). We argue that our  $\ell$ MBOT approach can adequately handle discontinuous phrases, which occur frequently in German. Other languages that exhibit such phenomena include Czech, Dutch, Russian, and Polish. Thus, we hope that our system can also successfully be applied for other language pairs, which we plan to pursue as well.

In other future work, we want to investigate full backwards application of  $\ell$ MBOT rules, which would be more suitable for the converse translation direction German  $\rightarrow$  English. The current independent LM scoring of components has some negative side-effects that we plan to circumvent with the use of lazy LM scoring.

## Abstract

Empty categories (EC) are artificial elements in Penn Treebanks motivated by the government-binding (GB) theory to explain certain language phenomena such as pro-drop. ECs are ubiquitous in languages like Chinese, but they are tacitly ignored in most machine translation (MT) work because of their elusive nature. In this paper we present a comprehensive treatment of ECs by first recovering them with a structured MaxEnt model with a rich set of syntactic and lexical features, and then incorporating the predicted ECs into a Chinese-to-English machine translation task through multiple approaches, including the extraction of EC-specific sparse features. We show that the recovered empty categories not only improve the word alignment quality, but also lead to significant improvements in a large-scale state-of-the-art syntactic MT system.

## 1 Introduction

One of the key challenges in statistical machine translation (SMT) is to effectively model inherent differences between the source and the target language. Take the Chinese-English SMT as an example: it is non-trivial to produce correct pronouns on the target side when the source-side pronoun is missing. In addition, the pro-drop problem can also degrade the word alignment quality in the training data. A sentence pair observed in the real data is shown in Figure 1 along with the word alignment obtained from an automatic word aligner, where the English subject pronoun

“that” is missing on the Chinese side. Consequently, “that” is incorrectly aligned to the second to the last Chinese word “De”, due to their high co-occurrence frequency in the training data. If the dropped pronoun were recovered, “that” would have been aligned with the dropped-pro (cf. Figure 3), which is a much more sensible alignment.

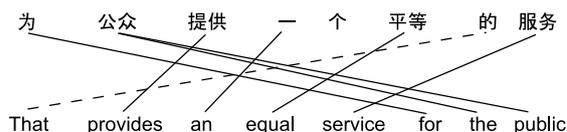

Figure 1: Example of incorrect word alignment due to missing pronouns on the Chinese side.

In order to account for certain language phenomena such as pro-drop and wh-movement, a set of special tokens, called empty categories (EC), are used in Penn Treebanks (Marcus et al., 1993; Bies and Maamouri, 2003; Xue et al., 2005). Since empty categories do not exist in the surface form of a language, they are often deemed elusive and recovering ECs is even figuratively called “chasing the ghost” (Yang and Xue, 2010).

In this work we demonstrate that, with the availability of large-scale EC annotations, it is feasible to predict and recover ECs with high accuracy. More importantly, with various approaches of modeling the recovered ECs in SMT, we are able to achieve significant improvements<sup>1</sup>.

The contributions of this paper include the following:

- Propose a novel structured approach to EC prediction, including the exact word-level lo-

\* This work was done when the author was with IBM.

<sup>1</sup>Hence “Enlisting the ghost” in the title of this paper.

cation and EC labels. Our results are significantly higher in accuracy than that of the state-of-the-art;

- Measure the effect of ECs on automatic word alignment for machine translation after integrating recovered ECs into the MT data;
- Design EC-specific features for phrases and syntactic tree-to-string rules in translation grammar;
- Show significant improvement on top of the state-of-the-art large-scale hierarchical and syntactic machine translation systems.

The rest of the paper is organized as follows. In Section 2, we present a structured approach to EC prediction. In Section 3, we describe the integration of Chinese ECs in MT. The experimental results for both EC prediction and SMT are reported in Section 4. A survey on the related work is conducted in Section 5, and Section 6 summarizes the work and introduces some future work.

## 2 Chinese Empty Category Prediction

The empty categories in the Chinese Treebank (CTB) include trace markers for A'- and A-movement, dropped pronoun, big PRO etc. A complete list of categories used in CTB is shown in Table 1 along with their intended usages. Readers are referred to the documentation (Xue et al., 2005) of CTB for detailed discussions about the characterization of empty categories.

EC	Meaning
*T*	trace of A'-movement
*	trace of A-movement
*PRO*	big PRO in control structures
*pro*	pro-drop
*OP*	operator in relative clauses
*RNR*	for right node raising

Table 1: List of empty categories in the CTB.

In this section, we tackle the problem of recovering Chinese ECs. The problem has been studied before in the literature. For instance, Yang and Xue (2010) attempted to predict the existence of an EC before a word; Luo and Zhao (2011) predicted ECs on parse trees, but the position information of some ECs is partially lost in their representation. Furthermore, Luo and Zhao (2011) conducted experiments on gold parse trees only. In

our opinion, recovering ECs from machine parse trees is more meaningful since that is what one would encounter when developing a downstream application such as machine translation. In this paper, we aim to have a more comprehensive treatment of the problem: all EC types along with their locations are predicted, and we will report the results on both human parse trees and machine-generated parse trees.

### 2.1 Representation of Empty Categories

Our effort of recovering ECs is a two-step process: first, at training time, ECs in the Chinese Treebank are moved and preserved in the portion of the tree structures pertaining to surface words only. Original ECs and their subtrees are then deleted without loss of information; second, a model is trained on transformed trees to predict and recover ECs.

Empty categories heavily depend on syntactic tree structure. For this reason, we choose to project them onto a parse tree node. To facilitate presentation, we first distinguish a *solid* vs. an *empty* non-terminal node. A non-terminal node is *solid* if and only if it contains at least one child node that spans one or more surface words (as opposed to an EC); accordingly, an *empty* node is a non-terminal node that spans only ECs. In the left half of Figure 2, the NP node that is the immediate child of IP has only one child node spanning an EC – (-NONE- \*pro\*), and is thus an *empty* node; while all other non-terminal nodes have at least one surface word as their child and are thus all *solid* nodes.

We decide to attach an EC to its lowest *solid* ancestor node. That is, the EC is moved up to the first solid node in the syntactic tree. After ECs are attached, all empty nodes and ECs are deleted from the tree. In order to uniquely recover ECs, we also need to encode the position information. To this end, the relative child index of an EC is affixed to the EC tag. Take the NP node spanning the \*pro\* in Figure 2 as an example, the \*pro\* is moved to the lowest solid ancestor, IP node, and its position is encoded by @1 since the deleted NP is the second child of the IP node (we use 0-based indices). With this transformation, we are able to recover not only the position of an EC, but its type as well. A special tag NULL is attached to non-terminal nodes without EC. Since an EC is introduced to express the structure of a sentence, it is a good practice to associate it with the syn-

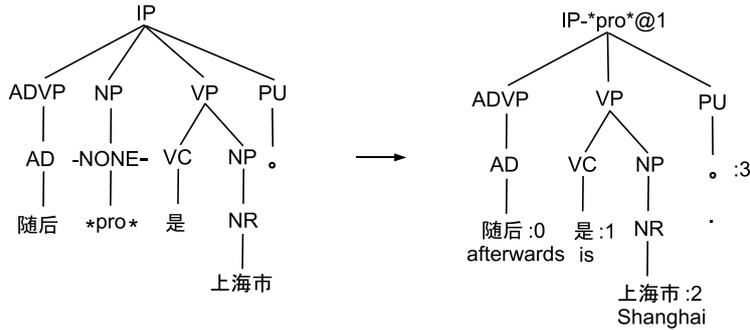

Figure 2: Example of tree transformation on training data to encode an empty category and its position information.

tactic tree, as opposed to simply attaching it to a neighboring word, as was done in (Yang and Xue, 2010). We believe this is one of the reasons why our model has better accuracy than that of (Yang and Xue, 2010) (cf. Table 7).

In summary, a projected tag consists of an EC type (such as `*pro*`) and the EC’s position information. The problem of predicting ECs is then cast into predicting an EC tag at each non-terminal node. Notice that the input to such a predictor is a syntactic tree without ECs, e.g., the parse tree on the right hand of Figure 2 without the EC tag `*pro*@1` is such an example.

## 2.2 A Structured Empty Category Model

We propose a structured MaxEnt model for predicting ECs. Specially, given a syntactic tree,  $T$ , whose ECs have been projected onto solid nodes with the procedure described in Section 2.1, we traverse it in post-order (i.e., child nodes are visited recursively first before the current node is visited). Let  $T = t_1 t_2 \cdots t_n$  be the sequence of nodes produced by the post-order traversal, and  $e_i (i = 1, 2, \cdots, n)$  be the EC tag associated with  $t_i$ . The probabilistic model is then:

$$\begin{aligned}
 P(e_1^n | T) &= \prod_{i=1}^n P(e_i | T, e_1^{i-1}) \\
 &= \prod_{i=1}^n \frac{\exp(\sum_k \lambda_k f_k(e_1^{i-1}, T, e_i))}{Z(e_1^{i-1}, T)} \quad (1)
 \end{aligned}$$

Eq. (1) is the familiar log linear (or MaxEnt) model, where  $f_k(e_1^{i-1}, T, e_i)$  is the feature function and

$Z(e_1^{i-1}, T) = \sum_{e \in \mathcal{E}} \exp(\sum_k \lambda_k f_k(e_1^{i-1}, T, e))$  is the normalization factor.  $\mathcal{E}$  is the set of ECs to be predicted. In the CTB 7.0 processed by the procedure in Section 2.1, the set consists of 32 EC tags

plus a special NULL symbol, obtained by modulating the list of ECs in Table 1 with their positions (e.g., `*pro*@1` in Figure 2).

Once the model is chosen, the next step is to decide a set of features  $\{f_k(e_1^{i-1}, T, e_i)\}$  to be used in the model. One advantage of having the representation in Section 2.1 is that it is very easy to compute features from tree structures. Indeed, all features used in our system are computed from the syntactic trees, including lexical features.

There are 3 categories of features used in the model: (1) tree label features; (2) lexical features; (3) EC features, and we list them in Table 2. In the feature description column, all node positions (e.g., “left”, “right”) are relative to the current node being predicted.

Feature 1 to 10 are computed directly from parse trees, and are straightforward. We include up to 2 siblings when computing feature 9 and 10. Feature 11 to 17 are lexical features. Note that we use words at the edge of the current node: feature 11 and 12 are words at the internal boundary of the current node, while feature 13 and 14 are the immediately neighboring word external to the current node. Feature 15 and 17 are from head word information of the current node and the parent node. Feature 18 and 19 are computed from predicted ECs in the past – that’s why the model in Eq. (1) conditions on  $e_1^{i-1}$ .

Besides the features presented in Table 2, we also use conjunction features between the current node label with the parent node label; the current node label with features computed from child nodes; the current node label with features from left and sibling nodes; the current node label with lexical features.

No.	Tree Label Features
1	current node label
2	parent node label
3	grand-parent node label
4	left-most child label or POS tag
5	right-most child label or POS tag
6	label or POS tag of the head child
7	the number of child nodes
8	one level CFG rule
9	left-sibling label or POS tag
10	right-sibling label or POS tag
<b>Lexical Features</b>	
11	left-most word under the current node
12	right-most word under the current node
13	word immediately left to the span of the current node
14	word immediately right to the span of the current node
15	head word of the current node
16	head word of the parent node
17	is the current node head child of its parent?
<b>EC Features</b>	
18	predicted EC of the left sibling
19	the set of predicted ECs of child nodes

Table 2: List of features.

### 3 Integrating Empty Categories in Machine Translation

In this section, we explore multiple approaches of utilizing recovered ECs in machine translation.

#### 3.1 Explicit Recovery of ECs in MT

We conducted some initial error analysis on our MT system output and found that most of the errors that are related to ECs are due to the missing *\*pro\** and *\*PRO\**. This is also consistent with the findings in (Chung and Gildea, 2010). One of the other frequent ECs, *\*OP\**, appears in the Chinese relative clauses, which usually have a Chinese word “De” aligned to the target side “that” or “which”. And the trace, *\*T\**, exists in both Chinese and English sides. For MT we want to focus on the places where there exist mismatches between the source and target languages. A straightforward way of utilizing the recovered *\*pro\** and *\*PRO\** is to pre-process the MT training and test data by inserting ECs into the original source text (i.e. Chinese in this case). As mentioned in the previous section, the output of our EC predictor is a new parse tree with the labels and positions

encoded in the tags. Based on the positional information in the tags, we can move the predicted ECs down to the surface level and insert them between original source words. The same prediction and “pull-down” procedure can be conducted consistently across the MT training and test data.

#### 3.2 Grammar Extraction on Augmented Data

With the pre-processed MT training corpus, an unsupervised word aligner, such as GIZA++, can be used to generate automatic word alignment, as the first step of a system training pipeline. The effect of inserting ECs is two-fold: first, it can impact the automatic word alignment since now it allows the target-side words, especially the function words, to align to the inserted ECs and fix some errors in the original word alignment; second, new phrases and rules can be extracted from the pre-processed training data. For example, for a hierarchical MT system, some phrase pairs and Hiero (Chiang, 2005) rules can be extracted with recovered *\*pro\** and *\*PRO\** at the Chinese side.

In this work we also take advantages of the augmented Chinese parse trees (with ECs projected to the surface) and extract tree-to-string grammar (Liu et al., 2006) for a tree-to-string MT system. Due to the recovered ECs in the source parse trees, the tree-to-string grammar extracted from such trees can be more discriminative, with an increased capability of distinguishing different context. An example of an augmented Chinese parse tree aligned to an English string is shown in Figure 3, in which the incorrect alignment in Figure 1 is fixed. A few examples of the extracted Hiero rules and tree-to-string rules are also listed, which we would not have been able to extract from the original incorrect word alignment when the *\*pro\** was missing.

#### 3.3 Soft Recovery: EC-Specific Sparse Features

Recovered ECs are often good indicators of what hypothesis should be chosen during decoding. In addition to the augmented syntax-based grammar, we propose sparse features as a soft constraint to boost the performance. For each phrase pair, Hiero rule or tree-to-string rule in the MT system, a binary feature  $f_k$  fires if there exists a *\*pro\** on the source side and it aligns to one of its most frequently aligned target words found in the training corpus. We also fire another feature if *\*pro\**

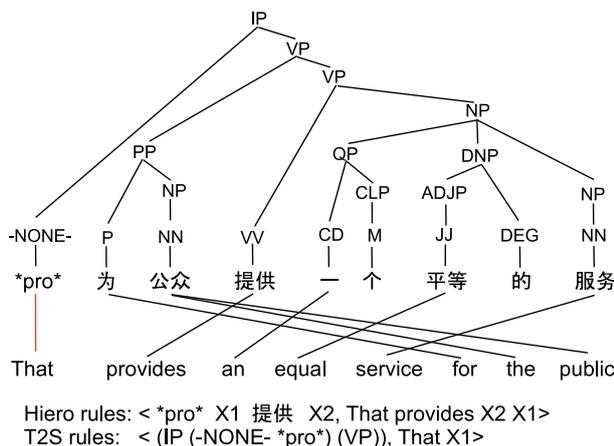

Figure 3: Fixed word alignment and examples of extracted Hiero rules and tree-to-string rules.

aligns to any other target words so the model can choose to penalize them based on a tuning set. Similar features can fire for \*PRO\*. The feature weights can be tuned on a tuning set in a log-linear model along with other usual features/costs, including language model scores, bi-direction translation probabilities, etc. The motivation for such sparse features is to reward those phrase pairs and rules that have highly confident lexical pairs specifically related to ECs, and penalize those who don't have such lexical pairs.

Table 3 listed some of the most frequent English words aligned to \*pro\* or \*PRO\* in a Chinese-English parallel corpus with 2M sentence pairs. Their co-occurrence counts and the lexical translation probabilities are also shown in the table. In total we use 15 sparse features for frequent lexical pairs, including 13 for \*pro\* and 2 for \*PRO\*, and two more features for any other target words that align to \*pro\* or \*PRO\*.

Source	Target	Counts	$P(t s)$
*pro*	the	93100	0.11
*pro*	to	86965	0.10
*pro*	it	45423	0.05
*pro*	in	36129	0.04
*pro*	we	24509	0.03
*pro*	which	17259	0.02
*PRO*	to	195464	0.32
*PRO*	for	31200	0.05

Table 3: Example of frequent word pairs used for sparse features.

## 4 Experimental Results

### 4.1 Empty Category Prediction

We use Chinese Treebank (CTB) v7.0 to train and test the EC prediction model. We partition the data into training, development and test sets. The training set includes 32925 sentences from CTB files 0001-0325, 0400-0454, 0500-0542, 0600-0840, 0590-0596, 1001-1120, 2000-3000, cctv, cnn, msnbc, and phoenix 00-06. The development set has 3033 sentences, from files 0549-0554, 0900-0931, 1136-1151, 3076-3145, and phoenix 10-11. The test set contains 3297 sentences, from files 0543-0548, 0841-0885, 1121-1135, 3001-3075, and phoenix 07-09.

To measure the accuracy of EC prediction, we project the predicted tags from the upper level nodes in the parse trees down to the surface level based on the position information encoded in the tags. The position index for each inserted EC, counted at the surface level, is attached for scoring purpose. The same operation is applied on both the reference and the system output trees. Such projection is necessary, especially when the two trees differ in structure (e.g. gold trees vs. machine-generated trees). We compute the precision, recall and F1 scores for each EC on the test set, and collect their counts in the reference and system output. The results are shown in Table 4, where the LDC gold parse trees are used to extract syntactic features for the model. The first row in the table shows the accuracy for the places where no EC should be inserted. The predictor achieves 99.5% F1 score for this category, with limited number of missing or false positives. The F1 scores for majority of the ECs are above 70%, except for “\*”, which is relatively rare in the data. For the two categories that are interesting to MT, \*pro\* and \*PRO\*, the predictor achieves 74.3% and 81.5% in F1 scores, respectively.

The results reported above are based on the LDC gold parse trees. To apply the EC prediction to NLP applications, such as MT, it is impossible to always rely on the gold trees due to its limited availability. We parse our test set with a maximum entropy based statistical parser (Ratnaparkhi, 1997) first. The parser accuracy is around 84% on the test set. Then we extract features based on the system-generated parse trees, and decode with the previously trained model. The results are shown in Table 5. Compared to those in Table 4, the F1 scores dropped by different degrees for dif-

Tag	Ref	Sys	P	R	F1
NULL	75159	75508	99.3	99.7	99.5
*pro*	1692	1442	80.8	68.9	74.3
*PRO*	1410	1282	85.6	77.8	81.5
*T*	1851	1845	82.8	82.5	82.7
*OP*	1721	1853	90.9	97.9	94.2
*RNR*	51	39	87.2	66.7	75.6
*	156	96	63.5	39.1	48.4

Table 4: Prediction accuracy with gold parse trees, where NULL represents the cases where no ECs should be produced.

ferent types. Such performance drop is expected since the system relies heavily on syntactic structure, and parsing errors create an inherent mismatching condition between the training and testing time. The smallest drop among all types is on NULL, at about 1.6%. The largest drop occurs for \*OP\*, at 27.1%, largely due to the parsing errors on the CP nodes. The F1 scores for \*pro\* and \*PRO\* when using system-generated parse trees are between 50% to 60%.

Tag	Precision	Recall	F1
NULL	97.6	98.2	97.9
*pro*	51.1	50.1	50.6
*PRO*	66.4	50.5	57.3
*T*	68.2	59.9	63.8
*OP*	66.8	67.3	67.1
*RNR*	70.0	54.9	61.5
*	60.9	35.9	45.2

Table 5: Prediction accuracy with system-generated parse trees.

To show the effect of ECs other than \*pro\* and \*PRO\*, we remove all ECs in the training data except \*pro\* and \*PRO\*. So the model only predicts NULL, \*pro\* or \*PRO\*. The results on the test set are listed in Table 6. There is 0.8% and 0.5% increase on NULL and \*pro\*, respectively. The F1 score for \*PRO\* drops by 0.2% slightly.

As mentioned earlier, for MT we focus on recovering \*pro\* and \*PRO\* only. The model generating the results in Table 6 is the one we applied in our MT experiments reported later.

In order to compare to the state-of-the-art models to see where our model stands, we switch our training, development and test data to those used in the work of (Yang and Xue, 2010) and (Cai et

Tag	Precision	Recall	F1
NULL	98.5	98.9	98.7
*pro*	51.0	51.1	51.1
*PRO*	66.0	50.4	57.1

Table 6: Prediction accuracy with system-generated parse trees, modeling \*pro\* and \*PRO\* only.

al., 2011), for the purpose of a direct comparison. The training set includes CTB files 0081 through 0900. The development set includes files 0041 to 0080, and the test set contains files 0001-0040 and 0901-0931. We merge all empty categories into a single type in the training data before training our EC prediction model. To compare the performance on system-generated parse trees, we also train a Berkeley parser on the same training data and parse the test set. The prediction accuracy for such single type on the test set with gold or system-generated parse trees is shown in Table 7, compared to the numbers reported in (Yang and Xue, 2010) and (Cai et al., 2011). The model we proposed achieves 6% higher F1 score than that in (Yang and Xue, 2010) and 2.6% higher than that in (Cai et al., 2011), which is significant. This shows the effectiveness of our structured approach.

Model	T	P	R	F1
(Yang and Xue, 2010)	G	95.9	83.0	89.0
Structured (this work)	G	96.5	93.6	95.0
(Yang and Xue, 2010)	S	80.3	52.1	63.2
(Cai et al., 2011)	S	74.0	61.3	67.0
Structured (this work)	S	74.9	65.1	69.6

## 4.2 MT Results

In the Chinese-to-English MT experiments, we test two state-of-the-art MT systems. One is an re-implementation of Hiero (Chiang, 2005), and the other is a hybrid syntax-based tree-to-string system (Zhao and Al-onaizan, 2008), where normal phrase pairs and Hiero rules are used as a backoff for tree-to-string rules.

The MT training data includes 2 million sentence pairs from the parallel corpora released by

LDC over the years, with the data from United Nations and Hong Kong excluded <sup>2</sup>. The Chinese text is segmented with a segmenter trained on the CTB data using conditional random field (CRF), followed by the longest-substring match segmentation in a second pass. Our language model (LM) training data consists of about 10 billion English words, which includes Gigaword and other newswire and web data released by LDC, as well as the English side of the parallel training corpus. We train a 6-gram LM with modified Kneser-Ney smoothing (Chen and Goodman, 1998). Our tuning set for MT contains 1275 sentences from LDC2010E30. We test our system on the NIST MT08 Newswire (691 sentences) and Weblog (666 sentences) sets. Both tuning and test sets have 4 sets of references for each sentence. The MT systems are optimized with pairwise ranking optimization (Hopkins and May, 2011) to maximize BLEU (Papineni et al., 2002).

We first predict \*pro\* and \*PRO\* with our annotation model for all Chinese sentences in the parallel training data, with \*pro\* and \*PRO\* inserted between the original Chinese words. Then we run GIZA++ (Och and Ney, 2000) to generate the word alignment for each direction and apply grow-diagonal-final (Koehn et al., 2003), same as in the baseline. We want to measure the impact on the word alignment, which is an important step for the system building. We append a 300-sentence set, which we have human hand alignment available as reference, to the 2M training sentence pairs before running GIZA++. The alignment accuracy measured on this alignment test set, with or without \*pro\* and \*PRO\* inserted before running GIZA++, is shown in Table 8. To make a fair comparison with the baseline alignment, any target words aligned to ECs are deemed as unaligned during scoring. We observe 1.2% improvement on function word related links, and almost the same accuracy on content words. This is understandable since \*pro\* and \*PRO\* are mostly aligned to the function words at the target side. The precision and recall for function words are shown in Table 9. We can see higher accuracy in both precision and recall when ECs (\*pro\* and \*PRO\*) are recovered in the Chinese side. Especially, the precision is improved by 2% absolute.

<sup>2</sup>The training corpora include LDC2003E07, LDC2003E08, LDC2005T10, LDC2006E26, LDC2006G05, LDC2007E103, LDC2008G05, LDC2009G01, and LDC2009G02.

System	Function	Content	All
Baseline	51.7	69.7	65.4
+EC	52.9	69.6	65.7

Table 8: Word alignment F1 scores with or without \*pro\* and \*PRO\*.

System	Precision	Recall	F1
Baseline	54.1	49.5	51.7
+EC	56.0	50.1	52.9

Table 9: Word alignment accuracy for function words only.

Next we extract phrase pairs, Hiero rules and tree-to-string rules from the original word alignment and the improved word alignment, and tune all the feature weights on the tuning set. The weights include those for usual costs and also the sparse features proposed in this work specifically for ECs. We test all the systems on the MT08 Newswire and Weblog sets.

The BLEU scores from different systems are shown in Table 10 and Table 11, respectively. We measure the incremental effect of prediction (inserting \*pro\* and \*PRO\*) and sparse features. Pre-processing of the data with ECs inserted improves the BLEU scores by about 0.6 for newswire and 0.2 to 0.3 for the weblog data, compared to each baseline separately. On top of that, adding sparse features helps by another 0.3 on newswire and 0.2 to 0.4 on weblog. Overall, the Hiero and tree-to-string systems are improved by about 1 point for newswire and 0.4 to 0.7 for weblog. The smaller gain on the weblog data could be due to the more difficult data to parse, which affects the accuracy of EC prediction. All the results in Table 10 and 11 marked with “\*” are statistically significant with  $p < 0.05$  using the sign test described in (Collins et al., 2005), compared to the baseline results in each table. Two MT examples are given in Table 12, which show the effectiveness of the recovered ECs in MT.

## 5 Related Work

Empty categories have been studied in recent years for several languages, mostly in the context of reference resolution and syntactic processing for English, such as in (Johnson, 2002; Dienes and Dubey, 2003; Gabbard et al., 2006). More recently, EC recovery for Chinese started emerging in literature. In (Guo et al., 2007), non-local dependencies are migrated from English to Chinese for generating proper predicate-argument-modifier structures from surface context free phrase structure trees. In (Zhao and Ng, 2007), a decision tree learning algorithm is presented to identify and resolve Chinese anaphoric zero pronouns. and achieves a performance comparable to a heuristic rule-based approach. Similar to the work in (Dienes and Dubey, 2003), empty detection is formulated as a tagging problem in (Yang and Xue, 2010), where each word in the sentence receives a tag indicating whether there is an EC before it. A maximum entropy model is utilized to predict the tags, but different types of ECs are not distinguished. In (Cai et al., 2011), a language-independent method was proposed to integrate the recovery of empty elements into syntactic parsing. As shown in the previous section, our model outperforms the model in (Yang and Xue, 2010) and (Cai et al., 2011) significantly using the same training and test data. (Luo and Zhao, 2011) also tries to predict the existence of an EC

in Chinese sentences, but the ECs in the middle of a tree constituent are lumped into a single position and are not uniquely recoverable.

There exists only a handful of previous work on applying ECs explicitly to machine translation so far. One of them is the work reported in (Chung and Gildea, 2010), where three approaches are compared, based on either pattern matching, CRF, or parsing. However, there is no comparison between using gold trees and automatic trees. There also exist a few major differences on the MT part between our work and theirs. First, in addition to the pre-processing of training data and inserting recovered empty categories, we implement sparse features to further boost the performance, and tune the feature weights directly towards maximizing the machine translation metric. Second, there is no discussion on the quality of word alignment in (Chung and Gildea, 2010), while we show the alignment improvement on a hand-aligned set. Last, they use a phase-based system trained on only 60K sentences, while we conduct experiments on more advanced Hiero and tree-to-string systems, trained on 2M sentences in a much larger corpus. We directly take advantage of the augmented parse trees in the tree-to-string grammar, which could have larger impact on the MT system performance.

## 6 Conclusions and Future Work

In this paper, we presented a novel structured approach to EC prediction, which utilizes a maximum entropy model with various syntactic features and shows significantly higher accuracy than the state-of-the-art approaches. We also applied the predicted ECs to a large-scale Chinese-to-English machine translation task and achieved significant improvement over two strong MT base-

lines, i.e. a hierarchical phase-based system and a tree-to-string syntax-based system. More work remain to be done next to further take advantages of ECs. For example, the recovered ECs can be encoded in a forest as the input to the MT decoder and allow the decoder to pick the best MT output based on various features in addition to the sparse features we proposed in this work. Many promising approaches can be explored in the future.

## Abstract

While domain adaptation techniques for SMT have proven to be effective at improving translation quality, their practicality for a multi-domain environment is often limited because of the computational and human costs of developing and maintaining multiple systems adapted to different domains. We present an architecture that delays the computation of translation model features until decoding, allowing for the application of mixture-modeling techniques at decoding time. We also describe a method for unsupervised adaptation with development and test data from multiple domains. Experimental results on two language pairs demonstrate the effectiveness of both our translation model architecture and automatic clustering, with gains of up to 1 BLEU over unadapted systems and single-domain adaptation.

## 1 Introduction

The effectiveness of domain adaptation approaches such as mixture-modeling (Foster and Kuhn, 2007) has been established, and has led to research on a wide array of adaptation techniques in SMT, for instance (Matsoukas et al., 2009; Shah et al., 2012). In all these approaches, adaptation is performed during model training, with respect to a representative development corpus, and the models are kept unchanged when the system is deployed. Therefore, when working with multiple and/or unlabelled domains, domain adaptation is often impractical for a number of reasons. Firstly, maintaining multiple systems for each language pair, each adapted to a different domain, is costly

in terms of computational and human resources: the full system development pipeline needs to be performed for all identified domains, all the models are separately stored and need to be switched at runtime. This is impractical in many real applications, in particular a web translation service which is faced with texts coming from many different domains. Secondly, domain adaptation bears a risk of performance loss. If there is a mismatch between the domain of the development set and the test set, domain adaptation can potentially harm performance compared to an unadapted baseline.

We introduce a translation model architecture that delays the computation of features to the decoding phase. The calculation is based on a vector of component models, with each component providing the sufficient statistics necessary for the computation of the features. With this framework, adaptation to a new domain simply consists of updating a weight vector, and multiple domains can be supported by the same system.

We also present a clustering approach for unsupervised adaptation in a multi-domain environment. In the development phase, a set of development data is clustered, and the models are adapted to each cluster. For each sentence that is being decoded, we choose the weight vector that is optimized on the closest cluster, allowing for adaptation even with unlabelled and heterogeneous test data.

## 2 Related Work

(Ortiz-Martínez et al., 2010) delay the computation of translation model features for the purpose of interactive machine translation with online training. The main difference to our approach is that we store sufficient statistics not for a single model, but a vector of models, which allows us to

weight the contribution of each component model to the feature calculation. The similarity suggests that our framework could also be used for interactive learning, with the ability to learn a model incrementally from user feedback, and weight it differently than the static models, opening new research opportunities.

(Sennrich, 2012b) perform instance weighting of translation models, based on the sufficient statistics. Our framework implements this idea, with the main difference that the actual combination is delayed until decoding, to support adaptation to multiple domains in a single system.

(Razmara et al., 2012) describe an ensemble decoding framework which combines several translation models in the decoding step. Our work is similar to theirs in that the combination is done at runtime, but we also delay the computation of translation model probabilities, and thus have access to richer sufficient statistics. In principle, our architecture can support all mixture operations that (Razmara et al., 2012) describe, plus additional ones such as forms of instance weighting, which are not possible after the translation probabilities have been computed.

(Banerjee et al., 2010) focus on the problem of domain identification in a multi-domain setting. They use separate translation systems for each domain, and a supervised setting, whereas we aim for a system that integrates support for multiple domains, with or without supervision.

(Yamamoto and Sumita, 2007) propose unsupervised clustering at both training and decoding time. The training text is divided into a number of clusters, a model is trained on each, and during decoding, each sentence is assigned to the closest cluster-specific model. Our approach bears resemblance to this clustering, but is different in that Yamamoto and Sumita assign each sentence to the closest model, and use this model for decoding, whereas in our approach, each cluster is associated with a mixture of models that is optimized to the cluster, and the number of clusters need not be equal to the number of component models.

### 3 Translation Model Architecture

This section covers the architecture of the multi-domain translation model framework. Our translation model is embedded in a log-linear model as is common for SMT, and treated as a single translation model in this log-linear combination. We im-

plemented this architecture for phrase-based models, and will use this terminology to describe it, but in principle, it can be extended to hierarchical or syntactic models.

The architecture has two goals: move the calculation of translation model features to the decoding phase, and allow for multiple knowledge sources (e.g. bitexts or user-provided data) to contribute to their calculation. Our immediate purpose for this paper is domain adaptation in a multi-domain environment, but the delay of the feature computation has other potential applications, e.g. in interactive MT.

We are concerned with calculating four features during decoding, henceforth just referred to as the translation model features:  $p(\bar{s}|\bar{t})$ ,  $lex(\bar{s}|\bar{t})$ ,  $p(\bar{t}|\bar{s})$  and  $lex(\bar{t}|\bar{s})$ .  $\bar{s}$  and  $\bar{t}$  denote the source and target phrase. We follow the definitions in (Koehn et al., 2003).

Traditionally, the phrase translation probabilities  $p(\bar{s}|\bar{t})$  and  $p(\bar{t}|\bar{s})$  are estimated through unsmoothed maximum likelihood estimation (MLE).

$$p(x|y) = \frac{c(x, y)}{c(y)} = \frac{c(x, y)}{\sum_{x'} c(x', y)} \quad (1)$$

where  $c$  denotes the count of an observation, and  $p$  the model probability.

The lexical weights  $lex(\bar{s}|\bar{t})$  and  $lex(\bar{t}|\bar{s})$  are calculated as follows, using a set of word alignments  $a$  between  $\bar{s}$  and  $\bar{t}$ :<sup>1</sup>

$$lex(\bar{s}|\bar{t}, a) = \prod_{i=1}^n \frac{1}{|\{j | (i, j) \in a\}|} \sum_{\forall (i, j) \in a} w(s_i | t_j) \quad (2)$$

A special NULL token is added to  $\bar{t}$  and aligned to each unaligned word in  $\bar{s}$ .  $w(s_i | t_j)$  is calculated through MLE, as in equation 1, but based on the word (pair) frequencies.

To combine statistics from a vector of  $n$  component corpora, we can use a weighted version of equation 1, which adds a weight vector  $\lambda$  of length  $n$  (Sennrich, 2012b):

$$p(x|y; \lambda) = \frac{\sum_{i=1}^n \lambda_i c_i(x, y)}{\sum_{i=1}^n \sum_{x'} \lambda_i c_i(x', y)} \quad (3)$$

The word translation probabilities  $w(t_i | s_j)$  are defined analogously, and used in equation 2 for a weighted version.

<sup>1</sup>The equation shows  $lex(\bar{s}|\bar{t})$ ;  $lex(\bar{t}|\bar{s})$  is computed analogously.

In order to compute the translation model features online, a number of sufficient statistics need to be accessible at decoding time. For  $p(\bar{s}|\bar{t})$  and  $p(\bar{t}|\bar{s})$ , we require the statistics  $c(\bar{s})$ ,  $c(\bar{t})$  and  $c(\bar{s}, \bar{t})$ . For accessing them during decoding, we simply store them in the decoder’s data structure, rather than storing pre-computed translation model features. This means that we can use existing, compact data formats for storing and accessing them.<sup>2</sup>

The statistics are accessed when the decoder collects all translation options for a phrase  $\bar{s}$  in the source sentence. We then access all translation options for each component table, obtaining a vector of statistics  $c(\bar{s})$  for the source phrase, and  $c(\bar{t})$  and  $c(\bar{s}, \bar{t})$  for each potential target phrase. For phrase pairs which are not found,  $c(\bar{s}, \bar{t})$  and  $c(\bar{t})$  are initially set to 0.

Note that  $c(\bar{t})$  is potentially incorrect at this point, since a phrase pair not being found does not entail that  $c(\bar{t})$  is 0. After all tables have been accessed, and we thus know the full set of possible translation options  $(\bar{s}, \bar{t})$ , we perform a second round of lookups for all  $c(\bar{t})$  in the vector which are still set to 0. We introduce a second table for accessing  $c(\bar{t})$  efficiently, again storing it in the decoder’s data structure. We can easily create such a table by inverting the source and target phrases, deduplicating it for compactness (we only need one entry per target phrase), and storing  $c(\bar{t})$  as only feature.

For  $lex(\bar{s}|\bar{t})$ , we require an alignment  $a$ , plus  $c(t_j)$  and  $c(s_i, t_j)$  for all pairs  $(i, j)$  in  $a$ .  $lex(\bar{t}|\bar{s})$  can be based on the same alignment  $a$  (with the exception of NULL alignments, which can be added online), but uses statistics  $c(s_j)$  and  $c(t_i, s_j)$ . For estimating the lexical probabilities, we load the frequencies into a vector of four hash tables.<sup>3</sup>

Both space and time complexity of the lookup is linear to the number of component tables. We deem it is still practical because the collection of translation options is typically only a small fraction of total decoding time, with search making up the largest part. For storing and accessing the sufficient statistics (except for the word (pair) frequencies), we use an on-disk data structure pro-

<sup>2</sup>We have released an implementation of the architecture as part of the Moses decoder.

<sup>3</sup> $c(s, t)$  and  $c(t, s)$  are not identical since the lexical probabilities are based on the unsymmetrized word alignment frequencies (in the Moses implementation which we implement).

phrase (pair)	$c_1(x)$	$c_2(x)$
row	300	80
(row, Zeile)	240	20
(row, Reihe)	60	60
$\lambda$	$p(\text{Zeile} \text{row})$	$p(\text{Reihe} \text{row})$
(1, 1)	0.68	0.32
(1, 10)	0.40	0.60
(10, 1)	0.79	0.21

Table 1: Illustration of instance weighting with weight vectors for two corpora.

vided by Moses, which reduces the memory requirements. Still, the number of components may need to be reduced, for instance through clustering of training data (Sennrich, 2012a).

With a small modification, our framework could be changed to use a single table that stores a vector of  $n$  statistics instead of a vector of  $n$  tables. While this would be more compact in terms of memory, and keep the number of table lookups independent of the number of components, we chose a vector of  $n$  tables for its flexibility. With a vector of tables, tables can be quickly added to or removed from the system (conceivable even at runtime), and can be polymorph. One applications where this could be desirable is interactive machine translation, where one could work with a mix of compact, static tables, and tables designed to be incrementally trainable.

In the unweighted variant, the resulting features are equivalent to training on the concatenation of all training data, excepting differences in word alignment, pruning<sup>4</sup> and rounding. The architecture can thus be used as a drop-in replacement for a baseline system that is trained on concatenated training data, with non-uniform weights only being used for texts for which better weights have been established. This can be done either using domain labels or unsupervised methods as described in the next section.

As a weighted combination method, we implemented instance weighting as described in equation 3. Table 1 shows the effect of weighting two corpora on the probability estimates for the translation of *row*. German *Zeile* (row in a table) is predominant in a bitext from the domain IT, whereas

<sup>4</sup>We prune the tables to the most frequent 50 phrase pairs per source phrase before combining them, since calculating the features for all phrase pairs of very common source phrases causes a significant slow-down. We found that this had no significant effects on BLEU.

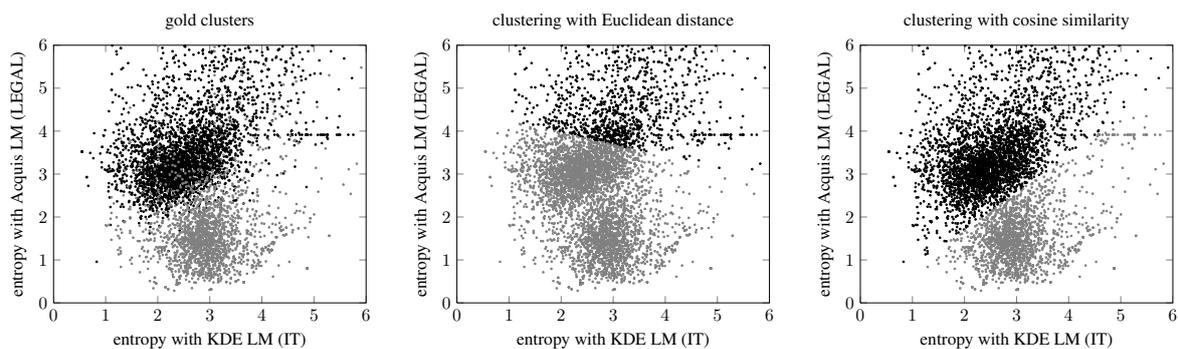

Figure 1: Clustering of data set which contains sentences from two domains: LEGAL and IT. Comparison between gold segmentation, and clustering with two alternative distance/similarity measures. Black: IT; grey: LEGAL.

*Reihe* (line of objects) occurs more often in a legal corpus. Note that the larger corpus (or more precisely, the one in which *row* occurs more often) has a stronger impact on the probability distribution with uniform weights (or in a concatenation of data sets). Instance weighting allows us to modify the contribution of each corpus. In our implementation, the weight vector is set globally, but can be overridden on a per-sentence basis. In principle, using different weight vectors for different phrase pairs in a sentence is conceivable. The framework can also be extended to support other combination methods, such as a linear interpolation of models.

#### 4 Unsupervised Clustering for Online Translation Model Adaptation

The framework supports decoding each sentence with a separate weight vector of size  $4n$ , 4 being the number of translation model features whose computation can be weighted, and  $n$  the number of model components. We now address the question of how to automatically select good weights in a multi-domain task. As a way of optimizing instance weights, (Sennrich, 2012b) minimize translation model perplexity on a set of phrase pairs, automatically extracted from a parallel development set. We follow this technique, but want to have multiple weight vectors, adapted to different texts, between which the system switches at decoding time. The goal is to perform domain adaptation without requiring domain labels or user input, neither for development nor decoding.

The basic idea consists of three steps:

1. Cluster a development set into  $k$  clusters.
2. Optimize translation model weights for each

cluster.

3. For each sentence in the test set, assign it to the nearest cluster and use the translation model weights associated with the cluster.

For step 2, we use the algorithm by (Sennrich, 2012b), implemented in the decoder to allow for a quick optimization of a running system. We will here discuss steps 1 and 3 in more detail.

##### 4.1 Clustering the Development Set

We use  $k$ -means clustering to cluster the sentences of the development set. We train a language model on the source language side of each of the  $n$  component bitexts, and compute an  $n$ -dimensional vector for each sentence by computing its entropy with each language model. Our aim is not to discriminate between sentences that are more likely and unlikely in general, but to cluster on the basis of relative differences between the language model entropies. For this purpose, we choose the cosine as our similarity measure. Figure 1 illustrates clustering in a two-dimensional vector space, and demonstrates that Euclidean distance is unsuitable because it may perform a clustering that is irrelevant to our purposes.

As a result of development set clustering, we obtain a bitext for each cluster, which we use to optimize the model weights, and a centroid per cluster. At decoding time, we need only perform an assignment step. Each test set sentence is assigned to the centroid that is closest to it in the vector space.

##### 4.2 Scalability Considerations

Our theoretical expectation is that domain adaptation will fail to perform well if the test data is from

a different domain than the development data, or if the development data is a heterogeneous mix of domains. A multi-domain setup can mitigate this risk, but only if the relevant domain is represented in the development data, and if the development data is adequately segmented for the optimization. We thus suggest that the development data should contain enough data from all domains that one wants to adapt to, and a high number of clusters.

While the resource requirements increase with the number of component models, increasing the number of clusters is computationally cheap at runtime. Only the clustering of the development set and optimization of the translation model weights for each clusters is affected by  $k$ . This means that the approach can in principle be scaled to a high number of clusters, and support a high number of domains.<sup>5</sup>

The biggest risk of increasing the number of clusters is that if the clusters become too small, perplexity minimization may overfit these small clusters. We will experiment with different numbers of clusters, but since we expect the optimal number of clusters to depend on the amount of development data, and the number of domains, we cannot make generalized statements about the ideal number of  $k$ .

While it is not the focus of this paper, we also evaluate language model adaptation. We perform a linear interpolation of models for each cluster, with interpolation coefficients optimized using perplexity minimization on the development set. The cost of moving language model interpolation into the decoding phase is far greater than for translation models, since the number of hypotheses that need to be evaluated by the language model is several orders of magnitudes higher than the number of phrase pairs used during the translation. For the experiments with language model adaptation, we have chosen to perform linear interpolation offline, and perform language model switching during decoding. While model switching is a fast operation, it also makes the space complexity of storing the language models linear to the number of clusters. For scaling the approach to a high number of clusters, we envision that multi-

<sup>5</sup>If the development set is labelled, one can also use a gold segmentation of development sets instead of  $k$ -means clustering. At decoding time, cluster assignment can be performed by automatically assigning each sentence to the closest centroid, or again through gold labels, if available.

pass decoding, with an unadapted language model in the first phase, and rescoring with a language model adapted online, could perform adequately, and keep the complexity independent of the number of clusters.

## 5 Evaluation

### 5.1 Data and Methods

We conduct all experiments with Moses (Koehn et al., 2007), SRILM (Stolcke, 2002), and GIZA++ (Och and Ney, 2003). Log-linear weights are optimized using MERT (Och and Ney, 2003). We keep the word alignment and lexical reordering models constant through the experiments to minimize the number of confounding factors. We report translation quality using BLEU (Papineni et

system	TM adaptation		LM adaptation		TM+LM adaptation	
	IT	LEGAL	IT	LEGAL	IT	LEGAL

al., 2002). We account for optimizer instability by running 3 independent MERT runs per system, and performing significance testing with MultEval (Clark et al., 2011). Systems significantly better than the baseline with  $p < 0.01$  are marked with (\*).

We conduct experiments on two data sets. The first is an English–German translation task with two domains, texts related to information technology (IT) and legal documents (LEGAL). We use data sets from both domains, plus out-of-domain corpora, as shown in table 2. 7 data sets come from the domain IT: 6 from OPUS (Tiedemann, 2009) and a translation memory (tm) provided by our industry partner. 3 data sets are from the legal domain: the ECB corpus from OPUS, plus the JRC-Acquis (Steinberger et al., 2006) and DGT-TM (Steinberger et al., 2012). 2 data sets are out-of-domain, made available by the 2012 Workshop on Statistical Machine Translation (Callison-Burch et al., 2012). The development sets are random samples from the respective in-domain bitexts (held-out from training). The test sets have been provided by Translated, our industry partner in the MATECAT project.

Our second data set is CzEng 0.9, a Czech–English parallel corpus (Bojar and Zabokrtský, 2009). It contains text from 7 different sources, on which we train separate component models. The size of the corpora is shown in table 3. As development and test sets, we use 500 sentences of held-out data per source.

For both data sets, language models are trained on the target side of the bitexts. In all experiments, we keep the number of component models constant: 12 for EN–DE, 7 for CZ–EN. We vary the number of clusters  $k$  from 1, which corresponds to adapting the models to the full development set, to 16. The baseline is the concatenation of all train-

ing data, with no adaptation performed. We also evaluate the labelled setting, where instead of unsupervised clustering, we use gold labels to split the development and test sets, and adapt the models to each labelled domain.

## 5.2 Results

Table 4 shows results for the EN–DE data set. For our clustering experiments, the development set is the concatenation of the LEGAL and IT development sets. However, we always use the gold segmentation between LEGAL and IT for MERT and testing. This allows for a detailed analysis of the effect of development data clustering for the purpose of model adaptation. In an unlabelled setting, one would have to run MERT either on the full development set (as we will do for the CZ–EN task) or separately on each cluster, or use an alternative approach to optimize log-linear weights in a multi-domain setting, such as feature augmentation as described by (Clark et al., 2012).

system	TM adaptation	LM adaptation	TM+LM adaptation
baseline	34.4	34.4	34.4
1 cluster (no split)	34.5	33.7	34.1
2 clusters	34.6	34.0	34.4
4 clusters	34.7*	34.3	34.6
8 clusters	34.7*	34.5	34.9*
16 clusters	34.7*	34.7*	35.0*
gold clusters	35.0*	35.0*	35.4*

Table 6: Translation experiments CZ–EN. BLEU scores reported.

We find that an adaptation of the TM and LM to the full development set (system “1 cluster”) yields the smallest improvements over the unadapted baseline. The reason for this is that the mixed-domain development set is not representative for the respective test sets. Using multiple adapted systems yields better performance. For the IT test set, the system with gold labels and TM adaptation yields an improvement of 0.7 BLEU (21.1  $\rightarrow$  21.8), LM adaptation yields 1.3 BLEU (21.1  $\rightarrow$  22.4), and adapting both models outperforms the baseline by 2.1 BLEU (21.1  $\rightarrow$  23.2). The systems that use unsupervised clusters reach a similar level of performance than those with gold clusters, with best results being achieved by the systems with 2–8 clusters. Some systems outperform both the baseline and the gold clusters, e.g. TM adaptation with 8 clusters (21.1  $\rightarrow$  21.8  $\rightarrow$  22.1), or LM adaptation with 4 or 8 clusters (21.1  $\rightarrow$  22.4  $\rightarrow$  23.1).

Results with 16 clusters are slightly worse than those with 2–8 clusters due to two effects. Firstly, for the system with adapted TM, one of the three MERT runs is an outlier, and the reported BLEU score of 21.1 is averaged from the three MERT runs achieving 22.1, 21.6, and 19.6 BLEU, respectively. Secondly, about one third of the IT test set is assigned to a cluster that is not IT-specific, which weakens the effect of domain adaptation for the systems with 16 clusters.

For the LEGAL subset, gains are smaller. This can be explained by the fact that the majority of training data is already from the legal domain, which makes it unnecessary to boost its impact on the probability distribution even further.

Table 5 shows the automatically obtained translation model weight vectors for two systems, “gold clusters” and “2 clusters”, for the feature  $p(\bar{t}|\bar{s})$ . It illustrates that all the corpora that we consider out-of-domain for IT are penalized by

a factor of 10–50 (relative to the in-domain *kde* corpus) for the computation of this feature. For the LEGAL domain, the weights are more uniform, which is congruent with our observation that BLEU changes little.

Table 6 shows results for the CZ–EN data set. For each system, MERT is performed on the full development set. As in the first task, adaptation to the full development set is least effective. The systems with unsupervised clusters significantly outperform the baseline. For the system with 16 clusters, we observe an improvement of 0.3 BLEU for TM adaptation, and 0.6 BLEU for adapting both models (34.4  $\rightarrow$  34.7  $\rightarrow$  35.0). The labelled system, i.e. the system with 7 clusters corresponding to the 7 data sources, both for the development and test set, performs best. We observe gains of 0.6 BLEU (34.4  $\rightarrow$  35.0) for TM or LM adaptation, and 1 BLEU (34.4  $\rightarrow$  35.4) when both models are adapted.

We conclude that the translation model architecture is effective in a multi-domain setting, both with unsupervised clusters and labelled domains. The fact that language model adaptation yields an additional improvement in our experiments suggests that it would be worthwhile to also investigate a language model data structure that efficiently supports multiple domains.

## 6 Conclusion

We have presented a novel translation model architecture that delays the computation of translation model features to the decoding phase, and uses a vector of component models for this computation. We have also described a usage scenario for this architecture, namely its ability to quickly switch between weight vectors in order to serve as an adapted model for multiple domains. A simple, unsupervised clustering of development data is sufficient to make use of this ability and imple-

ment a multi-domain translation system. If available, one can also use the architecture in a labelled setting.

Future work could involve merging our translation model framework with the online adaptation of other models, or the log-linear weights. Our approach is orthogonal to that of (Clark et al., 2012), who perform feature augmentation to obtain multiple sets of adapted log-linear weights. While (Clark et al., 2012) use labelled data, their approach could in principle also be applied after unsupervised clustering.

The translation model framework could also serve as the basis of real-time adaptation of translation systems, e.g. by using incremental means to update the weight vector, or having an incrementally trainable component model that learns from the post-edits by the user, and is assigned a suitable weight.

## Abstract

This paper proposes a nonparametric Bayesian method for inducing Part-of-Speech (POS) tags in dependency trees to improve the performance of statistical machine translation (SMT). In particular, we extend the monolingual infinite tree model (Finkel et al., 2007) to a bilingual scenario: each hidden state (POS tag) of a source-side dependency tree emits a source word together with its aligned target word, either jointly (joint model), or independently (independent model). Evaluations of Japanese-to-English translation on the NTCIR-9 data show that our induced Japanese POS tags for dependency trees improve the performance of a forest-to-string SMT system. Our independent model gains over 1 point in BLEU by resolving the sparseness problem introduced in the joint model.

## 1 Introduction

In recent years, syntax-based SMT has made promising progress by employing either dependency parsing (Lin, 2004; Ding and Palmer, 2005; Quirk et al., 2005; Shen et al., 2008; Mi and Liu, 2010) or constituency parsing (Huang et al., 2006; Liu et al., 2006; Galley et al., 2006; Mi and Huang, 2008; Zhang et al., 2008; Cohn and Blunsom, 2009; Liu et al., 2009; Mi and Liu, 2010; Zhang et al., 2011) on the source side, the target side, or both. However, dependency parsing, which is a popular choice for Japanese, can incorporate only shallow syntactic information, i.e., POS tags, compared with the richer syntactic phrasal categories in constituency parsing. Moreover, existing POS tagsets might not be optimal for SMT because they are constructed without considering the language in the other side. Consider the examples in Figure 1. The Japanese noun “利用” in

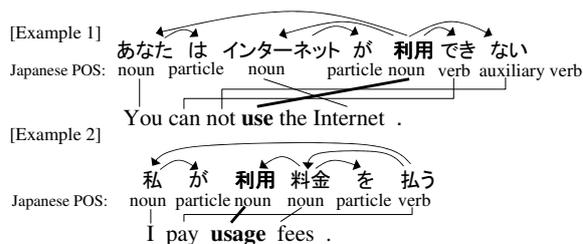

Figure 1: Examples of Existing Japanese POS Tags and Dependency Structures

Example 1 corresponds to the English verb “use”, while that in Example 2 corresponds to the English noun “usage”. Thus, Japanese nouns act like verbs in English in one situation, and nouns in English in another. If we could discriminate POS tags for two cases, we might improve the performance of a Japanese-to-English SMT system.

In the face of the above situations, this paper proposes an unsupervised method for inducing POS tags for SMT, and aims to improve the performance of syntax-based SMT by utilizing the induced POS tagset. The proposed method is based on the infinite tree model proposed by Finkel et al. (2007), which is a nonparametric Bayesian method for inducing POS tags from syntactic dependency structures. In this model, hidden states represent POS tags, the observations they generate represent the words themselves, and tree structures represent syntactic dependencies between pairs of POS tags.

The proposed method builds on this model by incorporating the aligned words in the other language into the observations. We investigate two types of models: (i) a joint model and (ii) an independent model. In the joint model, each hidden state jointly emits both a source word and its aligned target word as an observation. The independent model separately emits words in two languages from hidden states. By inferring POS

tags based on bilingual observations, both models can induce POS tags by incorporating information from the other language. Consider, for example, inducing a POS tag for the Japanese word “利用” in Figure 1. Under a monolingual induction method (e.g., the infinite tree model), the “利用” in Example 1 and 2 would both be assigned the same POS tag since they share the same observation. However, our models would assign separate tags for the two different instances since the “利用” in Example 1 and Example 2 could be disambiguated by encoding the target-side information, either “use” or “usage”, in the observations.

Inference is efficiently carried out by beam sampling (Gael et al., 2008), which combines slice sampling and dynamic programming. Experiments are carried out on the NTCIR-9 Japanese-to-English task using a binarized forest-to-string SMT system with dependency trees as its source side. Our bilingually-induced tagset significantly outperforms the original tagset and the monolingually-induced tagset. Further, our independent model achieves a more than 1 point gain in BLEU, which resolves the sparseness problem introduced by the bi-word observations.

## 2 Related Work

A number of unsupervised methods have been proposed for inducing POS tags. Early methods have the problem that the number of possible POS tags must be provided preliminarily. This limitation has been overcome by automatically adjusting the number of possible POS tags using non-parametric Bayesian methods (Finkel et al., 2007; Gael et al., 2009; Blunsom and Cohn, 2011; Sirts and Alumäe, 2012). Gael et al. (2009) applied infinite HMM (iHMM) (Beal et al., 2001; Teh et al., 2006), a nonparametric version of HMM, to POS induction. Blunsom and Cohn (2011) used a hierarchical Pitman-Yor process prior to the transition and emission distribution for sophisticated smoothing. Sirts and Alumäe (2012) built a model that combines POS induction and morphological segmentation into a single learning problem. Finkel et al. (2007) proposed the infinite tree model, which represents recursive branching structures over infinite hidden states and induces POS tags from syntactic dependency structures. In the following, we overview the infinite tree model, which is the basis of our proposed model. In particular, we will describe the independent children

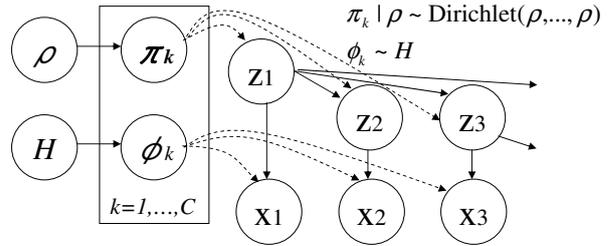

Figure 2: A Graphical Representation of the Finite Tree Model

model (Finkel et al., 2007), where children are dependent only on their parents, used in our proposed model<sup>1</sup>.

### 2.1 Finite Tree Model

We first review the finite tree model, which can be graphically represented in Figure 2. Let  $T_t$  denote the tree whose root node is  $t$ . A node  $t$  has a hidden state  $z_t$  (the POS tag) and an observation  $x_t$  (the word). The probability of a tree  $T_t$ ,  $p_T(T_t)$ , is recursively defined:  $p_T(T_t) = p(x_t|z_t) \prod_{t' \in c(t)} p(z_{t'}|z_t) p_T(T_{t'})$ ,

where  $c(t)$  is the set of the children of  $t$ .

Let each hidden state variable have  $C$  possible values indexed by  $k$ . For each state  $k$ , there is a parameter  $\phi_k$  which parameterizes the observation distribution for that state:  $x_t|z_t \sim F(\phi_{z_t})$ .  $\phi_k$  is distributed according to a prior distribution  $H$ :  $\phi_k \sim H$ .

Transitions between states are governed by Markov dynamics parameterized by  $\pi$ , where  $\pi_{ij} = p(z_{c(t)} = j|z_t = i)$  and  $\pi_k$  are the transition probabilities from the parent’s state  $k$ .  $\pi_k$  is distributed according to a Dirichlet distribution with parameter  $\rho$ :  $\pi_k|\rho \sim \text{Dirichlet}(\rho, \dots, \rho)$ . The hidden state of each child  $z_{t'}$  is distributed according to a multinomial distribution  $\pi_{z_t}$  specific to the parent’s state  $z_t$ :  $z_{t'}|z_t \sim \text{Multinomial}(\pi_{z_t})$ .

### 2.2 Infinite Tree Model

In the infinite tree model, the number of possible hidden states is potentially infinite. The infinite model is formed by extending the finite tree model using a hierarchical Dirichlet process (HDP) (Teh et al., 2006). The reason for using an HDP rather

<sup>1</sup>Finkel et al. (2007) originally proposed three types of models: besides the independent children model, the simultaneous children model and the markov children model. Although we could apply the other two models, we leave this for future work.

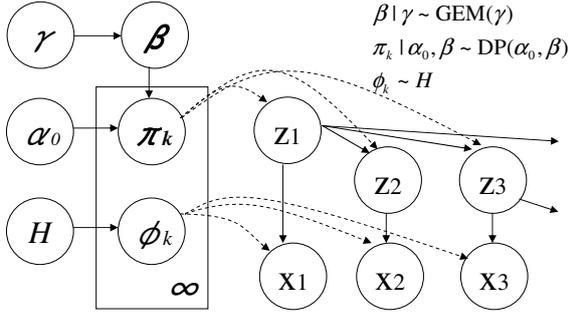

Figure 3: A Graphical Representation of the Infinite Tree Model

than a simple Dirichlet process (DP)<sup>2</sup> (Ferguson, 1973) is that we have to introduce coupling across transitions from different parent’s states. A similar measure was adopted in iHMM (Beal et al., 2001).

HDP is a set of DPs coupled through a shared random base measure which is itself drawn from a DP: each  $G_k \sim \text{DP}(\alpha_0, G_0)$  with a shared base measure  $G_0$ , and  $G_0 \sim \text{DP}(\gamma, H)$  with a global base measure  $H$ . From the viewpoint of the stick-breaking construction<sup>3</sup> (Sethuraman, 1994), the

HDP is interpreted as follows:  $G_0 = \sum_{k'=1}^{\infty} \beta_{k'} \delta_{\phi_{k'}}$

and  $G_k = \sum_{k'=1}^{\infty} \pi_{kk'} \delta_{\phi_{k'}}$ , where  $\beta \sim \text{GEM}(\gamma)$ ,  $\pi_k \sim \text{DP}(\alpha_0, \beta)$ , and  $\phi_{k'} \sim H$ .

We regard each  $G_k$  as two coindexed distributions:  $\pi_k$ , a distribution over the transition probabilities from the parent’s state  $k$ , and  $\phi_{k'}$ , an observation distribution for the state  $k'$ . Then, the infinite tree model is formally defined as follows:

$$\begin{aligned} \beta | \gamma &\sim \text{GEM}(\gamma), \\ \pi_k | \alpha_0, \beta &\sim \text{DP}(\alpha_0, \beta), \\ \phi_k &\sim H, \\ z_t | z_t &\sim \text{Multinomial}(\pi_{z_t}), \\ x_t | z_t &\sim F(\phi_{z_t}). \end{aligned}$$

Figure 3 shows the graphical representation of the infinite tree model. The primary difference be-

<sup>2</sup>DP is a measure on measures. It has two parameters, a scaling parameter  $\alpha$  and a base measure  $H$ :  $\text{DP}(\alpha, H)$ .

<sup>3</sup>Sethuraman (1994) showed a definition of a measure  $G \sim \text{DP}(\alpha_0, G_0)$ . First, infinite sequences of i.i.d variables  $(\pi'_k)_{k=1}^{\infty}$  and  $(\phi_k)_{k=1}^{\infty}$  are generated:  $\pi'_k | \alpha_0 \sim \text{Beta}(1, \alpha_0)$ ,  $\phi_k \sim G_0$ . Then,  $G$  is defined as:  $\pi_k = \pi'_k \sum_{l=1}^{k-1} (1 - \pi'_l)$ ,  $G = \sum_{k=1}^{\infty} \pi_k \delta_{\phi_k}$ . If  $\pi$  is defined by this process, then we write  $\pi \sim \text{GEM}(\alpha_0)$ .

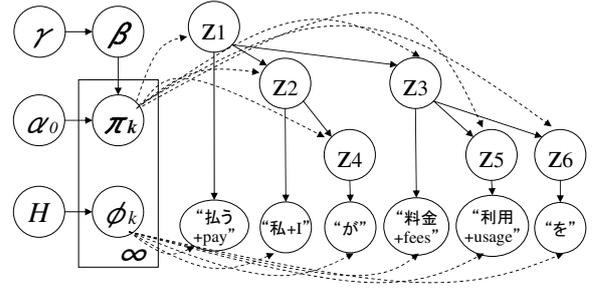

Figure 4: An Example of the Joint Model

tween Figure 2 and Figure 3 is whether the number of copies of the state is finite or not.

### 3 Bilingual Infinite Tree Model

We propose a bilingual variant of the infinite tree model, the bilingual infinite tree model, which utilizes information from the other language. Specifically, the proposed model introduces bilingual observations by embedding the aligned target words in the source-side dependency trees. This paper proposes two types of models that differ in their processes for generating observations: the joint model and the independent model.

#### 3.1 Joint Model

The joint model is a simple application of the infinite tree model under a bilingual scenario. The model is formally defined in the same way as in Section 2.2 and is graphically represented similarly to Figure 3. The only difference from the infinite tree model is the instances of observations ( $x_t$ ). Observations in the joint model are the combination of source words and their aligned target words<sup>4</sup>, while observations in the monolingual infinite tree model represent only source words. For each source word, all the aligned target words are copied and sorted in alphabetical order, and then concatenated into a single observation. Therefore, a single target word may be emitted multiple times if the target word is aligned with multiple source words. Likewise, there may be target words which may not be emitted by our model, if the target words are not aligned.

Figure 4 shows the process of generating Example 2 in Figure 1 through the joint model, where aligned words are jointly emitted as observations. In Figure 4, the POS tag of “利用” ( $z_5$ ) generates

<sup>4</sup>When no target words are aligned, we simply add a NULL target word.

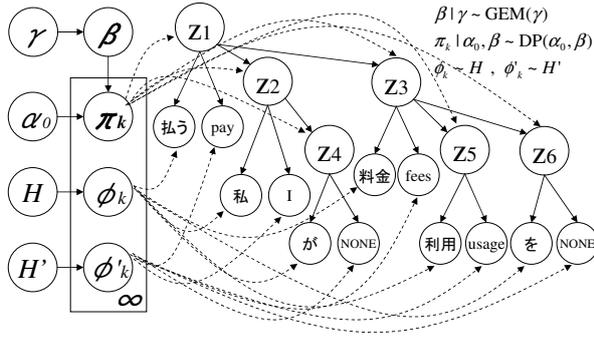

Figure 5: A Graphical Representation of the Independent Model

the string “利用+usage” as the observation ( $x_5$ ). Similarly, the POS tag of “利用” in Example 1 would generate the string “利用+use”. Hence, this model can assign different POS tags to the two different instances of the word “利用”, based on the different observation distributions in inference.

### 3.2 Independent Model

The joint model is prone to a data sparseness problem, since each observation is a combination of a source word and its aligned target word. Thus, we propose an independent model, where each hidden state generates a source word and its aligned target word separately. For the aligned target side, we introduce an observation variable  $x'_t$  for each  $z_t$  and a parameter  $\phi'_k$  for each state  $k$ , which parameterizes a distinct distribution over the observations  $x'_t$  for that state.  $\phi'_k$  is distributed according to a prior distribution  $H'$ . Specifically, the independent model is formally defined as follows:

$$\begin{aligned} \beta | \gamma &\sim \text{GEM}(\gamma), \\ \pi_k | \alpha_0, \beta &\sim \text{DP}(\alpha_0, \beta), \\ \phi_k &\sim H, \quad \phi'_k \sim H', \\ z_{t'} | z_t &\sim \text{Multinomial}(\pi_{z_t}), \\ x_t | z_t &\sim F(\phi_{z_t}), \quad x'_t | z_t \sim F'(\phi'_{z_t}). \end{aligned}$$

When multiple target words are aligned to a single source word, each aligned word is generated separately from observation distribution parameterized by  $\phi'_k$ .

Figure 5 graphs the process of generating Example 2 in Figure 1 using the independent model.  $x'_t$  and  $\phi'_k$  are introduced for aligned target words. The state of “利用” ( $z_5$ ) generates the Japanese word “利用” as  $x_5$  and the English word “usage” as  $x'_5$ . Due to this factorization, the independent model is less subject to the sparseness problem.

### 3.3 Introduction of Other Factors

We assumed the surface form of aligned target words as additional observations in previous sections. Here, we introduce additional factors, i.e., the POS of aligned target words, in the observations. Note that POSs of target words are assigned by a POS tagger in the target language and are not inferred in the proposed model.

First, we can simply replace surface forms of target words with their POSs to overcome the sparseness problem. Second, we can incorporate both information from the target language as observations. In the joint model, two pieces of information are concatenated into a single observation. In the independent model, we introduce observation variables (e.g.,  $x'_t$  and  $x''_t$ ) and parameters (e.g.,  $\phi'_k$  and  $\phi''_k$ ) for each information. Specifically,  $x'_t$  and  $\phi'_k$  are introduced for the surface form of aligned words, and  $x''_t$  and  $\phi''_k$  for the POS of aligned words. Consider, for example, Example 1 in Figure 1. The POS tag of “利用” generates the string “利用+use+verb” as the observation in the joint model, while it generates “利用”, “use”, and “verb” independently in the independent model.

### 3.4 POS Refinement

We have assumed a completely unsupervised way of inducing POS tags in dependency trees. Another realistic scenario is to refine the existing POS tags (Finkel et al., 2007; Liang et al., 2007) so that each refined sub-POS tag may reflect the information from the aligned words while preserving the handcrafted distinction from original POS tagset. Major difference is that we introduce separate transition probabilities  $\pi_k^s$  and observation distributions ( $\phi_k^s, \phi'_k{}^s$ ) for each existing POS tag  $s$ . Then, each node  $t$  is constrained to follow the distributions indicated by the initially assigned POS tag  $s_t$ , and we use the pair  $(s_t, z_t)$  as a state representation.

### 3.5 Inference

In inference, we find the state set that maximizes the posterior probability of state transitions given observations (i.e.,  $P(z_{1:n} | x_{1:n})$ ). However, we cannot evaluate the probability for all possible states because the number of states is infinite. Finkel et al. (2007) presented a sampling algorithm for the infinite tree model, which is based on the Gibbs sampling in the direct assignment representation for iHMM (Teh et al., 2006). In the

Gibbs sampling, individual hidden state variables are resampled conditioned on all other variables. Unfortunately, its convergence is slow in HMM settings because sequential data is likely to have a strong correlation between hidden states (Gael et al., 2008).

We present an inference procedure based on beam sampling (Gael et al., 2008) for the joint model and the independent model. Beam sampling limits the number of possible state transitions for each node to a finite number using slice sampling (Neal, 2003), and then efficiently samples whole hidden state transitions using dynamic programming. Beam sampling does not suffer from slow convergence as in Gibbs sampling by sampling the whole state variables at once. In addition, Gael et al. (2008) showed that beam sampling is more robust to initialization and hyperparameter choice than Gibbs sampling.

Specifically, we introduce an auxiliary variable  $u_t$  for each node in a dependency tree to limit the number of possible transitions. Our procedure alternates between sampling each of the following variables: the auxiliary variables  $\mathbf{u}$ , the state assignments  $\mathbf{z}$ , the transition probabilities  $\boldsymbol{\pi}$ , the shared DP parameters  $\boldsymbol{\beta}$ , and the hyperparameters  $\alpha_0$  and  $\gamma$ . We can parallelize procedures in sampling  $\mathbf{u}$  and  $\mathbf{z}$  because the slice sampling for  $\mathbf{u}$  and the dynamic programming for  $\mathbf{z}$  are independent for each sentence. See Gael et al. (2009) for details.

The only difference between inferences in the joint model and the independent model is in computing the posterior probability of state transitions given observations (e.g.,  $p(z_{1:n}|x_{1:n})$  and  $p(z_{1:n}|x_{1:n}, x'_{1:n})$ ) in sampling  $\mathbf{z}$ . In the following, we describe each sampling stage. See Teh et al., (2006) for details of sampling  $\boldsymbol{\pi}$ ,  $\boldsymbol{\beta}$ ,  $\alpha_0$  and  $\gamma$ .

### Sampling $\mathbf{u}$ :

Each  $u_t$  is sampled from the uniform distribution on  $[0, \pi_{z_{d(t)}z_t}]$ , where  $d(t)$  is the parent of  $t$ :  $u_t \sim \text{Uniform}(0, \pi_{z_{d(t)}z_t})$ . Note that  $u_t$  is a positive number, since each transition probability  $\pi_{z_{d(t)}z_t}$  is larger than zero.

### Sampling $\mathbf{z}$ :

Possible values  $k$  of  $z_t$  are divided into the two sets using  $u_t$ : a finite set with  $\pi_{z_{d(t)}k} > u_t$  and an infinite set with  $\pi_{z_{d(t)}k} \leq u_t$ . The beam sampling considers only the former set. Owing to the truncation of the latter set, we can compute the posterior probability of a state  $z_t$  given ob-

servations for all  $t$  ( $t = 1, \dots, T$ ) using dynamic programming as follows:

In the joint model,  $p(z_t|x_{\sigma(t)}, u_{\sigma(t)}) \propto p(x_t|z_t) \cdot \sum_{z_{d(t)}: \pi_{z_{d(t)}z_t} > u_t} p(z_{d(t)}|x_{\sigma(d(t))}, u_{\sigma(d(t))})$ ,

and in the independent model,  $p(z_t|x_{\sigma(t)}, x'_{\sigma(t)}, u_{\sigma(t)}) \propto p(x_t|z_t) \cdot p(x'_t|z_t) \cdot \sum_{z_{d(t)}: \pi_{z_{d(t)}z_t} > u_t} p(z_{d(t)}|x_{\sigma(d(t))}, x'_{\sigma(d(t))}, u_{\sigma(d(t))})$ ,

where  $x_{\sigma(t)}$  (or  $u_{\sigma(t)}$ ) denotes the set of  $x_t$  (or  $u_t$ ) on the path from the root node to the node  $t$  in a tree.

In our experiments, we assume that  $F(\phi_k)$  is Multinomial( $\phi_k$ ) and  $H$  is Dirichlet( $\rho, \dots, \rho$ ), which is the same in Finkel et al. (2007). Under this assumption, the posterior probability of an observation is as follows:  $p(x_t|z_t) = \frac{\dot{n}_{x_tk} + \rho}{\dot{n}_{\cdot k} + N\rho}$ , where  $\dot{n}_{x_tk}$  is the number of observations  $x$  with state  $k$ ,  $\dot{n}_{\cdot k}$  is the number of hidden states whose values are  $k$ , and  $N$  is the total number of observations  $\mathbf{x}$ . Similarly,  $p(x'_t|z_t) = \frac{\dot{n}'_{x'_tk} + \rho'}{\dot{n}'_{\cdot k} + N'\rho'}$ , where  $N'$  is the total number of observations  $\mathbf{x}'$ .

When the posterior probability of a state  $z_t$  given observations for all  $t$  can be computed, we first sample the state of each leaf node and then perform backtrack sampling for every other  $z_t$  where the  $z_t$  is sampled given the sample for  $z_{c(t)}$  as follows:  $p(z_t|z_{c(t)}, x_{1:T}, u_{1:T}) \propto p(z_t|x_{\sigma(t)}, u_{\sigma(t)}) \prod_{t' \in c(t)} p(z_{t'}|z_t, u_{t'})$ .

### Sampling $\boldsymbol{\pi}$ :

We introduce a count variable  $n_{ij} \in \mathbf{n}$ , which is the number of observations with state  $j$  whose parent's state is  $i$ . Then, we sample  $\boldsymbol{\pi}$  using the Dirichlet distribution:  $(\pi_{k1}, \dots, \pi_{kK}, \sum_{k'=K+1}^{\infty} \pi_{kk'}) \sim \text{Dirichlet}(n_{k1} + \alpha_0\beta_1, \dots, n_{kK} + \alpha_0\beta_K, \alpha_0 \sum_{k'=K+1}^{\infty} \beta_{k'})$ , where  $K$  is the number of distinct states in  $\mathbf{z}$ .

### Sampling $\boldsymbol{\beta}$ :

We introduce a set of auxiliary variables  $\mathbf{m}$ , where  $m_{ij} \in \mathbf{m}$  is the number of elements of  $\boldsymbol{\pi}_j$  corresponding to  $\beta_i$ . The conditional distribution of each variable is  $p(m_{ij} = m|z, \boldsymbol{\beta}, \alpha_0) \propto S(n_{ij}, m)(\alpha_0\beta_j)^m$ , where  $S(n, m)$  are unsigned Stirling numbers of the first kind<sup>5</sup>.

<sup>5</sup> $S(0, 0) = S(1, 1) = 1$ ,  $S(n, 0) = 0$  for  $n > 0$ ,  $S(n, m) = 0$  for  $m > n$ , and  $S(n + 1, m) = S(n, m - 1) + nS(n, m)$  for others.

The parameters  $\beta$  are sampled using the Dirichlet distribution:  $(\beta_1, \dots, \beta_K, \sum_{k'=K+1}^{\infty} \beta_{k'}) \sim \text{Dirichlet}(m_{\cdot 1}, \dots, m_{\cdot K}, \gamma)$ , where  $m_{\cdot k} = \sum_{k'=1}^K m_{k'k}$ .

### Sampling $\alpha_0$ :

$\alpha_0$  is parameterized by a gamma hyperprior with hyperparameters  $\alpha_a$  and  $\alpha_b$ . We introduce two types of auxiliary variables for each state ( $k = 1, \dots, K$ ),  $w_k \in [0, 1]$  and  $v_k \in \{0, 1\}$ . The conditional distribution of each  $w_k$  is  $p(w_k|\alpha_0) \propto w_k^{\alpha_0} (1-w_k)^{n_{\cdot k}-1}$  and that of each  $v_k$  is  $p(v_k|\alpha_0) \propto \left(\frac{n_{\cdot k}}{\alpha_0}\right)^{v_k}$ , where  $n_{\cdot k} = \sum_{k'=1}^K n_{k'k}$ . The conditional distribution of  $\alpha_0$  given  $w_k$  and  $v_k$  ( $k = 1, \dots, K$ ) is  $p(\alpha_0|\mathbf{w}, \mathbf{v}) \propto \alpha_0^{\alpha_a-1+m_{\cdot\cdot}-\sum_{k=1}^K v_k} e^{-\alpha_0(\alpha_b-\sum_{k=1}^K \log w_k)}$ , where  $m_{\cdot\cdot} = \sum_{k'=1}^K \sum_{k''=1}^K m_{k'k''}$ .

### Sampling $\gamma$ :

$\gamma$  is parameterized by a gamma hyperprior with hyperparameters  $\gamma_a$  and  $\gamma_b$ . We introduce an auxiliary variable  $\eta$ , whose conditional distribution is  $p(\eta|\gamma) \propto \eta^\gamma (1-\eta)^{m_{\cdot\cdot}-1}$ . The conditional distribution of  $\gamma$  given  $\eta$  is  $p(\gamma|\eta) \propto \gamma^{\gamma_a-1+K} e^{-\gamma(\gamma_b-\log \eta)}$ .

## 4 Experiment

We tested our proposed models under the NTCIR-9 Japanese-to-English patent translation task (Goto et al., 2011), consisting of approximately 3.2 million bilingual sentences. Both the development data and the test data consist of 2,000 sentences. We also used the NTCIR-7 development data consisting of 2,741 sentences for development testing purposes.

### 4.1 Experimental Setup

We evaluated our bilingual infinite tree model for POS induction using an in-house developed syntax-based forest-to-string SMT system. In the training process, the following steps are performed sequentially: preprocessing, inducing a POS tagset for a source language, training a POS tagger and a dependency parser, and training a forest-to-string MT model.

#### Step 1. Preprocessing

We used the first 10,000 Japanese-English sentence pairs in the NTCIR-9 training data for in-

ducing a POS tagset for Japanese<sup>6</sup>. The Japanese sentences were segmented using MeCab<sup>7</sup>, and the English sentences were tokenized and POS tagged using TreeTagger (Schmid, 1994), where 43 and 58 types of POS tags are included in the Japanese sentences and the English sentences, respectively. The Japanese POS tags come from the second-level POS tags in the IPA POS tagset (Asahara and Matsumoto, 2003) and the English POS tags are derived from the Penn Treebank. Note that the Japanese POS tags are used for initialization of hidden states and the English POS tags are used as observations emitted by hidden states.

Word-by-word alignments for the sentence pairs are produced by first running GIZA++ (Och and Ney, 2003) in both directions and then combining the alignments using the “grow-diag-final-and” heuristic (Koehn et al., 2003). Note that we ran GIZA++ on all of the NTCIR-9 training data in order to obtain better alignments.

The Japanese sentences are parsed using CaboCha (Kudo and Matsumoto, 2002), which generates dependency structures using a phrasal unit called a *bunsetsu*<sup>8</sup>, rather than a word unit as in English or Chinese dependency parsing. Since we focus on the word-level POS induction, each *bunsetsu*-based dependency tree is converted into its corresponding word-based dependency tree using the following heuristic<sup>9</sup>: first, the last function word inside each *bunsetsu* is identified as the head word<sup>10</sup>; then, the remaining words are treated as dependents of the head word in the same *bunsetsu*; finally, a *bunsetsu*-based dependency structure is transformed to a word-based dependency structure by preserving the head/modifier relationships of the determined head words.

#### Step 2. POS Induction

A POS tag for each word in the Japanese sentences is inferred by our bilingual infinite tree model, ei-

<sup>6</sup>Due to the high computational cost, we did not use all the NTCIR-9 training data. We leave scaling up to a larger dataset for future work.

<sup>7</sup><http://mecab.googlecode.com/svn/trunk/mecab/doc/index.html>

<sup>8</sup>A *bunsetsu* is the smallest meaningful sequence consisting of a content word and accompanying function words (e.g., a noun and a particle).

<sup>9</sup>We could use other word-based dependency trees such as trees by the infinite PCFG model (Liang et al., 2007) and syntactic-head or semantic-head dependency trees in Nakazawa and Kurohashi (2012), although it is not our major focus. We leave this for future work.

<sup>10</sup>If no function words exist in a *bunsetsu*, the last content word is treated as the head word.

ther jointly (*Joint*) or independently (*Ind*). We also performed monolingual induction of Finkel et al. (2007) for comparison (*Mono*). In each model, a sequence of sampling  $u$ ,  $z$ ,  $\pi$ ,  $\beta$ ,  $\alpha_0$ , and  $\gamma$  is repeated 10,000 times. In sampling  $\alpha_0$  and  $\gamma$ , hyperparameters  $\alpha_a$ ,  $\alpha_b$ ,  $\gamma_a$ , and  $\gamma_b$  are set to 2, 1, 1, and 1, respectively, which is the same setting in Gael et al. (2008). In sampling  $z$ , parameters  $\rho$ ,  $\rho'$ ,  $\dots$ , are set to 0.01. In the experiments, three types of factors for the aligned English words are compared: surface forms ('s'), POS tags ('P'), and the combination of both ('s+P'). Further, two types of inference frameworks are compared: *induction* (*IND*) and *refinement* (*REF*). In both frameworks, each hidden state  $z_t$  is first initialized to the POS tags assigned by MeCab (the IPA POS tagset), and then each state is updated through the inference procedure described in Section 3.5. Note that in *REF*, the sampling distribution over  $z_t$  is constrained to include only states that are a refinement of the initially assigned POS tag.

### Step 3. Training a POS Tagger and a Dependency Parser

In this step, we train a Japanese dependency parser from the 10,000 Japanese dependency trees with the induced POS tags which are derived from Step 2. We employed a transition-based dependency parser which can jointly learn POS tagging and dependency parsing (Hatori et al., 2011) under an incremental framework<sup>11</sup>. Note that the learned parser can identify dependencies between words and attach an induced POS tag for each word.

### Step 4. Training a Forest-to-String MT

In this step, we train a forest-to-string MT model based on the learned dependency parser in Step 3. We use an in-house developed hypergraph-based toolkit, *cicada*, for training and decoding with a tree-to-string model, which has been successfully employed in our previous work for system combination (Watanabe and Sumita, 2011) and online learning (Watanabe, 2012). All the Japanese and English sentences in the NTCIR-9 training data are segmented in the same way as in Step 1, and then each Japanese sentence is parsed by the dependency parser learned in Step 3, which simultaneously assigns induced POS tags and word dependencies. Finally, a forest-to-string MT model is learned with Zhang et al., (2011), which extracts translation rules by a forest-based variant of

<sup>11</sup><http://triple.cc/software/corbit/>

<i>Joint</i> [P]	26.36	26.72
<i>Joint</i> [s+P]	<b>27.99</b>	<b>27.82</b>
<i>Ind</i> [s]	<b>28.00</b>	<b>27.93</b>
<i>Ind</i> [P]	<b>28.11</b>	<b>28.63</b>
<i>Ind</i> [s+P]	<b>28.13</b>	<b>28.62</b>

Table 1: Performance on Japanese-to-English Translation Measured by BLEU (%)

the GHKM algorithm (Mi and Huang, 2008) after each parse tree is restructured into a binarized packed forest. Parameters are tuned on the development data using xBLEU (Rosti et al., 2011) as an objective and L-BFGS (Liu and Nocedal, 1989) as an optimization toolkit, since it is stable and less prone to randomness, unlike MERT (Och, 2003) or PRO (Hopkins and May, 2011). The development test data is used to set up hyperparameters, i.e., to terminate tuning iterations.

When translating Japanese sentences, a parse tree for each sentence is constructed in the same way as described earlier in this step, and then the parse trees are translated into English sentences using the learned forest-to-string MT model.

## 4.2 Experimental Results

Table 1 shows the performance for the test data measured by case sensitive BLEU (Papineni et al., 2002). We also present the performance of our baseline forest-to-string MT system (*BS*) using the original IPA POS tags. In Table 1, numbers in bold indicate that the systems outperform the baselines, *BS* and *Mono*. Under the Moses phrase-based SMT system (Koehn et al., 2007) with the default settings, we achieved a 26.80% BLEU score.

Table 1 shows that the proposed systems outperform the baseline *Mono*. The differences between the performance of *Ind*[s+P] and *Mono* are statistically significant in the bootstrap method (Koehn, 2004), with a 1% significance level both in *IND* and *REF*. The results indicate that integrating the aligned target-side information in POS induction makes inferred tagsets more suitable for SMT.

Table 1 also shows that the independent model is more effective for SMT than the joint model. This means that sparseness is a severe problem in

Model	<i>IND</i>	<i>REF</i>
<i>Joint</i> [s+P]	164	620
<i>Ind</i> [s+P]	102	517
IPA POS tags	42	

Table 2: The Number of POS Tags

POS induction when jointly encoding bilingual information into observations. Additionally, all the systems using the independent model outperform *BS*. The improvements are statistically significant in the bootstrap method (Koehn, 2004), with a 1% significance level. The results show that the proposed models can generate more favorable POS tagsets for SMT than an existing POS tagset.

In Table 1, *REF*s are at least comparable to, or better than, *IND*s except for *Mono*. This shows that *REF* achieves better performance by preserving the clues from the original POS tagset. However, *REF* may suffer severe overfitting problem for *Mono* since no bilingual information was incorporated. Further, when the full-level IPA POS tags<sup>12</sup> were used in *BS*, the system achieved a 27.49% BLEU score, which is worse than the result using the second-level IPA POS tags. This means that manual refinement without bilingual information may also cause an overfitting problem in MT.

## 5 Discussion

### 5.1 Comparison to the IPA POS Tagset

Table 2 shows the number of the IPA POS tags used in the experiments and the POS tags induced by the proposed models. This table shows that each induced tagset contains more POS tags than the IPA POS tagset. In the experimental data, some of Japanese verbs correspond to genuine English verbs, some are nominalized, and others correspond to English past participle verbs or present participle verbs which modify other words. Respective examples are “I use a card.”, “Using the index is faster.”, and “I explain using an example.”, where all the underlined words correspond to the same Japanese word, “用い”, whose IPA POS tag is a verb. *Ind*[s+P] in *REF* generated the POS tagset where the three types are assigned to separate POS groups.

The Japanese particle “に” is sometimes attached to nouns to give them adverb roles. For

<sup>12</sup>377 types of full-level IPA POS tags were included in our experimental data.

	Tagging		Dependency	
	<i>IND</i>	<i>REF</i>	<i>IND</i>	<i>REF</i>
<i>Original</i>	90.37		93.62	
<i>Mono</i>	90.75	88.04	91.77	91.51
<i>Joint</i> [s]	89.08	86.73	91.55	91.14
<i>Joint</i> [P]	80.54	79.98	91.06	91.29
<i>Joint</i> [s+P]	87.56	84.92	91.31	91.10
<i>Ind</i> [s]	87.62	84.33	92.06	92.58
<i>Ind</i> [P]	90.21	88.50	92.85	93.03
<i>Ind</i> [s+P]	89.57	86.12	92.96	92.78

Table 3: Tagging and Dependency Accuracy (%)

example, “相互 (mutual) に” is translated as the adverb “mutually” in English. Other times, it is attached to words to make them the objects of verbs. For example, “彼 (he) に 与える (give)” is translated as “give him”. The POS tags by *Ind*[s+P] in *REF* discriminated the two types.

These examples show that the proposed models can disambiguate POS tags that have different functions in English, whereas the IPA POS tagset treats them jointly. Thus, such discrimination improves the performance of a forest-to-string SMT.

### 5.2 Impact of Tagging and Dependency Accuracy

The performance of our methods depends not only on the quality of the induced tag sets but also on the performance of the dependency parser learned in Step 3 of Section 4.1. We cannot directly evaluate the tagging accuracy of the parser trained through Step 3 because we do not have any data with induced POS tags other than the 10,000-sentence data gained through Step 2. Thus we split the 10,000 data into the first 9,000 data for training and the remaining 1,000 for testing, and then a dependency parser was learned in the same way as in Step 3.

Table 3 shows the results. *Original* is the performance of the parser learned from the training data with the original POS tagset. Note that the dependency accuracies are measured on the automatically parsed dependency trees, not on the syntactically correct gold standard trees. Thus *Original* achieved the best dependency accuracy.

In Table 3, the performance for our bilingually-induced POSs, *Joint* and *Ind*, are lower than *Original* and *Mono*. It seems performing parsing and tagging with the bilingually-induced POS tagset is too difficult when only monolingual in-

formation is available to the parser. However, our bilingually-induced POSs, except for *Joint[P]*, with the lower accuracies are more effective for SMT than the monolingually-induced POSs and the original POSs, as indicated in Table 1. The tagging accuracies for *Joint[P]* both in *IND* and *REF* are significantly lower than the others, while the dependency accuracies do not differ significantly. The lower tagging accuracies may directly reflect the lower translation qualities for *Joint[P]* in Table 1.

## 6 Conclusion

We proposed a novel method for inducing POS tags for SMT. The proposed method is a non-parametric Bayesian method, which infers hidden states (i.e., POS tags) based on observations representing not only source words themselves but also aligned target words. Our experiments showed that a more favorable POS tagset can be induced by integrating aligned information, and furthermore, the POS tagset generated by the proposed method is more effective for SMT than an existing POS tagset (the IPA POS tagset).

Even though we employed word alignment from GIZA++ with potential errors, large gains were achieved using our proposed method. We would like to investigate the influence of alignment errors in the future. In addition, we are planning to prove the effectiveness of our proposed method for language pairs other than Japanese-to-English. We are also planning to introduce our proposed method to other syntax-based SMT, such as a string-to-tree SMT and a tree-to-tree SMT.

## Acknowledgments

We thank Isao Goto for helpful discussions and anonymous reviewers for valuable comments. We also thank Jun Hatori for helping us to apply his software, Corbit, to our induced POS tagsets.

## Abstract

Community question answering (CQA) has become an increasingly popular research topic. In this paper, we focus on the problem of question retrieval. Question retrieval in CQA can automatically find the most relevant and recent questions that have been solved by other users. However, the word ambiguity and word mismatch problems bring about new challenges for question retrieval in CQA. State-of-the-art approaches address these issues by implicitly expanding the queried questions with additional words or phrases using monolingual translation models. While useful, the effectiveness of these models is highly dependent on the availability of quality parallel monolingual corpora (e.g., question-answer pairs) in the absence of which they are troubled by noise issue. In this work, we propose an alternative way to address the word ambiguity and word mismatch problems by taking advantage of potentially rich semantic information drawn from other languages. Our proposed method employs statistical machine translation to improve question retrieval and enriches the question representation with the translated words from other languages via matrix factorization. Experiments conducted on a real CQA data show that our proposed approach is promising.

## 1 Introduction

With the development of Web 2.0, community question answering (CQA) services like Yahoo!

Answers,<sup>1</sup> Baidu Zhidao<sup>2</sup> and WkiAnswers<sup>3</sup> have attracted great attention from both academia and industry (Jeon et al., 2005; Xue et al., 2008; Adamic et al., 2008; Wang et al., 2009; Cao et al., 2010). In CQA, anyone can ask and answer questions on any topic, and people seeking information are connected to those who know the answers. As answers are usually explicitly provided by human, they can be helpful in answering real world questions.

In this paper, we focus on the task of question retrieval. Question retrieval in CQA can automatically find the most relevant and recent questions (historical questions) that have been solved by other users, and then the best answers of these historical questions will be used to answer the users' queried questions. However, question retrieval is challenging partly due to the **word ambiguity** and **word mismatch** between the queried questions and the historical questions in the archives. **Word ambiguity** often causes the retrieval models to retrieve many historical questions that do not match the users' intent. This problem is also amplified by the high diversity of questions and users. For example, depending on different users, the word "interest" may refer to "curiosity", or "a charge for borrowing money".

Another challenge is **word mismatch** between the queried questions and the historical questions. The queried questions may contain words that are different from, but related to, the words in the relevant historical questions. For example, if a queried question contains the word "company" but a relevant historical question instead contains the word "firm", then there is a mismatch and the historical

word ambiguity	How do I get a loan from a <b>bank</b> ?	我(wǒ) 如何(rúhé) 从(cóng) 银行(yínháng) 贷款(dàikuǎn) ?
	How to reach the <b>bank</b> of the river?	如何(rúhé) 前往(qiánwǎng) 河岸(héàn) ?
word mismatch	company	公司(gōngsī)
	firm	公司(gōngsī)
	rheum	感冒(gǎnmào)
	catarrh	感冒(gǎnmào)

Table 1: Google translate: some illustrative examples.

question may not be easily distinguished from an irrelevant one.

Researchers have proposed the use of word-based translation models (Berger et al., 2000; Jeon et al., 2005; Xue et al., 2008; Lee et al., 2008; Bernhard and Gurevych, 2009) to solve the word mismatch problem. As a principle approach to capture semantic word relations, word-based translation models are built by using the IBM model 1 (Brown et al., 1993) and have been shown to outperform traditional models (e.g., VSM, BM25, LM) for question retrieval. Besides, Riezler et al. (2007) and Zhou et al. (2011) proposed the phrase-based translation models for question and answer retrieval. The basic idea is to capture the contextual information in modeling the translation of phrases as a whole, thus the word ambiguity problem is somewhat alleviated. However, all these existing studies in the literature are basically *monolingual approaches* which are restricted to the use of original language of questions. While useful, the effectiveness of these models is highly dependent on the availability of quality parallel monolingual corpora (e.g., question-answer pairs) in the absence of which they are troubled by noise issue. In this work, we propose an alternative way to address the word ambiguity and word mismatch problems by taking advantage of potentially rich semantic information drawn from other languages. Through other languages, various ways of adding semantic information to a question could be available, thereby leading to potentially more improvements than using the original language only.

Taking a step toward using other languages, we propose the use of *translated representation* by alternatively enriching the original questions with the words from other languages. The idea of improving question retrieval with statistical machine translation is based on the following two observa-

tions: (1) Contextual information is exploited during the translation from one language to another. For example in Table 1, English words “interest” and “bank” that have multiple meanings under different contexts are correctly addressed by using the state-of-the-art translation tool — **Google Translate**.<sup>4</sup> Thus, word ambiguity based on contextual information is naturally involved when questions are translated. (2) Multiple words that have similar meanings in one language may be translated into an unique word or a few words in a foreign language. For example in Table 1, English words such as “company” and “firm” are translated into “公司(gōngsī)”, “rheum” and “catarrh” are translated into “感冒(gǎnmào)” in Chinese. Thus, word mismatch problem can be somewhat alleviated by using other languages.

Although Zhou et al. (2012) exploited bilingual translation for question retrieval and obtained the better performance than traditional monolingual translation models. However, there are two problems with this enrichment: (1) enriching the original questions with the translated words from other languages increases the dimensionality and makes the question representation even more sparse; (2) statistical machine translation may introduce noise, which can harm the performance of question retrieval. To solve these two problems, we propose to leverage statistical machine translation to improve question retrieval via matrix factorization.

The remainder of this paper is organized as follows. Section 2 describes the proposed method by leveraging statistical machine translation to improve question retrieval via matrix factorization. Section 3 presents the experimental results. In section 4, we conclude with ideas for future research.

<sup>4</sup><http://translate.google.com/translate.t>

## 2 Our Approach

### 2.1 Problem Statement

This paper aims to leverage statistical machine translation to enrich the question representation. In order to address the word ambiguity and word mismatch problems, we expand a question by adding its translation counterparts. Statistical machine translation (e.g., Google Translate) can utilize contextual information during the question translation, so it can solve the word ambiguity and word mismatch problems to some extent.

Let  $L = \{l_1, l_2, \dots, l_P\}$  denote the language set, where  $P$  is the number of languages considered in the paper,  $l_1$  denotes the original language (e.g., English) while  $l_2$  to  $l_P$  are the foreign languages. Let  $D_1 = \{d_1^{(1)}, d_2^{(1)}, \dots, d_N^{(1)}\}$  be the set of historical question collection in original language, where  $N$  is the number of historical questions in  $D_1$  with vocabulary size  $M_1$ . Now we first translate each original historical question from language  $l_1$  into other languages  $l_p$  ( $p \in [2, P]$ ) by Google Translate. Thus, we can obtain  $D_2, \dots, D_P$  in different languages, and  $M_p$  is the vocabulary size of  $D_p$ . A question  $d_i^{(p)}$  in  $D_p$  is simply represented as a  $M_p$  dimensional vector  $\mathbf{d}_i^{(p)}$ , in which each entry is calculated by tf-idf. The  $N$  historical questions in  $D_p$  are then represented in a  $M_p \times N$  term-question matrix  $\mathbf{D}_p = \{\mathbf{d}_1^{(p)}, \mathbf{d}_2^{(p)}, \dots, \mathbf{d}_N^{(p)}\}$ , in which each row corresponds to a term and each column corresponds to a question.

Intuitively, we can enrich the original question representation by adding the translated words from language  $l_2$  to  $l_P$ , the original vocabulary size is increased from  $M_1$  to  $\sum_{p=1}^P M_p$ . Thus, the term-question matrix becomes  $\mathbf{D} = \{\mathbf{D}_1, \mathbf{D}_2, \dots, \mathbf{D}_P\}$  and  $\mathbf{D} \in \mathbb{R}^{(\sum_{p=1}^P M_p) \times N}$ . However, there are two problems with this enrichment: (1) enriching the original questions with the translated words from other languages makes the question representation even more sparse; (2) statistical machine translation may introduce noise.<sup>5</sup> To solve these two problems, we propose to leverage statistical machine translation to improve question retrieval via matrix factorization. Figure 1 presents the framework of our proposed method, where  $q_i$  represents a queried question, and  $\mathbf{q}_i$  is a vector representation of  $q_i$ .

<sup>5</sup>Statistical machine translation quality is far from satisfactory in real applications.

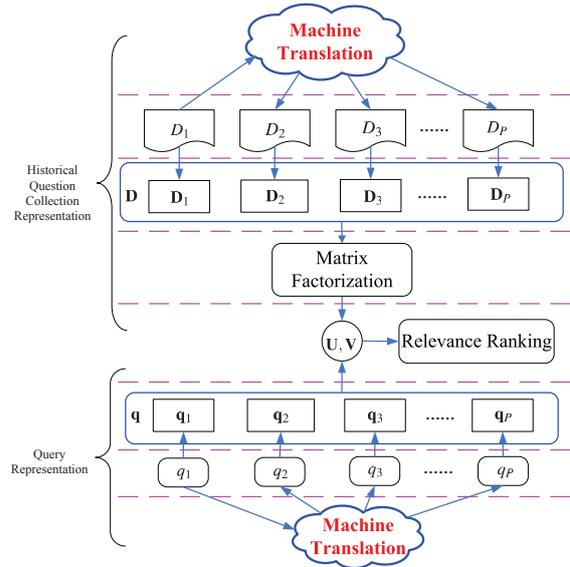

Figure 1: Framework of our proposed approach for question retrieval.

### 2.2 Model Formulation

To tackle the data sparseness of question representation with the translated words, we hope to find two or more lower dimensional matrices whose product provides a good approximate to the original one via matrix factorization. Previous studies have shown that there is psychological and physiological evidence for parts-based representation in the human brain (Wachsmuth et al., 1994). The non-negative matrix factorization (NMF) is proposed to learn the parts of objects like text documents (Lee and Seung, 2001). NMF aims to find two non-negative matrices whose product provides a good approximation to the original matrix and has been shown to be superior to SVD in document clustering (Xu et al., 2003; Tang et al., 2012).

In this paper, NMF is used to induce the reduced representation  $\mathbf{V}_p$  of  $\mathbf{D}_p$ ,  $\mathbf{D}_p$  is independent on  $\{\mathbf{D}_1, \mathbf{D}_2, \dots, \mathbf{D}_{p-1}, \mathbf{D}_{p+1}, \dots, \mathbf{D}_P\}$ . When ignoring the coupling between  $\mathbf{V}_p$ , it can be solved by minimizing the objective function as follows:

$$\mathcal{O}_1(\mathbf{U}_p, \mathbf{V}_p) = \min_{\mathbf{U}_p \geq 0, \mathbf{V}_p \geq 0} \|\mathbf{D}_p - \mathbf{U}_p \mathbf{V}_p\|_F^2 \quad (1)$$

where  $\|\cdot\|_F$  denotes Frobenius norm of a matrix. Matrices  $\mathbf{U}_p \in \mathbb{R}^{M_p \times K}$  and  $\mathbf{V}_p \in \mathbb{R}^{K \times N}$  are the reduced representation for terms and questions in the  $K$  dimensional space, respectively.

To reduce the noise introduced by statistical machine translation, we assume that  $\mathbf{V}_p$  from language  $\mathbf{D}_p$  ( $p \in [2, P]$ ) should be close to  $\mathbf{V}_1$

from the original language  $\mathbf{D}_1$ . Based on this assumption, we minimize the distance between  $\mathbf{V}_p$  ( $p \in [2, P]$ ) and  $\mathbf{V}_1$  as follows:

$$\mathcal{O}_2(\mathbf{V}_p) = \min_{\mathbf{V}_p \geq 0} \sum_{p=2}^P \|\mathbf{V}_p - \mathbf{V}_1\|_F^2 \quad (2)$$

Combining equations (1) and (2), we get the following objective function:

$$\begin{aligned} \mathcal{O}(\mathbf{U}_1, \dots, \mathbf{U}_P; \mathbf{V}_1, \dots, \mathbf{V}_P) \\ = \sum_{p=1}^P \|\mathbf{D}_p - \mathbf{U}_p \mathbf{V}_p\|_F^2 + \sum_{p=2}^P \lambda_p \|\mathbf{V}_p - \mathbf{V}_1\|_F^2 \end{aligned} \quad (3)$$

where parameter  $\lambda_p$  ( $p \in [2, P]$ ) is used to adjust the relative importance of these two components. If we set a small value for  $\lambda_p$ , the objective function behaves like the traditional NMF and the importance of data sparseness is emphasized; while a big value of  $\lambda_p$  indicates  $\mathbf{V}_p$  should be very closed to  $\mathbf{V}_1$ , and equation (3) aims to remove the noise introduced by statistical machine translation.

By solving the optimization problem in equation (4), we can get the reduced representation of terms and questions.

$$\begin{aligned} \min \mathcal{O}(\mathbf{U}_1, \dots, \mathbf{U}_P; \mathbf{V}_1, \dots, \mathbf{V}_P) \\ \text{subject to : } \mathbf{U}_p \geq 0, \mathbf{V}_p \geq 0, p \in [1, P] \end{aligned} \quad (4)$$

### 2.3 Optimization

The objective function  $\mathcal{O}$  defined in equation (4) performs data sparseness and noise removing simultaneously. There are  $2P$  coupling components in  $\mathcal{O}$ , and  $\mathcal{O}$  is not convex in both  $\mathbf{U}$  and  $\mathbf{V}$  together. Therefore it is unrealistic to expect an algorithm to find the global minima. In the following, we introduce an iterative algorithm which can achieve local minima. In our optimization framework, we optimize the objective function in equation (4) by alternatively minimizing each component when the remaining  $2P - 1$  components are fixed. This procedure is summarized in Algorithm 1.

#### 2.3.1 Update of Matrix $\mathbf{U}_p$

Holding  $\mathbf{V}_1, \dots, \mathbf{V}_P$  and  $\mathbf{U}_1, \dots, \mathbf{U}_{p-1}, \mathbf{U}_{p+1}, \dots, \mathbf{U}_P$  fixed, the update of  $\mathbf{U}_p$  amounts to the following optimization problem:

$$\min_{\mathbf{U}_p \geq 0} \|\mathbf{D}_p - \mathbf{U}_p \mathbf{V}_p\|_F^2 \quad (5)$$

---

#### Algorithm 1 Optimization framework

---

**Input:**  $\mathbf{D}_p \in \mathbb{R}^{m_p \times N}$ ,  $p \in [1, P]$   
1: **for**  $p = 1 : P$  **do**  
2:  $\mathbf{V}_p^{(0)} \in \mathbb{R}^{K \times N} \leftarrow$  random matrix  
3: **for**  $t = 1 : T$  **do**  $\triangleright T$  is iteration times  
4:  $\mathbf{U}_p^{(t)} \leftarrow$  Update $\mathbf{U}(\mathbf{D}_p, \mathbf{V}_p^{(t-1)})$   
5:  $\mathbf{V}_p^{(t)} \leftarrow$  Update $\mathbf{V}(\mathbf{D}_p, \mathbf{U}_p^{(t)})$   
6: **end for**  
7: **return**  $\mathbf{U}_p^{(T)}, \mathbf{V}_p^{(T)}$   
8: **end for**

---

---

#### Algorithm 2 Update $\mathbf{U}_p$

---

**Input:**  $\mathbf{D}_p \in \mathbb{R}^{M_p \times N}$ ,  $\mathbf{V}_p \in \mathbb{R}^{K \times N}$   
1: **for**  $i = 1 : M_p$  **do**  
2:  $\bar{\mathbf{u}}_i^{(p)*} = (\mathbf{V}_p \mathbf{V}_p^T)^{-1} \mathbf{V}_p \bar{\mathbf{d}}_i^{(p)}$   
3: **end for**  
4: **return**  $\mathbf{U}_p$

---

Let  $\bar{\mathbf{d}}_i^{(p)} = (d_{i1}^{(p)}, \dots, d_{iK}^{(p)})^T$  and  $\bar{\mathbf{u}}_i^{(p)} = (u_{i1}^{(p)}, \dots, u_{iK}^{(p)})^T$  be the column vectors whose entries are those of the  $i^{th}$  row of  $\mathbf{D}_p$  and  $\mathbf{U}_p$  respectively. Thus, the optimization of equation (5) can be decomposed into  $M_p$  optimization problems that can be solved independently, with each corresponding to one row of  $\mathbf{U}_p$ :

$$\min_{\bar{\mathbf{u}}_i^{(p)} \geq 0} \|\bar{\mathbf{d}}_i^{(p)} - \mathbf{V}_p^T \bar{\mathbf{u}}_i^{(p)}\|_2^2 \quad (6)$$

for  $i = 1, \dots, M_p$ .

Equation (6) is a standard least squares problems in statistics and the solution is:

$$\bar{\mathbf{u}}_i^{(p)*} = (\mathbf{V}_p \mathbf{V}_p^T)^{-1} \mathbf{V}_p \bar{\mathbf{d}}_i^{(p)} \quad (7)$$

Algorithm 2 shows the procedure.

#### 2.3.2 Update of Matrix $\mathbf{V}_p$

Holding  $\mathbf{U}_1, \dots, \mathbf{U}_P$  and  $\mathbf{V}_1, \dots, \mathbf{V}_{p-1}, \mathbf{V}_{p+1}, \dots, \mathbf{V}_P$  fixed, the update of  $\mathbf{V}_p$  amounts to the optimization problem divided into two categories.

if  $p \in [2, P]$ , the objective function can be written as:

$$\min_{\mathbf{V}_p \geq 0} \|\mathbf{D}_p - \mathbf{U}_p \mathbf{V}_p\|_F^2 + \lambda_p \|\mathbf{V}_p - \mathbf{V}_1\|_F^2 \quad (8)$$

if  $p = 1$ , the objective function can be written as:

$$\min_{\mathbf{V}_p \geq 0} \|\mathbf{D}_p - \mathbf{U}_p \mathbf{V}_p\|_F^2 + \lambda_p \|\mathbf{V}_p\|_F^2 \quad (9)$$

Let  $\mathbf{d}_j^{(p)}$  be the  $j^{\text{th}}$  column vector of  $\mathbf{D}_p$ , and  $\mathbf{v}_j^{(p)}$  be the  $j^{\text{th}}$  column vector of  $\mathbf{V}_p$ , respectively. Thus, equation (8) can be rewritten as:

$$\min_{\{\mathbf{v}_j^{(p)} \geq 0\}} \sum_{j=1}^N \|\mathbf{d}_j^{(p)} - \mathbf{U}_p \mathbf{v}_j^{(p)}\|_2^2 + \sum_{j=1}^N \lambda_p \|\mathbf{v}_j^{(p)} - \mathbf{v}_j^{(1)}\|_2^2 \quad (10)$$

which can be decomposed into  $N$  optimization problems that can be solved independently, with each corresponding to one column of  $\mathbf{V}_p$ :

$$\min_{\mathbf{v}_j^{(p)} \geq 0} \|\mathbf{d}_j^{(p)} - \mathbf{U}_p \mathbf{v}_j^{(p)}\|_2^2 + \lambda_p \|\mathbf{v}_j^{(p)} - \mathbf{v}_j^{(1)}\|_2^2 \quad (11)$$

for  $j = 1, \dots, N$ .

Equation (12) is a least square problem with  $L_2$  norm regularization. Now we rewrite the objective function in equation (12) as

$$\mathcal{L}(\mathbf{v}_j^{(p)}) = \|\mathbf{d}_j^{(p)} - \mathbf{U}_p \mathbf{v}_j^{(p)}\|_2^2 + \lambda_p \|\mathbf{v}_j^{(p)} - \mathbf{v}_j^{(1)}\|_2^2 \quad (12)$$

where  $\mathcal{L}(\mathbf{v}_j^{(p)})$  is convex, and hence has a unique solution. Taking derivatives, we obtain:

$$\frac{\partial \mathcal{L}(\mathbf{v}_j^{(p)})}{\partial \mathbf{v}_j^{(p)}} = -2\mathbf{U}_p^T (\mathbf{d}_j^{(p)} - \mathbf{U}_p \mathbf{v}_j^{(p)}) + 2\lambda_p (\mathbf{v}_j^{(p)} - \mathbf{v}_j^{(1)}) \quad (13)$$

Forcing the partial derivative to be zero leads to

$$\mathbf{v}_j^{(p)*} = (\mathbf{U}_p^T \mathbf{U}_p + \lambda_p \mathbf{I})^{-1} (\mathbf{U}_p^T \mathbf{d}_j^{(p)} + \lambda_p \mathbf{v}_j^{(1)}) \quad (14)$$

where  $p \in [2, P]$  denotes the foreign language representation.

Similarly, the solution of equation (9) is:

$$\mathbf{v}_j^{(p)*} = (\mathbf{U}_p^T \mathbf{U}_p + \lambda_p \mathbf{I})^{-1} \mathbf{U}_p^T \mathbf{d}_j^{(p)} \quad (15)$$

where  $p = 1$  denotes the original language representation.

Algorithm 3 shows the procedure.

## 2.4 Time Complexity Analysis

In this subsection, we discuss the time complexity of our proposed method. The optimization  $\bar{\mathbf{u}}_i^{(p)}$  using Algorithm 2 should calculate  $\mathbf{V}_p \mathbf{V}_p^T$  and  $\mathbf{V}_p \bar{\mathbf{d}}_i^{(p)}$ , which takes  $O(NK^2 + NK)$  operations. Therefore, the optimization  $\mathbf{U}_p$  takes  $O(NK^2 + M_p NK)$  operations. Similarly, the time complexity of optimization  $\mathbf{V}_i$  using Algorithm 3 is  $O(M_p K^2 + M_p NK)$ .

Another time complexity is the iteration times  $T$  used in Algorithm 1 and the total number of

---

## Algorithm 3 Update $\mathbf{V}_p$

---

**Input:**  $\mathbf{D}_p \in \mathbb{R}^{M_p \times N}$ ,  $\mathbf{U}_p \in \mathbb{R}^{M_p \times K}$   
1:  $\Sigma \leftarrow (\mathbf{U}_p^T \mathbf{U}_p + \lambda_p \mathbf{I})^{-1}$   
2:  $\Phi \leftarrow \mathbf{U}_p^T \mathbf{D}_p$   
3: **if**  $p = 1$  **then**  
4:   **for**  $j = 1 : N$  **do**  
5:      $\mathbf{v}_j^{(p)} \leftarrow \Sigma \phi_j$ ,  $\phi_j$  is the  $j^{\text{th}}$  column of  $\Phi$   
6:   **end for**  
7: **end if**  
8: **return**  $\mathbf{V}_1$   
9: **if**  $p \in [2, P]$  **then**  
10:   **for**  $j = 1 : N$  **do**  
11:      $\mathbf{v}_j^{(p)} \leftarrow \Sigma (\phi_j + \lambda_p \mathbf{v}_j^{(1)})$   
12:   **end for**  
13: **end if**  
14: **return**  $\mathbf{V}_p$

---

languages  $P$ , the overall time complexity of our proposed method is:

$$\sum_{p=1}^P T \times O(NK^2 + M_p K^2 + 2M_p NK) \quad (16)$$

For each language  $\mathbf{D}_p$ , the size of vocabulary  $M_p$  is almost constant as the number of questions increases. Besides,  $K \ll \min(M_p, N)$ , theoretically, the computational time is almost linear with the number of questions  $N$  and the number of languages  $P$  considered in the paper. Thus, the proposed method can be easily adapted to the large-scale information retrieval task.

## 2.5 Relevance Ranking

The advantage of incorporating statistical machine translation in relevance ranking is to reduce ‘‘word ambiguity’’ and ‘‘word mismatch’’ problems. To do so, given a queried question  $q$  and a historical question  $d$  from Yahoo! Answers, we first translate  $q$  and  $d$  into other foreign languages (e.g., Chinese, French etc.) and get the corresponding translated representation  $q_i$  and  $d_i$  ( $i \in [2, P]$ ), where  $P$  is the number of languages considered in the paper. For queried question  $q = q_1$ , we represent it in the reduced space:

$$\mathbf{v}_{q_1} = \arg \min_{\mathbf{v} \geq 0} \|\mathbf{q}_1 - \mathbf{U}_1 \mathbf{v}\|_2^2 + \lambda_1 \|\mathbf{v}\|_2^2 \quad (17)$$

where vector  $\mathbf{q}_1$  is the tf-idf representation of queried question  $q_1$  in the term space. Similarly, for historical question  $d = d_1$  (and its tf-idf representation  $\mathbf{d}_1$  in the term space) we represent it in the reduced space as  $\mathbf{v}_{d_1}$ .

The relevance score between the queried question  $q_1$  and the historical question  $d_1$  in the reduced space is, then, calculated as the cosine similarity between  $\mathbf{v}_{q_1}$  and  $\mathbf{v}_{d_1}$ :

$$s(q_1, d_1) = \frac{\langle \mathbf{v}_{q_1}, \mathbf{v}_{d_1} \rangle}{\|\mathbf{v}_{q_1}\|_2 \cdot \|\mathbf{v}_{d_1}\|_2} \quad (18)$$

For translated representation  $q_i$  ( $i \in [2, P]$ ), we also represent it in the reduced space:

$$\mathbf{v}_{q_i} = \arg \min_{\mathbf{v} \geq 0} \|\mathbf{q}_i - \mathbf{U}_i \mathbf{v}\|_2^2 + \lambda_i \|\mathbf{v} - \mathbf{v}_{q_1}\|_2^2 \quad (19)$$

where vector  $\mathbf{q}_i$  is the tf-idf representation of  $q_i$  in the term space. Similarly, for translated representation  $d_i$  (and its tf-idf representation  $\mathbf{d}_i$  in the term space) we also represent it in the reduced space as  $\mathbf{v}_{d_i}$ . The relevance score  $s(q_i, d_i)$  between  $q_i$  and  $d_i$  in the reduced space can be calculated as the cosine similarity between  $\mathbf{v}_{q_i}$  and  $\mathbf{v}_{d_i}$ .

Finally, we consider learning a relevance function of the following general, linear form:

$$Score(q, d) = \boldsymbol{\theta}^T \cdot \boldsymbol{\Phi}(q, d) \quad (20)$$

where feature vector  $\boldsymbol{\Phi}(q, d) = (s_{VSM}(q, d), s(q_1, d_1), s(q_2, d_2), \dots, s(q_P, d_P))$ , and  $\boldsymbol{\theta}$  is the corresponding weight vector, we optimize this parameter for our evaluation metrics directly using the Powell Search algorithm (Paul et al., 1992) via cross-validation.  $s_{VSM}(q, d)$  is the relevance score in the term space and can be calculated using Vector Space Model (VSM).

## 3 Experiments

### 3.1 Data Set and Evaluation Metrics

We collect the data set from Yahoo! Answers and use the *getByCategory* function provided in Yahoo! Answers API<sup>6</sup> to obtain CQA threads from the Yahoo! site. More specifically, we utilize the *resolved* questions and the resulting question repository that we use for question retrieval contains 2,288,607 questions. Each resolved question consists of four parts: “question title”, “question description”, “question answers” and “question category”. For question retrieval, we only use the “question title” part. It is assumed that question title already provides enough semantic information for understanding the users’ information needs (Duan et al., 2008). There are 26 categories

Category	#Size	Category	#Size
Arts & Humanities	86,744	Home & Garden	35,029
Business & Finance	105,453	Beauty & Style	37,350
Cars & Transportation	145,515	Pet	54,158
Education & Reference	80,782	Travel	305,283
Entertainment & Music	152,769	Health	132,716
Family & Relationships	34,743	Sports	214,317
Politics & Government	59,787	Social Science	46,415
Pregnancy & Parenting	43,103	Ding out	46,933
Science & Mathematics	89,856	Food & Drink	45,055
Computers & Internet	90,546	News & Events	20,300
Games & Recreation	53,458	Environment	21,276
Consumer Electronics	90,553	Local Businesses	51,551
Society & Culture	94,470	Yahoo! Products	150,445

Table 2: Number of questions in each first-level category.

at the first level and 1,262 categories at the leaf level. Each question belongs to a unique leaf category. Table 2 shows the distribution across first-level categories of the questions in the archives.

We use the same test set in previous work (Cao et al., 2009; Cao et al., 2010). This set contains 252 queried questions and can be freely downloaded for research communities.<sup>7</sup>

The original language of the above data set is English ( $l_1$ ) and then they are translated into four other languages (Chinese ( $l_2$ ), French ( $l_3$ ), German ( $l_4$ ), Italian ( $l_5$ )), thus the number of language considered is  $P = 5$  by using the state-of-the-art translation tool -- Google Translate.

**Evaluation Metrics:** We evaluate the performance of question retrieval using the following metrics: Mean Average Precision (MAP) and Precision@N (P@N). MAP rewards methods that return relevant questions early and also rewards correct ranking of the results. P@N reports the fraction of the top- $N$  questions retrieved that are relevant. We perform a significant test, i.e., a  $t$ -test with a default significant level of 0.05.

We tune the parameters on a small development set of 50 questions. This development set is also extracted from Yahoo! Answers, and it is not included in the test set. For parameter  $K$ , we do an experiment on the development set to determine the optimal values among 50, 100, 150,  $\dots$ , 300 in terms of MAP. Finally, we set  $K = 100$  in the experiments empirically as this setting yields the best performance. For parameter  $\lambda_1$ , we set  $\lambda_1 = 1$  empirically, while for parameter  $\lambda_i$  ( $i \in [2, P]$ ), we set  $\lambda_i = 0.25$  empirically and ensure that  $\sum_i \lambda_i = 1$ .

Table 3: Comparison with different methods for question retrieval.

### 3.2 Question Retrieval Results

Table 3 presents the main retrieval performance. Row 1 and row 2 are two baseline systems, which model the relevance score using VSM (Cao et al., 2010) and language model (LM) (Zhai and Lafferty, 2001; Cao et al., 2010) in the term space. Row 3 and row 6 are monolingual translation models to address the word mismatch problem and obtain the state-of-the-art performance in previous work. Row 3 is the word-based translation model (Jeon et al., 2005), and row 4 is the word-based translation language model, which linearly combines the word-based translation model and language model into a unified framework (Xue et al., 2008). Row 5 is the phrase-based translation model, which translates a sequence of words as whole (Zhou et al., 2011). Row 6 is the entity-based translation model, which extends the word-based translation model and explores strategies to learn the translation probabilities between words and the concepts using the CQA archives and a popular entity catalog (Singh, 2012). Row 7 is the bilingual translation model, which translates the English questions from Yahoo! Answers into Chinese questions using Google Translate and expands the English words with the translated Chinese words (Zhou et al., 2012). For these previous work, we use the same parameter settings in the original papers. Row 8 and row 9 are our proposed method, which leverages statistical machine translation to improve question retrieval via matrix factorization. In row 8, we only consider two languages (English and Chinese) and translate English questions into Chinese using Google Translate in order to compare with Zhou et al. (2012). In row 9, we translate English questions into other four languages. There are some clear trends in the result of Table 3:

(1) Monolingual translation models significantly outperform the VSM and LM (row 1 and

row 2 vs. row 3, row 4, row 5 and row 6).

(2) Taking advantage of potentially rich semantic information drawn from other languages via statistical machine translation, question retrieval performance can be significantly improved (row 3, row 4, row 5 and row 6 vs. row 7, row 8 and row 9, all these comparisons are statistically significant at  $p < 0.05$ ).

(3) Our proposed method (leveraging statistical machine translation via matrix factorization, SMT + MF) significantly outperforms the bilingual translation model of Zhou et al. (2012) (row 7 vs. row 8, the comparison is statistically significant at  $p < 0.05$ ). The reason is that matrix factorization used in the paper can effectively solve the data sparseness and noise introduced by the machine translator simultaneously.

(4) When considering more languages, question retrieval performance can be further improved (row 8 vs. row 9).

Note that Wang et al. (2009) also addressed the word mismatch problem for question retrieval by using syntactic tree matching. We do not compare with Wang et al. (2009) in Table 3 because previous work (Ming et al., 2010) demonstrated that word-based translation language model (Xue et al., 2008) obtained the superior performance than the syntactic tree matching (Wang et al., 2009). Besides, some other studies attempt to improve question retrieval with category information (Cao et al., 2009; Cao et al., 2010), label ranking (Li et al., 2011) or world knowledge (Zhou et al., 2012). However, their methods are orthogonal to ours, and we suspect that combining the category information or label ranking into our proposed method might get even better performance. We leave it for future research.

### 3.3 Impact of the Matrix Factorization

Our proposed method (SMT + MF) can effectively solve the data sparseness and noise via matrix factorization. To further investigate the impact of the matrix factorization, one intuitive way is to expand the original questions with the translated words from other four languages, without considering the data sparseness and noise introduced by machine translator. We compare our SMT + MF with this intuitive enriching method (SMT + IEM). Besides, we also employ our proposed matrix factorization to the original question representation (VSM + MF). Table 4 shows the comparison.

#	Methods	MAP	P@10
1	VSM	0.242	0.226
2	VSM + MF	0.411	0.253
3	SMT + IEM ( $P = 5$ )	0.495	0.280
4	SMT + MF ( $P = 5$ )	0.564	0.291

Table 4: The impact of matrix factorization.

(1) Our proposed matrix factorization can significantly improve the performance of question retrieval (row 1 vs. row 2; row 3 vs. row 4, the improvements are statistically significant at  $p < 0.05$ ). The results indicate that our proposed matrix factorization can effectively address the issues of data sparseness and noise introduced by statistical machine translation.

(2) Compared to the relative improvements of row 3 and row 4, the relative improvements of row 1 and row 2 is much larger. The reason may be that although matrix factorization can be used to reduce dimension, it may impair the meaningful terms.

(3) Compared to VSM, the performance of SMT + IEM is significantly improved (row 1 vs. row 3), which supports the motivation that the word ambiguity and word mismatch problems could be partially addressed by Google Translate.

### 3.4 Impact of the Translation Language

One of the success of this paper is to take advantage of potentially rich semantic information drawn from other languages to solve the word ambiguity and word mismatch problems. So we construct a dummy translator (DT) that translates an English word to itself. Thus, through this translation, we do not add any semantic information into the original questions. The comparison is presented in Table 5. Row 1 (DT + MF) represents integrating two copies of English questions with our proposed matrix factorization. From Table 5, we have several different findings:

(1) Taking advantage of potentially rich semantic information drawn from other languages can significantly improve the performance of question retrieval (row 1 vs. row 2, row 3, row 4 and row 5, the improvements relative to DT + MF are statistically significant at  $p < 0.05$ ).

(2) Different languages contribute unevenly for question retrieval (e.g., row 2 vs. row 3). The reason may be that the improvements of leveraging different other languages depend on the quality of machine translation. For example, row 3

#	Methods	MAP
1	DT + MF ( $l_1, l_1$ )	0.352
2	SMT + MF ( $P = 2, l_1, l_2$ )	0.527
3	SMT + MF ( $P = 2, l_1, l_3$ )	0.553
4	SMT + MF ( $P = 2, l_1, l_4$ )	0.536
5	SMT + MF ( $P = 2, l_1, l_5$ )	0.545
6	SMT + MF ( $P = 3, l_1, l_2, l_3$ )	0.559
7	SMT + MF ( $P = 4, l_1, l_2, l_3, l_4$ )	0.563
8	SMT + MF ( $P = 5, l_1, l_2, l_3, l_4, l_5$ )	0.564

Table 5: The impact of translation language.

Method	Translation	MAP
SMT + MF ( $P = 2, l_1, l_2$ )	Dict	0.468
	GTrans	0.527

Table 6: Impact of the contextual information.

is better than row 2 because the translation quality of English-French is much better than English-Chinese.

(3) Using much more languages does not seem to produce significantly better performance (row 6 and row 7 vs. row 8). The reason may be that inconsistency between different languages may exist due to statistical machine translation.

### 3.5 Impact of the Contextual Information

In this paper, we translate the English questions into other four languages using Google Translate (GTrans), which takes into account contextual information during translation. If we translate a question word by word, it discards the contextual information. We would expect that such a translation would not be able to solve the word ambiguity problem.

To investigate the impact of contextual information for question retrieval, we only consider two languages and translate English questions into Chinese using an English to Chinese lexicon (Dict) in StarDict<sup>8</sup>. Table 6 shows the experimental results, we can see that the performance is degraded when the contextual information is not considered for the translation of questions. The reason is that GTrans is context-dependent and thus produces different translated Chinese words depending on the context of an English word. Therefore, the word ambiguity problem can be solved during the English-Chinese translation.

## 4 Conclusions and Future Work

In this paper, we propose to employ statistical machine translation to improve question retrieval and

<sup>8</sup>StarDict is an open source dictionary software, available at <http://stardict.sourceforge.net/>.

enrich the question representation with the translated words from other languages via matrix factorization. Experiments conducted on a real CQA data show some promising findings: (1) the proposed method significantly outperforms the previous work for question retrieval; (2) the proposed matrix factorization can significantly improve the performance of question retrieval, no matter whether considering the translation languages or not; (3) considering more languages can further improve the performance but it does not seem to produce significantly better performance; (4) different languages contribute unevenly for question retrieval; (5) our proposed method can be easily adapted to the large-scale information retrieval task.

As future work, we plan to incorporate the question structure (e.g., question topic and question focus (Duan et al., 2008)) into the question representation for question retrieval. We also want to further investigate the use of the proposed method for other kinds of data set, such as categorized questions from forum sites and FAQ sites.

## Abstract

Subcategorization frames (SCFs), selectional preferences (SPs) and verb classes capture related aspects of the predicate-argument structure. We present the first unified framework for unsupervised learning of these three types of information. We show how to utilize Determinantal Point Processes (DPPs), elegant probabilistic models that are defined over the possible subsets of a given dataset and give higher probability mass to high quality and diverse subsets, for clustering. Our novel clustering algorithm constructs a joint SCF-DPP DPP kernel matrix and utilizes the efficient sampling algorithms of DPPs to cluster together verbs with similar SCFs and SPs. We evaluate the induced clusters in the context of the three tasks and show results that are superior to strong baselines for each <sup>1</sup>.

## 1 Introduction

Verb classes (VCs), subcategorization frames (SCFs) and selectional preferences (SPs) capture different aspects of predicate-argument structure. SCFs describe the syntactic realization of verbal predicate-argument structure, SPs capture the semantic preferences verbs have for their arguments and VCs in the Levin (1993) tradition provide a shared level of abstraction for verbs that share many aspects of their syntactic and semantic behavior.

These three of types of information have proved useful for Natural Language Processing (NLP)

<sup>1</sup>The source code of the clustering algorithms and evaluation is submitted with this paper and will be made publicly available upon acceptance of the paper.

tasks which require information about predicate-argument structure, including parsing (Shi and Mihalcea, 2005; Cholakov and van Noord, 2010; Zhou et al., 2011), semantic role labeling (Swier and Stevenson, 2004; Dang, 2004; Bharati et al., 2005; Moschitti and Basili, 2005; zap, 2008; Zapi- rain et al., 2009), and word sense disambiguation (Dang, 2004; Thater et al., 2010; Ó Séaghdha and Korhonen, 2011), among many others.

Because lexical information is highly sensitive to domain variation, approaches that can identify VCs, SCFs and SPs in corpora have become increasingly popular, e.g. (O'Donovan et al., 2005; Schulte im Walde, 2006; Erk, 2007; Preiss et al., 2007; Van de Cruys, 2009; Reisinger and Mooney, 2011; Sun and Korhonen, 2011; Lippincott et al., 2012).

The task of SCF induction involves identifying the arguments of a verb lemma and generalizing about the frames (i.e. SCFs) taken by the verb, where each frame includes a number of arguments and their syntactic types. For example, in (1), the verb "show" takes the frame SUBJ-DOBJ-CCOMP (subject, direct object, and clausal complement).

(1) [A number of SCF acquisition papers]SUBJ [show]VERB [their readers]DOBJ [which features are most valuable for the acquisition process]CCOMP.

SP induction involves identifying and classifying the lexical items in a given argument slot. In sentence (2), for example, the verb "show" takes the frame SUBJ-DOBJ. The direct object in this frame is likely to be inanimate.

(2) [Most SCF and SP acquisition papers]SUBJ,

[show]VERB [no evidence to the usefulness of joint learning leaning for these tasks]DOBJ.

Finally, VC induction involves clustering together verbs with similar meaning, reflected in similar SCFs and SPs. For example, "show" in the above examples could get clustered together with "demonstrate" and "indicate".

Because these challenging tasks capture complementary information about predicate argument structure, they should be able to inform and support each other. Recently, researchers have begun to investigate the benefits of their joint learning. Schulte im Walde et al. (2008) integrated SCF and VC acquisition and used it for WordNet-based SP classification. Ó Séaghdha (2010) presented a "dual-topic" model for SPs that induces also verb clusters. Both works reported SP evaluation with promising results. Lippincott et al. (2012) presented a joint model for inducing simple syntactic frames and VCs. They reported high accuracy results on VCs. de Cruys et al. (2012) introduced a joint model for SCF and SP acquisition. They evaluated both the SCFs and SPs, obtaining reasonable result on both tasks.

In this paper, we present the first unified framework for unsupervised learning of the three types of information - SCFs, SPs and VCs. Our framework is based on Determinantal Point Processes (DPPs, (Kulesza, 2012; Kulesza and Taskar, 2012c)), elegant probabilistic models that are defined over the possible subsets of a given dataset and give higher probability mass to high quality and diverse subsets.

We first show how individual-task DPP kernel matrices can be naturally combined to construct a joint kernel. We use this to construct a joint SCF-SP kernel. We then introduce a novel clustering algorithm based on iterative DPP sampling which can (contrary to other probabilistic frameworks such as Markov random fields) be performed both accurately and efficiently. When defined over the joint SCF and SP kernel, this new algorithm can be used to induce VCs that are valuable for both tasks.

We also contribute by evaluating the value of the clusters induced by our model for the acquisition of the three information types. Our evaluation against a well-known VC gold standard shows that our clustering model outperforms the state-of-the-art verb clustering algorithm of Sun and Korhonen

(2009), in our setup where no manually created SCF or SP data is available. Our evaluation against a well-known SCF gold standard and in the context of SP disambiguation tasks shows results that are superior to strong baselines, demonstrating the benefit our approach.

## 2 Previous Work

**SCF acquisition** Most current works induce SCFs from the output of an unlexicalized parser (i.e. a parser trained without SCF annotations) using hand-written rules (Briscoe and Carroll, 1997; Korhonen, 2002; Preiss et al., 2007) or grammatical relation (GR) co-occurrence statistics (O'Donovan et al., 2005; Chesley and Salmon-Alt, 2006; Ienco et al., 2008; Messiant et al., 2008; Lenci et al., 2008; Altamirano and Alonso i Alemany, 2010; Kawahara and Kurohashi, 2010).

Only a handful of SCF induction works are unsupervised. Carroll and Rooth (1996) applied an EM-based approach to a context-free grammar based model, Dkebowski (2009) used point-wise co-occurrence of arguments in parsed Polish data and Lippincott et al. (2012) presented a Bayesian network model for syntactic frame induction that identifies SPs on argument types. However, the frames induced by Lippincott et al. (2012) do not capture sets of arguments for verbs so are far simpler than traditional SCFs.

Current approaches to SCF acquisition suffer from lack of semantic information which is needed to guide the purely syntax-driven acquisition process. Previous works have showed the benefit of hand-coded semantic information in SCF acquisition (Korhonen, 2002). We will address this problem in an unsupervised way: our approach is to consider SCFs together with semantic SPs through VCs which generalize over syntactically and semantically similar verbs.

**SP acquisition** Considerable research has been conducted on SP acquisition, with a variety of unsupervised models proposed for this task that use no hand-crafted information during training. The latter approaches include latent variable models (Ó Séaghdha, 2010; Ritter and Etzioni, 2010; Reisinger and Mooney, 2011), distributional similarity methods (Bhagat et al., 2007; Basili et al., 2007; Erk, 2007) and methods based on non-negative tensor factorization (Van de Cruys, 2009). These works use a variety of linguistic features in the acquisition process but none of them

integrates the three information types covered in our work.

**Verb clustering** A variety of VC approaches have been proposed in the literature. These include syntactic, semantic and mixed syntactic-semantic classifications (Grishman et al., 1994; Miller, 1995; Baker et al., 1998; Palmer et al., 2005; Schuler, 2006; Hovy et al., 2006). We focus on Levin style classes (Levin, 1993) which are defined in terms of diathesis alternations and capture generalizations over a range of syntactic and semantic properties. Previous unsupervised VC acquisition approaches clustered a variety of linguistic features using different (e.g. K-means and spectral) algorithms (Schulte im Walde, 2006; Joanis et al., 2008; Sun et al., 2008; Li and Brew, 2008; Korhonen et al., 2008; Sun and Korhonen, 2009; Vlachos et al., 2009; Sun and Korhonen, 2011). The linguistic features included SCFs and SPs, but these were induced separately and then feeded as features to the clustering algorithm. Our framework combines together SCF-motivated and SP-motivated kernel matrices, and uses the joint kernel to induce verb clusters which are likely to be highly relevant for both tasks. Importantly, no manual or automatic system for SCF or SP acquisition has been utilized when constructing the kernel matrices, we only consider features extracted from the output of an unlexicalized parser. Our approach hence provides a framework for acquiring valuable information for the three tasks together.

**Joint Modeling** A small number of works have recently investigated joint approaches to SCFs, SPs and VCs. Each of them has addressed only a subset of the tasks and all but one have evaluated the performance in the context of one task only. Ó Séaghdha (2010) presented a “dual-topic” model for SPs that induces VCs, reporting evaluation of SPs only. Lippincott et al. (2012) presented a Bayesian network model for syntactic frame (rather than full SCF) induction that induces VCs. Only VCs are evaluated. de Cruys et al. (2012) presented a joint unsupervised model of SCF and SP acquisition based on non-negative tensor factorization. Both SCFs and SPs were evaluated. Finally, the model of Schulte im Walde et al. (2008) addresses the three types of information but SP parameters are estimated with a WordNet based method and only the SPs are evaluated. Although evaluation of these recent joint models has been partial, the results have been encouraging and fur-

ther motivate the development of a framework that acquires the three types of information together.

### 3 The Unified Framework

In this section we present our unified framework. Our idea is to utilize DPPs for verb clustering that informs both SCF and SP acquisition. DPPs define a probability distribution over the possible subsets of a given set. These models assign higher probability mass to subsets that are both high quality and diverse.

Our novel clustering algorithm makes use of three DPP properties that are appealing for our purpose: (1) The existence of efficient sampling algorithms for these models, which enable tractable sampling of high quality and diverse verb subsets; (2) Such verb subsets form natural high quality seeds for hierarchical clustering; and (3) Given individual-task DPP kernel matrices there are various simple and natural ways to combine them into a new DPP kernel matrix.

Individual task DPP kernels represent (i) the quality of a data point (verb) as its average feature-based similarity with the other points in the data set and (ii) the divergence between a pair of points as the inverse similarity between them. For different tasks, different feature sets are used for the kernel construction. The high quality and diverse subsets sampled from the DPP model are considered good cluster seeds as they are likely to be relatively uniformly spread and to provide good coverage of the data set. The algorithm induces an hierarchical clustering, which is particularly suitable for semantic tasks, where a set of clusters that share a parent consists of pure members (i.e. most of the points in each cluster member belong to the same gold cluster) and together provide good coverage of the verb space.

After a brief description of the Determinantal Point Processes (DPP) framework (Section 3.1), we discuss the construction of the joint DPP kernel, given a kernel for each individual task, In section 3.3 we present the DPP-Cluster clustering algorithm.

#### 3.1 Determinantal Point Processes

Determinantal point processes (DPPs) are elegant probabilistic models of repulsion that offer efficient and exact algorithms for sampling, marginalization, conditioning, and other inference tasks. Recently (Kulesza, 2012; Kulesza and Taskar,

2012c) introduced them to the machine learning community and demonstrated their usefulness for a variety of tasks including document summarization, image search, modeling non-overlapping human poses in images and video and automatically building timelines of important news stories (Kulesza and Taskar, 2010; Kulesza and Taskar, 2012a; Gillenwater et al., 2012; Kulesza and Taskar, 2012b). Below we provide a brief description of the framework, a comprehensive survey can be found in (Kulesza and Taskar, 2012c).

Given a set of items  $\mathcal{Y} = \{y_1, \dots, y_N\}$ , a DPP  $\mathcal{P}$  defines a probability measure on the set of all subsets of  $\mathcal{Y}$ ,  $2^{\mathcal{Y}}$ . Kulesza and Taskar (2012c) restricted their discussion of DPPs to L-ensembles, where the probability of a subset  $\mathbf{Y} \in \mathcal{Y}$  is defined through a positive semi-definite matrix  $L$  indexed by the elements of  $\mathcal{Y}$ :

$$\mathcal{P}_L(\mathbf{Y} = Y) = \frac{\det(L_Y)}{\sum_{Y \subseteq \mathcal{Y}} \det(L_Y)} = \frac{\det(L_Y)}{\det(L + I)} \quad (1)$$

Where  $I$  is the  $N \times N$  identity matrix and  $\det(L_\phi) = 1$ . Since  $L$  is positive semi-definite, it can be decomposed to  $L = B^T B$ . This allows the construction of an intuitively interpretable model where each column  $B_i$  is the product of a quality term  $q_i \in R^+$  and a vector of (normalized) diversity features  $\phi_i \in R^D$ ,  $\|\phi_i\| = 1$ . In this model,  $q_i$  measures an inherent quality of the  $i$ -th item in  $\mathcal{Y}$  while  $\phi_i^T \phi_j \in [-1, 1]$  is a similarity measure between items  $i$  and  $j$ . With this representation we can write:

$$L_{ij} = q_i \phi_i^T \phi_j q_j \quad (2)$$

$$S_{ij} = \phi_i^T \phi_j = \frac{L_{ij}}{\sqrt{L_{ii} L_{jj}}} \quad (3)$$

$$\mathcal{P}_L(\mathbf{Y} = Y) \propto \left( \prod_{i \in Y} q_i^2 \right) \det(S_Y) \quad (4)$$

It can be shown that the first term in equation 4 increases with the quality of the selected items, and the second term increases with their diversity. As a consequence, this distribution places most of its weight on sets that are both high quality and diverse.

Although the number of possible realizations of  $Y$  is exponential in  $N$ , many inference procedures can be performed accurately and efficiently (i.e. in polynomial time which is very short in practice). In particular, sampling, which NP-hard for

alternative models such as Markov Random Fields (MRFs), is efficient, theoretically and practically, for DPPs.

### 3.2 Constructing a Joint Kernel Matrix

DPPs are particularly suitable for joint modeling as they come with various simple and intuitive ways to combine individual model kernel matrices into a joint kernel. This stems from the fact that every positive-semidefinite matrix forms a legal DPP kernel (equation 1). Given individual model DPP kernels, we would therefore like to combine them into a positive-semidefinite matrix.

While there are various ways to construct a positive-semidefinite matrix from two positive-semidefinite matrices – for example, by taking their sum – in this work we are motivated by the product of experts approach (Hinton, 2002), reasoning that high quality assignments according to a product of models have to be of high quality according to each individual model, and sick for a product combination.<sup>2</sup>

In practice we construct the joint kernel in the following way. We build on the aforementioned property that a matrix  $L$  is positive semi-definite iff  $L = B^T B$ . Given two DPPs,  $\mathcal{P}_{L^1}$  defined by  $L^1 = A_1^T A_1$  and  $\mathcal{P}_{L^2}$  defined by  $L^2 = A_2^T A_2$ , we construct the joint kernel  $L^{12}$ :

$$L^{12} = L^1 L^2 L^2 L^1 = C^T C \quad (5)$$

Where  $C = A_2^T A_2 A_1^T A_1$  and  $C^T = A_1^T A_1 A_2^T A_2$ .

### 3.3 Clustering Algorithm

Algorithm (1) and Figure (1) provide a pseudocode of the algorithm and an example output. Below is a detailed description.

**Features** Our algorithm builds two DPP kernel matrices (the *GenKernelMatrix* function), in which the rows and columns correspond to the verbs in the data set, such that the  $(i, j)$ -th entry corresponds to verbs number  $i$  and  $j$ . Following equations 2 and 3 one matrix is built for SCF and one for SP, and they are then combined into the

<sup>2</sup>Note that we do not take a product of the individual models but only of their kernel matrices. Yet, if we construct the joint matrix by a multiplication then it follows from a simple generalization of the Cauchy-Binet formula that its principle minors, which define the subset probabilities (equation 1), are a sum of multiplications of the principle minors of the individual model kernels. Still, we do not have guarantees that our choice of kernel combination is the right one. We leave this for future research.

joint kernel matrix (the *GenJointMat* function) following equation 5. Each kernel matrix requires a proper feature representation  $\phi$  and quality score  $q$ .

In both kernels we represent a verb by the counts of the grammatical relations (GRs) it participates in. In the SCF kernel a GR is represented by the GR type and the POS tags of the verb and its arguments. In the SP kernels the GRs are represented by the POS tags of the verb and its arguments as well as by the argument head word. Based on this feature representation, the similarity (opposite divergence) is encoded to the model by equation 3 as the dot product between the normalized feature vectors. The quality score  $q_i$  of the  $i$ -th verb is the average similarity of this verb with the other verbs in the dataset.

**Cluster set construction** In its while loop, the algorithm iteratively generates fixed-size cluster sets such that each data point belongs to exactly one cluster in one set. These cluster sets form the leaf level of the tree in Figure (1). It does so by extracting the  $T$  highest probability  $K$ -point samples from a set of  $M$  subsets, each of which sampled from the joint DPP model, and clustering them by the *cluster* procedure. The sampling is done by the K-DPP sampling process ((Kulesza and Taskar, 2012c), page 62)<sup>3</sup>.

The *cluster* procedure first seeds a  $K$ -cluster set with the highest probability sample. Then, it gradually extends the clusters by iteratively mapping the samples, in decreasing order of probability, to the existing clusters (the *m1Mapping* function). Mapping is done by attaching every point in the mapped subset to its closet cluster, where the distance between a point and the cluster is the maximum over the distances between the point and each of the points in the cluster. The mapping is many-to-one, that is, multiple points in the subset can be assigned to the same cluster.

Based on the DPP properties, the higher the probability of a sampled subset, the more likely it is to consist of distinct points that provide a good coverage of the verb set. By iteratively extending the clusters with high probability subsets, we thus expect each cluster set to consist of clusters that demonstrate these properties.

<sup>3</sup>K-DPP is a DPP conditioned on the sample size. As shown in ((Kulesza and Taskar, 2012c), Section 2.4.3) this conditional distribution is also a DPP. We could have obtained samples of size  $K$  by sampling the DPP and rejecting samples of other sizes but this would have been slower.

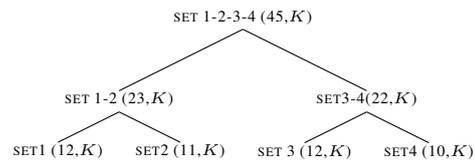

Figure 1: An example output hierarchy of DPP-Cluster for a set of 45 data points. Each set is augmented with the number of points (left number) and clusters (right number) it includes. The iterative DPP-samples clustering (the While loop) generates the lowest level of the tree, by dividing the data set into cluster sets, each of which consists of  $K$  clusters. Each point in the data set belongs to exactly one cluster in exactly one set. The agglomerative clustering then iteratively combines cluster sets such that in each iteration two sets are combined to one set with  $K$  clusters.

**Agglomerative Clustering** Finally, the *AgglomerativeClustering* function builds a hierarchy of cluster sets, by iteratively combining cluster set pairs. In each iteration it computes the similarity between any such pair, defined to be the lowest similarity between their cluster members, which is in turn defined to be the lowest cosine similarity between their point members. The most similar cluster sets are combined such that each of the clusters in one set is mapped to its most similar cluster in the other set. In this step the algorithm generates data partitions at different granularity levels from finest (from the iterative sampling step) to the coarsest set (generated by the last agglomerative clustering iteration and consisting of exactly  $K$  clusters). This property is useful as the optimal level of generalization may be task dependent.

## 4 Evaluation

**Data sets and gold standards** We evaluated the SCFs and verb clusters on gold standard datasets. We based our set of the largest available joint set for SCFs and VCs - that of (de Cruys et al., 2012). It provides SCF annotations for 183 verbs (an average of 12.3 SCF types per verb) obtained by annotating 250 corpus occurrences per verb with the SCF types of (de Cruys et al., 2012). The verbs represent a range of Levin classes at the top level of the hierarchy in VerbNet (Kipper-Schuler, 2005). Where a verb has more than one VerbNet class, we assign it to the one supported by the highest number of member verbs. To ensure suf-

Model	C  = 20, 21.6			C  = 40, 41			C  = 60, 58.6			C  = 69, 77.6			C  = 89, 97.4

Table 2: Performance of the Corpus Statistics SP baseline (non-filtered, NF) as well as for three filtering methods: frequency based (filter-baseline, B), DPP-cluster based (DPP) and AC cluster based (AC). P (method) and R (method) present the precision and recall of the method respectively. The error reduction ratio (ERR) is the ratio between the reduction in precision error achieved by each method and the increase in recall error (each method is compared to the NF baseline). Ratio greater than 1 means that the reduction in precision error is larger than the increase in recall error (see text for exact definition). DPP based filtering provides substantially better ratio.

efficient representation of each class, we collected from VerbNet the verbs for which at least one of the possible classes is represented in the 183 verbs set by at least one and at most seven verbs. This yielded 101 additional verbs which we added to the gold standard with the initial 183 verbs.

We parsed the BNC corpus with the RASP parser (Briscoe et al., 2006) and used it for feature extraction. Since 176 out of the 183 initial verbs are represented in this corpus, our final gold standard consists of 34 classes containing 277 verbs, of which 176 have SCF gold standard and has been evaluated for this task. We set the parameters of our algorithm on an held-out data, consisting of different verbs than those used in our experiments, to be  $M = 10000$ ,  $K = 20$  and  $T = 10$ .

**Clustering Evaluation** We first evaluate the quality of the clusters induced by our algorithm (DPP-cluster) compared to the gold standard VCs (table 1). To evaluate the importance of the DPP component, we compare to the performance of a version of our algorithm where everything is kept fixed except from the sampling which is done from a uniform distribution rather than from the DPP joint kernel (this model is denoted in the table with AC for agglomerative clustering)<sup>4</sup>. We also compare to the state-of-the-art spectral clustering method of Sun and Korhonen (2009) where our

<sup>4</sup>Importantly, the kernel matrix  $L$  used in the agglomerative clustering process is also used by AC.

kernel matrix is used for the distance between data points (SC)<sup>5</sup>.

We evaluated the unified cluster set induced in each iteration of our algorithm and of the AC baseline and induced the same number of clusters as in each iteration of our algorithm using the SC baseline. Since the number of clusters in each iteration is not an argument for our algorithm or for the AC baseline, the number of clusters slightly differ between the two. The AC and SC baseline results were averaged over 5 and 100 runs respectively. DPP-cluster has produced identical output across runs.

The table demonstrates the superiority of the DPP-cluster model. For four out of five conditions its F-score performance outperforms the baselines by 4.2-8.3%. Moreover, in all conditions its recall performances are substantially higher than those of the baselines (by 9.7-26.1%). Note that DPP-cluster runs for 17 iterations while the AC baseline performs only 6. We therefore evaluated only the last 5 iterations of each model<sup>6</sup>.

**SCF evaluation** For this evaluation, we first built a baseline SCF lexicon based on the parsed

<sup>5</sup>Sun and Korhonen (2009) report better results than those we report for their algorithm (on a different data set). Note, however, that they used the output of a rule-based SCF system as a source of features, as opposed to our unsupervised approach.

<sup>6</sup>For the additional comparable iteration the result pattern is very similar to the ( $C = 89, 97.4$ ) case in the table, and is not presented due to space limitations.

---

**Algorithm 1** The DPP-cluster clustering algorithm.  $K$  is the size of the sampled subsets,  $M$  is the number of subsets sampled at each iteration,  $\mathcal{Y}$  is the verb set,  $T$  is the number of most probable samples to be used in each iteration

BNC corpus. We do this by gathering the GR combinations for each of the verbs in our gold standard, assuming they are frames and gathering their frequencies. Note that this *corpus statistics* baseline is a very strong baseline that performs very similarly to (de Cruys et al., 2012), the best unsupervised SCF model we are aware of, when run on their dataset<sup>7</sup>.

As shown in table 3 the corpus statistics baseline achieves high recall (84%) at the cost of low precision (52.5%) (similar pattern has been

---

<sup>7</sup>personal communication with the authors.

demonstrated for the system of de Cruys et al. (2012)). On the other extreme, two other commonly used baselines strongly prefer precision. These are the Most Frequent SCF (O’Donovan et al., 2005) which uniformly assigns to all verbs the two most frequent SCFs in general language, transitive (SUBJ-DOBJ) and intransitive (SUBJ) (and results in poor F-score), and a filtering that removes frames with low corpus frequencies (which results in low recall even when trying to provide the maximum recall for a given precision level). The task we address is therefore to improve the precision of the corpus statistics baseline in a way that does not substantially harm the F-score.

To remedy this imbalance, we apply a cluster based filtering method on top of the maximum-recall frequency filter. This filter excludes a candidate frame from a verb’s lexicon only if it meets the frequency filter criterion and appears in no more than  $N$  other members of the cluster of the verb in question. The filter utilizes the clustering produced by the seventh to last iteration of DPP-cluster that contains seven clusters with approximately 30 members each. Such clustering should provide a good generalization level for the task.

We report results for moderate as well as aggressive filtering ( $N = 3$  and  $N = 7$  respectively). Table 3 clearly demonstrates that cluster based filtering (DPP-cluster and AC) is the only method that provides a good balance between the recall and the precision of the SCF lexicon. Moreover, the lexicon induced by this method includes a substantially higher number of frames per verb compared to the other filtering methods. While both AC and DPP-cluster still prefer recall to precision, DPP-cluster does so to a smaller extent<sup>8</sup>. This clearly demonstrates that the clustering serves to provide SCF acquisition with semantic information needed for improved performance.

**SP evaluation** We explore a variant of the pseudo-disambiguation task of Rooth et al. (1999) which has been applied to SP acquisition by a number of recent papers (e.g. (de Cruys et al., 2012)). Rooth et al. (1999) proposed to judge which of two verbs  $v$  and  $\tilde{v}$  is more likely to take a given noun  $n$  as its argument. In their experiments the model has to choose between a pair  $(v, n)$  that

---

<sup>8</sup>We show results for the maximum recall frequency filtering with precision equals to 80 or 90. When the frequency threshold is further reduced from 0.03, the same result pattern hold. We do not give a detailed description due to space limitations.

		Corpus Statistics: [P = 52.5, R = 84, F = 64.6, AF = 12.3] Most Frequent SCF: [P = 86.7, R = 22.5, F = 35.8, AF = 2]							
		Clustering Moderate				Clustering Aggressive			
Maximum Recall Frequency Threshold	Model	P	R	F	AF	P	R	F	AF
threshold = 0.03, Prec. > 80 [P=88.7,R=52.4,F=65.9,AF=4.5]	DPP-cluster	60.8	68.3	64.3	8.7	64.1	64.2	64.2	7.7
	AC	58	73.2	64.6	9.7	61.3	68.9	64.7	8.6
threshold = 0.05, Prec. > 90 [P=92.3,R=44.4,F=59.9,AF=3.7]	DPP-cluster	60.1	64.6	62.3	8.7	63.3	59.3	61.3	7.2
	AC	57.5	70.6	63.2	9.4	60.7	65.4	62.7	8.3

Table 3: SCF Results for the DPP-cluster model compared to the Corpus Statistics baseline, Most Frequent SCF baseline, maximum-recall frequency thresholding with the maximum threshold values that keep precision above 80 (threshold = 0.03) and above 90 (threshold = 0.05), and the AC clustering baseline. AF is the average number of frames per verb. **All methods except from cluster based filtering (DPP-cluster and AC) induce lexicons with strong recall/precision imbalance. Cluster based filtering keeps a larger number of frames in the lexicon compared to the frequency thresholding baseline, while keeping similar F-score levels.** DPP-cluster provides better recall/precision balance than AC.

appears only in the test corpus and a pair  $(\tilde{v}, n)$  that appears neither in the test nor in the training corpus. Note, however, that this test only evaluates the capability of a model to distinguish a correct unseen verb-argument pair from an incorrect one, but not its capability to identify erroneous pairs when no alternative pair is presented. This last property can strongly affect the precision of the model.

We therefore propose to measure both aspects of the SP task by computing both the recall and the precision between the list of possible arguments a verb can take according to the model and the corresponding test corpus list<sup>9</sup>.

We evaluate the value of our clustering for SP acquisition in the particularly challenging scenario of domain adaptation. For each of the verbs in our set we induce a list of possible noun direct objects from the BNC corpus and an equivalent list from the North American News Text (NANT) corpus. Following previous work (e.g. (de Cruys et al., 2012)) arguments are identified using a parser (RASP in our case). Using the verb clusters we create a filtered version of the BNC argument lexicon which includes in the noun argument list of a verb only those nouns that appear in the BNC as arguments of that verb and of one of its cluster members. For each verb we then compare the filtered as well as the non-filtered BNC induced lexicon to the NANT lexicon by computing the average recall and precision between the argument lists

<sup>9</sup>In principle these measures can take into account the probability assigned by the model to each argument and the corresponding test corpus frequency. In this work we compute probability-ignorant scores and keep more sophisticated evaluations for future research.

and then report the average scores across all verbs. We compare to a baseline which maintains only noun arguments that appear at least twice in BNC<sup>10</sup>. As a final measure of performance we compute the ratio between the reduction in precision error (i.e.  $\frac{p_{model} - p_{baseline}}{100 - p_{baseline}}$ ) and the increase in recall error ( $\frac{r_{baseline} - r_{model}}{100 - r_{model}}$ ).

Table 2 presents the results for verbs with up to 200, 600 and 1000 noun arguments in the training data. In all cases, the relative error reduction of the DPP cluster filter is substantially higher than that of the frequency baseline. Note that for this task the baseline AC clusters are of low quality which is reflected by an error reduction ratio of up to 0.5.

## 5 Conclusions and Future Work

In this paper we have presented the first unified framework for the induction of verb clusters, sub-categorization frames and selectional preferences from corpus data. Our key idea is to cluster together verbs with similar SCFs and SPs and to use the resulting clusters for SCF and SP induction. To implement our idea we presented a novel method which involves constructing a product DPP model for SCFs and SPs and introduced a new algorithm that utilizes the efficient DPP sampling algorithms to cluster together verbs with similar SCFs and SPs. The induced clusters performed well in evaluation against a VerbNet -based gold standard and proved useful in improving the quality of SCFs and SPs over strong baselines.

Our results demonstrate the benefits of a unified framework for acquiring lexical informa-

<sup>10</sup>we experimented with other threshold values for this baseline but the recall in those case becomes very low.

tion about different aspects of verbal predicate-argument structure. Not only the acquisition of different types information (syntactic and semantic) can support and inform each other, but also a unified framework can be useful for NLP tasks and applications which require rich information about predicate-argument structure. In future work we plan to apply our approach on larger scale data sets and gold standards and to evaluate it in different domains, languages and in the context of NLP tasks such as syntactic parsing and SRL.

In addition, in our current framework SCF and SP information is used for clustering which is in turn used to improve SCF and SP quality. At this stage no further information flows from the SCF and SP models to the clustering model. A natural extension of our unified framework is to construct a joint model in which the predictions for all three tasks inform each other at all stages of the prediction process.

## Abstract

Semantic frames are a rich linguistic resource. There has been much work on semantic frame parsers, but less that applies them to general NLP problems. We address a task to predict change in stock price from financial news. Semantic frames help to generalize from specific sentences to scenarios, and to detect the (positive or negative) roles of specific companies. We introduce a novel tree representation, and use it to train predictive models with tree kernels using support vector machines. Our experiments test multiple text representations on two binary classification tasks, change of price and polarity. Experiments show that features derived from semantic frame parsing have significantly better performance across years on the polarity task.

## 1 Introduction

A growing literature evaluates the financial effects of media on the market (Tetlock, 2007; Engelberg and Parsons, 2011). Recent work has applied NLP techniques to various financial media (conventional news, tweets) to detect sentiment in conventional news (Devitt and Ahmad, 2007; Haider and Mehrotra, 2011) or message boards (Chua et al., 2009), or discriminate expert from non-expert investors in financial tweets (Bar-Haim et al., 2011). With the exception of Bar-Haim et al. (2011), these NLP studies have relied on small corpora of hand-labeled data for training or evaluation, and the connection to market events is done indirectly through sentiment detection. We hypothesize that conventional news can be used to predict changes in the stock price of specific companies, and that the semantic features that best represent relevant aspects of the news vary across

On Wednesday, April 11th, 2012, **Google Inc** announced its first **quarterly earnings** report, a week before the April 20 options contracts expiration in *contrast* to its history of reporting a day before monthly options expirations. The **stock price of Google** *surged* 3.85% from April 10th's \$626.86 to 12th's \$651.01. On Friday, April 13th, news reported **Oracle Corp** would *sue* **Google Inc**, claiming **Google's Android operating system** *tramples* **its intellectual property rights**. Jury selection was set for the next Monday. **Google's stock price** *tumbled* 4.06% on Friday, and continued to drop in the following week.

Figure 1: Summary of financial news items pertaining to *Google* in April, 2012.

market sectors. To test this hypothesis, we use price information to label data from six years of financial news. Our experiments test several document representations for two binary classification tasks, change of price and polarity. Our main contribution is a novel tree representation based on semantic frame parses that performs significantly better than enriched bag-of-words vectors.

Figure 1 shows a constructed example based on extracts from financial news about *Google* in April, 2012. It illustrates how a series of events reported in the news precedes and potentially predicts a large change in *Google's* stock price. *Google's* early announcement of quarterly earnings possibly presages trouble, and its stock price falls soon after reports of a legal action against *Google* by *Oracle*. To produce a coherent story, the original sentences were edited for Figure 1, but they are in the style of actual sentences from our dataset. Accurate detection of events and relations that might have an impact on stock price should benefit from document representation that captures sentiment in lexical items (e.g., *aggressive*) combined with the conceptual relations captured by FrameNet (Ruppenhofer and Rehbein, 2012). A frame is a lexical semantic representa-

tion of the conceptual roles played by parts of a clause, and relates different lexical items (e.g., *report*, *announce*) to the same situation type. In the figure, some of the words that evoke frames have been underlined, and role fillers are outlined by boxes or ovals. Sentiment words are in italics.

To the best of our knowledge, this paper is the first to apply semantic frames in this domain. On the polarity task, the semantic frame features encoded as trees perform significantly better across years and sectors than bag-of-words vectors (BOW), and outperform BOW vectors enhanced with semantic frame features, and a supervised topic modeling approach. The results on the price change task show the same trend, but are not statistically significant, possibly due to the volatility of the market in 2007 and the following several years. Yet even modest predictive performance on both tasks could have an impact, as discussed below, if incorporated into financial models such as Rydberg and Shephard (2003). We first discuss the motivation and related work. Section 4 presents vector-based and tree-based features from semantic frame parses, and section 5 describes our dataset. The experimental design and results appear in the following section, followed by discussion and conclusions.

## 2 Motivation

Financial news is a rich vein for NLP applications to mine. Many news organizations that feature financial news, such as Reuters, the Wall Street Journal and Bloomberg, devote significant resources to the analysis of corporate news.

Much of the data that would support studies of a link between the news media and the market are publicly available. As pointed out by Tetlock et al. (2008), linguistic communication is a potentially important source of information about firms' fundamental values. Because very few stock market investors directly observe firms' production activities, they get most of their information secondhand. Their three main sources are analysts' forecasts, quantifiable publicly disclosed accounting variables, and descriptions of firms' current and future profit-generating activities. If analyst and accounting variables are incomplete or biased measures of firms' fundamental values, linguistic variables may have incremental explanatory power for firms' future earnings and returns.

Consider the following sentences:

*Oracle sued Google in August 2010, saying Google's Android mobile operating system infringes its copyrights and patents for the Java programming language.* (a)

*Oracle has accused Google of violating its intellectual property rights to the Java programming language.* (b)

*Oracle has blamed Google and alleged that the latter has committed copyright infringement related to Java programming language held by Oracle.* (c)

*Oracle's Ellison says couldn't sway Google on Java.* (d)

Sentences *a*, *b* and *c* are semantically similar, but lexically rather distinct: the shared words are the company names and *Java (programming language)*. Bag-of-Words (BOW) document representation is difficult to surpass for many document classification tasks, but cannot capture the degree of semantic similarity among these sentences. Methods that have proven successful for paraphrase detection (Deerwester et al., 1990; Dolan et al., 2004), as in the main clauses of *b* and *c*, include latent variable models that simultaneously capture the semantics of words and sentences, such as latent semantic analysis (LSA) or latent Dirichlet allocation (LDA). However, our task goes beyond paraphrase detection. The first three sentences all indicate an adversarial relation of *Oracle* to *Google* involving a negative judgement. It would be useful to capture the similarities among all three of these sentences, and to distinguish the role of each company (who is suing and who is being sued). Further, these three sentences potentially have a greater impact on market perception of *Google* in contrast to a sentence like *d*, that refers to the same conflict more indirectly, and whose main clause verb is *say*. We hypothesize that semantic frames can address these issues.

Most of the NLP literature on semantic frames addresses how to build robust semantic frame parsers, with intrinsic evaluation against gold standard parses. There have been few applications of semantic frame parsing for extrinsic tasks. To test for measurable benefits of semantic frame parsing, this paper poses the following questions:

1. Are semantic frames useful for document representation of financial news?
2. What aspects of frames are most useful?
3. What is the relative performance of document representation that relies on frames?

4. What improvements could be made to best exploit semantic frames?

Our work is not aimed at investment profit. Rather, we investigate whether computational linguistic methodologies can improve our understanding of a company’s fundamental market value, and whether linguistic information derived from news produces a consistent enough result to benefit more comprehensive financial models.

### 3 Related Work

NLP has recently been applied to financial text for market analysis, primarily using bag-of-words (BOW) document representation. Luss and d’Aspremont (2008) use text classification to model price movements of financial assets on a per-day basis. They try to predict the direction of return, and abnormal returns, defined as an absolute return greater than a predefined threshold. Kogan et al. (2009) address a text regression problem to predict the financial risk of investment in companies. They analyze 10-K reports to predict stock return volatility. They also predict whether a company will be delisted following its 10-K report. Ruiz et al. (2012) correlate text with financial time series volume and price data. They find that graph centrality measures like page rank and degree are more strongly correlated to both price and traded volume for an aggregation of similar companies, while individual stocks are less correlated. Lavrenko et al. (2000) present an approach to identify news stories that influence the behavior of financial markets, and predict trends in stock prices based on the content of news stories that precede the trends. Luss and d’Aspremont (2008) and Lavrenko et al. (2000) both point out the desire for document feature engineering as future research directions. We explore a rich feature space that relies on frame semantic parsing.

Sentiment analysis figures strongly in NLP work on news. General Inquirer (GI), a content analysis program, is used to quantify pessimism of news in Tetlock (2007) and Tetlock et al. (2008). Other resources for sentiment detection include the Dictionary of Affect in Language (DAL) to score the prior polarity of words, as in Agarwal et al. (2011) on social media data. Our study incorporates DAL scores along with other features.

FrameNet is a rich lexical resource (Fillmore et al., 2003), based on the theory of frame semantics (Fillmore, 1976). There is active research

Category	Features	Value type
Frame attributes	F, FT, FE wF, wFT, wFE	$\mathbb{N}$ $\mathbb{R}_{\geq 0}$
BOW	UniG, BiG, TriG wUniG, wBiG, wTriG	$\mathbb{N}$ $\mathbb{R}_{\geq 0}$
pDAL	all-Pls, all-Act, all-Img VB-Pls, VB-Act, VB-Img JJ-Pls, JJ-Act, JJ-Img RB-Pls, RB-Act, RB-Img	$\mathbb{R}_{\sim\mu=0, std=1}$ $\mathbb{R}_{\sim\mu=0, std=1}$ $\mathbb{R}_{\sim\mu=0, std=1}$ $\mathbb{R}_{\sim\mu=0, std=1}$

Table 1: FWD features (Frame, bag-of-Words, part-of-speech DAL score) and their value types.

to build more accurate parsers (Das and Smith, 2011; Das and Smith, 2012). Semantic role labeling using FrameNet has been used to identify an opinion with its holder and topic (Kim and Hovy, 2006). For deep representation of sentiment analysis, Ruppenhofer and Rehbein (2012) propose SentiFrameNet.

Our work addresses classification tasks that have potential relevance to an influential financial model (Rydberg and Shephard, 2003). This model decomposes stock price analysis of financial data into a three-part ADS model - *activity* (a binary process modeling the price move or not), *direction* (another binary process modeling the direction of the moves) and *size* (a number quantifying the size of the moves). Our two binary classification tasks for news, price change and polarity, are analogous to their *activity* and *direction*. In contrast to the ADS model, our approach does not calculate the conditional probability of each factor. At present, our goal is limited to the determination of whether NLP features can uncover information from news that could help predict stock price movement or support analysts’ investigations.

### 4 Methods

We propose two approaches for the use of semantic frames. The first is a rich vector space based on semantic frames, word forms and DAL affect scores. The second is a tree representation that encodes semantic frame features, and depends on tree kernel measures for support vector machine classification. The semantic parses of both methods are derived from SEMAFOR<sup>1</sup> (Das and Smith, 2012; Das and Smith, 2011), which solves the semantic parsing problem by rule-based target identification, log-linear model based frame identification and frame element filling.

<sup>1</sup><http://www.ark.cs.cmu.edu/SEMAFOR>.

Frame (F)	Judgment_comm.	Commerce_buy
Target (FT)	accuse sue charge	buy purchase bid
Frame Element (FE)	COMMUNICATOR EVALUEE REASON	BUYER SELLER GOODS

Table 2: Sample frames.

#### 4.1 Semantic Frame based FWD Features

Table 1 lists 24 types of features, including semantic Frame attributes, bag-of-Words, and scores for words in the Dictionary of Affect in Language by part of speech (pDAL). We refer to these features as **FWD** features throughout the paper. FWD features are used alone and in combinations.

FrameNet defines hundreds of frames, each of which represents a scenario associated with semantic roles, or frame elements, that serve as participants in the scenario the frame signifies. Table 2 shows two frames. The frame *Judgment\_communication* (*JC* or *Judgment\_comm.* in the rest of the paper) represents a scenario in which a COMMUNICATOR communicates a judgment of an EVALUEE for some REASON. It is evoked by (target) words such as *accuse* or *sue*.

Here we use **F** for the frame name, **FT** for the target words, and **FE** for frame elements. We use both frequency and weighted scores. For example, we define *idf*-adjusted weighted frame features, such as  $wF$  for attribute  $F$  in document  $d$  as  $wF_{F,d} = f(F, d) \times \log \frac{|D|}{|d \in D: F \in d|}$ , where  $f(F, d)$  is the frequency of frame  $F$  in  $d$ ,  $D$  is the whole document set and  $|\cdot|$  is the cardinality operator.

Bag-of-Words features include term frequency and *tfidf* of unigrams, bigrams, and trigrams.

DAL (Dictionary of Affect in Language) is a psycholinguistic resource to measure the emotional meaning of words and texts (Whissel, 1989). It includes 8,742 words that were annotated for three dimensions: Pleasantness (Pls), Activation (Act), and Imagery (Img). Agarwal et al. (2009) introduced part-of-speech specific DAL features for sentiment analysis. We follow their approach by averaging the scores for all words, verb only, adjective only, and adverb only words. Feature values are normalized to mean of zero and standard deviation of one.

#### 4.2 SemTree Feature Space and Kernels

We propose **SemTree** as another feature space to encode semantic information in trees. SemTree

can distinguish the roles of each company of interest, or *designated object* (e.g. who is suing and who is being sued).

##### 4.2.1 Construction of Tree Representation

The semantic frame parse of a sentence is a forest of trees, each of which corresponds to a semantic frame. SemTree encodes the original frame structure and its leaf words and phrases, and highlights a designated object at a particular node as follows. For each lexical item (target) that evokes a frame, a backbone is found by extracting the path from the root to the role filler mentioning a designated object; the backbone is then reversed to promote the designated object. If multiple frames have been assigned to the same designated object, their backbones are merged. Lastly, the frame elements and frame targets are inserted at the frame root.

The top of Figure 2 shows the semantic parse for sentence  $a$  from section 2; we use it to illustrate tree construction for designated object *Oracle*. The parse has two frames (Figure 2-(1)&(2)), one corresponding to the main clause (verb *sue*), and the other for the tenseless adjunct (verb *say*). The reversed paths extracted from each frame root to the designated object *Oracle* become the backbones (Figures 2-(3)&(4)). After merging the two backbones we get the resulting SemTree, as shown in Figure 2-(5). By the same steps, this sentence would also yield a SemTree with *Google* at the root, in the role of EVALUEE.

##### 4.2.2 Kernels and Tree Substructures

The tree kernel (Moschitti, 2006; Collins and Duffy, 2002) is a function of tree similarity, based on common substructures (tree fragments). There are two types of substructures. A subtree (ST) is defined as any node of a tree along with all its descendants. A subset tree (SST) is defined as any node along with its immediate children and, optionally, part or all of the children’s descendants. Each tree is represented by a  $d$  dimensional vector where the  $i$ ’th component counts the number of occurrences of the  $i$ ’th tree fragment.

Define the function  $h_i(T)$  as the number of occurrences of the  $i$ ’th tree fragment in tree  $T$ , so that  $T$  is now represented as  $\mathbf{h}(T) = (h_1(T), h_2(T), \dots, h_d(T))$ . We define the set of nodes in tree  $T_1$  and  $T_2$  as  $N_{T_1}$  and  $N_{T_2}$  respectively. We define the indicator function  $I_i(n)$  to be 1 if subtree  $i$  is seen rooted at node  $n$ , and 0 otherwise. It follows that  $h_i(T_1) = \sum_{n_1 \in N_{T_1}} I_i(n_1)$

Designated object: Oracle (ORCL)  
Sentence: Oracle sued Google in August 2010, saying Google’s Android mobile operating system infringes its copyrights and patents for the Java programming language.  
SRL: [Oracle<sub>JC.FE.Communicator</sub>, Stmt.FE.Speaker] [sued<sub>JC.Target</sub>] [Google<sub>JC.FE.Evaluee</sub>] in August 2010, [saying<sub>Stmt.Target</sub>] [Google’s Android mobile operating system infringes its copyrights and patents for the Java programming language<sub>Stmt.FE.Message</sub>].

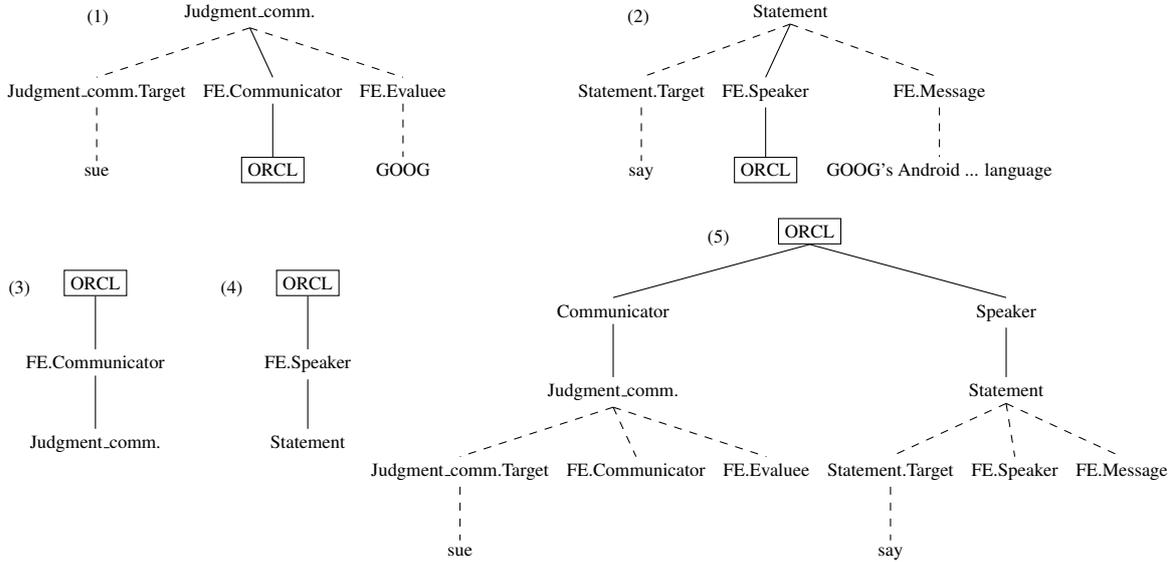

Figure 2: Constructing a tree representation for the designated object *Oracle* in sentence shown.

and  $h_i(T_2) = \sum_{n_2 \in N_{T_2}} I_i(n_2)$ . Their similarity can be efficiently computed by the inner product,

$$\begin{aligned}
K(T_1, T_2) &= \mathbf{h}(T_1) \cdot \mathbf{h}(T_2) \\
&= \sum_i h_i(T_1) h_i(T_2) \\
&= \sum_i (\sum_{n_1 \in N_{T_1}} I_i(n_1)) (\sum_{n_2 \in N_{T_2}} I_i(n_2)) \\
&= \sum_{n_1 \in N_{T_1}} \sum_{n_2 \in N_{T_2}} \sum_i I_i(n_1) I_i(n_2) \\
&= \sum_{n_1 \in N_{T_1}} \sum_{n_2 \in N_{T_2}} \Delta(n_1, n_2)
\end{aligned}$$

where  $\Delta(n_1, n_2)$  is the number of common fragments rooted in the nodes  $n_1$  and  $n_2$ . If the productions of these two nodes (themselves and their immediate children) differ,  $\Delta(n_1, n_2) = 0$ ; otherwise iterate their children recursively to evaluate  $\Delta(n_1, n_2) = \prod_j^{|\text{children}|} (\sigma + \Delta(c_{n_1}^j, c_{n_2}^j))$ , where  $\sigma = 0$  for ST kernel and  $\sigma = 1$  for SST kernel.

The kernel computational complexity is  $O(|N_{T_1}| \times |N_{T_2}|)$ , where all pairwise comparisons are carried out between  $T_1$  and  $T_2$ . However, there are fast algorithms for kernel computation that run in linear time on average, either by dynamic programming (Collins and Duffy, 2002), or pre-sorting production rules before training (Moschitti, 2006). We use the latter.

## 5 Dataset

We use publicly available financial news from Reuters from January 2007 through August 2012. This time frame includes a severe economic downturn in 2007-2010 followed by a modest recovery in 2011-2012.

An information extraction pipeline is used to pre-process the data. News full text is extracted from HTML. The timestamp of the news is extracted for a later alignment with stock price information, which will be discussed in section 6. The company mentioned is identified by a rule-based matching of a finite list of companies.

There are a total of 10 sectors in the Global Industry Classification Standard (GICS), an industry taxonomy used by the S&P 500.<sup>2</sup> To explore our approach for this domain, we select three sectors for our experiment: Telecommunication Services (TS, the sector with the smallest number of companies), Information Technology (IT), and Consumer Staples (CS), due to our familiarity with the companies in these sectors and an expectation of different characteristics they may exhibit. In the expectation there would be semantic differences associated with these sectors, experiments are performed independently for each sector. There are also differences in the number of companies in the sector, and the amount of news.

We bin news articles by sector. We remove articles that only list stock prices or only show tables of accounting reports. The first preprocessing step is to extract sentences that mention the

<sup>2</sup>Standard & Poor’s 500 is an equity market index that includes 500 U.S. leading companies in leading industries.

	CS (N=40)	IT (N=69)	TS (N=8)

Table 3: Data statistics of mean and standard deviation by year from January 2007 to August 2012, for three sectors, with the number of companies.

relevant companies. Each data instance is a sentence and one of the target companies it mentions. Table 3 summarizes the data statistics. For example, the consumer staples sector has 40 companies. It has an average of 5,702 news articles (16,090 sentences) per year. Each sentence that mentions a consumer staple company mentions 1.07 companies on average. On average, this sector has 17,131 instances per year.

## 6 Experiments

Our current experiments are carried out for each year, training on one year and testing on the next. The choice to use a coarse time interval with no overlap was an expedience to permit more numerous exploratory experiments, given the computational resources these experiments require. We test the influence of news to predict (1) a change in stock price (*change* task), and (2) the polarity of change (increase vs. decrease; *polarity* task). Experiments evaluate the FWD and SemTree feature spaces compared to two baselines: bag-of-words (BOW) and supervised latent Dirichlet allocation (sLDA) (Blei and McAuliffe, 2007). BOW includes features of unigram, bigram and trigram. sLDA is a statistical model to classify documents based on LDA topic models, using labeled data. It has been applied to and shown good performance in topical text classification, collaborative filtering, and web page popularity prediction problems.

### 6.1 Labels, Evaluation Metrics, and Settings

We align publicly available daily stock price data from Yahoo Finance with the Reuters news using a method to avoid back-casting. In particular, we use the daily adjusted closing price - the price quoted at the end of a trading day (4PM US Eastern Time), then adjusted by dividends, stock split, and other corporate actions. We create two types of labels for news documents using the price data, to label the existence of a change and the direction of change. Both tasks are treated as binary classification problems. Based on the finding of

a one-day delay of the price response to the information embedded in the news by Tetlock et al. (2008), we use  $\Delta t = 1$  in our experiment. To constrain the number of parameters, we also use a threshold value ( $r$ ) of a 2% change, based on the distribution of price changes across our data. In future work, this could be tuned to sector or time.

$$\text{change} = \begin{cases} +1 & \text{if } \frac{|p_{t(0)+\Delta t} - p_{t(-1)}|}{p_{t(-1)}} > r \\ -1 & \text{otherwise} \end{cases}$$

$$\text{polarity} = \begin{cases} +1 & \text{if } p_{t(0)+\Delta t} > p_{t(-1)} \text{ and } \text{change} = +1 \\ -1 & \text{if } p_{t(0)+\Delta t} < p_{t(-1)} \text{ and } \text{change} = +1 \end{cases}$$

$p_{t(-1)}$  is the adjusted closing price at the end of the last trading day, and  $p_{t(0)+\Delta t}$  is the price of the end of the trading day after the  $\Delta t$  day delay. Only the instances with changes are included in the *polarity* task.

There is high variance across years in the proportion of positive labels, and often highly skewed classes in one direction or the other. The average ratios of +/- classes for *change* and *polarity* over the six years' data are 0.73 (std=0.35) and 1.12 (std=0.25), respectively. Because the time frame for our experiments includes an economic crisis followed by a recovery period, we note that the ratio between increase and decrease of price flips between 2007, where it is 1.40, and 2008, where it is 0.71. Accuracy is very sensitive to skew: when a class has low frequency, accuracy can be high using a baseline that makes prediction on the majority class. Given the high data skew, and the large changes from year to year in positive versus negative skew, we use a more robust evaluation metric.

Our evaluation relies on the Matthews correlation coefficient (MCC, also known as the  $\phi$ -coefficient) (Matthews, 1975) to avoid the bias of accuracy due to data skew, and to produce a robust summary score independent of whether the positive class is skewed to the majority or minority. In contrast to f-measure, which is a class-specific weighted average of precision and recall, and whose weighted version depends on a choice of whether the class-specific weights should come from the training or testing data, MCC is a single summary value that incorporates all 4 cells of a  $2 \times 2$  confusion matrix (TP, FP, TN and FN for True or False Positive or Negative). We have also observed that MCC has a lower relative standard deviation than f-measure.

For a  $2 \times 2$  contingency table, MCC corresponds to the square root of the average  $\chi^2$  statistic  $\sqrt{\chi^2/n}$ , with values in  $[-1,1]$ . It has been sug-

Table 4: Average MCC for the change and polarity tasks by feature representation, for 2008-2010; for 2011-2012; for all 5 years and associated p-values of ANOVAs for comparison to BOW.

gested as one of the best methods to summarize into a single value the confusion matrix of a binary classification task (Jurman and Furlanello, 2010; Baldi et al., 2000). Given the confusion matrix  $\begin{pmatrix} TP & FN \\ FP & TN \end{pmatrix}$ :

$$MCC = \frac{TP \cdot TN - FP \cdot FN}{\sqrt{(TP+FP)(TP+FN)(TN+FP)(TN+FN)}}.$$

All sentences with at least one company mention are used for the experiment. We remove stop words and use Stanford CoreNLP for part-of-speech tagging and named entity recognition. Models are constructed using linear kernel support vector machines for both classification tasks. SVM-light with tree kernels<sup>3</sup> (Joachims, 2006; Moschitti, 2006) is used for both the FWD and SemTree feature spaces.

## 6.2 Results

Table 4 shows the mean MCC values for each task, for each sector. Separate means are shown for the test years of financial crisis (2008-2010) and economic recovery (2011-2012) to highlight the differences in performance that might result from market volatility.

Table 5: Sample sLDA topics for consumer staples for test year 2010 (train on 2009), polarity task.

SemTree combined with FWD (SemTreeFWD) generally gives the best performance in both *change* and *polarity* tasks. SemTree results here are based on the subset tree (SST) kernel, because of its greater precision in computing common frame structures and consistently better performance over the subtree (ST) kernel. SemTree also provides interpretable features for manual analysis as discussed in the next section.

Analysis of Variance (ANOVA) tests were performed on the full 5 years for each sector, to compare each feature representation as a predictor of MCC score with the baseline BOW. The ANOVAs yield the p-values shown in Table 4. There were no significant differences from BOW on the *change* task. For *polarity* detection, SemTreeFWD was significantly better than BOW for each sector (see boldface p-values). No other method was significantly better than BOW, although FWD approaches significance on all sectors, and sLDA approaches significance on IT.

sLDA has promising MCC scores for the telecommunication sector, which has only 8 companies, thus many fewer data instances. Table 5 displays a sample of sLDA topics with good performance on polarity for the consumer staples sector for training year 2009. The positive topics are related to stock index details and retail data. The negative topics contain many words with negative sentiment (e.g., *hurt*, *disappointing*).

## 7 Discussion

### 7.1 Semantic Parse Quality

In general, SEMAFOR parses capture most of the important frames for our purposes. There is, however, significant room for improvement. On a small, randomly selected sample of sentences from all three sectors, two of the authors working independently evaluated the semantic parses, with approximately 80% agreement. Some of the inaccuracies in frame parses result from errors prior to the SEMAFOR parse, such as tokenization or

```

+ (Target(beats))
...
- (PHENOMENON(Perception_active(Target)(PERCEIVER
_AGENTIVE)(PHENOMENON)))
- (TRIGGER(Response))
- (Target(cuts))
- (VICTIM(Cause_Harm(Target(hurt))(VICTIM)))

```

Figure 3: Best performing SemTree fragments for increase (+) and decrease (-) of price for consumer staples sector across training years.

dependency parsing errors. The average sentence length for the sample was 33.3 words, with an average of 14 frames per sentence, 3 of them with a GICS company as a role filler. Because SemTree encodes only the frames containing a designated object (company), these are the frames we evaluated. On average, about half the frames with a designated object were correct, and two thirds of those frames we judged to be important. Besides errors due to incorrect tokenization or dependency parsing, we observed that about 8% to 10% of frames were incorrectly assigned to due word sense ambiguity.

## 7.2 Feature Analysis

The experimental results show the SemTree space to be the one representation tested here that is significantly better than BOW, but only for the *polarity* task. Post hoc analysis indicates this may be due to the aptness of semantic frame parsing for polarity. Limitations in our treatment of time point to directions for improvement regarding the *change* task.

Some strengths of our approach are the separate treatment of different sectors, and the benefits of SemTree features. To analyze which were the best performing features within sectors, we extracted the best performing frame fragments for the *polarity* task using a tree kernel feature engineering method presented in Pighin and Moschitti (2009). The algorithm selects the most relevant features in accordance with the weights estimated by SVM, and uses these features to build an explicit representation of the kernel space. Figure 3 shows the best performing SemTree fragments of the *polarity* task for the consumer staples sector.

Recall that we hypothesized differences in

semantic frame features across sectors. This shows up as large differences in the strength of features across sectors. More strikingly, the same feature can differ in polarity across sectors. For example, in consumer staples, (EVAL-UEE(*Judgment\_communication*)) has positive polarity, compared with negative polarity in information technology sector. The examples we see indicate that the positive cases pertain to aggressive retail practices that lead to lawsuits with only small fines, but whose larger impact benefits the bottom line. A typical case is the sentence, *The plaintiffs accused Wal-Mart of discriminating against disabled customers by mounting “point-of-sale” terminals in many stores at elevated heights that cannot be reached.* Lawsuits in the IT sector, on the other hand, are often about technology patent disputes, and are more negative, as illustrated by our example sentence in Figure 2.

SemTree features capture the differences between semantic roles for the same frame, and between the same semantic role in different frames. For example, the PERCEIVER\_AGENTIVE role of the *Perception\_active* frame contributes to prediction of an increase in price, as in *R.J. Reynolds is watching this situation closely and will respond as appropriate.* Conversely, a company that fills the PHENOMENON role of the same frame contributes to prediction of a price decrease, as in *Investors will get a clearer look at how the market values the Philip Morris tobacco businesses when Altria Group Inc. “when-issued” shares begin trading on Tuesday.* When a company fills the VICTIM role in the *Cause\_harm* frame, this can predict a decrease in price, as in *Hershey has been hurt by soaring prices for cocoa, energy and other commodities,* whereas filling the VICTIM role in the *Defend* frame is associated with an increase in price, as in *At Berkshire’s annual shareholder meeting earlier this month, Warren Buffett defended Wal-Mart, saying the scandal did not change his opinion of the company.*

One weakness of our approach that we discussed above is that there is a strong effect of time that we do not address. The same SemTree feature can be predictive for one time period and not for another. (GOODS(*Commerce\_sell*)) is related to a decrease in price for 2008 and 2009 but to an increase in price for 2010-2012. There is clearly an influence of the overall economic context that we do not take into account. For example,

the practices of acquiring or selling a business are different in downturning versus recovering markets. An important observation of the MCC values, especially in the case of SemTreeFWD is that MCC increases during the years 2011-2012. We attribute this change to the difficulty of predicting stock price trends when there is the high volatility typical of a financial crisis. The effect of news on volatility, however, can be explored independently. For example, Creamer et al. (2012) detect a strong association.

Another weakness of our approach is that we take sentences out of context, which can lead to prediction errors. For example, the sentence *Longs' real estate assets alone are worth some \$2.9 billion, or \$71.50 per share, Ackman wrote, meaning that [CVS] would essentially be paying for real estate, but gaining Longs' pharmacy benefit management business and retail operations for free* is treated as predicting a positive polarity for CVS. This would be accurate if CVS was actually going to acquire Longs' business. Later in the same news item, however, there is a sentence indicating that the sale will not go through, which predicts negative polarity for CVS: *Pershing Square Capital Management said on Thursday it won't support a tender offer from CVS Caremark Corp for rival Longs Drug Stores Corp because the offer price "materially understates the fair value of the company," according to a filing.*

## 8 Conclusion

We have presented a model for predicting stock price movement from news. We proposed FWD (Frames, BOW, and part-of-speech specific DAL) features and SemTree data representations. Our semantic frame-based model benefits from tree kernel learning using support vector machines. The experimental results for our feature representation perform significantly better than BOW on the *polarity* task, and show promise on the *change* task. It also facilitates human interpretable analysis to understand the relation between a company's market value and its business activities. The signals generated by this algorithm could improve the prediction of a financial time series model, such as ADS (Rydberg and Shephard, 2003).

Our future work will consider the contextual information for sentence selection, and an aggregation of weighted news content based on the decay effect over time for individual companies. We plan

to use a moving window for training and testing. We will also explore different labeling methods, such as a threshold for price change tuned by sectors and background economics.

## Abstract

This paper proposes a novel *smoothing model* with a *combinatorial optimization scheme* for all-words word sense disambiguation from untagged corpora. By generalizing discrete senses to a continuum, we introduce a smoothing in context-sense space to cope with *data-sparsity* resulting from a large variety of linguistic context and sense, as well as to exploit *sense-interdependency* among the words in the same text string. Through the smoothing, all the optimal senses are obtained at one time under maximum marginal likelihood criterion, by competitive probabilistic kernels made to reinforce one another among nearby words, and to suppress conflicting sense hypotheses within the same word. Experimental results confirmed the superiority of the proposed method over conventional ones by showing the better performances beyond most-frequent-sense baseline performance where none of SemEval-2 unsupervised systems reached.

## 1 Introduction

Word Sense Disambiguation (WSD) is a task to identify the intended sense of a word based on its context. *All-words WSD* is its variant, where all the unrestricted running words in text are expected to be disambiguated. In the all-words task, all the senses in a dictionary are potentially the target destination of classification, and purely supervised approaches inherently suffer from *data-sparsity* problem. The all-words task is also characterized by *sense-interdependency* of target words. As the target words are typically taken from the same

text string, they are naturally expected to be inter-related. Disambiguation of a word should affect other words as an important clue.

From such characteristics of the task, knowledge-based unsupervised approaches have been extensively studied. They compute dictionary-based sense similarity to find the most related senses among the words within a certain range of text. (For reviews, see (Agirre and Edmonds, 2006; Navigli, 2009).) In recent years, graph-based methods have attracted considerable attentions (Mihalcea, 2005; Navigli and Lapata, 2007; Agirre and Soroa, 2009). On the graph structure of lexical knowledge base (LKB), random-walk or other well-known graph-based techniques have been applied to find mutually related senses among target words. Unlike earlier studies disambiguating word-by-word, the graph-based methods obtain *sense-interdependent* solution for target words. However, those methods mainly focus on modeling sense distribution and have less attention to contextual smoothing/generalization beyond immediate context.

There exist several studies that enrich immediate context with large corpus statistics. McCarthy et al. (2004) proposed a method to combine sense similarity with distributional similarity and configured predominant sense score. Distributional similarity was used to weight the influence of context words, based on large-scale statistics. The method achieved successful WSD accuracy. Agirre et al. (2009) used a *k*-nearest words on distributional similarity as context words. They apply a LKB graph-based WSD to a target word together with the distributional context words, and showed that it yields better results on a domain dataset than just using immediate context words. Though these

studies are word-by-word WSD for target words, they demonstrated the effectiveness to enrich immediate context by corpus statistics.

This paper proposes a *smoothing model* that integrates dictionary-based semantic similarity and corpus-based context statistics, where a *combinatorial optimization scheme* is employed to deal with sense interdependency of the all-words WSD task. The rest of this paper is structured as follows. We first describe our smoothing model in the following section. The combinatorial optimization method with the model is described in Section 3. Section 4 describes a specific implementation for evaluation. The evaluation is performed with the SemEval-2 English all-words dataset. We present the performance in Section 5. In Section 6 we discuss whether the intended context-to-sense mapping and the sense-interdependency are properly modeled. Finally we review related studies in Section 7 and conclude in Section 8.

## 2 Smoothing Model

Let us introduce in this section the basic idea for modeling context-to-sense mapping. The distance (or similarity) metrics are assumed to be given for context and for sense. A specific implementation of these metrics is described later in this paper, for now the context metric is generalized with a distance function  $d_x(\cdot, \cdot)$  and the sense metric with  $d_s(\cdot, \cdot)$ . Actually these functions may be arbitrary ones that accept two elements and return a positive real number.

Now suppose we are given a dataset concerning  $N$  number of target words. This dataset is denoted by  $X = \{x_i\}_{i=1}^N$ , where  $x_i$  corresponds to the context of the  $i$ -th word but not the word by itself. For each  $x_i$ , the intended sense of the word is to be found in a set of sense candidates  $S_i = \{s_{ij}\}_{j=1}^{M_i} \subseteq S$ , where  $M_i$  is the number of sense candidates for the  $i$ -th word,  $S$  is the whole set of sense inventories in a dictionary. Let the two-tuple  $h_{ij} = (x_i, s_{ij})$  be the hypothesis that the intended sense in  $x_i$  is  $s_{ij}$ . The hypothesis is an element of the direct product  $H = X \times S$ . As  $(X, d_x)$  and  $(S, d_s)$  each composes a metric space,  $H$  is also a metric space, provided a proper distance definition with  $d_x$  and  $d_s$ .

Here, we treat the space  $H$  as a continuous one, which means that we assume *the relationship between context and sense can be generalized in continuous fashion*. In natural language processing,

continuity has been sometimes assumed for linguistic phenomena including word context for corpus based WSD. As for classes or senses, it may not be a common assumption. However, when the classes for all-words WSD are enormous, fine-grained, and can be associated with distance, we can rather naturally assume the continuity also for senses. According to the nature of continuity, once given a hypothesis  $h_{ij}$  for a certain word, we can extrapolate the hypothesis for another word of another sense  $h_{i'j'} = (x_{i'}, s_{i'j'})$  sufficiently close to  $h_{ij}$ . Using a Gaussian kernel (Parzen, 1962) as a smoothing model, the probability density extrapolated at  $h_{i'j'}$  given  $h_{ij}$  is defined by their distance as follows:

$$\begin{aligned} \mathcal{K}(h_{ij}, h_{i'j'}) & \\ \equiv \frac{1}{2\pi\sigma_x\sigma_s} \exp \left[ -\frac{d_x^2(x_i, x_{i'})}{2\sigma_x^2} - \frac{d_s^2(s_{ij}, s_{i'j'})}{2\sigma_s^2} \right], & \end{aligned} \quad (1)$$

where  $\sigma_x$  and  $\sigma_s$  are parameters of positive real number  $\sigma_x, \sigma_s \in \mathbb{R}^+$  called *kernel bandwidths*. They control the smoothing intensity in context and in sense, respectively.

Our objective is to determine the optimal sense for all the target words simultaneously. It is essentially a 0-1 integer programming problem, and is not computationally tractable. We relax the integer constraints by introducing a *sense probability* parameter  $\pi_{ij}$  corresponding to each  $h_{ij}$ .  $\pi_{ij}$  denotes the probability by which  $h_{ij}$  is true. As  $\pi_{ij}$  is a probability, it satisfies the constraints  $\forall i \sum_j \pi_{ij} = 1$  and  $\forall i, j \ 0 \leq \pi_{ij} \leq 1$ . The probability density extrapolated at  $h_{i'j'}$  by a *probabilistic* hypothesis  $h_{ij}$  is given as follows:

$$\mathcal{Q}_{ij}(h_{i'j'}) \propto \pi_{ij} \mathcal{K}(h_{ij}, h_{i'j'}). \quad (2)$$

The proposed model is illustrated in Figure 1. Due to the limitation of drawing, both the context metric space and the sense metric space are drawn schematically as 1-dimensional spaces (axes), actually arbitrary metric spaces similarity-based or feature-based are applicable. The product metric space of the context metric space and the sense metric space composes a hypothesis space. In the hypothesis space,  $n$  sense hypotheses for a certain word is represented as  $n$  points on the hyperplane that spreads across the sense metric space. The two small circles in the middle of the figure represent the two sense hypotheses for a single word. The position of a hypothesis represents which sense is assigned to the current word in

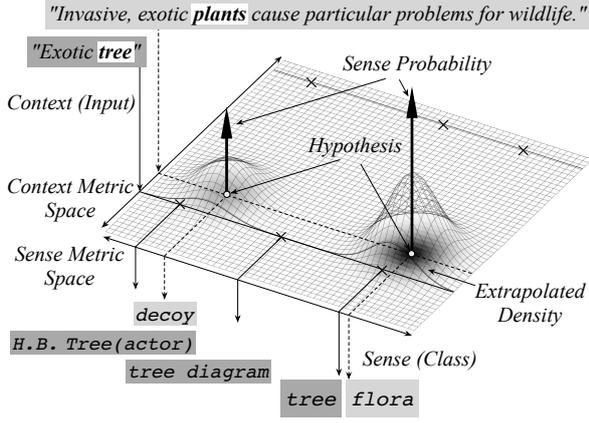

Figure 1: Proposed probability distribution model for context-to-sense mapping space.

what context. The upward arrow on a hypothesis represents the magnitude of its probability.

Centered on each hypotheses, a Gaussian kernel is placed as a smoothing model. It extrapolates the hypotheses of other words around it. In accordance with geometric intuition, intensity of extrapolation is affected by the distance from a hypothesis, and by the probability of the hypothesis by itself. Extrapolated probability density is represented by shadow thickness and surface height. If there is another word in nearby context, the kernels can validate the sense of that word. In the figure, there are two kernels in the context “*Invasive, exotic ...*”. They are two competing hypothesis for the senses *decoy* and *flora* of the word *plants*. These kernels affect the senses of another ambiguous word *tree* in nearby context “*Exotic ...*”, and extrapolate the most at the sense *tree* nearby *flora*. The extrapolation has non-linear effect. It affects little to the word far away in context or in sense as is the case for the background word in the figure. Strength of smoothing is determined by kernel bandwidths. Wider bandwidths bring stronger effect of generalization to further hypotheses, but too wide bandwidths smooth out detailed structure. The bandwidths are the key for disambiguation, therefore they are to be optimized on a dataset together with sense probabilities.

### 3 Simultaneous Optimization of All-words WSD

Given the smoothing model to extrapolate the senses of other words, we now make its instances interact to obtain the optimal combination of senses for all the words.

### 3.1 Likelihood Definition

Let us first define the likelihood of model parameters for a given dataset. The parameters consist of a context bandwidth  $\sigma_x$ , a sense bandwidth  $\sigma_s$ , and sense probabilities  $\pi_{ij}$  for all  $i$  and  $j$ . For convenience of description, the sense probabilities are all together denoted as a vector  $\boldsymbol{\pi} = (\dots, \pi_{ij}, \dots)^\top$ , in which actual order is not the matter.

Now remind that our dataset  $X = \{x_i\}_{i=1}^N$  is composed of  $N$  instances of *unlabeled* word context. We consider all the mappings from context to sense are latent, and find the optimal parameters by maximizing marginal pseudo likelihood based on probability density. The likelihood is defined as follows:

$$\mathcal{L}(\boldsymbol{\pi}, \sigma_x, \sigma_s; X) \equiv \ln \prod_i \sum_j \pi_{ij} \mathcal{Q}(h_{ij}), \quad (3)$$

where  $\prod_i$  denotes the product over  $x_i \in X$ ,  $\sum_j$  denotes the summation over all possible senses  $s_{ij} \in S_i$  for the current  $i$ -th context.  $\mathcal{Q}(h_{ij})$  denotes the probability density at  $h_{ij}$ . We compute  $\mathcal{Q}(h_{ij})$  using *leave-one-out cross-validation* (LOOCV), so as to prevent kernels from overfitting to themselves, as follows:

$$\begin{aligned} \mathcal{Q}(h_{ij}) & \\ \equiv \frac{1}{N - N_i} \sum_{i': w_{i'} \neq w_i} \sum_{j'} \pi_{i'j'} \mathcal{K}(h_{ij}, h_{i'j'}), & \quad (4) \end{aligned}$$

where  $N_i$  denotes the number of occurrences of a word type  $w_i$  in  $X$ , and  $\sum_{i': w_{i'} \neq w_i}$  denotes the summation over  $x_{i'} \in X$  except the case that the word type  $w_{i'}$  equals to  $w_i$ .  $\sum_{j'}$  denotes the summation over  $s_{i'j'} \in S_{i'}$ . We take as the unit of LOOCV not a word instance but a word type, because the instances of the same word type invariably have the same sense candidates, which still cause overfitting when optimizing the sense bandwidth.

### 3.2 Parameter Optimization

We are now ready to calculate the optimal senses. The optimal parameters  $\boldsymbol{\pi}^*$ ,  $\sigma_x^*$ ,  $\sigma_s^*$  are obtained by maximizing the likelihood  $\mathcal{L}$  subject to the constraints on  $\boldsymbol{\pi}$ , that is  $\forall i \sum_j \pi_{ij} = 1$ <sup>1</sup>. Using the Lagrange multipliers  $\{\lambda_i\}_{i=1}^N$  for every  $i$ -th constraint, the solution for the constrained maximiza-

<sup>1</sup>It is guaranteed that the other constraints  $\forall i, j 0 \leq \pi_{ij} \leq 1$  are satisfied according to Equation (7).

tion of  $\mathcal{L}$  is obtained as the solution for the equivalent unconstrained maximization of  $\check{\mathcal{L}}$  as follows:

$$\boldsymbol{\pi}^*, \sigma_x^*, \sigma_s^* = \arg \max_{\boldsymbol{\pi}, \sigma_x, \sigma_s} \check{\mathcal{L}}, \quad (5)$$

where

$$\check{\mathcal{L}} \equiv \mathcal{L} + \sum_i \lambda_i \left( \sum_j \pi_{ij} - 1 \right). \quad (6)$$

When we optimize the parameters, the first term of Equation (6) in the right-hand side acts *to reinforce* nearby hypotheses among different words, whereas the second term acts *to suppress* conflicting hypotheses of the same word.

Taking  $\nabla \check{\mathcal{L}} = 0$ , erasing  $\lambda_i$ , and rearranging, we obtain the optimal parameters as follows:

$$\pi_{ij} = \frac{\sum_{\substack{i', j' \\ w_{i'} \neq w_i}} \mathcal{R}_{i'j'}^{ij} + \sum_{\substack{i', j' \\ w_{i'} \neq w_i}} \mathcal{R}_{ij}^{i'j'}}{1 + \sum_j \sum_{\substack{i', j' \\ w_{i'} \neq w_i}} \mathcal{R}_{ij}^{i'j'}} \quad (7)$$

$$\sigma_x^2 = \frac{1}{N} \sum_{\substack{i, i', j, j' \\ w_{i'} \neq w_i}} \mathcal{R}_{i'j'}^{ij} d_x^2(x_i, x_{i'}) \quad (8)$$

$$\sigma_s^2 = \frac{1}{N} \sum_{\substack{i, i', j, j' \\ w_{i'} \neq w_i}} \mathcal{R}_{i'j'}^{ij} d_s^2(s_{ij}, s_{i'j'}), \quad (9)$$

where  $\mathcal{R}_{i'j'}^{ij}$  denotes the *responsibility* of  $h_{i'j'}$  to  $h_{ij}$ : the ratio of total expected density at  $h_{ij}$ , taken up by the expected density extrapolated by  $h_{i'j'}$ , normalized to the total for  $x_i$  be 1. It is defined as

$$\mathcal{R}_{i'j'}^{ij} \equiv \frac{\pi_{ij} \mathcal{Q}_{i'j'}(h_{ij})}{\sum_j \pi_{ij} \mathcal{Q}(h_{ij})}. \quad (10)$$

$\mathcal{Q}_{i'j'}(h_{ij})$  denotes the probability density at  $h_{ij}$  extrapolated by  $h_{i'j'}$  alone, defined as follows:

$$\mathcal{Q}_{i'j'}(h_{ij}) \equiv \frac{1}{N - N_i} \pi_{i'j'} \mathcal{K}(h_{ij}, h_{i'j'}). \quad (11)$$

Intuitively, Equations (7)-(9) are interpreted as follows. As for Equation (7), the right-hand side of the equation can be divided as the left term and the right term both in the numerator and in the denominator. The left term requires  $\pi_{ij}$  to agree with the ratio of responsibility *of the whole to  $h_{ij}$* . The right term requires  $\pi_{ij}$  to agree with the ratio of responsibility *of  $h_{ij}$  to the whole*. As for Equation (8), (9), the optimal solution is the mean squared distance in context, and in sense, weighted by responsibility.

To obtain the actual values of the optimal parameters, EM algorithm (Dempster et al., 1977) is applied. This is because Equations (7)-(9) are circular definitions, which include the objective parameters implicitly in the right hand side, thus the solution is not obtained analytically. EM algorithm is an iterative method for finding maximum likelihood estimates of parameters in statistical models, where the model depends on unobserved latent variables. Applying the EM algorithm to our model, we obtain the following steps:

**Step 1. Initialization:** Set initial values to  $\boldsymbol{\pi}$ ,  $\sigma_x$ , and  $\sigma_s$ . As for sense probabilities, we set the uniform probability in accordance with the number of sense candidates, thereby  $\pi_{ij} \leftarrow |S_i|^{-1}$ , where  $|S_i|$  denotes the size of  $S_i$ . As for bandwidths, we set the mean squared distance in each metric; thereby  $\sigma_x^2 \leftarrow N^{-1} \sum_{i, i'} d_x^2(x_i, x_{i'})$  for context bandwidth, and  $\sigma_s^2 \leftarrow (\sum_i |S_i|)^{-1} \sum_{i, i'} \sum_{j, j'} d_s^2(s_{ij}, s_{i'j'})$  for sense bandwidth.

**Step 2. Expectation:** Using the current parameters  $\boldsymbol{\pi}$ ,  $\sigma_x$ , and  $\sigma_s$ , calculate the responsibilities  $\mathcal{R}_{i'j'}^{ij}$  according to Equation (10).

**Step 3. Maximization:** Using the current responsibility  $\mathcal{R}_{i'j'}^{ij}$ , update the parameters  $\boldsymbol{\pi}$ ,  $\sigma_x$ , and  $\sigma_s$ , according to Equation (7)-(9).

**Step 4. Convergence test:** Compute the likelihood. If its ratio to the previous iteration is sufficiently small, or predetermined number of iterations has been reached, then terminate the iteration. Otherwise go back to Step 2.

To visualize how it works, we applied the above EM algorithm to pseudo 2-dimensional data. The results are shown in Figure 2. It simulates WSD for an  $N = 5$  words dataset, whose contexts are depicted by five lines. The sense hypotheses are depicted by twelve upward arrows. At the base of each arrow, there is a Gaussian kernel. Shadow thickness and surface height represents the composite probability distribution of all the twelve kernels. Through the iterative parameter update, sense probabilities and kernel bandwidths were optimized to the dataset. Figure 2(a) illustrates the initial status, where all the sense hypothesis are equivalently probable, thus they are in the most ambiguous status. Initial bandwidths are set to the mean squared distance of all the hypotheses pairs,

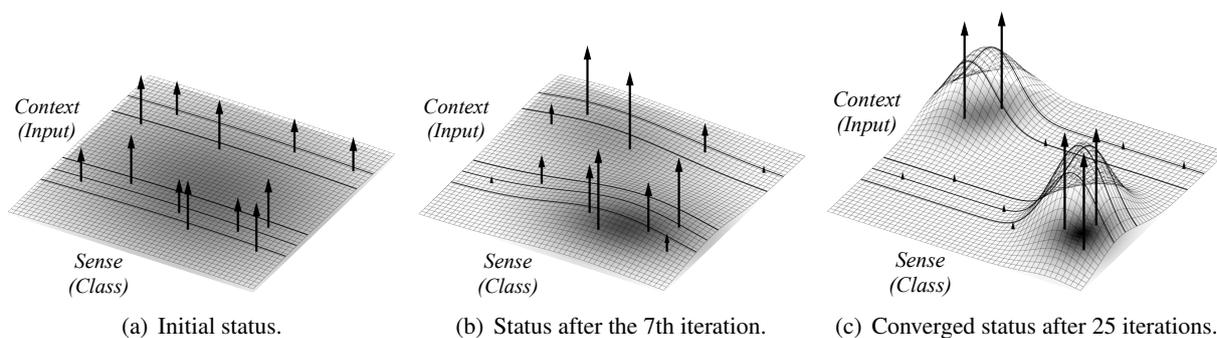

Figure 2: Pseudo 2D data simulation to visualize the dynamics of the proposed simultaneous all-words WSD with ambiguous five words and twelve sense hypotheses. (There are twelve Gaussian kernels at the base of each arrow, though the figure shows just their composite distribution. Those kernels reinforce and compete one another while being fitted their affecting range, and finally settle down to the most consistent interpretation for the words with appropriate generalization. For the dynamics with an actual dataset, see Figure 5.)

which is rather broad and makes kernels strongly smoothed, thus the model captures general structure of space. Figure 2(b) shows the status after the 7th iteration. Bandwidths are shrinking especially in context, and two context clusters, so to speak, two usages, are found. Figure 2(c) shows the status of convergence after 25 iterations. All the arrow lengths incline to either 1 or 0 along with their neighbors, thus all the five words are now disambiguated.

Note that this is not the conventional clustering of observed data. If, for instance, the Gaussian mixture clustering of 2-mixtures is applied to the positions of these hypotheses, it will find the clusters just like Figure 2(b) and will stop. The cluster centers are located at the means of hypotheses including miscellaneous alternatives not intended, thus the estimated probability distribution is, roughly speaking, offset toward the center of WordNet, which is not what we want. In contrast, the proposed method proceeds to Figure 2(c) and finds clusters *in the data after conflicting data is erased*. This is because our method is aiming at modeling not the disambiguation of cluster-memberships but the disambiguation of senses for each word.

#### 4 Metric Space Implementation

So far, we have dealt with general metrics for context and for sense. This section describes a specific implementation of those metrics employed in the evaluation. We followed the previous study by McCarthy et al. (2004), (2007), and implemented a type-based WSD. The context of word

instances are tied to the distributional context of the word type in a large corpus. To calculate sense similarities, we used the WordNet similarity package by Pedersen et al. (2004), version 2.05. Two measures proposed by Jiang and Conrath (1997) and Lesk (1986) were examined, which performed best in the previous study (McCarthy et al., 2004).

Distributional similarity (Lin, 1998) was computed among target words, based on the statistics of the test set and the background text provided as the official dataset of the SemEval-2 English all-words task (Agirre et al., 2010). Those texts were parsed using RASP parser (Briscoe et al., 2006) version 3.1, to obtain grammatical relations for the distributional similarity, as well as to obtain lemmata and part-of-speech (POS) tags which are required to look up the sense inventory of WordNet. Based on the distributional similarity, we just used  $k$ -nearest neighbor words as the context of each target word. Although it is an approximation, we can expect reliability improvement often seen by ignoring the lower part. In addition, this limitation of interactions highly reduces computational cost in particular when applying to larger-scale problems. To do this, the exhaustive sum  $\sum_{i, i': w_i \neq w_{i'}}$  in Equation (7)-(9) is altered by the local sum  $\sum_{i, i': (w_i, w_{i'}) \in P_{kNN}}$ , where  $P_{kNN}$  denotes the set of word pairs of which either is a  $k$ -nearest neighbors of the other. The normalizing factors 1,  $N$ , and  $N - N_i$  in Equation (7), (8)-(9), and (11) are altered by the actual sum of responsibilities within those neighbors as  $\sum_{i', j, j': (w_i, w_{i'}) \in P_{kNN}} \mathcal{R}_{i'j'}^{ij}$ ,

$\sum_{i, i', j, j': (w_i, w_{i'}) \in P_{k\text{NN}}} \mathcal{R}_{i'j'}^{ij}$ , and  
 $\sum_{i, i', j, j': (w_i, w_{i'}) \in P_{k\text{NN}} \wedge i \neq i'} \mathcal{R}_{i'j'}^{ij}$ , respectively.

To treat the above similarity functions of context and of sense as distance functions, we use the conversion:  $d(\cdot, \cdot) \equiv -\alpha \ln(f(\cdot, \cdot)/f_{\max})$ , where  $d$  denotes the objective distance function, i.e.,  $d_x$  for context and  $d_s$  for sense, while  $f$  and  $f_{\max}$  denote the original similarity function and its maximum, respectively.  $\alpha$  is a *standardization coefficient*, which is determined so that the mean squared distance be 1 in a dataset. According to this standardization, initial values of  $\sigma_x^2$ ,  $\sigma_s^2$  are always 1.

## 5 Evaluation

To confirm the effect of the proposed smoothing model and its combinatorial optimization scheme, we conducted WSD evaluations. The primary evaluations compare our method with conventional ones, in Section 5.2. Supplementary evaluations are described in the subsequent sections that include the comparison with SemEval-2 participating systems, and the analysis of model dynamics with the experimental data.

### 5.1 Evaluation Scheme

To make the evaluation comparable to state-of-the-art systems, we used the official dataset of the SemEval-2 English all-words WSD task (Agirre et al., 2010), which is currently the latest public dataset available with published results. The dataset consists of test data and background documents of the same *environment* domain. The test data consists of 1,398 target words (1,032 nouns and 366 verbs) in 5.3K running words. The background documents consists of 2.7M running words, which was used to compute distributional similarity.

Precisions and recalls were all computed using the official evaluation tool `scorer2` in fine-grained measure. The tool accepts answers either in probabilistic format (senses with probabilities for each target word) or in deterministic format (most likely senses, with no score information). As the proposed method is a probability model, we evaluated in the probabilistic way unless explicitly noted otherwise. For this reason, we evaluated all the sense probabilities as they were. Disambiguations were executed in separate runs for nouns and verbs, because no interaction takes place across POS in this metric implementation. The two runs'

results were combined later to a single answer to be input to `scorer2`.

The context metric space was composed by  $k$ -nearest neighbor words of distributional similarity (Lin, 1998), as is described in Section 4. The value of  $k$  was evaluated for  $\{2, 3, 5, 10, 20, 30, 50, 100, 200, 300\}$ . As for sense metric space, we evaluated two measures i.e., (Jiang and Conrath, 1997) denoted as *JCN*, and (Lesk, 1986) denoted as *Lesk*. In every condition, stopping criterion of iteration is always the number of iteration (500 times), irrespective of the convergence in likelihood.

Primary evaluations compared our method with two conventional methods. Those methods differ to ours only in scoring schemes. The first one is the method by McCarthy et al. (2004), which determines the word sense based on sense similarity and distributional similarity to the  $k$ -nearest neighbor words of a target word by distributional similarity. Our major advantage is the combinatorial optimization framework, while the conventional one employs word-by-word scheme. The second one is based on the method by Patwardhan et al. (2007), which determines the word sense by maximizing the sum of sense similarity to the  $k$  immediate neighbor words of a target word. The  $k$  words were forced to be selected from other target words of the same POS to the word of interest, so as to make information resource equivalent to the other comparable two methods. It is also a word-by-word method. It exploits no distributional similarity. Our major advantages are the combinatorial optimization scheme and the smoothing model to integrate distributional similarity. In the following section, these comparative methods are referred to as *Mc2004* and *Pat2007*, respectively.

### 5.2 Comparison with Conventional Methods

Let us first confirm our advantages compared to the conventional methods of *Mc2004* and *Pat2007*. The comparative results are shown in Figure 3 in recall measure. Precisions are simply omitted because the difference to the recalls are always the number of failures on referring to WordNet by mislabeling of lemmata or POSs, which is always the same for the three methods. Vertical range depicts 95% confidence intervals. The graphs also indicate the most-frequent-sense (MFS) baseline estimated from out-of-domain corpora, whose recall is 0.505 (Agirre et al., 2010).

As we can see in Figure 3(a) and 3(b), higher

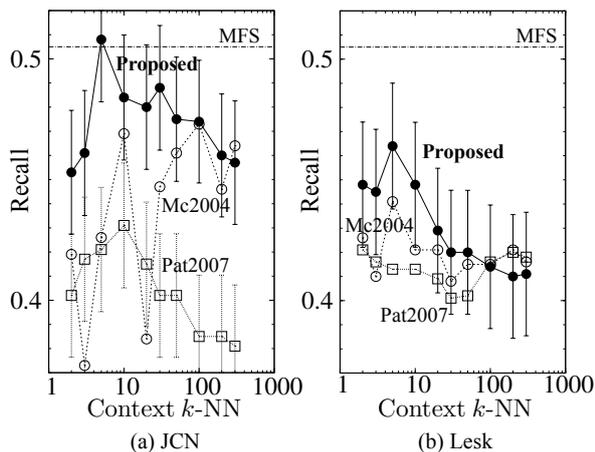

Figure 3: Comparison to the conventional methods that differ to our method only in scoring schemes.

Table 1: Comparison with the top-5 knowledge-based systems in SemEval-2 (JCN/ $k=5$ ).

Rank	Participants	R	P	Rn	Rv
-	<b>Proposed (best)</b>	<b>50.8</b>	<b>51.0</b>	<b>52.5</b>	<b>46.2</b>
-	<i>MFS Baseline</i>	50.5	50.5	52.7	44.3
1	Kulkarni et al. (2010)	49.5	51.2	51.6	43.4
2	Tran et al. (2010)	49.3	50.6	51.6	42.6
3	Tran et al. (2010)	49.1	50.4	51.5	42.5
4	Soroa et al. (2010)	48.1	48.1	48.7	46.2
5	Tran et al. (2010)	47.9	49.2	49.4	43.4
...	...	...	...	...	...
-	<i>Random Baseline</i>	23.2	23.2	25.3	17.2

recalls are obtained in the order of the proposed method, Mc2004, and Pat2007 on the whole. Comparing JCN and Lesk, difference among the three is smaller in Lesk. It is possibly because Lesk is a score not normalized for different word pairs, which makes the effect of distributional similarity unsteady especially when combining many  $k$ -nearest words. Therefore the recalls are expected to improve if proper normalization is applied to the proposed method and Mc2004. In JCN, the recalls of the proposed method significantly improve compared to Pat2007. Our best recall is 0.508 with JCN and  $k=5$ . Thus we can conclude that, though significance depends on metrics, our smoothing model and the optimization scheme are effective to improve accuracies.

### 5.3 Comparison with SemEval-2 Systems

We compared our best results with the participating systems of the task. Table 1 compares the details to the top-5 systems, which only includes unsupervised/knowledge-based ones and excludes supervised/weakly-supervised ones. Those values

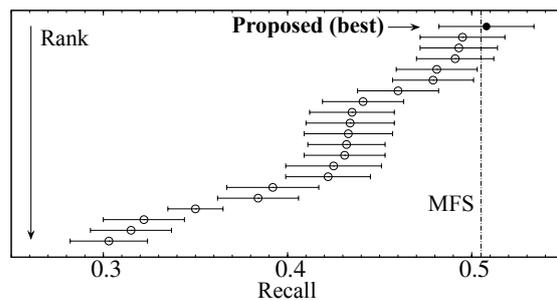

Figure 4: Comparison with the all 20 knowledge-based systems in SemEval-2 (JCN/ $k=5$ ).

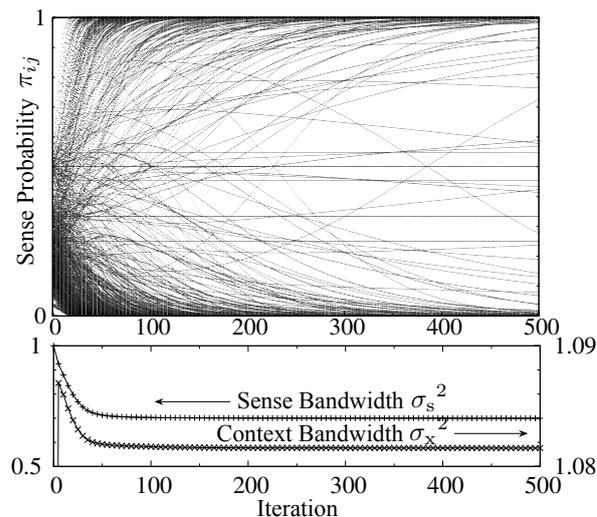

Figure 5: Model dynamics through iteration with SemEval-2 nouns (JCN/ $k=5$ ).

are transcribed from the official report (Agirre et al., 2010). “R” and “P” denote the recall and the precision for the whole dataset, while “Rn” and “Rv” denote the recall for nouns and verbs, respectively. The results are ranked by “R”, in accordance with the original report. As shown in the table, our best results outperform all of the systems and the MFS baseline.

Overall rankings are depicted in Figure 4. It maps our best results in the distribution of all the 20 unsupervised/knowledge-based participating systems. The ranges spreading left and right are 95% confidence intervals. As is seen from the figure, our best results are located above the top group, which are outside the confidence intervals of the other participants ranked intermediate or lower.

### 5.4 Analysis on Model Dynamics

This section examines the model dynamics with the SemEval-2 data, which has been illustrated

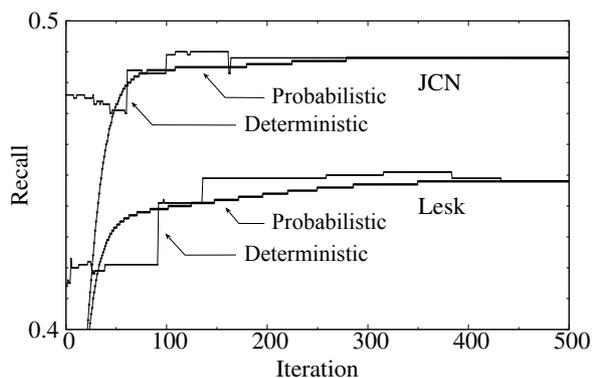

Figure 6: Recall improvement via iteration with SemEval-2 all POSs (JCN/ $k=30$ , Lesk/ $k=10$ ).

with pseudo data in Section 3.2. Let us start by looking at the upper half of Figure 5, which shows the change of sense probabilities through iteration. At the initial status (iteration 0), the probabilities were all  $1/2$  for bi-semous words, all  $1/3$  for tri-semous words, and so forth. As iteration proceeded, the probabilities gradually spread out to either side of 1 or 0, and finally at iteration 500, we can observe that almost all the words were clearly disambiguated. The lower half of Figure 5 shows the dynamics in bandwidths. Vertical axis on the left is for the sense bandwidth, and on the right is for the context bandwidth. We can observe those bandwidths became narrower as iteration proceeded. Intensity of smoothing was dynamically adjusted by the whole disambiguation status. These behaviors confirm that even with an actual dataset, it works as is expected, just as illustrated in Figure 2.

## 6 Discussion

This section discusses the validity of the proposed method as to i) sense-interdependent disambiguation and ii) reliability of data smoothing. We here analyze the second peak conditions at  $k = 30$  (JCN) and  $k = 10$  (Lesk) instead of the first peak at  $k = 5$ , because we can observe tendency the better with the larger number of word interactions.

### 6.1 Effects of Sense-interdependent Disambiguation

Let us first examine the effect of our sense-interdependent disambiguation. We would like to confirm that how the progressive disambiguation is carried out. Figure 6 shows the change of recall through iteration for JCN ( $k = 30$ ) and Lesk ( $k = 10$ ). Those recalls were obtained by

evaluating the status after each iteration. The recalls were here evaluated both in probabilistic format and in deterministic format. From the figure we can observe that the deterministic recalls also increased as well as the probabilistic recalls. This means that the ranks of sense candidates for each word were frequently altered through iteration, which further means that some new information not obtained earlier was delivered one after another to sense disambiguation for each word. From these results, we could confirm the expected sense-interdependency effect that a sense disambiguation of certain word affected to other words.

### 6.2 Reliability of Smoothing as Supervision

Let us now discuss the reliability of our smoothing model. In our method, sense disambiguation of a word is guided by its nearby words' extrapolation (smoothing). Sense accuracy fully depends on the reliability of the extrapolation. Generally speaking, statistical reliability increases as the number of random sampling increases. If we take sufficient number of *random words* as nearby words, the sense distribution comes close to the true distribution, and then we expect the statistically true sense distribution should find out the true sense of the target word, according to the *distributional hypotheses* (Harris, 1954). On the contrary, if we take nearby words that are biased to particular words, the sense distribution also becomes biased, and the extrapolation becomes less reliable.

We can compute the randomness of words that affect for sense disambiguation, by *word perplexity*. Let the word of interest be  $w \in V$ . The word perplexity is calculated as  $2^{H|w}$ , where  $H|w$  denotes the entropy defined as  $H|w \equiv -\sum_{w' \in V \setminus \{w\}} p(w'|w) \log_2 p(w'|w)$ . The conditional probability  $p(w'|w)$  denotes the probability with which a certain word  $w' \in V \setminus \{w\}$  determines the sense of  $w$ , which can be defined as the density ratio:  $p(w'|w) \propto \sum_{i: w_i=w} \sum_{i': w_{i'}=w'} \sum_{j, j'} Q_{i'j'} \mathcal{Q}_{ij}(h_{ij})$ .

The relation between word perplexity and probability change for ground-truth senses of nouns (JCN/ $k = 30$ ) is shown in Figure 7. The upper histogram shows the change in iteration 1-100, and the lower shows that of iteration 101-500. We divide the analysis at iteration 100, because roughly until the 100th iteration, the change in bandwidths converged, and the number of words to interact settled, as can be seen in Figure 5. The bars that

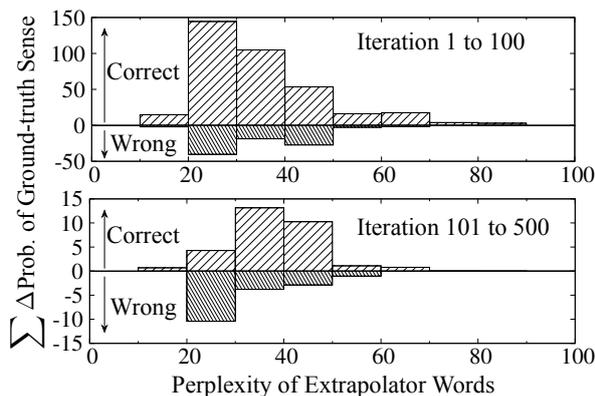

Figure 7: Correlation between reliability and perplexity with SemEval-2 nouns ( $JCN/k = 30$ ).

extend upward represent the sum of the amount raised (correct change), and the bars that extend downward represent the sum of the amount reduced (wrong change). From these figures, we observe that when perplexity is sufficiently large ( $\geq 30$ ), change occurred largely (79%) to the correct direction. In contrast, at the lower left of the figure, where perplexity is small ( $< 30$ ) and bandwidths has been narrowed at iteration 101-500, correct change occupied only 32% of the whole. Therefore, we can conclude that if sufficiently random samples of nearby words are provided, our smoothing model is reliable, though it is trained in an unsupervised fashion.

## 7 Related Work

As described in Section 1, graph-based WSD has been extensively studied, since graphs are favorable structure to deal with interactions of data on vertices. Conventional studies typically consider as vertices the instances of input or target class, e.g. knowledge-based approaches typically regard *senses as vertices* (see Section 1), and corpus-based approaches such as (Véronis, 2004) regard *words as vertices* or (Niu et al., 2005) regards *context as vertices*. Our method can be viewed as one of graph-based methods, but it regards *input-to-class mapping as vertices*, and the edges represent the relations both together in context and in sense. Mihalcea (2005) proposed graph-based methods, whose vertices are sense label hypotheses on word sequence. Our method generalize context representation.

In the evaluation, our method was compared to SemEval-2 systems. The main subject of the SemEval-2 task was domain adaptation, therefore

those systems each exploited their own adaptation techniques. Kulkarni et al. (2010) used a WordNet pre-pruning. Disambiguation is performed by considering only those candidate synsets that belong to the top- $k$  largest connected components of the WordNet on domain corpus. Tran et al. (2010) used over 3TB domain documents acquired by Web search. They parsed those documents and extracted the statistics on dependency relation for disambiguation. Soroa et al. (2010) used the method by Agirre et al. (2009) described in Section 1. They disambiguated each target word using its distributionally similar words instead of its immediate context words.

The proposed method is an extension of density estimation (Parzen, 1962), which is a construction of an estimate based on *observed data*. Our method naturally extends the density estimation in two points, which make it applicable to unsupervised knowledge-based WSD. First, we introduce stochastic treatment of data, which is no longer observations but hypotheses having ambiguity. This extension makes the hypotheses possible to cross-validate the plausibility each other. Second, we extend the definition of density from Euclidean distance to general metric, which makes the proposed method applicable to a wide variety of corpus-based context similarities and dictionary-based sense similarities.

## 8 Conclusions

We proposed a novel *smoothing model* with a *combinatorial optimization scheme* for all-words WSD from untagged corpora. Experimental results showed that our method significantly improves the accuracy of conventional methods by exceeding most-frequent-sense baseline performance where none of SemEval-2 unsupervised systems reached. Detailed inspection of dynamics clearly show that the proposed optimization method effectively exploit the sense-dependency of all-words. Moreover, our smoothing model, though unsupervised, provides reliable supervision when sufficiently random samples of words are available as nearby words. Thus it was confirmed that this method is valid for finding the optimal combination of word senses with large untagged corpora. We hope this study would elicit further investigation in this important area.

## Abstract

Modelling the compositional process by which the meaning of an utterance arises from the meaning of its parts is a fundamental task of Natural Language Processing. In this paper we draw upon recent advances in the learning of vector space representations of sentential semantics and the transparent interface between syntax and semantics provided by Combinatory Categorical Grammar to introduce Combinatory Categorical Autoencoders. This model leverages the CCG combinatory operators to guide a non-linear transformation of meaning within a sentence. We use this model to learn high dimensional embeddings for sentences and evaluate them in a range of tasks, demonstrating that the incorporation of syntax allows a concise model to learn representations that are both effective and general.

## 1 Introduction

Since Frege stated his ‘Principle of Semantic Compositionality’ in 1892 researchers have pondered both how the meaning of a complex expression is determined by the meanings of its parts, and how those parts are combined. (Frege, 1892; Pelletier, 1994). Over a hundred years on the choice of representational unit for this process of compositional semantics, and how these units combine, remain open questions.

Frege’s principle may be debatable from a linguistic and philosophical standpoint, but it has provided a basis for a range of formal approaches to semantics which attempt to capture meaning in logical models. The Montague grammar (Montague, 1970) is a prime example for this, building a model of composition based on lambda-calculus and formal logic. More recent work

in this field includes the Combinatory Categorical Grammar (CCG), which also places increased emphasis on syntactic coverage (Szabolcsi, 1989).

Recently those searching for the right representation for compositional semantics have drawn inspiration from the success of distributional models of lexical semantics. This approach represents single words as distributional vectors, implying that a word’s meaning is a function of the environment it appears in, be that its syntactic role or co-occurrences with other words (Pereira et al., 1993; Schütze, 1998). While distributional semantics is easily applied to single words, sparsity implies that attempts to directly extract distributional representations for larger expressions are doomed to fail. Only in the past few years has it been attempted to extend these representations to semantic composition. Most approaches here use the idea of vector-matrix composition to learn larger representations from single-word encodings (Baroni and Zamparelli, 2010; Grefenstette and Sadrzadeh, 2011; Socher et al., 2012b). While these models have proved very promising for compositional semantics, they make minimal use of linguistic information beyond the word level.

In this paper we bridge the gap between recent advances in machine learning and more traditional approaches within computational linguistics. We achieve this goal by employing the CCG formalism to consider compositional structures at any point in a parse tree. CCG is attractive both for its transparent interface between syntax and semantics, and a small but powerful set of combinatory operators with which we can parametrise our non-linear transformations of compositional meaning.

We present a novel class of recursive models, the Combinatory Categorical Autoencoders (CCA), which marry a semantic process provided by a recursive autoencoder with the syntactic representations of the CCG formalism. Through this model we seek to answer two ques-

representations have then successfully been applied to a number of tasks including word sense disambiguation (Schütze, 1998) and selectional preference (Pereira et al., 1993; Lin, 1999).

While it is theoretically possible to apply the same mechanism to larger expressions, sparsity prevents learning meaningful distributional representations for expressions much larger than single words.<sup>2</sup>

Vector space models of compositional semantics aim to fill this gap by providing a methodology for deriving the representation of an expression from those of its parts. While distributional representations frequently serve to encode single words in such approaches this is not a strict requirement.

There are a number of ideas on how to define composition in such vector spaces. A general framework for semantic vector composition was proposed in Mitchell and Lapata (2008), with Mitchell and Lapata (2010) and more recently Blacoe and Lapata (2012) providing good overviews of this topic. Notable approaches to this issue include Baroni and Zamparelli (2010), who compose nouns and adjectives by representing them as vectors and matrices, respectively, with the compositional representation achieved by multiplication. Grefenstette and Sadrzadeh (2011) use a similar approach with matrices for relational words and vectors for arguments. These two approaches are combined in Grefenstette et al. (2013), producing a tensor-based semantic framework with tensor contraction as composition operation.

Another set of models that have very successfully been applied in this area are recursive autoencoders (Socher et al., 2011a; Socher et al., 2011b), which are discussed in the next section.

### 2.3 Recursive Autoencoders

Autoencoders are a useful tool to compress information. One can think of an autoencoder as a funnel through which information has to pass (see Figure 2). By forcing the autoencoder to reconstruct an input given only the reduced amount of information available inside the funnel it serves as a compression tool, representing high-dimensional objects in a lower-dimensional space.

Typically a given autoencoder, that is the functions for encoding and reconstructing data, are

<sup>2</sup>The experimental setup in (Baroni and Zamparelli, 2010) is one of the few examples where distributional representations are used for word pairs.

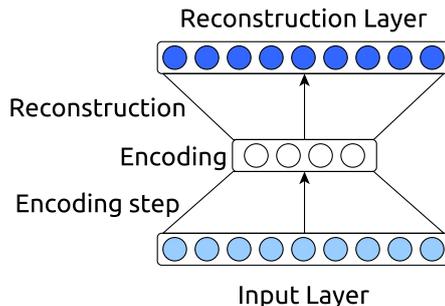

Figure 2: A simple three-layer autoencoder. The input represented by the vector at the bottom is being encoded in a smaller vector (middle), from which it is then reconstructed (top) into the same dimensionality as the original input vector.

used on multiple inputs. By optimizing the two functions to minimize the difference between all inputs and their respective reconstructions, this autoencoder will effectively discover some hidden structures within the data that can be exploited to represent it more efficiently.

As a simple example, assume input vectors  $x_i \in \mathbb{R}^n, i \in (0..N)$ , weight matrices  $W^{enc} \in \mathbb{R}^{(m \times n)}$ ,  $W^{rec} \in \mathbb{R}^{(n \times m)}$  and biases  $b^{enc} \in \mathbb{R}^m$ ,  $b^{rec} \in \mathbb{R}^n$ . The encoding matrix and bias are used to create an encoding  $e_i$  from  $x_i$ :

$$e_i = f^{enc}(x_i) = W^{enc}x_i + b^{enc} \quad (1)$$

Subsequently  $e \in \mathbb{R}^m$  is used to reconstruct  $x$  as  $x'$  using the reconstruction matrix and bias:

$$x'_i = f^{rec}(e_i) = W^{rec}e_i + b^{rec} \quad (2)$$

$\theta = (W^{enc}, W^{rec}, b^{enc}, b^{rec})$  can then be learned by minimizing the error function describing the difference between  $x'$  and  $x$ :

$$E = \frac{1}{2} \sum_i^N \|x'_i - x_i\|^2 \quad (3)$$

Now, if  $m < n$ , this will intuitively lead to  $e_i$  encoding a latent structure contained in  $x_i$  and shared across all  $x_j, j \in (0..N)$ , with  $\theta$  encoding and decoding to and from that hidden structure.

It is possible to apply multiple autoencoders on top of each other, creating a deep autoencoder (Bengio et al., 2007; Hinton and Salakhutdinov, 2006). For such a multi-layered model to learn anything beyond what a single layer could learn, a non-linear transformation  $g$  needs to be applied at each layer. Usually, a variant of the sigmoid ( $\sigma$ )

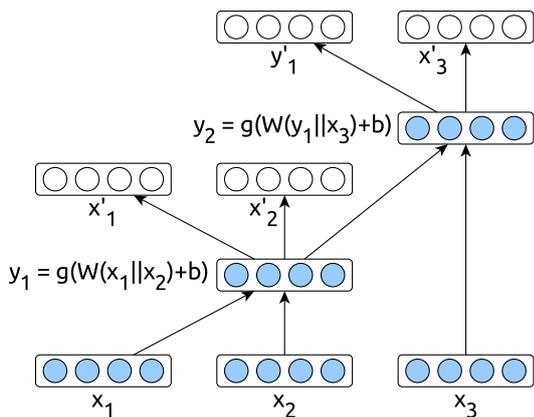

Figure 3: RAE with three inputs. Vectors with filled (blue) circles represent input and hidden units; blanks (white) denote reconstruction layers.

or hyperbolic tangent ( $\tanh$ ) function is used for  $g$  (LeCun et al., 1998).

$$\begin{aligned} f^{enc}(x_i) &= g(W^{enc}x_i + b^{enc}) \\ f^{rec}(e_i) &= g(W^{rec}e_i + b^{rec}) \end{aligned} \quad (4)$$

Furthermore, autoencoders can easily be used as a composition function by concatenating two input vectors, such that:

$$\begin{aligned} e &= f(x_1, x_2) = g(W(x_1||x_2) + b) \\ (x'_1||x'_2) &= g(W'e + b') \end{aligned} \quad (5)$$

Extending this idea, recursive autoencoders (RAE) allow the modelling of data of variable size. By setting the  $n = 2m$ , it is possible to recursively combine a structure into an autoencoder tree. See Figure 3 for an example, where  $x_1, x_2, x_3$  are recursively encoded into  $y_2$ .

The recursive application of autoencoders was first introduced in Pollack (1990), whose recursive auto-associative memories learn vector representations over pre-specified recursive data structures. More recently this idea was extended and applied to dynamic structures (Socher et al., 2011b).

These types of models have become increasingly prominent since developments within the field of Deep Learning have made the training of such hierarchical structures more effective and tractable (LeCun et al., 1998; Hinton et al., 2006).

Intuitively the top layer of an RAE will encode aspects of the information stored in all of the input vectors. Previously, RAE have successfully been applied to a number of tasks including sentiment analysis, paraphrase detection, relation extraction

Model	CCG Elements
CCAIE-A	parse
CCAIE-B	parse + rules
CCAIE-C	parse + rules + types
CCAIE-D	parse + rules + child types

Table 1: Aspects of the CCG formalism used by the different models explored in this paper.

and 3D object identification (Blacoe and Lapata, 2012; Socher et al., 2011b; Socher et al., 2012a).

### 3 Model

The models in this paper combine the power of recursive, vector-based models with the linguistic intuition of the CCG formalism. Their purpose is to learn semantically meaningful vector representations for sentences and phrases of variable size, while the purpose of this paper is to investigate the use of syntax and linguistic formalisms in such vector-based compositional models.

We assume a CCG parse to be given. Let  $C$  denote the set of combinatory rules, and  $T$  the set of categories used, respectively. We use the parse tree to structure an RAE, so that each combinatory step is represented by an autoencoder function. We refer to these models Categorical Combinatory Autoencoders (CCAIE). In total this paper describes four models making increasing use of the CCG formalism (see table 1).

As an internal baseline we use model CCAIE-A, which is an RAE structured along a CCG parse tree. CCAIE-A uses a single weight matrix each for the encoding and reconstruction step (see Table 2). This model is similar to Socher et al. (2011b), except that we use a fixed structure in place of the greedy tree building approach. As CCAIE-A uses only minimal syntactic guidance, this should allow us to better ascertain to what degree the use of syntax helps our semantic models.

Our second model (CCAIE-B) uses the composition function in equation (6), with  $c \in C$ .

$$\begin{aligned} f^{enc}(x, y, c) &= g(W_{enc}^c(x||y) + b_{enc}^c) \\ f^{rec}(e, c) &= g(W_{rec}^c e + b_{rec}^c) \end{aligned} \quad (6)$$

This means that for every combinatory rule we define an equivalent autoencoder composition function by parametrizing both the weight matrix and bias on the combinatory rule (e.g. Figure 4).

In this model, as in the following ones, we assume a reconstruction step symmetric with the

Model	Encoding Function
CCAIE-A	$f(x, y) = g(W(x  y) + b)$
CCAIE-B	$f(x, y, c) = g(W^c(x  y) + b^c)$
CCAIE-C	$f(x, y, c, t) = g\left(\sum_{p \in \{c, t\}} (W^p(x  y) + b^p)\right)$
CCAIE-D	$f(x, y, c, tx, ty) = g(W^c(W^{tx}x + W^{ty}y) + b^c)$

Table 2: Encoding functions of the four CCAIE models discussed in this paper.

$$\frac{\alpha : X/Y \quad \beta : Y}{\alpha\beta : X} \rightarrow g(W_{enc}^>(\alpha||\beta) + b_{enc}^>)$$

Figure 4: Forward application as CCG combinator and autoencoder rule respectively.

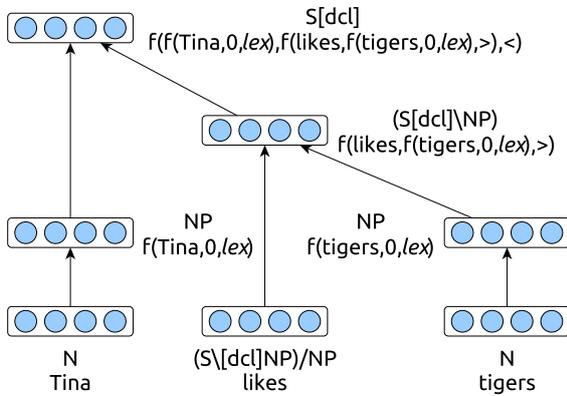

Figure 5: CCAIE-B applied to *Tina likes tigers*. Next to each vector are the CCG category (top) and the word or function representing it (bottom). *lex* describes the unary type-changing operation.  $>$  and  $<$  are forward and backward application.

composition step. For the remainder of this paper we will focus on the composition step and drop the use of *enc* and *rec* in variable names where it isn't explicitly required. Figure 5 shows model CCAIE-B applied to our previous example sentence.

While CCAIE-B uses only the combinatory rules, we want to make fuller use of the linguistic information available in CCG. For this purpose, we build another model CCAIE-C, which parametrizes on both the combinatory rule  $c \in C$  and the CCG category  $t \in T$  at every step (see Figure 2). This model provides an additional degree of insight, as the categories  $T$  are semantically and syntactically more expressive than the CCG combinatory rules by themselves. Summing over weights parametrised on  $c$  and  $t$  respectively, adds an additional degree of freedom and also al-

lows for some model smoothing.

An alternative approach is encoded in model CCAIE-D. Here we consider the categories not of the element represented, but of the elements it is generated from together with the combinatory rule applied to them. The intuition is that in the first step we transform two expressions based on their syntax. Subsequently we combine these two conditioned on their joint combinatory rule.

## 4 Learning

In this section we briefly discuss unsupervised learning for our models. Subsequently we describe how these models can be extended to allow for semi-supervised training and evaluation.

Let  $\theta = (W, B, L)$  be our model parameters and  $\lambda$  a vector with regularization parameters for all model parameters.  $W$  represents the set of all weight matrices,  $B$  the set of all biases and  $L$  the set of all word vectors. Let  $N$  be the set of training data consisting of tree-nodes  $n$  with inputs  $x_n, y_n$  and reconstruction  $r_n$ . The error given  $n$  is:

$$E(n|\theta) = \frac{1}{2} \left\| r_n - (x_n || y_n) \right\|^2 \quad (7)$$

The gradient of the regularised objective function then becomes:

$$\frac{\partial J}{\partial \theta} = \frac{1}{N} \sum_n \frac{\partial E(n|\theta)}{\partial \theta} + \lambda \theta \quad (8)$$

We learn the gradient using backpropagation through structure (Goller and Küchler, 1996), and minimize the objective function using L-BFGS.

For more details about the partial derivatives used for backpropagation, see the documentation accompanying our model implementation.<sup>3</sup>

<sup>3</sup><http://www.karlmoritz.com/>

## 4.1 Supervised Learning

The unsupervised method described so far learns a vector representation for each sentence. Such a representation can be useful for some tasks such as paraphrase detection, but is not sufficient for other tasks such as sentiment classification, which we are considering in this paper.

In order to extract sentiment from our models, we extend them by adding a supervised classifier on top, using the learned representations  $v$  as input for a binary classification model:

$$\text{pred}(l=1|v, \theta) = \text{sigmoid}(W_{\text{label}} v + b_{\text{label}}) \quad (9)$$

Given our corpus of CCG parses with label pairs  $(N, l)$ , the new objective function becomes:

$$J = \frac{1}{N} \sum_{(N,l)} E(N, l, \theta) + \frac{\lambda}{2} \|\theta\|^2 \quad (10)$$

Assuming each node  $n \in N$  contains children  $x_n, y_n$ , encoding  $e_n$  and reconstruction  $r_n$ , so that  $n = \{x, y, e, r\}$  this breaks down into:

$$E(N, l, \theta) = \sum_{n \in N} \alpha E_{\text{rec}}(n, \theta) + (1 - \alpha) E_{\text{lbl}}(e_n, l, \theta) \quad (11)$$

$$E_{\text{rec}}(n, \theta) = \frac{1}{2} \left\| [x_n \| y_n] - r_n \right\|^2 \quad (12)$$

$$E_{\text{lbl}}(e, l, \theta) = \frac{1}{2} \|l - e\|^2 \quad (13)$$

This method of introducing a supervised aspect to the autoencoder largely follows the model described in Socher et al. (2011b).

## 5 Experiments

We describe a number of standard evaluations to determine the comparative performance of our model. The first task of sentiment analysis allows us to compare our CCG-conditioned RAE with similar, existing models. In a second experiment, we apply our model to a compound similarity evaluation, which allows us to evaluate our models against a larger class of vector-based models (Blacoe and Lapata, 2012). We conclude with some qualitative analysis to get a better idea of whether the combination of CCG and RAE can learn semantically expressive embeddings.

In our experiments we use the hyperbolic tangent as nonlinearity  $g$ . Unless stated otherwise we

use word-vectors of size 50, initialized using the embeddings provided by Turian et al. (2010) based on the model of Collobert and Weston (2008).<sup>4</sup>

We use the C&C parser (Clark and Curran, 2007) to generate CCG parse trees for the data used in our experiments. For models CCAE-C and CCAE-D we use the 25 most frequent CCG categories (as extracted from the British National Corpus) with an additional general weight matrix in order to catch all remaining types.

### 5.1 Sentiment Analysis

We evaluate our model on the MPQA opinion corpus (Wiebe et al., 2005), which annotates expressions for sentiment.<sup>5</sup> The corpus consists of 10,624 instances with approximately 70 percent describing a negative sentiment. We apply the same pre-processing as (Nakagawa et al., 2010) and (Socher et al., 2011b) by using an additional sentiment lexicon (Wilson et al., 2005) during the model training for this experiment.

As a second corpus we make use of the sentence polarity (SP) dataset v1.0 (Pang and Lee, 2005).<sup>6</sup> This dataset consists of 10662 sentences extracted from movie reviews which are manually labelled with positive or negative sentiment and equally distributed across sentiment.

**Experiment 1: Semi-Supervised Training** In the first experiment, we use the semi-supervised training strategy described previously and initialize our models with the embeddings provided by Turian et al. (2010). The results of this evaluation are in Table 3. While we achieve the best performance on the MPQA corpus, the results on the SP corpus are less convincing. Perhaps surprisingly, the simplest model CCAE-A outperforms the other models on this dataset.

When considering the two datasets, sparsity seems a likely explanation for this difference in results: In the MPQA experiment most instances are very short with an average length of 3 words, while the average sentence length in the SP corpus is 21 words. The MPQA task is further simplified through the use of an additional sentiment lexicon. Considering dictionary size, the SP corpus has a dictionary of 22k words, more than three times the size of the MPQA dictionary.

Method	MPQA	SP
Voting with two lexica	81.7	63.1
MV-RNN (Socher et al., 2012b)	-	79.0
RAE (rand) (Socher et al., 2011b)	85.7	76.8
TCRF (Nakagawa et al., 2010)	86.1	77.3
RAE (init) (Socher et al., 2011b)	86.4	77.7
NB (Wang and Manning, 2012)	86.7	79.4
CCAЕ-A	86.3	77.8
CCAЕ-B	87.1	77.1
CCAЕ-C	87.1	77.3
CCAЕ-D	<b>87.2</b>	76.7

Table 3: Accuracy of sentiment classification on the sentiment polarity (SP) and MPQA datasets. For NB we only display the best result among a larger group of models analysed in that paper.

This issue of sparsity is exacerbated in the more complex CCAE models, where the training points are spread across different CCG types and rules. While the initialization of the word vectors with previously learned embeddings (as was previously shown by Socher et al. (2011b)) helps the models, all other model variables such as composition weights and biases are still initialised randomly and thus highly dependent on the amount of training data available.

**Experiment 2: Pretraining** Due to our analysis of the results of the initial experiment, we ran a second series of experiments on the SP corpus. We follow (Scheible and Schütze, 2013) for this second series of experiments, which are carried out on a random 90/10 training-testing split, with some data reserved for development.

Instead of initialising the model with external word embeddings, we first train it on a large amount of data with the aim of overcoming the sparsity issues encountered in the previous experiment. Learning is thus divided into two steps:

The first, unsupervised training phase, uses the British National Corpus together with the SP corpus. In this phase only the reconstruction signal is used to learn word embeddings and transformation matrices. Subsequently, in the second phase, only the SP corpus is used, this time with both the reconstruction and the label error.

By learning word embeddings and composition matrices on more data, the model is likely to generalise better. Particularly for the more complex models, where the composition functions are conditioned on various CCG parameters, this should

Model	Training	
	Regular	Pretraining
CCAЕ-A	77.8	79.5
CCAЕ-B	76.9	79.8
CCAЕ-C	77.1	81.0
CCAЕ-D	76.9	79.7

Table 4: Effect of pretraining on model performance on the SP dataset. Results are reported on a random subsection of the SP corpus; thus numbers for the regular training method differ slightly from those in Table 3.

help to overcome issues of sparsity.

If we consider the results of the pre-trained experiments in Table 4, this seems to be the case. In fact, the trend of the previous results has been reversed, with the more complex models now performing best, whereas in the previous experiments the simpler models performed better. Using the Turian embeddings instead of random initialisation did not improve results in this setup.

## 5.2 Compound Similarity

In a second experiment we use the dataset from Mitchell and Lapata (2010) which contains similarity judgements for adjective-noun, noun-noun and verb-object pairs.<sup>7</sup> All compound pairs have been ranked for semantic similarity by a number of human annotators. The task is thus to rank these pairs of word pairs by their semantic similarity.

For instance, the two compounds *vast amount* and *large quantity* are given a high similarity score by the human judges, while *northern region* and *early age* are assigned no similarity at all.

We train our models as fully unsupervised autoencoders on the British National Corpus for this task. We assume fixed parse trees for all of the compounds (Figure 6), and use these to compute compound level vectors for all word pairs. We subsequently use the cosine distance between each compound pair as our similarity measure. We use Spearman’s rank correlation coefficient ( $\rho$ ) for evaluation; hence there is no need to rescale our scores (-1.0 – 1.0) to the original scale (1.0 – 7.0).

Blacoe and Lapata (2012) have an extensive comparison of the performance of various vector-based models on this data set to which we compare our model in Table 5. The CCAE models outper-

form the RAE models provided by Blacoe and Lapata (2012), and score towards the upper end of the range of other models considered in that paper.

### 5.3 Qualitative Analysis

To get better insight into our models we also perform a small qualitative analysis. Using one of the models trained on the MPQA corpus, we generate word-level representations of all phrases in this corpus and subsequently identify the most related expressions by using the cosine distance measure. We perform this experiment on all expressions of length 5, considering all expressions with a word length between 3 and 7 as potential matches.

As can be seen in Table 6, this works with varying success. Linking expressions such as *conveying the message of peace* and *safeguard(ing) peace and security* suggests that the model does learn some form of semantics.

On the other hand, the connection between *expressed their satisfaction and support* and *expressed their admiration and surprise* suggests that the pure word level content still has an impact on the model analysis. Likewise, the expressions *is a story of success* and *is a staunch supporter* have some lexical but little semantic overlap. Further reducing this link between the lexical and the semantic representation is an issue that should be addressed in future work in this area.

## 6 Discussion

Overall, our models compare favourably with the state of the art. On the MPQA corpus model CCAE-D achieves the best published results we are aware of, whereas on the SP corpus we achieve competitive results. With an additional, unsupervised training step we achieved results beyond the current state of the art on this task, too.

**Semantics** The qualitative analysis and the experiment on compounds demonstrate that the CCAE models are capable of learning semantics. An advantage of our approach—and of autoencoders generally—is their ability to learn in an unsupervised setting. The pre-training step for the sentiment task was essentially the same training step as used in the compound similarity task. While other models such as the MV-RNN (Socher et al., 2012b) achieve good results on a particular task, they do not allow unsupervised training. This prevents the possibility of pretraining, which we showed to have a big impact on results, and further prevents the training of general models: The CCAE models can be used for multiple tasks without the need to re-train the main model.

**Complexity** Previously in this paper we argued that our models combined the strengths of other approaches. By using a grammar formalism we increase the expressive power of the model while the complexity remains low. For the complexity analysis see Table 7. We strike a balance between the greedy approaches (e.g. Socher et al. (2011b)), where learning is quadratic in the length of each sentence and existing syntax-driven approaches such as the MV-RNN of Socher et al. (2012b), where the size of the model, that is the number of variables that needs to be learned, is quadratic in the size of the word-embeddings.

**Sparsity** Parametrizing on CCG types and rules increases the size of the model compared to a greedy RAE (Socher et al., 2011b). The effect of this was highlighted by the sentiment analysis task, with the more complex models performing

Expression	Most Similar
convey the message of peace	safeguard peace and security
keep alight the flame of	keep up the hope
has a reason to repent	has no right
a significant and successful strike	a much better position
it is reassuring to believe	it is a positive development
expressed their satisfaction and support	expressed their admiration and surprise
is a story of success	is a staunch supporter
are lining up to condemn	are going to voice their concerns
more sanctions should be imposed	charges being leveled
could fray the bilateral goodwill	could cause serious damage

Table 6: Phrases from the MPQA corpus and their semantically closest match according to CCAE-D.

Model	Complexity	
	Size	Learning
MV-RNN	$\mathcal{O}(nw^2)$	$\mathcal{O}(l)$
RAE	$\mathcal{O}(nw)$	$\mathcal{O}(l^2)$
CCAЕ-*	$\mathcal{O}(nw)$	$\mathcal{O}(l)$

Table 7: Comparison of models.  $n$  is dictionary size,  $w$  embedding width,  $l$  is sentence length. We can assume  $l \gg n \gg w$ . Additional factors such as CCG rules and types are treated as small constants for the purposes of this analysis.

worse in comparison with the simpler ones. We were able to overcome this issue by using additional training data. Beyond this, it would also be interesting to investigate the relationships between different types and to derive functions to incorporate this into the learning procedure. For instance model learning could be adjusted to enforce some mirroring effects between the weight matrices of forward and backward application, or to support similarities between those of forward application and composition.

**CCG-Vector Interface** Exactly how the information contained in a CCG derivation is best applied to a vector space model of compositionality is another issue for future research. Our investigation of this matter by exploring different model setups has proved somewhat inconclusive. While CCAE-D incorporated the deepest conditioning on the CCG structure, it did not decisively outperform the simpler CCAE-B which just conditioned on the combinatory operators. Issues of sparsity, as shown in our experiments on pretraining, have a significant influence, which requires further study.

## 7 Conclusion

In this paper we have brought a more formal notion of semantic compositionality to vector space models based on recursive autoencoders. This was achieved through the use of the CCG formalism to provide a conditioning structure for the matrix vector products that define the RAE.

We have explored a number of models, each of which conditions the compositional operations on different aspects of the CCG derivation. Our experimental findings indicate a clear advantage for a deeper integration of syntax over models that use only the bracketing structure of the parse tree.

The most effective way to condition the compositional operators on the syntax remains unclear. Once the issue of sparsity had been addressed, the complex models outperformed the simpler ones. Among the complex models, however, we could not establish significant or consistent differences to convincingly argue for a particular approach.

While the connections between formal linguistics and vector space approaches to NLP may not be immediately obvious, we believe that there is a case for the continued investigation of ways to best combine these two schools of thought. This paper represents one step towards the reconciliation of traditional formal approaches to compositional semantics with modern machine learning.

## Acknowledgements

We thank the anonymous reviewers for their feedback and Richard Socher for providing additional insight into his models. Karl Moritz would further like to thank Sebastian Riedel for hosting him at UCL while this paper was written. This work has been supported by the EPSRC.

# Margin-based Decomposed Amortized Inference

Gourab Kundu\* and Vivek Srikumar\* and Dan Roth

University of Illinois, Urbana-Champaign

Urbana, IL. 61801

{kundu2, vsrikum2, danr}@illinois.edu

## Abstract

Given that structured output prediction is typically performed over entire datasets, one natural question is whether it is possible to re-use computation from earlier inference instances to speed up inference for future instances. Amortized inference has been proposed as a way to accomplish this. In this paper, first, we introduce a new amortized inference algorithm called the *Margin-based Amortized Inference*, which uses the notion of structured margin to identify inference problems for which previous solutions are provably optimal. Second, we introduce *decomposed amortized inference*, which is designed to address very large inference problems, where earlier amortization methods become less effective. This approach works by decomposing the output structure and applying amortization piece-wise, thus increasing the chance that we can re-use previous solutions for *parts* of the output structure. These parts are then combined to a global coherent solution using Lagrangian relaxation. In our experiments, using the NLP tasks of semantic role labeling and entity-relation extraction, we demonstrate that with the margin-based algorithm, we need to call the inference engine only for a third of the test examples. Further, we show that the decomposed variant of margin-based amortized inference achieves a greater reduction in the number of inference calls.

## 1 Introduction

A wide variety of NLP problems can be naturally cast as structured prediction problems. For

some structures like sequences or parse trees, specialized and tractable dynamic programming algorithms have proven to be very effective. However, as the structures under consideration become increasingly complex, the computational problem of predicting structures can become very expensive, and in the worst case, intractable.

In this paper, we focus on an inference technique called *amortized inference* (Srikumar et al., 2012), where previous solutions to inference problems are used to speed up new instances. The main observation that leads to amortized inference is that, very often, for different examples of the same size, the structures that maximize the score are identical. If we can efficiently identify that two inference problems have the same solution, then we can re-use previously computed structures for newer examples, thus giving us a speedup.

This paper has two contributions. First, we describe a novel algorithm for amortized inference called *margin-based amortization*. This algorithm is on an examination of the structured margin of a prediction. For a new inference problem, if this margin is larger than the sum of the decrease in the score of the previous prediction *and* any increase in the score of the second best one, then the previous solution will be the highest scoring one for the new problem. We formalize this intuition to derive an algorithm that finds provably optimal solutions and show that this approach is a generalization of previously identified schemes (based on Theorem 1 of (Srikumar et al., 2012)).

Second, we argue that the idea of amortization is best exploited at the level of *parts* of the structures rather than the entire structure because we expect a much higher redundancy in the parts. We introduce the notion of *decomposed amortized inference*, whereby we can attain a significant improvement in speedup by considering repeated sub-structures across the dataset and applying any amortized inference algorithm for the parts.

---

\* These authors contributed equally to this work.

We evaluate the two schemes and their combination on two NLP tasks where the output is encoded as a structure: PropBank semantic role labeling (Punyakanok et al., 2008) and the problem of recognizing entities and relations in text (Roth and Yih, 2007; Kate and Mooney, 2010). In these problems, the inference problem has been framed as an integer linear program (ILP). We compare our methods with previous amortized inference methods and show that margin-based amortization combined with decomposition significantly outperforms existing methods.

## 2 Problem Definition and Notation

Structured output prediction encompasses a wide variety of NLP problems like part-of-speech tagging, parsing and machine translation. The language of 0-1 integer linear programs (ILP) provides a convenient analytical tool for representing structured prediction problems. The general setting consists of binary inference variables each of which is associated with a score. The goal of inference is to find the highest scoring global assignment of the variables from a feasible set of assignments, which is defined by linear inequalities.

While efficient inference algorithms exist for special families of structures (like linear chains and trees), in the general case, inference can be computationally intractable. One approach to deal with the computational complexity of inference is to use an off-the-shelf ILP solver for solving the inference problem. This approach has seen increasing use in the NLP community over the last several years (for example, (Roth and Yih, 2004; Clarke and Lapata, 2006; Riedel and Clarke, 2006) and many others). Other approaches for solving inference include the use of cutting plane inference (Riedel, 2009), dual decomposition (Koo et al., 2010; Rush et al., 2010) and the related method of Lagrangian relaxation (Rush and Collins, 2011; Chang and Collins, 2011).

(Srikumar et al., 2012) introduced the notion of an *amortized inference algorithm*, defined as an inference algorithm that can use previous predictions to speed up inference time, thereby giving an amortized gain in inference time over the lifetime of the program.

The motivation for amortized inference comes from the observation that though the number of possible structures could be large, in practice, only a small number of these are ever seen in real

data. Furthermore, among the observed structures, a small subset typically occurs much more frequently than the others. Figure 1 illustrates this observation in the context of part-of-speech tagging. If we can efficiently characterize and identify inference instances that have the same solution, we can take advantage of previously performed computation without paying the high computational cost of inference.

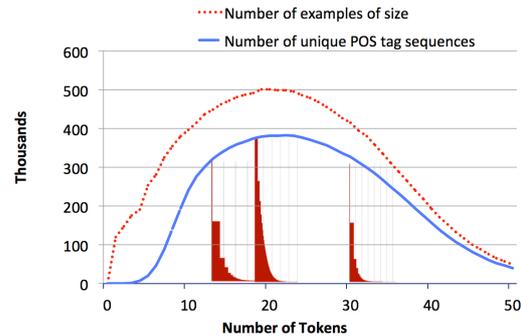

Figure 1: Comparison of number of instances and the number of unique observed part-of-speech structures in the Gigaword corpus. Note that the number of observed structures (blue solid line) is much lower than the number of sentences (red dotted line) for all sentence lengths, with the difference being very pronounced for shorter sentences. Embedded in the graph are three histograms that show the distribution of observed structures for sentences of length 15, 20 and 30. In all cases, we see that a small number of tag sequences are much more frequent than the others.

We denote inference problems by the bold-faced letters  $\mathbf{p}$  and  $\mathbf{q}$ . For a problem  $\mathbf{p}$ , the goal of inference is to jointly assign values to the parts of the structure, which are represented by a collection of inference variables  $\mathbf{y} \in \{0, 1\}^n$ . For all vectors, subscripts represent their  $i^{\text{th}}$  component.

Each  $y_i$  is associated with a real valued  $c_{\mathbf{p},i} \in \mathbb{R}$  which is the score for the variable  $y_i$  being assigned the value 1. We denote the vector comprising of all the  $c_{\mathbf{p},i}$  as  $\mathbf{c}_{\mathbf{p}}$ . The search space for assignments is restricted via constraints, which can be written as a collection of linear inequalities,  $\mathbf{M}^T \mathbf{y} \leq \mathbf{b}$ . For a problem  $\mathbf{p}$ , we denote this feasible set of structures by  $K_{\mathbf{p}}$ .

The inference problem is that of finding the feasible assignment to the structure which maximizes the dot product  $\mathbf{c}^T \mathbf{y}$ . Thus, the prediction problem can be written as

$$\arg \max_{\mathbf{y} \in K_{\mathbf{p}}} \mathbf{c}^T \mathbf{y}. \quad (1)$$

We denote the solution of this maximization problem as  $\mathbf{y}_p$ .

Let the set  $P = \{\mathbf{p}^1, \mathbf{p}^2, \dots\}$  denote previously solved inference problems, along with their respective solutions  $\{\mathbf{y}_p^1, \mathbf{y}_p^2, \dots\}$ . An *equivalence class* of integer linear programs, denoted by  $[P]$ , consists of ILPs which have the same number of inference variables and the same feasible set. Let  $K_{[P]}$  denote the feasible set of an equivalence class  $[P]$ . For a program  $\mathbf{p}$ , the notation  $\mathbf{p} \sim [P]$  indicates that it belongs to the equivalence class  $[P]$ .

(Srikumar et al., 2012) introduced a set of amortized inference schemes, each of which provides a condition for a new ILP to have the same solution as a previously seen problem. We will briefly review one exact inference scheme introduced in that work. Suppose  $\mathbf{q}$  belongs to the same equivalence class of ILPs as  $\mathbf{p}$ . Then the solution to  $\mathbf{q}$  will be the same as that of  $\mathbf{p}$  if the following condition holds for all inference variables:

$$(2\mathbf{y}_{p,i} - 1)(\mathbf{c}_{q,i} - \mathbf{c}_{p,i}) \geq 0. \quad (2)$$

This condition, referred to as *Theorem 1* in that work, is the baseline for our experiments.

In general, for any amortization scheme  $A$ , we can define two primitive operators  $\text{TESTCONDITION}_A$  and  $\text{SOLUTION}_A$ . Given a collection of previously solved problems  $P$  and a new inference problem  $\mathbf{q}$ ,  $\text{TESTCONDITION}_A(P, \mathbf{q})$  checks if the solution of the new problem is the same as that of some previously solved one and if so,  $\text{SOLUTION}_A(P, \mathbf{q})$  returns the solution.

### 3 Margin-based Amortization

In this section, we will introduce a new method for amortizing inference costs over time. The key observation that leads to this theorem stems from the *structured margin*  $\delta$  for an inference problem  $\mathbf{p} \sim [P]$ , which is defined as follows:

$$\delta = \min_{\mathbf{y} \in K_{[P]}, \mathbf{y} \neq \mathbf{y}_p} \mathbf{c}_p^T (\mathbf{y}_p - \mathbf{y}). \quad (3)$$

That is, for all feasible  $\mathbf{y}$ , we have  $\mathbf{c}_p^T \mathbf{y}_p \geq \mathbf{c}_p^T \mathbf{y} + \delta$ . The margin  $\delta$  is the upper limit on the *change in objective* that is allowed for the constraint set  $K_{[P]}$  for which the solution will not change.

For a new inference problem  $\mathbf{q} \sim [P]$ , we define  $\Delta$  as the maximum change in objective value that can be effected by an assignment that is *not* the

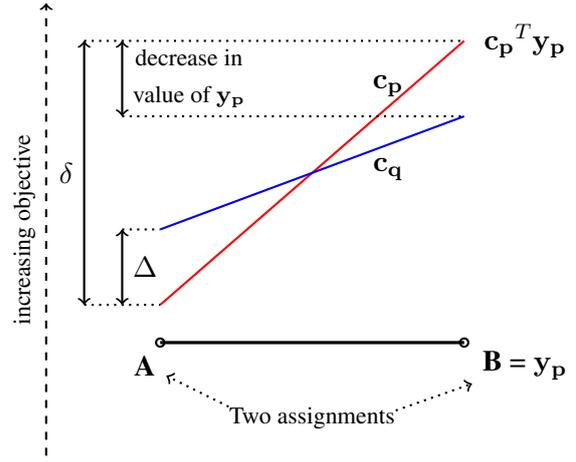

Figure 2: An illustration of the margin-based amortization scheme showing the very simple case with only two competing assignments  $\mathbf{A}$  and  $\mathbf{B}$ . Suppose  $\mathbf{B}$  is the solution  $\mathbf{y}_p$  for the inference problem  $\mathbf{p}$  with coefficients  $\mathbf{c}_p$ , denoted by the red hyperplane, and  $\mathbf{A}$  is the second-best assignment. For a new coefficient vector  $\mathbf{c}_q$ , if the margin  $\delta$  is greater than the sum of the decrease in the objective value of  $\mathbf{y}_p$  and the maximum increase in the objective of another solution ( $\Delta$ ), then the solution to the new inference problem will still be  $\mathbf{y}_p$ . The margin-based amortization theorem captures this intuition.

solution. That is,

$$\Delta = \max_{\mathbf{y} \in K_{[P]}, \mathbf{y} \neq \mathbf{y}_p} (\mathbf{c}_q - \mathbf{c}_p)^T \mathbf{y} \quad (4)$$

Before stating the theorem, we will provide an intuitive explanation for it. Moving from  $\mathbf{c}_p$  to  $\mathbf{c}_q$ , consider the sum of the decrease in the value of the objective for the solution  $\mathbf{y}_p$  and  $\Delta$ , the maximum change in objective value for an assignment that is not the solution. If this sum is less than the margin  $\delta$ , then no other solution will have an objective value higher than  $\mathbf{y}_p$ . Figure 2 illustrates this using a simple example where there are only two competing solutions.

This intuition is captured by our main theorem which provides a condition for problems  $\mathbf{p}$  and  $\mathbf{q}$  to have the same solution  $\mathbf{y}_p$ .

**Theorem 1 (Margin-based Amortization).** *Let  $\mathbf{p}$  denote an inference problem posed as an integer linear program belonging to an equivalence class  $[P]$  with optimal solution  $\mathbf{y}_p$ . Let  $\mathbf{p}$  have a structured margin  $\delta$ , i.e., for any  $\mathbf{y}$ , we have  $\mathbf{c}_p^T \mathbf{y}_p \geq \mathbf{c}_p^T \mathbf{y} + \delta$ . Let  $\mathbf{q} \sim [P]$  be another inference instance in the same equivalence class and let  $\Delta$  be defined as in Equation 4. Then,  $\mathbf{y}_p$  is the solution of the problem  $\mathbf{q}$  if the following holds:*

$$-(\mathbf{c}_q - \mathbf{c}_p)^T \mathbf{y}_p + \Delta \leq \delta \quad (5)$$

*Proof.* For some feasible  $\mathbf{y}$ , we have

$$\begin{aligned} \mathbf{c}_q^T \mathbf{y}_p - \mathbf{c}_q^T \mathbf{y} &\geq \mathbf{c}_q^T \mathbf{y}_p - \mathbf{c}_p^T \mathbf{y} - \Delta \\ &\geq \mathbf{c}_q^T \mathbf{y}_p - \mathbf{c}_p^T \mathbf{y}_p + \delta - \Delta \\ &\geq 0 \end{aligned}$$

The first inequality comes from the definition of  $\Delta$  in (4) and the second one follows from the definition of  $\delta$ . The condition of the theorem in (5) gives us the final step. For any feasible  $\mathbf{y}$ , the objective score assigned to  $\mathbf{y}_p$  is greater than the score assigned to  $\mathbf{y}$  according to problem  $\mathbf{q}$ . That is,  $\mathbf{y}_p$  is the solution to the new problem.  $\square$

The margin-based amortization theorem provides a general, new amortized inference algorithm. Given a new inference problem, we check whether the inequality (5) holds for any previously seen problems in the same equivalence class. If so, we return the cached solution. If no such problem exists, then we make a call to an ILP solver.

Even though the theorem provides a condition for two integer linear programs to have the same solution, checking the validity of the condition requires the computation of  $\Delta$ , which in itself is another integer linear program. To get around this, we observe that if any constraints in Equation 4 are relaxed, the value of the resulting maximum can only increase. Even with the increased  $\Delta$ , if the condition of the theorem holds, then the rest of the proof follows and hence the new problem will have the same solution. In other words, we can solve relaxed, tractable variants of the maximization in Equation 4 and still retain the guarantees provided by the theorem. The tradeoff is that, by doing so, the condition of the theorem will apply to fewer examples than theoretically possible. In our experiments, we will define the relaxation for each problem individually and even with the relaxations, the inference algorithm based on the margin-based amortization theorem outperforms all previous amortized inference algorithms.

The condition in inequality (5) is, in fact, a strict generalization of the condition for Theorem 1 in (Srikumar et al., 2012), stated in (2). If the latter condition holds, then we can show that  $\Delta \leq 0$  and  $(\mathbf{c}_q - \mathbf{c}_p)^T \mathbf{y}_p \geq 0$ . Since  $\delta$  is, by definition, non-negative, the margin-based condition is satisfied.

## 4 Decomposed Amortized Inference

One limitation in previously considered approaches for amortized inference stems from the

expectation that the same *full* assignment maximizes the objective score for different inference problems, or equivalently, that the entire structure is repeated multiple times. Even with this assumption, we observe a speedup in prediction.

However, intuitively, even if entire structures are not repeated, we expect parts of the assignment to be the same across different instances. In this section, we address the following question: *Can we take advantage of the redundancy in components of structures to extend amortization techniques to cases where the full structured output is not repeated?* By doing so, we can store partial computation for future inference problems.

For example, consider the task of part of speech tagging. While the likelihood of two long sentences having the same part of speech tag sequence is not high, it is much more likely that shorter sections of the sentences will share the same tag sequence. We see from Figure 1 that the number of possible structures for shorter sentences is much smaller than the number of sentences. This implies that many shorter sentences share the same structure, thus improving the performance of an amortized inference scheme for such inputs. The goal of decomposed amortized inference is to extend this improvement to larger problems by increasing the size of equivalence classes.

To decompose an inference problem, we use the approach of Lagrangian Relaxation (Lemaréchal, 2001) that has been used successfully for various NLP tasks (Chang and Collins, 2011; Rush and Collins, 2011). We will briefly review the underlying idea<sup>1</sup>. The goal is to solve an integer linear program  $\mathbf{q}$ , which is defined as

$$\mathbf{q} : \max_{\mathbf{M}^T \mathbf{y} \leq \mathbf{b}} \mathbf{c}_q^T \mathbf{y}$$

We partition the constraints into two sets, say  $C_1$  denoting  $\mathbf{M}_1^T \mathbf{y} \leq \mathbf{b}_1$  and  $C_2$ , denoting constraints  $\mathbf{M}_2^T \mathbf{y} \leq \mathbf{b}_2$ . The assumption is that in the absence the constraints  $C_2$ , the inference problem becomes computationally easier to solve. In other words, we can assume the existence of a subroutine that can efficiently compute the solution of the relaxed problem  $\mathbf{q}'$ :

$$\mathbf{q}' : \max_{\mathbf{M}_1^T \mathbf{y} \leq \mathbf{b}_1} \mathbf{c}_q^T \mathbf{y}$$

<sup>1</sup>For simplicity, we only write inequality constraints in the paper. However, all the results here are easily extensible to equality constraints by removing the non-negativity constraints from the corresponding dual variables.

We define Lagrange multipliers  $\Lambda \geq \mathbf{0}$ , with one  $\lambda_i$  for each constraint in  $C_2$ . For problem  $\mathbf{q}$ , we can define the Lagrangian as

$$L(\mathbf{y}, \Lambda) = \mathbf{c}_{\mathbf{q}}^T \mathbf{y} - \Lambda^T (\mathbf{M}_2^T \mathbf{y} - \mathbf{b}_2)$$

Here, the domain of  $\mathbf{y}$  is specified by the constraint set  $C_1$ . The dual objective is

$$\begin{aligned} L(\Lambda) &= \max_{\mathbf{M}_1^T \mathbf{y} \leq \mathbf{b}_1} \mathbf{c}_{\mathbf{q}}^T \mathbf{y} - \Lambda^T (\mathbf{M}_2^T \mathbf{y} - \mathbf{b}_2) \\ &= \max_{\mathbf{M}_1^T \mathbf{y} \leq \mathbf{b}_1} (\mathbf{c}_{\mathbf{q}} - \Lambda^T \mathbf{M}_2)^T \mathbf{y} + \Lambda^T \mathbf{b}_2. \end{aligned}$$

Note that the maximization in the definition of the dual objective has the same functional form as  $\mathbf{q}'$  and any approach to solve  $\mathbf{q}'$  can be used here to find the dual objective  $L(\Lambda)$ . The dual of the problem  $\mathbf{q}$ , given by  $\min_{\Lambda \geq \mathbf{0}} L(\Lambda)$ , can be solved using subgradient descent over the dual variables.

Relaxing the constraints  $C_2$  to define the problem  $\mathbf{q}'$  has several effects. First, it can make the resulting inference problem  $\mathbf{q}'$  easier to solve. More importantly, removing constraints can also lead to the merging of multiple equivalence classes, leading to fewer, more populous equivalence classes. Finally, removing constraints can decompose the inference problem  $\mathbf{q}'$  into smaller independent sub-problems  $\{\mathbf{q}^1, \mathbf{q}^2, \dots\}$  such that no constraint that is in  $C_1$  has active variables from two different sets in the partition.

For the sub-problem  $\mathbf{q}^i$  comprising of variables  $\mathbf{y}^i$ , let the corresponding objective coefficients be  $\mathbf{c}_{\mathbf{q}^i}$  and the corresponding sub-matrix of  $\mathbf{M}_2$  be  $\mathbf{M}_2^i$ . Now, we can define the dual-augmented sub-problem as

$$\max_{\mathbf{M}_1^T \mathbf{y} \leq \mathbf{b}_1} (\mathbf{c}_{\mathbf{q}^i} - \Lambda^T \mathbf{M}_2^i)^T \mathbf{y}^i \quad (6)$$

Solving all such sub-problems will give us a complete assignment for all the output variables.

We can now define the decomposed amortized inference algorithm (Algorithm 1) that performs sub-gradient descent over the dual variables. The input to the algorithm is a collection of previously solved problems with their solutions, a new inference problem  $\mathbf{q}$  and an amortized inference scheme  $A$  (such as the margin-based amortization scheme). In addition, for the task at hand, we first need to identify the set of constraints  $C_2$  that can be introduced via the Lagrangian.

First, we check if the solution can be obtained without decomposition (lines 1–2). Otherwise,

---

### Algorithm 1 Decomposed Amortized Inference

---

**Input:** A collection of previously solved inference problems  $P$ , a new problem  $\mathbf{q}$ , an amortized inference algorithm  $A$ .

**Output:** The solution to problem  $\mathbf{q}$

```

1: if TESTCONDITION( $A, \mathbf{q}, P$ ) then
2:   return SOLUTION( $A, \mathbf{q}, P$ )
3: else
4:   Initialize  $\lambda_i \leftarrow 0$  for each constraint in  $C_2$ .
5:   for  $t = 1 \dots T$  do
6:     Partition the problem  $\mathbf{q}$  into sub-
       problems  $\mathbf{q}^1, \mathbf{q}^2, \dots$  such that no con-
       straint in  $C_1$  has active variables from
       two partitions.
7:     for partition  $\mathbf{q}^i$  do
8:        $\mathbf{y}^i \leftarrow$  Solve the maximization prob-
       lem for  $\mathbf{q}^i$  (Eq. 6) using the amortized
       scheme  $A$ .
9:     end for
10:    Let  $\mathbf{y} \leftarrow [\mathbf{y}^1; \mathbf{y}^2; \dots]$ 
11:    if  $\mathbf{M}_2 \mathbf{y} \leq \mathbf{b}_2$  and  $(\mathbf{b}_2 - \mathbf{M}_2 \mathbf{y})_i \lambda_i = 0$ 
       then
12:      return  $\mathbf{y}$ 
13:    else
14:       $\Lambda \leftarrow [\Lambda - \mu_t (\mathbf{b}_2 - \mathbf{M}_2^T \mathbf{y})]_+$ 
15:    end if
16:  end for
17:  return solution of  $\mathbf{q}$  using a standard infer-
       ence algorithm
18: end if

```

---

we initialize the dual variables  $\Lambda$  and try to obtain the solution iteratively. At the  $t^{\text{th}}$  iteration, we partition the problem  $\mathbf{q}$  into sub-problems  $\{\mathbf{q}^1, \mathbf{q}^2, \dots\}$  as described earlier (line 6). Each partition defines a smaller inference problem with its own objective coefficients and constraints. We can apply the amortization scheme  $A$  to each sub-problem to obtain a complete solution for the relaxed problem (lines 7–10). If this solution satisfies the constraints  $C_2$  and complementary slackness conditions, then the solution is provably the maximum of the problem  $\mathbf{q}$ . Otherwise, we take a subgradient step to update the value of  $\Lambda$  using a step-size  $\mu_t$ , subject to the constraint that all dual variables must be non-negative (line 14). If we do not converge to a solution in  $T$  iterations, we call the underlying solver on the full problem.

In line 8 of the algorithm, we make multiple calls to the underlying amortized inference procedure to solve each sub-problem. If the sub-

problem cannot be solved using the procedure, then we can either solve the sub-problem using a different approach (effectively giving us the standard Lagrangian relaxation algorithm for inference), or we can treat the full instance as a cache miss and make a call to an ILP solver. In our experiments, we choose the latter strategy.

## 5 Experiments and Results

Our experiments show two results: 1. The margin-based scheme outperforms the amortized inference approaches from (Srikumar et al., 2012). 2. Decomposed amortized inference gives further gains in terms of re-using previous solutions.

### 5.1 Tasks

We report the performance of inference on two NLP tasks: semantic role labeling and the task of extracting entities and relations from text. In both cases, we used an existing formulation for structured inference and only modified the inference calls. We will briefly describe the problems and the implementation and point the reader to the literature for further details.

**Semantic Role Labeling (SRL)** Our first task is that of identifying arguments of verbs in a sentence and annotating them with semantic roles (Gildea and Jurafsky, 2002; Palmer et al., 2010). For example, in the sentence *Mrs. Haag plays Eltiani.*, the verb *plays* takes two arguments: *Mrs. Haag*, the actor, labeled as A0 and *Eltiani*, the role, labeled as A1. It has been shown in prior work (Punyakank et al., 2008; Toutanova et al., 2008) that making a globally coherent prediction boosts performance of SRL.

In this work, we used the SRL system of (Punyakank et al., 2008), where one inference problem is generated for each verb and each inference variable encodes the decision that a given constituent in the sentence takes a specific role. The scores for the inference variables are obtained from a classifier trained on the PropBank corpus. Constraints encode structural and linguistic knowledge about the problem. For details about the formulations of the inference problem, please see (Punyakank et al., 2008).

Recall from Section 3 that we need to define a relaxed version of the inference problem to efficiently compute  $\Delta$  for the margin-based approach. For a problem instance with coefficients  $c_q$  and cached coefficients  $c_p$ , we take the sum of the

highest  $n$  values of  $c_q - c_p$  as our  $\Delta$ , where  $n$  is the number of argument candidates to be labeled.

To identify constraints that can be relaxed for the decomposed algorithm, we observe that most constraints are not predicate specific and apply for all predicates. The only constraint that is predicate specific requires that each predicate can only accept roles from a list of roles that is defined for that predicate. By relaxing this constraint in the decomposed algorithm, we effectively merge all the equivalence classes for all predicates with a specific number of argument candidates.

**Entity-Relation extraction** Our second task is that of identifying the types of entities in a sentence and the relations among them, which has been studied by (Roth and Yih, 2007; Kate and Mooney, 2010) and others. For the sentence *Oswald killed Kennedy*, the words *Oswald* and *Kennedy* will be labeled by the type PERSON, and the KILL relation exists between them.

We followed the experimental setup as described in (Roth and Yih, 2007). We defined one inference problem for each sentence. For every entity (which is identified by a constituent in the sentence), an inference variable is introduced for each entity type. For each pair of constituents, an inference variable is introduced for each relation type. Clearly, the assignment of types to entities and relations are not independent. For example, an entity of type ORGANIZATION cannot participate in a relation of type BORN-IN because this relation label can connect entities of type PERSON and LOCATION only. Incorporating these natural constraints during inference were shown to improve performance significantly in (Roth and Yih, 2007). We trained independent classifiers for entities and relations and framed the inference problem as in (Roth and Yih, 2007). For further details, we refer the reader to that paper.

To compute the value of  $\Delta$  for the margin-based algorithm, for a new instance with coefficients  $c_q$  and cached coefficients  $c_p$ , we define  $\Delta$  to be the sum of all non-negative values of  $c_q - c_p$ .

For the decomposed inference algorithm, if the number of entities is less than 5, no decomposition is performed. Otherwise, the entities are partitioned into two sets: set  $A$  includes the first four entities and set  $B$  includes the rest of the entities. We relaxed the relation constraints that go across these two sets of entities to obtain two independent inference problems.

## 5.2 Experimental Setup

We follow the experimental setup of (Srikumar et al., 2012) and simulate a long-running NLP process by caching problems and solutions from the Gigaword corpus. We used a database engine to cache ILP and their solutions along with identifiers for the equivalence class and the value of  $\delta$ .

For the margin-based algorithm and the Theorem 1 from (Srikumar et al., 2012), for a new inference problem  $\mathbf{p} \sim [P]$ , we retrieve all inference problems from the database that belong to the same equivalence class  $[P]$  as the test problem  $\mathbf{p}$  and find the cached assignment  $\mathbf{y}$  that has the highest score according to the coefficients of  $\mathbf{p}$ . We only consider cached ILPs whose solution is  $\mathbf{y}$  for checking the conditions of the theorem. This optimization ensures that we only process a small number of cached coefficient vectors.

In a second efficiency optimization, we pruned the database to remove redundant inference problems. A problem is redundant if solution to that problem can be inferred from the other problems stored in the database that have the same solution and belong to the same equivalence class. However, this pruning can be computationally expensive if the number of problems with the same solution and the same equivalence class is very large. In that case, we first sampled a 5000 problems randomly and selected the non-redundant problems from this set to keep in the database.

## 5.3 Results

We compare our approach to a state-of-the-art ILP solver<sup>2</sup> and also to Theorem 1 from (Srikumar et al., 2012). We choose this baseline because it is shown to give the highest improvement in wall-clock time and also in terms of the number of cache hits. However, we note that the results presented in our work outperform all the previous amortization algorithms, including the approximate inference methods.

We report two performance metrics – the percentage decrease in the number of ILP calls, and the percentage decrease in the wall-clock inference time. These are comparable to the *speedup* and *clock speedup* defined in (Srikumar et al., 2012). For measuring time, since other aspects of prediction (like feature extraction) are the same across all settings, we only measure the time taken for inference and ignore other aspects. For both

<sup>2</sup>We used the Gurobi optimizer for our experiments.

tasks, we report the runtime performance on section 23 of the Penn Treebank. Note that our amortization schemes *guarantee optimal solution*. Consequently, using amortization, task accuracy remains the same as using the original solver.

Table 1 shows the percentage reduction in the number of calls to the ILP solver. Note that for both the SRL and entity-relation problems, the margin-based approach, even without using decomposition (the columns labeled **Original**), outperforms the previous work. Applying the decomposed inference algorithm improves both the baseline and the margin-based approach. Overall, however, the fewest number of calls to the solver is made when combining the decomposed inference algorithm with the margin-based scheme. For the semantic role labeling task, we need to call the solver only for one in six examples while for the entity-relations task, only one in four examples require a solver call.

Table 2 shows the corresponding reduction in the wall-clock time for the various settings. We see that once again, the margin based approach outperforms the baseline. While the decomposed inference algorithm improves running time for SRL, it leads to a slight increase for the entity-relation problem. Since this increase occurs in spite of a reduction in the number of solver calls, we believe that this aspect can be further improved with an efficient implementation of the decomposed inference algorithm.

## 6 Discussion

**Lagrangian Relaxation in the literature** In the literature, in applications of the Lagrangian relaxation technique (such as (Rush and Collins, 2011; Chang and Collins, 2011; Reichart and Barzilay, 2012) and others), the relaxed problems are solved using specialized algorithms. However, in both the relaxations considered in this paper, even the relaxed problems cannot be solved without an ILP solver, and yet we can see improvements from decomposition in Table 1.

To study the impact of amortization on running time, we modified our decomposition based inference algorithm to solve each sub-problem using the ILP solver instead of amortization. In these experiments, we ran Lagrangian relaxation for until convergence or at most  $T$  iterations. After  $T$  iterations, we call the ILP solver and solve the original problem. We set  $T$  to 100 in one set of exper-

Method	% ILP Solver calls required			
	Semantic Role Labeling		Entity-Relation Extraction	
	Original	+ Decomp.	Original	+ Decomp.
ILP Solver	100	–	100	–
(Srikumar et al., 2012)	41	24.4	59.5	57.0
Margin-based	32.7	16.6	28.2	25.4

Table 1: Reduction in number of inference calls

Method	% time required compared to ILP Solver			
	Semantic Role Labeling		Entity-Relation Extraction	
	Original	+ Decomp.	Original	+ Decomp.
ILP Solver	100	–	100	–
(Srikumar et al., 2012)	54.8	40.0	81	86
Margin-based	45.9	38.1	58.1	61.3

Table 2: Reduction in inference time

iments (call it  $Lag1$ ) and  $T$  to 1 (call it  $Lag2$ ). In SRL, compared to solving the original problem with ILP Solver, both  $Lag1$  and  $Lag2$  are roughly 2 times slower. For entity relation task, compared to ILP Solver,  $Lag1$  is 186 times slower and  $Lag2$  is 1.91 times slower. Since we used the same implementation of the decomposition in all experiments, this shows that the decomposed inference algorithm crucially benefits from the underlying amortization scheme.

**Decomposed amortized inference** The decomposed amortized inference algorithm helps improve amortized inference in two ways. First, since the number of structures is a function of its size, considering smaller sub-structures will allow us to cache inference problems that cover a larger subset of the space of possible sub-structures. We observed this effect in the problem of extracting entities and relations in text. Second, removing a constraint need not always partition the structure into a set of smaller structures. Instead, by removing the constraint, examples that might have otherwise been in different equivalence classes become part of a combined, larger equivalence class. Increasing the size of the equivalence classes increases the probability of a cache-hit. In our experiments, we observed this effect in the SRL task.

## 7 Conclusion

Amortized inference takes advantage of the regularities in structured output to re-use previous computation and improve running time over the lifetime of a structured output predictor. In this paper, we have described two approaches for amortizing inference costs over datasets. The first, called the *margin-based amortized inference*, is a

new, provably exact inference algorithm that uses the notion of a structured margin to identify previously solved problems whose solutions can be re-used. The second, called *decomposed amortized inference*, is a meta-algorithm over any amortized inference that takes advantage of previously computed sub-structures to provide further reductions in the number of inference calls. We show via experiments that these methods individually give a reduction in the number of calls made to an inference engine for semantic role labeling and entity-relation extraction. Furthermore, these approaches complement each other and, together give an additional significant improvement.

## Abstract

Finding concepts in natural language utterances is a challenging task, especially given the scarcity of labeled data for learning semantic ambiguity. Furthermore, data mismatch issues, which arise when the expected test (target) data does not exactly match the training data, aggravate this scarcity problem. To deal with these issues, we describe an efficient semi-supervised learning (SSL) approach which has two components: (i) *Markov Topic Regression* is a new probabilistic model to cluster words into semantic tags (concepts). It can efficiently handle semantic ambiguity by extending standard topic models with two new features. First, it encodes word n-gram features from labeled source and unlabeled target data. Second, by going beyond a bag-of-words approach, it takes into account the *inherent sequential nature* of utterances to learn semantic classes based on context. (ii) *Retrospective Learner* is a new learning technique that adapts to the unlabeled target data. Our new SSL approach improves semantic tagging performance by 3% absolute over the baseline models, and also compares favorably on semi-supervised syntactic tagging.

## 1 Introduction

Semantic tagging is used in natural language understanding (NLU) to recognize words of semantic importance in an utterance, such as entities. Typically, a semantic tagging model requires large amount of domain specific data to achieve good

performance (Tur and DeMori, 2011). This requires a tedious and time intensive data collection and labeling process. In the absence of large labeled training data, the tagging model can behave poorly on test data (target domain). This is usually caused by data mismatch issues and lack of coverage that arise when the target data does not match the training data.

To deal with these issues, we present a new semi-supervised learning (SSL) approach, which mainly has two components. It initially starts with training supervised Conditional Random Fields (CRF) (Lafferty et al., 2001) on the source training data which has been semantically tagged. Using the trained model, it decodes unlabeled dataset from the target domain. With the data mismatch issues in mind, to correct errors that the supervised model make on the target data, the SSL model leverages the additional information by way of a new clustering method. Our first contribution is a new probabilistic topic model, *Markov Topic Regression* (MTR), which uses rich features to capture the degree of association between words and semantic tags. First, it encodes the n-gram context features from the labeled source data and the unlabeled target data as prior information to learn semantic classes based on context. Thus, each latent semantic class corresponds to one of the semantic tags found in labeled data. MTR is not invariant to reshuffling of words due to its Markovian property; hence, word-topic assignments are also affected by the topics of the surrounding words. Because of these properties, MTR is less sensitive to the errors caused by the semantic ambiguities. Our SSL uses MTR to smooth the semantic tag posteriors on the unlabeled target data (decoded using the CRF model) and later obtains the best tag sequences. Using the labeled source and automati-

cally labeled target data, it re-trains a new CRF-model.

Although our iterative SSL learning model can deal with the training and test data mismatch, it neglects the performance effects caused by adapting the source domain to the target domain. In fact, most SSL methods used for adaptation, e.g., (Zhu, 2005), (Daumé-III, 2010), (Subramanya et al., 2010), etc., do not emphasize this issue. With this in mind, we introduce a new iterative training algorithm, *Retrospective Learning*, as our second contribution. While retrospective learning iteratively trains CRF models with the automatically annotated target data (explained above), it keeps track of the errors of the previous iterations so as to carry the properties of both the source and target domains.

In short, through a series of experiments we show how MTR clustering provides additional information to SSL on the target domain utterances, and greatly impacts semantic tagging performance. Specifically, we analyze MTR’s performance on two different types of semantic tags: named-entities and descriptive tags as shown in Table 1. Our experiments show that it is much harder to detect descriptive tags compared to named-entities.

Our SSL approach uses probabilistic clustering method tailored for tagging natural language utterances. To the best of our knowledge, our work is the first to explore the unlabeled data to iteratively adapt the semantic tagging models for target domains, preserving information from the previous iterations. With the hope of spurring related work in domains such as entity detection, syntactic tagging, etc., we extend the earlier work on SSL part-of-speech (POS) tagging and show in the experiments that our approach is not only useful for semantic tagging but also syntactic tagging.

The remainder of this paper is divided as follows: §2 gives background on SSL and semantic clustering methods, §3 describes our new clustering approach, §4 presents the new iterative learning, §5 presents our experimental results and §6 concludes our paper.

## 2 Related Work and Motivation

**(I) Semi-Supervised Tagging.** Supervised methods for semantic tagging in NLU require a large number of in-domain human-labeled utterances and gazetteers (movie, actor names, etc.), increas-

<ul style="list-style-type: none"> <li>• Are there any [<i>comedies</i>] with [<i>Ryan Gosling</i>]?</li> <li>• How about [<i>oscar winning</i>] movies by [<i>James Cameron</i>]?</li> <li>• Find [<i>Woody Allen</i>] movies similar to [<i>Manhattan</i>].</li> </ul> <p>[Named Entities]</p> <p>director: <i>James Cameron, Woody Allen,...</i></p> <p>actor: <i>Ryan Gosling, Woody Allen,...</i></p> <p>title: <i>Manhattan, Midnight in Paris,...</i></p> <p>[Descriptive Tags]</p> <p>restriction: <i>similar, suitable, free, rate,...</i></p> <p>description: <i>oscar winning, new release, gardening,...</i></p> <p>genre: <i>spooky, comedies, feel good, romance,...</i></p>
--

Table 1: Samples of semantically tagged utterances from movie domain, named-entities and descriptive tags.

ing the need for significant manual labor (Tur and DeMori, 2011). Recent work on similar tasks overcome these challenges using SSL methods as follows:

- (Wang et al., 2009; Li et al., 2009; Li, 2010; Liu et al., 2011) investigate web query tagging using semi-supervised sequence models. They extract semantic lexicons from unlabeled web queries, to use as features. Our work differs from these, in that, rather than just detecting named-entities, our utterances include *descriptive* tags (see Table 1).

- Typically the source domain has different distribution than the target domain, due to topic shifts in time, newly introduced features (e.g., until recently online articles did not include facebook “like” feature.), etc. Adapting the source domain using unlabeled data is the key to achieving good performance across domains. Recent adaptation methods for SSL use: expectation minimization (Daumé-III, 2010) graph-based learning (Chapelle et al., 2006; Zhu, 2005), etc. In (Subramanya et al., 2010) an efficient iterative SSL method is described for syntactic tagging, using graph-based learning to smooth POS tag posteriors. However, (Reisinger and Mooney, 2011) argues that vector space models, such as graph-learning, may fail to capture the richness of word meaning, as similarity is not a globally consistent metric. Rather than graph-learning, we present a new SSL using a probabilistic model, MTR, to cluster words based on co-occurrence statistics.

- Most iterative SSL methods, do not keep track of the errors made, nor consider the divergence from the original model. (Lavoie et al., 2011) argues that iterative learning models should mitigate new errors made by the model at each iteration by

keeping the history of the prior predictions. This ensures that a penalty is paid for diverging from the previous model’s predictions, which will be traded off against the benefit of reducing classification loss. We present a *retrospective* SSL for CRF, in that, the iterative learner keeps track of the errors of the previous iterations so as to carry the properties of both the source and target domains.

**(II) Semantic Clustering.** A common property of several context-based word clustering techniques, e.g., Brown clustering (Brown et al., 1992), Clustering by Committee (Pantel, 2003), etc., is that they mainly cluster based on local context such as nearby words. Standard topic models, such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003), use a *bag-of-words* approach, which disregards word order and clusters words together that appear in a similar global context. Such models have been effective in discovering lexicons in many NLP tasks, e.g., named-entity recognition (Guo et al., 2009), word-sense disambiguation (Boyd-Graber et al., 2007; Li et al., 2010), syntactic/semantic parsing (Griffiths et al., 2005; Singh et al., 2010), speaker identification (Nyugen et al., 2012), etc. Recent topic models consider word sequence information in documents (Griffiths et al., 2005; Moon et al., 2010). The Hidden Topic Markov Model (HTMM) by (Gruber et al., 2005), for instance, models sentences in documents as Markov chains, assuming all words in a sentence have the *same* topic. While MTR has a similar Markovian property, we encode features on words to allow each word in an utterance to sample from any of the given semantic tags, as in “what are [scary]<sub>genre</sub> movies by [Hitchcock]<sub>director</sub>?”.

In LDA, common words tend to dominate all topics causing related words to end up in different topics. In (Petterson et al., 2010), the vector-based features of words are used as prior information in LDA so that the words that are synonyms end up in same topic. Thus, we build a semantically rich topic model, MTR, using *word context* features as side information. Using a smoothing prior for each word-topic pair (instead of a constant  $\beta$  smoother), MTR assures that the words are distributed over topics based on how similar they are. (e.g., “scary” and “spooky”, which have similar context features, go into the same semantic tag, “genre”). Thus, to best of our knowledge, MTR is the first topic model to incorporate word features while considering the sequence of words.

### 3 Markov Topic Regression - MTR

#### 3.1 Model and Abstractions

LDA assumes that the latent topics of documents are sampled independently from one of  $K$  topics. MTR breaks down this independence assumption by allowing Markov relations between the hidden tags to capture the relations between consecutive words (as sketched in Figure 1 and Algorithm 1).

**(I) Semantic Tags ( $s_i$ ):** Each word  $w_i$  of a given utterance with  $N_j$  words,  $u_j = \{w_i\}_{i=1}^{N_j} \in U$ ,  $j=1, \dots, |U|$ , from a set of utterances  $U$ , is associated with a latent semantic tag (state) variable  $s_i \in \mathcal{S}$ , where  $\mathcal{S}$  is the set of semantic tags. We assume a fixed  $K$  topics corresponding to semantic tags of labeled data. In a similar way to HTMM (Gruber et al., 2005) described for documents, MTR samples each  $s_i$  from a Markov chain that is specific to its utterance  $u_j$ . Each state  $s_i$  generates a word,  $w_i$ , based on the word-state co-occurrences. MTR allows for sampling of consecutive words from different tag clusters. The initial probabilities of the latent states are sampled from a Dirichlet distribution over state variables,  $\theta_j$ , with  $\alpha$  hyperparameter for each  $u_j$ .

**(II) Tag Transition Indicator ( $\psi_v$ ):** Given utterance  $u_j$ , the decision to sample a  $w_i$  from a new topic is determined by an indicator variable,  $c_{j,i}$ , that is sampled from a *Binomial*( $\psi_{v=w_i}$ ) distribution with a *Beta* conjugate prior. (There are  $v$  binomials for each vocabulary term.)  $c_{j,i}=1$  suggests that a new state be sampled from  $K$  possible tags for the word  $w_i$  in  $u_j$ , and  $c_{j,i}=0$  suggests that the state  $s_i$  of  $w_i$  should be the same as the previous word’s latent state  $s_{i-1}$ . The first position of the sequence is sampled from a new state, hence  $c_{j,i=1}=1$ .

**(III) Tag Transition Base Measure ( $\eta$ ):** Prior probability of a word given a tag should increase the chances of sampling words from the correct semantic tag. MTR constrains the generation of a tag  $s_i$  given the previous tag  $s_{i-1}$  and the current  $w_i$  based on  $c_{j,i}$  by using a vocabulary specific Beta prior,  $\psi_v \sim \text{Beta}(\eta_v)$ <sup>1</sup>, on each word in vocabulary  $w_{v=1, \dots, V}$ . We inject the prior information on semantic tags to define values of the base measure  $\eta_v$  using external knowledge from two sources:

(a) **Entity Priors ( $\eta_S$ ):** Prior probability on named-entities and descriptive tags denoted as

<sup>1</sup>For each beta distribution we use symmetric  $\text{Beta}(\eta_v) = \text{Beta}(\alpha=\eta_v, \beta=\eta_v)$ .

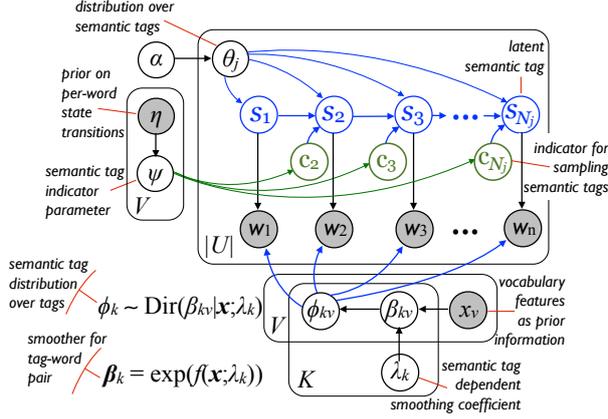

Figure 1: The graph representation of the Markov Topic Regression (MTR). To demonstrate hidden state Markov Chain, the generation of each word is explicitly shown (inside of the plate).

$\eta_S = p(s_i | s_{i-1}, w_i = v, w_{i-1})$ . We use web sources (wiki pages on movies and urls such as imdb.com) and labeled training data to extract entity lists that correspond to the semantic tags of our domains. We keep the frequency of each n-gram to convert into (empirical) prior probability distribution.

(b) **Language Model Prior ( $\eta_W$ ):** Probabilities on word transitions denoted as  $\eta_W = p(w_i = v | w_{i-1})$ . We built a language model using SRILM (Stolcke, 2002) on the domain specific sources such as top wiki pages and blogs on online movie reviews, etc., to obtain the probabilities of domain-specific n-grams, up to 3-grams. The observed priors,  $\eta_S$  and  $\eta_W$ , are used for calculating the base measure  $\eta$  for each vocabulary  $w_v$  as:

$$\eta_v^{s_i | s_{i-1}} = \begin{cases} \eta_S^{s_i | s_{i-1}, w_i = v}, & \text{if } \eta_S^{s_i | s_{i-1}, w_i = v} \text{ exists,} \\ \eta_W^{w_i = v, w_{i-1}}, & \text{otherwise} \end{cases} \quad (1)$$

In Eq.(1), we assume that the prior on the semantic tags,  $\eta_S$ , is more indicative of the decision for sampling a  $w_i$  from a new tag compared to language model posteriors on word sequences,  $\eta_W$ . Here we represent the base-measure (hyper-parameter) of the semantic tag indicator variable, which is not to be confused with a probability measure<sup>2</sup>

We update the indicator parameter via mean criteria,  $\psi_{v=w_i} = \sum_{i,j=1}^K \eta_{v=w_i}^{s_i | s_j} / (K^2)$ . If no prior on

<sup>2</sup>The base-measure used in Eq.(1) does not relate to a back-off model in LM sense. Here, instead of using a constant value for the hyper-parameters, we use probability scores that we obtain from LM.

### Algorithm 1 Markov Topic Regression

- 1: **for** each semantic tag topic  $s_k, k \leftarrow 1, \dots, K$  **do**
- 2:   – draw a topic mixture  $\phi_k \sim \text{Dir}(\beta_k | \lambda_k, \mathbf{x})$ ,
- 3:   – let  $\beta_k = \exp(f(\mathbf{x}; \lambda_k))$ ;  $\mathbf{x} = \{x_v\}_{v=1}^{V_i}$ ,  $\beta_k \in \mathcal{R}^{V_i}$
- 4: **for** each word  $w_v$  in vocabulary  $v \leftarrow 1, \dots, V$  **do**
- 5:   – draw a tag indicator mixture  $\psi_v \sim \text{Beta}(\eta)$ ,
- 6: **for** each utterance  $j \leftarrow 1, \dots, |U|$  **do**
- 7:   – draw transition distribution  $\theta_j^s \sim \text{Dir}(\alpha)$
- 8:   over states  $s_i$  and set  $c_{j1}=1$ .
- 9:   – **for** words  $w_i$  in  $u_j, i \leftarrow 1, \dots, N_j$  **do**
- 10:     – if  $i > 1$ , toss a coin  $c_{j,i} \sim \text{Binomial}(\psi_{w_i})$ .
- 11:     – if  $c_{j,i}=1$ , draw  $s_i \sim \text{Multi}(\theta_j^{s_i, s_{i-1}})$ <sup>†</sup>
- 12:     – otherwise  $s_i = s_{i-1}$ .
- 13:     – Sample  $w_i \sim \text{Multi}(\phi_{s_i})$ .

<sup>†</sup> Markov assumption over utterance words is used (See Eq.(4)).

a specific word exists, a default value is used for base measure,  $\eta_v = 0.01$ .

(IV) **Topic-Word Distribution Priors ( $\beta_k$ ):** Different from (Mimno et al., 2008), which uses asymmetric hyper-parameters on document-topic distributions, in MTR, we learn the asymmetric hyper-parameters of the semantic tag-word distributions. We use blocked Gibbs sampling, in which the topic assignments  $s_k$  and hyper-parameters  $\{\beta_k\}_{k=1}^K$  are alternately sampled at each Gibbs sampling lag period  $g$  given all other variables. We impose the prior knowledge on naturally related words, such that if two words "funny" and "hilarious" indicate the same given "genre" class, then their latent tag distributions should also be similar. We enforce this on smoothing parameter  $\beta_{k,v}$ , e.g.,  $\beta_{k, \text{'funny'}} \sim \beta_{k, \text{'hilarious'}}$  for a given tag  $k$  as follows:

At each  $g$  lag period of the Gibbs sampling,  $K$  log-linear models with parameters,  $\lambda_k^{(g)} \in \mathcal{R}^M$ , is trained to predict  $\beta_{kv}^{(g)} \in \beta_k$ , for each  $w_v$  of a tag  $s_k$ :

$$\beta_k^{(g)} = \exp(f(\mathbf{x}^l; \lambda_k^{(g)})) \quad (2)$$

where the log-linear function  $f$  is:

$$n_{kv}^{(g)} = f(\mathbf{x}_v^l; \lambda_k^{(g)}) = \sum_m \lambda_{k,m}^{(g)} x_{v,m}^l \quad (3)$$

Here  $\mathbf{x} \in \mathcal{R}^{V \times M}$  is the input matrix  $\mathbf{x}$ , wherein rows  $x_v \in \mathcal{R}^M$  represents  $M$ -dimensional scalar vector of explanatory features on vocabulary words. We use the word-tag posterior probabilities obtained from a CRF sequence model trained on labeled utterances as features. The  $\mathbf{x} = \{\mathbf{x}^l, \mathbf{x}^u\}$  has labeled ( $l$ ) and unlabeled ( $u$ ) parts. The labeled part contains  $V_l$  size vocabulary of which we know the semantic tags,  $\mathbf{x}^l = \{(x_{1^l, s_1}^l), \dots, (x_{V_l^l, s_{V_l}^l})\}$ . At the start of the Gibbs sampling, we designate the

$K$  latent topics to the  $K$  semantic tags of our labeled data. Therefore, we assign labeled words to their designated topics. This way we use observed scalar counts of each labeled word  $v$  associated with its semantic tag  $k$ ,  $n_{kv}^{(g)}$ , as the output label of its input vector,  $x_v^l$ ; an indication of likelihood of words getting sampled from the corresponding semantic label  $s_k$ . Since the impact of the asymmetric prior is equivalent to adding pseudo-counts to the sufficient statistics of the semantic tag to which the word belongs, we predict the pseudo-counts  $\beta_{kv}^{(g)}$  using the scalar counts of the labeled data,  $n_{kv}^{(g)}$ , based on the log-linear model in Eq. (2). At  $g=0$ , we use  $\beta_{kv}^{(0)}=2^8$ , if  $x_v \in X^l$ ; otherwise  $\beta_{kv}^{(0)}=2^{-2}$ , commonly used values for large and small  $\beta$ . Note that larger  $\beta$ -values indicate correlation between the word and the topic.

### 3.2 Collapsed Sampler

The goal of MTR is to infer the degree of relationship between a word  $v$  and each semantic tag  $k$ ,  $\phi_{kv}$ . To perform inference we need two components:

- a sampler which can draw from conditional  $P_{\text{MTR}}(s_{ji}=k|s_{ji-1}, s_{\setminus ji}, \alpha, \psi_i, \beta_{ji})$ , when  $c_{j,i}=1$ , where  $s_{ji}$  and  $s_{ji-1}$  are the semantic tags of the current  $w_i=v$  of vocabulary  $v$  and previous word  $w_{i-1}$  in utterance  $u_j$ , and  $s_{\setminus ji}$  are the semantic tag topics of all words except for  $w_i$ ; and,
- an estimation procedure for  $(\beta_{kv}, \lambda_k)$  (see §3.1).

We integrate out the multinomial and binomial parameters of the model: utterance-tag distributions  $\theta_j$ , binomial state transition indicator distribution per each word  $\psi_v$ , and  $\phi_k$  for tag-word distributions. We use collapsed Gibbs sampling to reduce random components and model the posterior distribution by obtaining samples  $(s_{ji}, c_{j,i})$  drawn from this distribution. Under the Markov assumption, for each word  $w_i=v$  in a given utterance  $u_j$ , if  $c_{j,i}=1$ , we sample a new tag  $s_i=k$  given the remaining tags and hyper-parameters  $\beta_k, \alpha$ , and  $\eta_{w_i=v}^{s_i|s_{i-1}}$ . Using the following parameters;  $n_{ji}^{(s_i)}$ , which is the number of words assigned to a semantic class  $s_i=k$  excluding case  $i$ , and  $n_{s_i}^{(s_{i-1})}$  is the number of transitions from class  $s_{i-1}$  to  $s_i$ , where indicator  $\mathbb{I}(s_{i-1}, s_i)=1$  if slot  $s_i=s_{i-1}$ , the update

equation is formulated as follows:

$$p(s_{ji} = k | \mathbf{w}, s_{-ji}, \alpha, \eta_{w_i}^{s_i|s_{i-1}}, \beta_k) \propto \frac{n_{ji}^{(s_i)} + \beta_{kw_i}}{n_{(\cdot)}^{(k)} + \sum_v \beta_{kv}} * (n_{s_i}^{(s_{i-1})} + \alpha) * \frac{(n_{s_{i+1}}^{(s_i)} + \mathbb{I}(s_{i-1}, s_i) + \mathbb{I}(s_{i+1}, s_i) + \alpha)}{n_{(\cdot)}^{(s_i)} + \mathbb{I}(s_{i-1}, k) + K\alpha} \quad (4)$$

## 4 Semi-Supervised Semantic Labeling

### 4.1 Semi Supervised Learning (SSL) with CRF

In (Subramanya et al., 2010), a new SSL method is described for adapting syntactic POS tagging of sentences in newswire articles along with search queries to a target domain of natural language (NL) questions. They decode unlabeled queries from target domain ( $t$ ) using a CRF model trained on the POS-labeled newswire data (source domain ( $o$ )). The unlabeled POS tag posteriors are then smoothed using a graph-based learning algorithm. On graph, the similarities are defined over sequences by constructing the graph over *types*, word 3-grams, where *types* capture the local context of words. Since CRF tagger only uses local features of the input to score tag pairs, they try to capture all the context with the graph with additional context features on *types*. Later, using viterbi decoding, they select the 1-best POS tag sequence,  $\mathbf{s}_j^*$  for each utterance  $u_j$ . Graph-based SSL defines a new CRF objective function:

$$\Lambda_{n+1}^{(t)} = \underset{\Lambda \in \mathcal{R}^K}{\text{argmin}} \left\{ - \sum_{j=1:l} \log p(\mathbf{s}_j | u_j; \Lambda_n^{(t)}) + \mu \|\Lambda_n^{(t)}\|^2 \right\} - \left\{ \tau \sum_{j=l}^{l+u} \log p_n(\mathbf{s}_j^* | u_j; \Lambda_n^{(t)}) \right\} \quad (5)$$

The first bracket in Eq.(5) is the loss on the labeled data and  $\mathcal{L}_2$  regularization on parameters,  $\Lambda_n^{(t)}$ , from  $n$ th iteration, same as standard CRF. The last term is the loss on unlabeled data from target domain with a hyper-parameter  $\tau$ . They use a small value for  $\tau$  to enable the new model to be as close as possible to the initial model trained on source data.

### 4.2 Retrospective Semi-Supervised CRF

We describe a *Retrospective* SSL (R-SSL) training with CRF (Algorithm 2), using MTR as a

smoothing model, instead of a graph-based model, as follows:

**I. DECODING and SMOOTHING.** The posterior probability of a tag  $s_{ji}=k$  given a word  $w_{ji}$  in unlabeled utterance  $u_j$  from target domain ( $t$ )  $\hat{p}_n(j, i)=\hat{p}_n(s_{ji}=k|w_{ji}; \Lambda_n^{(t)})$ , is decoded using the  $n$ -th iteration CRF model. MTR uses the decoded probabilities as semantic tag prior features on vocabulary items. We generate a word-tag matrix of posteriors,  $\mathbf{x} \in (0, 1)^{V \times K}$ , where  $K$  is the number of semantic tags and  $V$  is the vocabulary size from  $n$ -th iteration. Each row is a  $K$  dimensional vector of tag posterior probabilities  $x_v=\{x_{v1}, \dots, x_{vK}\}$  on the vocabulary term,  $w_v$ . The labeled rows  $\mathbf{x}^l$  of the vocabulary matrix,  $\mathbf{x}=\{\mathbf{x}^l, \mathbf{x}^u\}$ , contain only  $\{0, 1\}$  values, indicating the word’s observed semantic tags in the labeled data. Since a labeled term  $w_v$  can have different tags (e.g., ”clint eastwood” may be tagged as *actor-name* and *director-name* in the training data),  $\sum_k x_{vk} \geq 1$  holds. The  $\mathbf{x}$  is used as the input matrix of the  $k$ th log-linear model (corresponding to  $k$ th semantic tag (topic)) to infer the  $\beta$  hyper-parameter of MTR in Eq. (2). MTR generates smoothed conditional probabilities  $\phi_{kv}$  for each vocabulary term  $v$  given semantic tag  $k$ .

**II. INTERPOLATION.** For each word  $w_{ji}=v$  in unlabeled utterance  $u_j$ , we interpolate tag marginals from CRF and MTR for each semantic tag  $s_{ji} = k$ :

$$\hat{q}_n(s_{ji}|w_{ij}; \Lambda_n^{(t)}) = \pi \overbrace{\hat{p}_n(s_{ji}|w_{ij}; \Lambda_n^{(t)})}^{\text{CRF posterior}} + (1 - \pi) \overbrace{\phi_{kv}}^{\text{MTR}} \quad (6)$$

**III. VITERBI.** Using viterbi decoding over the tag marginals,  $\hat{q}_n(s_{ji}|w_{ij}; \Lambda_n^{(t)})$ , and transition probabilities obtained from the CRF model of  $n$ -th iteration, we get  $\hat{p}_n(s_j^*|u_j; \Lambda_n^{(t)})$ , the 1-best decode  $s_j^*$  of each unlabeled utterance  $u_j \in \mathcal{U}_n^u$ .

**IV. RETROSPECTIVE SSL (R-SSL).** After we decode the unlabeled data, we re-train a new CRF model at each iteration. Each iteration makes predictions on the semantic tags of unlabeled data with varying posterior probabilities. Motivated by (Lavoie et al., 2011), we want the loss function to have a dependency on the prior model predictions. Thus, R-SSL encodes the history of the prior pre-

---

## Algorithm 2 Retrospective Semi-Supervised CRF

---

**Input:** Labeled  $\mathcal{U}^l$ , and unlabeled  $\mathcal{U}^u$  data.

**Process:**  $\Lambda_n^{(o)} = \text{crf-train}(\mathcal{U}_l)$  at  $n=0, n=n+1$  †.

**While** not converged

$\hat{p} = \text{posterior-decode}(\mathcal{U}_n^u, \Lambda_n^{(o)})$

$\phi = \text{smooth-posteriors}(\hat{p})$  using MTR,

$\hat{q} = \text{interpolate-posteriors}(\hat{p}, \phi)$ ,

$\mathcal{U}_n^u = \text{viterbi-decode}(\hat{q})$

$\Lambda_{n+1}^{(t)} = \text{crf-retrospective}(\mathcal{U}^l, \mathcal{U}_n^u, \dots, \mathcal{U}_1^u, \Lambda_n^{(t)})$

† (n):iteration, (t):target, (o):source domains.

---

dictions, as follows:

$$\Lambda_{n+1}^{(t)} = \underset{\Lambda \in \mathcal{R}^K}{\text{argmin}} \left\{ \begin{aligned} & - \sum_{j=1:l} \log p(s_j|u_j; \Lambda_n^{(t)}) + \mu \|\Lambda_n^{(t)}\|^2 \\ & - \sum_{j=1:(l+u)} \max\{0, \hat{p}_n^{**}\} \end{aligned} \right\} \quad (7)$$

where,  $\hat{p}_n^{**} = 1 - \log h_n(u_j) \hat{p}_n(s_j^*|u_j; \Lambda_n^{(t)})$ . The first two terms are same as standard CRF. The last term ensures that the predictions of the current model have the same sign as the predictions of the previous models (using labeled and unlabeled data), denoted by a maximum margin hinge weight,  $h_n(u_j) = \frac{1}{n-1} \sum_{i=1}^{n-1} \hat{p}_n(s_j^*|u_j; \Lambda_n^{(t)})$ . It should also be noted that with MTR, the R-SSL learns the word-tag relations by using features that describe the words in context, eliminating the need for additional *type* representation of graph-based model. MTR provides a separate probability distribution  $\theta_j$  over tags for each utterance  $j$ , implicitly allowing for the same word  $v$  in separate utterances to differ in tag posteriors  $\phi_{kv}$ .

## 5 Experiments

### 5.1 Datasets and Tagsets

#### 5.1.1 Semantic Tagging Datasets

We focus here on audiovisual media in the *movie* domain. The user is expected to interact by voice with a system than can perform a variety of tasks such as browsing, searching, querying information, etc. To build initial NLU models for such a dialog system, we used crowd-sourcing to collect and annotate utterances, which we consider our source domain. Given movie domain-specific tasks, we asked the crowd about how they would

interact with the media system as if they were talking to a person.

Our data from target domain is internally collected from real-use scenarios of our spoken dialog system. The transcribed text forms of these utterances are obtained from speech recognition engine. Although the crowd-sourced data is similar to target domain, in terms of pre-defined user intentions, the target domain contains more descriptive vocabulary, which is almost twice as large as the source domain. This causes data-mismatch issues and hence provides a perfect test-bed for a domain adaptation task. In total, our corpus has a 40K semantically tagged utterances from each source and target domains. There are around 15 named-entity and 10 descriptive tags. We separated 5K utterances to test the performance of the semantic tagging models. The most frequent entities are: *movie-director* ('James Cameron'), *movie-title* ('Die Hard'), etc.; whereas top descriptive tags are: *genre* ('feel good'), *description* ('black and white', 'pg 13'), *review-rate* ('epic', 'not for me'), *theater-location* ('near me', 'city center'), etc.

Unlabeled utterances similar to the movie domain are pulled from a month old web query logs and extracted over 2 million search queries from well-known sites, e.g., IMDB, Netflix, etc. We filtered queries that are similar to our target set that start with *wh*-phrases ('what', 'who', etc.) as well as imperatives 'show', 'list', etc. In addition, we extracted web n-grams and entity lists (see §3) from movie related web sites, and online blogs and reviews. We collected around 300K movie review and blog entries on the entities observed in our data. We extract prior distributions for entities and n-grams to calculate entity list  $\eta$  and word-tag  $\beta$  priors (see §3.1).

### 5.1.2 Syntactic Tagging Datasets

We use the Wall Street Journal (WSJ) section of the Penn Treebank as our labeled source data. Following previous research, we train on sections 00-18, comprised of 38,219 POS-tagged sentences. To evaluate the domain adaptation (DA) approach and to compare with results reported by (Subramanya et al., 2010), we use the first and second half of QuestionBank (Judge et al., 2006) as our development and test sets (target). The QuestionBank contains 4000 POS-tagged questions, however it is difficult to tag with WSJ-trained taggers because the word order is different than WSJ

and contains a test-set vocabulary that is twice as large as the one in the development set. As for unlabeled data we crawled the web and collected around 100,000 questions that are similar in style and length to the ones in QuestionBank, e.g. "wh" questions. There are 36 different tag sets in the Penn dataset which includes tag labels for verbs, nouns, adjectives, adverbs, modal, determiners, prepositions, etc. More information about the Penn Tree-bank tag set can be found here (Marcus et al., 1993).

## 5.2 Models

We evaluated several baseline models on two tasks:

### 5.2.1 Semantic Clustering

Since **MTR** provides a mixture of properties adapted from earlier models, we present performance benchmarks on tag clustering using: (i) **LDA**; (ii) Hidden Markov Topic Model **HMTM** (Gruber et al., 2005); and, (iii) **w-LDA** (Petterson et al., 2010) that uses word features as priors in LDA. When a uniform  $\beta$  hyper-parameter is used with no external information on the state transitions in MTR, it reduces to a HMTM model. Similarly, if no Markov properties are used (bag-of-words), MTR reduces to w-LDA. Each topic model uses Gibbs sampling for inference and parameter learning. We sample models for 1000 iterations, with a 500-iteration burn-in and a sampling lag of 10. For testing we iterated the Gibbs sampler using the trained model for 10 iterations on the testing data.

### 5.2.2 SSL for Semantic/Syntactic Tagging

We evaluated three different baselines against our SSL models:

- \* **CRF**: a standard supervised sequence tagging.
- \* **Self-CRF**: a wrapper method for SSL using self-training. First a supervised learning algorithm is used to build a CRF model based on the labeled data. A CRF model is used to decode the unlabeled data to generate more labeled examples for re-training.
- \* **SSL-Graph**: A SSL model presented in (Subramanya et al., 2010) that uses graph-based learning as posterior tag smoother for CRF model using Eq.(5).

In addition to the three baseline, we evaluated three variations of our SSL method:

- \* **SSL-MTR**: Our first version of SSL uses MTR to

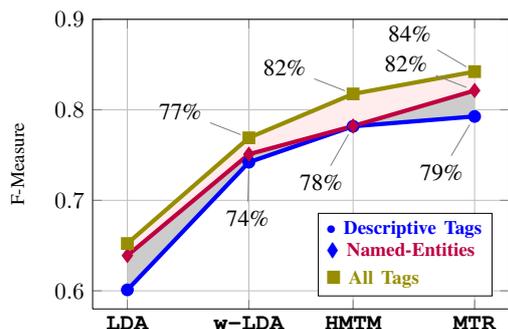

Figure 2: F-measure for semantic clustering performance. Performance differences for three different baseline models and our MTR approach by different semantic tags.

smooth the semantic tag posteriors of a unlabeled data decoded by the CRF model using Eq.(5).

★ **R-SSL-Graph:** Our second version uses graph-learning to smooth the tag posteriors and re-train a new CRF model using *retrospective* SSL in Eq.(7).

★ **R-SSL-MTR:** Our full model uses MTR as a Bayesian smoothing model, and retrospective SSL in Eq.(7) for iterative CRF training.

For all the CRF models, we use lexical features consisting of unigrams in a five-word window around the current word. To include contextual information, we add binary features for all possible tags. We inject dictionary constraints to all CRF models, such as features indicating label prior information. For each model we use several named entity features, e.g., *movie-title*, *actor-name*, etc., non-named entity (descriptive) features, e.g., *movie-description*, *movie-genre*, and domain independent dictionaries, e.g. *time*, *location*, etc. For graph-based learning, we implemented the algorithm presented in (Subramanya et al., 2010) and used the same hyper-parameters and features. For the rest of the hyper-parameters, we used:  $\alpha=0.01$  for MTR,  $\pi=0.5$  for interpolation mixing. These parameters were chosen based on the performance of the development set. All CRF objective functions were optimized using Stochastic Gradient Descent.

### 5.3 Results and Discussions

#### 5.3.1 Experiment 1: Clustering Semantic Tags.

Here, we want to demonstrate the performance of MTR model for capturing relationships between words and semantic tags against baseline topic

models: LDA, HMTM, w-LDA. We take the semantically labeled utterances from the movie target domain and use the first half for training and the rest for performance testing. We use all the collected unlabeled web queries from the movie domain. For fair comparison, each benchmark topic model is provided with prior information on word-semantic tag distributions based on the labeled training data, hence, each  $K$  latent topic is assigned to one of  $K$  semantic tags at the beginning of Gibbs sampling.

We evaluate the performance separately on descriptive tags, named-entities, and all tags together. The performance of the four topic models are reported in Figure 2. LDA shows the worst performance, even though some supervision is provided by way of labeled semantic tags. Although w-LDA improves semantic clustering performance over LDA, the fact that it does not have Markov properties makes it fall short behind MTR. As for the effect of word features in MTR, we see a 3% absolute performance gain over the second best performing HMTM baseline on named-entity tags, a 1% absolute gain on descriptive tags and a 2% absolute overall gain. As expected, we see a drop in F-measure on all models on descriptive tags.

#### 5.3.2 Experiment 2: Domain Adaptation Task.

We compare the performance of our SSL model to that of state-of-the-art models on semantic and syntactic tagging. Each SSL model is built using labeled training data from the source domain and unlabeled training data from target domain. In Table 2 we show the results on Movie and QuestionBank target test datasets. The results of SSL-Graph on QuestionBank is taken from (Subramanya et al., 2010). The self-training model, Self-CRF adds 3% improvement over supervised CRF models on movie domain, but does not improve syntactic tagging. Because it is always inherently biased towards the source domain, self-training tends to reinforce the knowledge that the supervised model already has. SSL-Graph works much better for both syntactic and semantic tagging compared to CRF and Self-CRF models. Our Bayesian MTR efficiently extracts information from the unlabeled data for the target domain. Combined with retrospective training, R-SSL-MTR demonstrates noticeable improvements,  $\sim 2\%$  on descriptive tags, and 1% absolute gains in overall semantic tag-

ging performance over SSL-Graph. On syntactic tagging, the two retrospective learning models is comparable, close to 1% improvement over the SSL-Graph and SSL-MTR.

Model	Movie Domain			QBank
	Desc.	NE	All	POS
<b>CRF</b>	75.05	75.84	75.84	83.80
<b>Self-CRF</b>	78.96	79.53	79.19	84.00
<b>SSL-Graph</b>	80.27	81.35	81.23	86.80
<b>SSL-MTR</b>	79.87	79.31	79.19	86.30
<b>R-SSL-Graph</b>	80.58	81.95	81.52	87.12
<b>R-SSL-MTR</b>	82.76	82.27	<b>82.24</b>	<b>87.34</b>

Table 2: Domain Adaptation performance in **F-measure** on Semantic Tagging on **Movie** Target domain and POS tagging on **QBank:QuestionBank**. Best performing models are **bolded**.

### 5.3.3 Experiment 3: Analysis of Semantic Disambiguation.

Here we focus on the accuracy of our models in tagging semantically ambiguous words. We investigate words that have more than one observed semantic tag in training data, such as "are there any [*war*]<sub>genre</sub> movies available.", "remove all movies about [*war*]<sub>description</sub>". Our corpus contained 30,000 unique vocabulary, 55% of which are contained in one or more semantic categories. Only 6.5% of those are tagged as multiple categories (polysemous), which are the sources of semantic ambiguity. Table-3 shows the precision of two best models for most confused words.

We compare our two best SSL models with different smoothing regularizes: R-SSL-MTR (**MTR**) and R-SSL-Graph (**GRAPH**). We use precision and recall criterion on semantically confused words.

In Table 3 we show two most frequent descriptive tags; *genre* and *description*, and commonly misclassified words by the two models. Results indicate that the R-SSL-MTR, performs better than the R-SSL-Graph, in activating the correct meaning of a word. The results indicate that incorporating context information with MTR is an effective option for identifying semantic ambiguity.

## 6 Conclusions

We have presented a novel semi supervised learning approach using a probabilistic clustering

Vocab.	genre		description	
	GRAPH	MTR	GRAPH	MTR
<i>war</i>	50%	100%	75%	88%
<i>popular</i>	90%	89%	80%	100%
<i>kids</i>	78%	86%	—	100%
<i>crime</i>	49%	80%	86%	67%
<i>zombie</i>	67%	89%	67%	86%

Table 3: Classification performance in F-measure for semantically ambiguous words on the most frequently confused descriptive tags in the movie domain.

method to semantically tag spoken language utterances. Our results show that encoding priors on words and context information contributes significantly to the performance of semantic clustering. We have also described an efficient iterative learning model that can handle data inconsistencies that leads to performance increases in semantic and syntactic tagging.

As a future work, we will investigate using session data, namely the entire dialog between the human and the computer. Rather than using single turn utterances, we hope to utilize the context information, e.g., information from previous turns for improving the performance of the semantic tagging of the current turns.

## Abstract

Hyperedge replacement grammar (HRG) is a formalism for generating and transforming graphs that has potential applications in natural language understanding and generation. A recognition algorithm due to Lautemann is known to be polynomial-time for graphs that are connected and of bounded degree. We present a more precise characterization of the algorithm's complexity, an optimization analogous to binarization of context-free grammars, and some important implementation details, resulting in an algorithm that is practical for natural-language applications. The algorithm is part of *Bolinas*, a new software toolkit for HRG processing.

## 1 Introduction

Hyperedge replacement grammar (HRG) is a context-free rewriting formalism for generating graphs (Drewes et al., 1997), and its synchronous counterpart can be used for transforming graphs to/from other graphs or trees. As such, it has great potential for applications in natural language understanding and generation, and semantics-based machine translation (Jones et al., 2012). Figure 1 shows some examples of graphs for natural-language semantics.

A polynomial-time recognition algorithm for HRGs was described by Lautemann (1990), building on the work of Rozenberg and Welzl (1986) on boundary node label controlled grammars, and others have presented polynomial-time algorithms as well (Mazanek and Minas, 2008; Moot, 2008). Although Lautemann's algorithm is correct and

tractable, its presentation is prefaced with the remark: "As we are only interested in distinguishing polynomial time from non-polynomial time, the analysis will be rather crude, and implementation details will be explicated as little as possible." Indeed, the key step of the algorithm, which matches a rule against the input graph, is described at a very high level, so that it is not obvious (for a non-expert in graph algorithms) how to implement it. More importantly, this step as described leads to a time complexity that is polynomial, but potentially of very high degree.

In this paper, we describe in detail a more efficient version of this algorithm and its implementation. We give a more precise complexity analysis in terms of the grammar and the size and maximum degree of the input graph, and we show how to optimize it by a process analogous to binarization of CFGs, following Gildea (2011). The resulting algorithm is practical and is implemented as part of the open-source Bolinas toolkit for hyperedge replacement grammars.

## 2 Hyperedge replacement grammars

We give a short example of how HRG works, followed by formal definitions.

### 2.1 Example

Consider a weighted graph language involving just two types of semantic frames (*want* and *believe*), two types of entities (*boy* and *girl*), and two roles (*arg0* and *arg1*). Figure 1 shows a few graphs from this language.

Figure 2 shows how to derive one of these graphs using an HRG. The derivation starts with a single edge labeled with the nonterminal symbol  $S$ . The first rewriting step replaces this edge with a subgraph, which we might read as "The

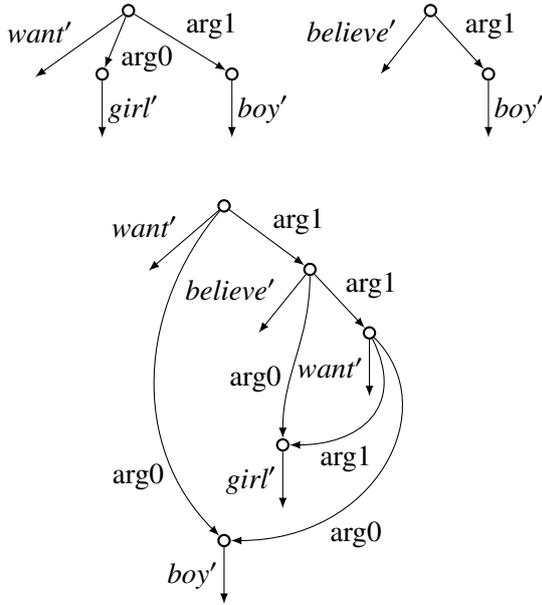

Figure 1: Sample members of a graph language, representing the meanings of (clockwise from upper left): “The girl wants the boy,” “The boy is believed,” and “The boy wants the girl to believe that he wants her.”

boy wants something ( $X$ ) involving himself.” The second rewriting step replaces the  $X$  edge with another subgraph, which we might read as “The boy wants the girl to believe something ( $Y$ ) involving both of them.” The derivation continues with a third rewriting step, after which there are no more nonterminal-labeled edges.

## 2.2 Definitions

The graphs we use in this paper have edge labels, but no node labels; while node labels are intuitive for many graphs in NLP, using both node and edge labels complicates the definition of hyperedge grammar and algorithms. All of our graphs are directed (ordered), as the purpose of most graph structures in NLP is to model dependencies between entities.

**Definition 1.** An *edge-labeled, ordered hypergraph* is a tuple  $H = \langle V, E, \ell \rangle$ , where

- $V$  is a finite set of nodes
- $E \subseteq V^+$  is a finite set of hyperedges, each of which connects one or more distinct nodes
- $\ell : E \rightarrow C$  assigns a label (drawn from the finite set  $C$ ) to each edge.

For brevity we use the terms *graph* and *hypergraph* interchangeably, and similarly for *edge* and *hyperedge*. In the definition of HRGs, we will use the notion of hypergraph fragments, which are the elementary structures that the grammar assembles into hypergraphs.

**Definition 2.** A *hypergraph fragment* is a tuple  $\langle V, E, \ell, X \rangle$ , where  $\langle V, E, \ell \rangle$  is a hypergraph and  $X \in V^+$  is a list of distinct nodes called the *external nodes*.

The function of graph fragments in HRG is analogous to the right-hand sides of CFG rules and to elementary trees in tree adjoining grammars (Joshi and Schabes, 1997). The external nodes indicate how to integrate a graph into another graph during a derivation, and are analogous to foot nodes. In diagrams, we draw them with a black circle ( $\bullet$ ).

**Definition 3.** A *hyperedge replacement grammar* (HRG) is a tuple  $G = \langle N, T, P, S \rangle$  where

- $N$  and  $T$  are finite disjoint sets of nonterminal and terminal symbols
- $S \in N$  is the start symbol
- $P$  is a finite set of productions of the form  $A \rightarrow R$ , where  $A \in N$  and  $R$  is a graph fragment over  $N \cup T$ .

We now describe the HRG rewriting mechanism.

**Definition 4.** Given a HRG  $G$ , we define the relation  $H \Rightarrow_G H'$  (or,  $H'$  is derived from  $H$  in one step) as follows. Let  $e = (v_1 \cdots v_k)$  be an edge in  $H$  with label  $A$ . Let  $(A \rightarrow R)$  be a production of  $G$ , where  $R$  has external nodes  $X_R = (u_1 \cdots u_k)$ . Then we write  $H \Rightarrow_G H'$  if  $H'$  is the graph formed by removing  $e$  from  $H$ , making an isomorphic copy of  $R$ , and identifying  $v_i$  with (the copy of)  $u_i$  for  $i = 1, \dots, k$ .

Let  $H \Rightarrow_G^* H'$  (or,  $H'$  is derived from  $H$ ) be the reflexive, transitive closure of  $\Rightarrow_G$ . The *graph language* of a grammar  $G$  is the (possibly infinite) set of graphs  $H$  that have no edges with nonterminal labels such that

$$\begin{array}{c} \circ \\ \downarrow S \\ \bullet \end{array} \Rightarrow_G^* H.$$

When a HRG rule  $(A \rightarrow R)$  is applied to an edge  $e$ , the mapping of external nodes in  $R$  to the

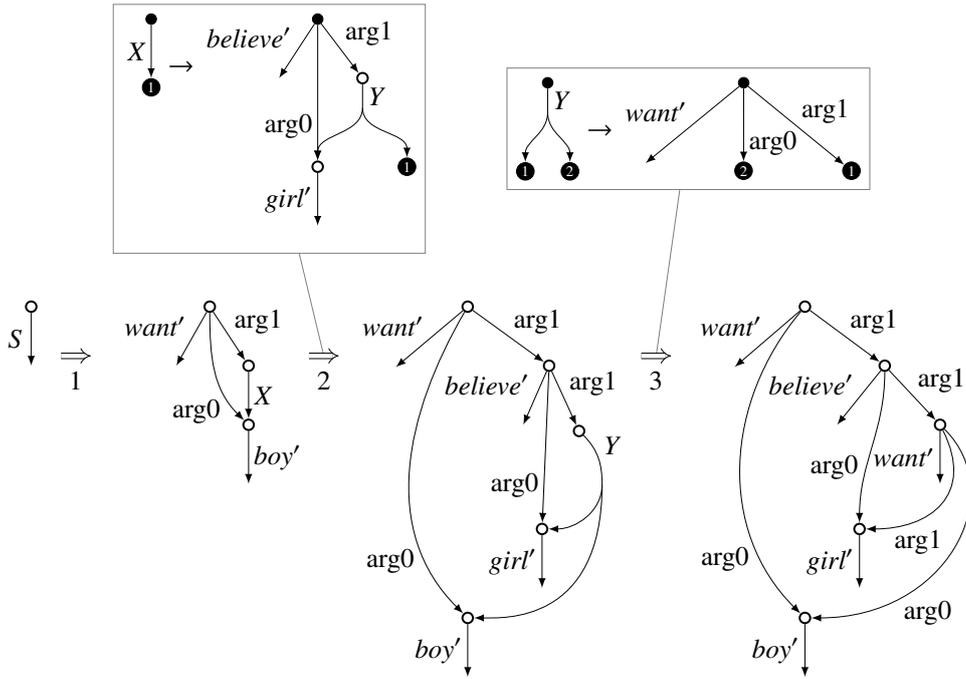

Figure 2: Derivation of a hyperedge replacement grammar for a graph representing the meaning of “The boy wants the girl to believe that he wants her.”

nodes of  $e$  is implied by the ordering of nodes in  $e$  and  $X_R$ . When writing grammar rules, we make this ordering explicit by writing the left hand side of a rule as an edge and indexing the external nodes of  $R$  on both sides, as shown in Figure 2.

HRG derivations are context-free in the sense that the applicability of each production depends on the nonterminal label of the replaced edge only. This allows us to represent a derivation as a derivation tree, and sets of derivations of a graph as a derivation forest (which can in turn be represented as hypergraphs). Thus we can apply many of the methods developed for other context free grammars. For example, it is easy to define weighted and synchronous versions of HRGs.

**Definition 5.** If  $K$  is a semiring, a  $K$ -weighted HRG is a tuple  $G = \langle N, T, P, S, \lambda \rangle$ , where  $\langle N, T, P, S \rangle$  is a HRG and  $\lambda : P \rightarrow K$  assigns a weight in  $K$  to each production. The weight of a derivation of  $G$  is the product of the weights of the productions used in the derivation.

We defer a definition of synchronous HRGs until Section 4, where they are discussed in detail.

### 3 Parsing

Lautemann’s recognition algorithm for HRGs is a generalization of the CKY algorithm for CFGs.

Its key step is the matching of a rule against the input graph, analogous to the concatenation of two spans in CKY. The original description leaves open how this matching is done, and because it tries to match the whole rule at once, it has asymptotic complexity exponential in the number of non-terminal edges. In this section, we present a refinement that makes the rule-matching procedure explicit, and because it matches rules little by little, similarly to binarization of CFG rules, it does so more efficiently than the original.

Let  $H$  be the input graph. Let  $n$  be the number of nodes in  $H$ , and  $d$  be the maximum degree of any node. Let  $G$  be a HRG. For simplicity, we assume that the right-hand sides of rules are connected. This restriction entails that each graph generated by  $G$  is connected; therefore, we assume that  $H$  is connected as well. Finally, let  $m$  be an arbitrary node of  $H$  called the *marker node*, whose usage will become clear below.<sup>1</sup>

#### 3.1 Representing subgraphs

Just as CKY deals with substrings  $(i, j]$  of the input, the HRG parsing algorithm deals with edge-induced subgraphs  $I$  of the input. An edge-induced subgraph of  $H = \langle V, E, \ell \rangle$  is, for some

<sup>1</sup>To handle the more general case where  $H$  is not connected, we would need a marker for each component.

subset  $E' \subseteq E$ , the smallest subgraph containing all edges in  $E'$ . From now on, we will assume that all subgraphs are edge-induced subgraphs.

In CKY, the two endpoints  $i$  and  $j$  completely specify the recognized part of the input,  $w_{i+1} \cdots w_j$ . Likewise, we do not need to store all of  $I$  explicitly.

**Definition 6.** Let  $I$  be a subgraph of  $H$ . A *boundary node* of  $I$  is a node in  $I$  which is either a node with an edge in  $H \setminus I$  or an external node. A *boundary edge* of  $I$  is an edge in  $I$  which has a boundary node as an endpoint. The *boundary representation* of  $I$  is the tuple  $\langle bn(I), be(I, v), m \in I \rangle$ , where

- $bn(I)$  is the set of boundary nodes of  $I$
- $be(I, v)$  be the set of boundary edges of  $v$  in  $I$
- $(m \in I)$  is a flag indicating whether the marker node is in  $I$ .

The boundary representation of  $I$  suffices to specify  $I$  compactly.

**Proposition 1.** *If  $I$  and  $I'$  are two subgraphs of  $H$  with the same boundary representation, then  $I = I'$ .*

*Proof.* Case 1:  $bn(I)$  is empty. If  $m \in I$  and  $m \in I'$ , then all edges of  $H$  must belong to both  $I$  and  $I'$ , that is,  $I = I' = H$ . Otherwise, if  $m \notin I$  and  $m \notin I'$ , then no edges can belong to either  $I$  or  $I'$ , that is,  $I = I' = \emptyset$ .

Case 2:  $bn(I)$  is nonempty. Suppose  $I \neq I'$ ; without loss of generality, suppose that there is an edge  $e$  that is in  $I \setminus I'$ . Let  $\pi$  be the shortest path (ignoring edge direction) that begins with  $e$  and ends with a boundary node. All the edges along  $\pi$  must be in  $I \setminus I'$ , or else there would be a boundary node in the middle of  $\pi$ , and  $\pi$  would not be the shortest path from  $e$  to a boundary node. Then, in particular, the last edge of  $\pi$  must be in  $I \setminus I'$ . Since it has a boundary node as an endpoint, it must be a boundary edge of  $I$ , but cannot be a boundary edge of  $I'$ , which is a contradiction.  $\square$

If two subgraphs are disjoint, we can use their boundary representations to compute the boundary representation of their union.

**Proposition 2.** *Let  $I$  and  $J$  be two subgraphs whose edges are disjoint. A node  $v$  is a boundary node of  $I \cup J$  iff one of the following holds:*

- (i)  $v$  is a boundary node of one subgraph but not the other

- (ii)  $v$  is a boundary node of both subgraphs, and has an edge which is not a boundary edge of either.

*An edge is a boundary edge of  $I \cup J$  iff it has a boundary node of  $I \cup J$  as an endpoint and is a boundary edge of  $I$  or  $J$ .*

*Proof.*  $(\Rightarrow)$   $v$  has an edge in either  $I$  or  $J$  and an edge  $e$  outside both  $I$  and  $J$ . Therefore it must be a boundary node of either  $I$  or  $J$ . Moreover,  $e$  is not a boundary edge of either, satisfying condition (ii).

$(\Leftarrow)$  Case (i): without loss of generality, assume  $v$  is a boundary node of  $I$ . It has an edge  $e$  in  $I$ , and therefore in  $I \cup J$ , and an edge  $e'$  outside  $I$ , which must also be outside  $J$ . For  $e' \notin J$  (because  $I$  and  $J$  are disjoint), and if  $e' \in J$ , then  $v$  would be a boundary node of  $J$ . Therefore,  $e' \notin I \cup J$ , so  $v$  is a boundary node of  $I \cup J$ . Case (ii):  $v$  has an edge in  $I$  and therefore  $I \cup J$ , and an edge not in either  $I$  or  $J$ .  $\square$

This result leads to Algorithm 1, which runs in time linear in the number of boundary nodes.

---

**Algorithm 1** Compute the union of two disjoint subgraphs  $I$  and  $J$ .

---

```

for all  $v \in bn(I)$  do
   $E \leftarrow be(I, v) \cup be(J, v)$ 
  if  $v \notin bn(J)$  or  $v$  has an edge not in  $E$  then
    add  $v$  to  $bn(I \cup J)$ 
     $be(I \cup J, v) \leftarrow E$ 
for all  $v \in bn(J)$  do
  if  $v \notin bn(I)$  then
    add  $v$  to  $bn(I \cup J)$ 
     $be(I \cup J, v) \leftarrow be(I, v) \cup be(J, v)$ 
 $(m \in I \cup J) \leftarrow (m \in I) \vee (m \in J)$ 

```

---

In practice, for small subgraphs, it may be more efficient simply to use an explicit set of edges instead of the boundary representation. For the Geo-Query corpus (Tang and Mooney, 2001), whose graphs are only 7.4 nodes on average, we generally find this to be the case.

### 3.2 Treewidth

Lautemann's algorithm tries to match a rule against the input graph all at once. But we can optimize the algorithm by matching a rule incrementally. This is analogous to the rank-minimization problem for linear context-free rewriting systems. Gildea has shown that this problem is related to

the notion of *treewidth* (Gildea, 2011), which we review briefly here.

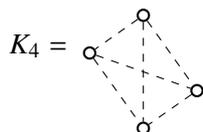

**Definition 7.** A *tree decomposition* of a graph  $H = \langle V, E \rangle$  is a tree  $T$ , each of whose nodes  $\eta$  is associated with sets  $V_\eta \subseteq V$  and  $E_\eta \subseteq E$ , with the following properties:

1. Vertex cover: For each  $v \in V$ , there is a node  $\eta \in T$  such that  $v \in V_\eta$ .
2. Edge cover: For each  $e = (v_1 \cdots v_k) \in E$ , there is exactly one node  $\eta \in T$  such that  $e \in E_\eta$ . We say that  $\eta$  *introduces*  $e$ . Moreover,  $v_1, \dots, v_k \in V_\eta$ .
3. Running intersection: For each  $v \in V$ , the set  $\{\eta \in T \mid v \in V_\eta\}$  is connected.

The *width* of  $T$  is  $\max |V_\eta| - 1$ . The *treewidth* of  $H$  is the minimal width of any tree decomposition of  $H$ .

A tree decomposition of a graph fragment  $\langle V, E, X \rangle$  is a tree decomposition of  $\langle V, E \rangle$  that has the additional property that all the external nodes belong to  $V_\eta$  for some  $\eta$ . (Without loss of generality, we assume that  $\eta$  is the root.)

For example, Figure 3b shows a graph, and Figure 3c shows a tree decomposition. This decomposition has width three, because its largest node has 4 elements. In general, a tree has width one, and it can be shown that a graph has treewidth at most two iff it does not have the following graph as a minor (Bodlaender, 1997):

Finding a tree decomposition with minimal width is in general NP-hard (Arnborg et al., 1987). However, we find that for the graphs we are interested in in NLP applications, even a naïve algorithm gives tree decompositions of low width in practice: simply perform a depth-first traversal of the edges of the graph, forming a tree  $T$ . Then, augment the  $V_\eta$  as necessary to satisfy the running intersection property.

As a test, we extracted rules from the GeoQuery corpus (Tang and Mooney, 2001) using the SYNSEM algorithm (Jones et al., 2012), and computed tree decompositions exactly using a branch-and-bound method (Gogate and Dechter, 2004) and this approximate method. Table 1 shows that, in practice, treewidths are not very high even when computed only approximately.

method	mean	max
exact	1.491	2
approximate	1.494	3

Table 1: Mean and maximum treewidths of rules extracted from the GeoQuery corpus, using exact and approximate methods.

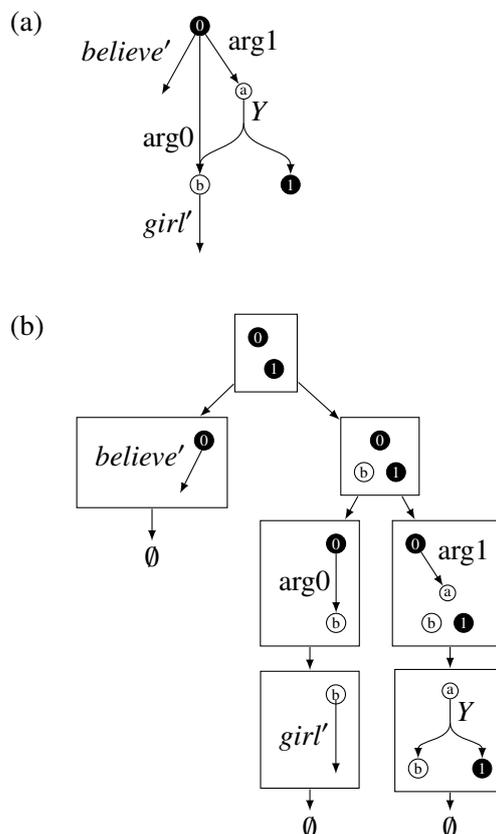

Figure 3: (a) A rule right-hand side, and (b) a nice tree decomposition.

Any tree decomposition can be converted into one which is *nice* in the following sense (simplified from Cygan et al. (2011)). Each tree node  $\eta$  must be one of:

- A leaf node, such that  $V_\eta = \emptyset$ .
- A unary node, which introduces exactly one edge  $e$ .
- A binary node, which introduces no edges.

The example decomposition in Figure 3c is nice. This canonical form simplifies the operation of the parser described in the following section.

Let  $G$  be a HRG. For each production  $(A \rightarrow R) \in G$ , find a nice tree decomposition of  $R$  and call it  $T_R$ . The treewidth of  $G$  is the maximum

treewidth of any right-hand side in  $G$ .

The basic idea of the recognition algorithm is to recognize the right-hand side of each rule incrementally by working bottom-up on its tree decomposition. The properties of tree decomposition allow us to limit the number of boundary nodes of the partially-recognized rule.

More formally, let  $R_{\succeq\eta}$  be the subgraph of  $R$  induced by the union of  $E_{\eta'}$  for all  $\eta'$  equal to or dominated by  $\eta$ . Then we can show the following.

**Proposition 3.** *Let  $R$  be a graph fragment, and assume a tree decomposition of  $R$ . All the boundary nodes of  $R_{\succeq\eta}$  belong to  $V_\eta \cap V_{parent(\eta)}$ .*

*Proof.* Let  $v$  be a boundary node of  $R_{\succeq\eta}$ . Node  $v$  must have an edge in  $R_{\succeq\eta}$  and therefore in  $R_{\eta'}$  for some  $\eta'$  dominated by or equal to  $\eta$ .

Case 1:  $v$  is an external node. Since the root node contains all the external nodes, by the running intersection property, both  $V_\eta$  and  $V_{parent(\eta)}$  must contain  $v$  as well.

Case 2:  $v$  has an edge not in  $R_{\succeq\eta}$ . Therefore there must be a tree node not dominated by or equal to  $\eta$  that contains this edge, and therefore  $v$ . So by the running intersection property,  $\eta$  and its parent must contain  $v$  as well.  $\square$

This result, in turn, will allow us to bound the complexity of the parsing algorithm in terms of the treewidth of  $G$ .

### 3.3 Inference rules

We present the parsing algorithm as a deductive system (Shieber et al., 1995). The items have one of two forms. A *passive* item has the form  $[A, I, X]$ , where  $X \in V^+$  is an explicit ordering of the boundary nodes of  $I$ . This means that we have recognized that  $A \Rightarrow_G^* I$ . Thus, the goal item is  $[S, H, \epsilon]$ . An *active* item has the form  $[A \rightarrow R, \eta, I, \phi]$ , where

- $(A \rightarrow R)$  is a production of  $G$
- $\eta$  is a node of  $T_R$
- $I$  is a subgraph of  $H$
- $\phi$  is a bijection between the boundary nodes of  $R_{\succeq\eta}$  and those of  $I$ .

The parser must ensure that  $\phi$  is a bijection when it creates a new item. Below, we use the notation  $\{e \mapsto e'\}$  or  $\{e \mapsto X\}$  for the mapping that sends each node of  $e$  to the corresponding node of  $e'$  or  $X$ .

Passive items are generated by the following rule:

- Root 
$$\frac{[B \rightarrow Q, \theta, J, \psi]}{[B, J, X]}$$

where  $\theta$  is the root of  $T_Q$ , and  $X_j = \psi(X_{Q,j})$ .

If we assume that the  $T_R$  are nice, then the inference rules that generate active items follow the different types of nodes in a nice tree decomposition:

- Leaf 
$$\overline{[A \rightarrow R, \eta, \emptyset, \emptyset]}$$

where  $\eta$  is a leaf node of  $T_R$ .

- (Unary) Nonterminal

$$\frac{[A \rightarrow R, \eta_1, I, \phi] \quad [B, J, X]}{[A \rightarrow R, \eta, I \cup J, \phi \cup \{e \mapsto X\}]}$$

where  $\eta_1$  is the only child of  $\eta$ , and  $e$  is introduced by  $\eta$  and is labeled with nonterminal  $B$ .

- (Unary) Terminal

$$\frac{[A \rightarrow R, \eta_1, I, \phi]}{[A \rightarrow R, \eta, I \cup \{e'\}, \phi \cup \{e \mapsto e'\}]}$$

where  $\eta_1$  is the only child of  $\eta$ ,  $e$  is introduced by  $\eta$ , and  $e$  and  $e'$  are both labeled with terminal  $a$ .

- Binary

$$\frac{[A \rightarrow R, \eta_1, I, \phi_1] \quad [A \rightarrow R, \eta_2, J, \phi_2]}{[A \rightarrow R, \eta, I \cup J, \phi_1 \cup \phi_2]}$$

where  $\eta_1$  and  $\eta_2$  are the two children of  $\eta$ .

In the Nonterminal, Terminal, and Binary rules, we form unions of subgraphs and unions of mappings. When forming the union of two subgraphs, we require that the subgraphs be disjoint (however, see Section 3.4 below for a relaxation of this condition). When forming the union of two mappings, we require that the result be a bijection. If either of these conditions is not met, the inference rule cannot apply.

For efficiency, it is important to index the items for fast access. For the Nonterminal inference rule, passive items  $[B, J, X]$  should be indexed by key  $\langle B, |bn(J)| \rangle$ , so that when the next item on the agenda is an active item  $[A \rightarrow R, \eta_1, I, \phi]$ , we know that all possible matching passive items are

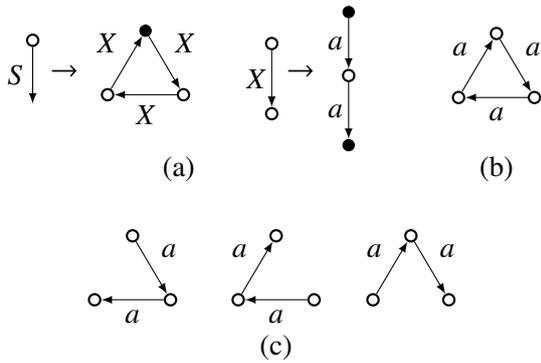

Figure 4: Illustration of unsoundness in the recognition algorithm without the disjointness check. Using grammar (a), the recognition algorithm would incorrectly accept the graph (b) by assembling together the three overlapping fragments (c).

under key  $\langle \ell(e), |e| \rangle$ . Similarly, active items should be indexed by key  $\langle \ell(e), |e| \rangle$  so that they can be found when the next item on the agenda is a passive item. For the Binary inference rule, active items should be indexed by their tree node ( $\eta_1$  or  $\eta_2$ ).

This procedure can easily be extended to produce a packed forest of all possible derivations of the input graph, representable as a hypergraph just as for other context-free rewriting formalisms. The Viterbi algorithm can then be applied to this representation to find the highest-probability derivation, or the Inside/Outside algorithm to set weights by Expectation-Maximization.

### 3.4 The disjointness check

A successful proof using the inference rules above builds an HRG derivation (comprising all the rewrites used by the Nonterminal rule) which derives a graph  $H'$ , as well as a graph isomorphism  $\phi : H' \rightarrow H$  (the union of the mappings from all the items).

During inference, whenever we form the union of two subgraphs, we require that the subgraphs be disjoint. This is a rather expensive operation: it can be done using only their boundary representations, but the best algorithm we are aware of is still quadratic in the number of boundary nodes.

Is it possible to drop the disjointness check? If we did so, it would become possible for the algorithm to recognize the same part of  $H$  twice. For example, Figure 4 shows an example of a grammar and an input that would be incorrectly recognized.

However, we can replace the disjointness check

with a weaker and faster check such that any derivation that merges two non-disjoint subgraphs will ultimately fail, and therefore the derived graph  $H'$  is isomorphic to the input graph  $H'$  as desired. This weaker check is to require, when merging two subgraphs  $I$  and  $J$ , that:

1.  $I$  and  $J$  have no boundary edges in common, and
2. If  $m$  belongs to both  $I$  and  $J$ , it must be a boundary node of both.

Condition (1) is enough to guarantee that  $\phi$  is *locally one-to-one* in the sense that for all  $v \in H'$ ,  $\phi$  restricted to  $v$  and its neighbors is one-to-one. This is easy to show by induction: if  $\phi_I : I' \rightarrow H$  and  $\phi_J : J' \rightarrow H$  are locally one-to-one, then  $\phi_I \cup \phi_J$  must also be, provided condition (1) is met. Intuitively, the consequence of this is that we can detect any place where  $\phi$  changes (say) from being one-to-one to two-to-one. So if  $\phi$  is two-to-one, then it must be two-to-one everywhere (as in the example of Figure 4).

But condition (2) guarantees that  $\phi$  maps only one node to the marker  $m$ . We can show this again by induction: if  $\phi_I$  and  $\phi_J$  each map only one node to  $m$ , then  $\phi_I \cup \phi_J$  must map only one node to  $m$ , by a combination of condition (2) and the fact that the inference rules guarantee that  $\phi_I$ ,  $\phi_J$ , and  $\phi_I \cup \phi_J$  are one-to-one on boundary nodes.

Then we can show that, since  $m$  is recognized exactly once, the whole graph is also recognized exactly once.

**Proposition 4.** *If  $H$  and  $H'$  are connected graphs,  $\phi : H' \rightarrow H$  is locally one-to-one, and  $\phi^{-1}$  is defined for some node of  $H$ , then  $\phi$  is a bijection.*

*Proof.* Suppose that  $\phi$  is not a bijection. Then there must be two nodes  $v'_1, v'_2 \in H'$  such that  $\phi(v'_1) = \phi(v'_2) = v \in H$ . We also know that there is a node, namely,  $m$ , such that  $m' = \phi^{-1}(m)$  is defined.<sup>2</sup> Choose a path  $\pi$  (ignoring edge direction) from  $v$  to  $m$ . Because  $\phi$  is a local isomorphism, we can construct a path from  $v'_1$  to  $m'$  that maps to  $\pi$ . Similarly, we can construct a path from  $v'_2$  to  $m'$  that maps to  $\pi$ . Let  $u'$  be the first node that these two paths have in common. But  $u'$  must have two edges that map to the same edge, which is a contradiction.  $\square$

<sup>2</sup>If  $H$  were not connected, we would choose the marker in the same connected component as  $v$ .

### 3.5 Complexity

The key to the efficiency of the algorithm is that the treewidth of  $G$  leads to a bound on the number of boundary nodes we must keep track of at any time.

Let  $k$  be the treewidth of  $G$ . The time complexity of the algorithm is the number of ways of instantiating the inference rules. Each inference rule mentions only boundary nodes of  $R_{\geq \eta}$  or  $R_{\geq \eta_i}$ , all of which belong to  $V_\eta$  (by Proposition 3), so there are at most  $|V_\eta| \leq k + 1$  of them. In the Nonterminal and Binary inference rules, each boundary edge could belong to  $I$  or  $J$  or neither. Therefore, the number of possible instantiations of any inference rule is in  $O((3^d n)^{k+1})$ .

The space complexity of the algorithm is the number of possible items. For each active item  $[A \rightarrow R, \eta, I, \phi]$ , every boundary node of  $R_{\geq \eta}$  must belong to  $V_\eta \cap V_{parent(\eta)}$  (by Proposition 3). Therefore the number of boundary nodes is at most  $k + 1$  (but typically less), and the number of possible items is in  $O((2^d n)^{k+1})$ .

## 4 Synchronous Parsing

As mentioned in Section 2.2, because HRGs have context-free derivation trees, it is easy to define *synchronous HRGs*, which define mappings between languages of graphs.

**Definition 8.** A *synchronous hyperedge replacement grammar* (SHRG) is a tuple  $G = \langle N, T, T', P, S \rangle$ , where

- $N$  is a finite set of nonterminal symbols
- $T$  and  $T'$  are finite sets of terminal symbols
- $S \in N$  is the start symbol
- $P$  is a finite set of productions of the form  $(A \rightarrow \langle R, R', \sim \rangle)$ , where  $R$  is a graph fragment over  $N \cup T$  and  $R'$  is a graph fragment over  $N \cup T'$ . The relation  $\sim$  is a bijection linking nonterminal mentions in  $R$  and  $R'$ , such that if  $e \sim e'$ , then they have the same label. We call  $R$  the *source* side and  $R'$  the *target* side.

Some NLP applications (for example, word alignment) require *synchronous parsing*: given a pair of graphs, finding the derivation or forest of derivations that simultaneously generate both the source and target. The algorithm to do this is a straightforward generalization of the HRG parsing

algorithm. For each rule  $(A \rightarrow \langle R, R', \sim \rangle)$ , we construct a nice tree decomposition of  $R \cup R'$  such that:

- All the external nodes of both  $R$  and  $R'$  belong to  $V_\eta$  for some  $\eta$ . (Without loss of generality, assume that  $\eta$  is the root.)
- If  $e \sim e'$ , then  $e$  and  $e'$  are introduced by the same tree node.

In the synchronous parsing algorithm, passive items have the form  $[A, I, X, I', X']$  and active items have the form  $[A \rightarrow R : R', \eta, I, \phi, I', \phi']$ . For brevity we omit a re-presentation of all the inference rules, as they are very similar to their non-synchronous counterparts. The main difference is that in the Nonterminal rule, two linked edges are rewritten simultaneously:

$$\frac{[A \rightarrow R : R', \eta_1, I, \phi, I', \phi'] \quad [B, J, X, J', X']}{[A \rightarrow R : R', \eta, I \cup J, \phi \cup \{e_j \mapsto X_j\}, I' \cup J', \phi' \cup \{e'_j \mapsto X'_j\}]}$$

where  $\eta_1$  is the only child of  $\eta$ ,  $e$  and  $e'$  are both introduced by  $\eta$  and  $e \sim e'$ , and both are labeled with nonterminal  $B$ .

The complexity of the parsing algorithm is again in  $O((3^d n)^{k+1})$ , where  $k$  is now the maximum treewidth of the dependency graph as defined in this section. In general, this treewidth will be greater than the treewidth of either the source or target side on its own, so that synchronous parsing is generally slower than standard parsing.

## 5 Conclusion

Although Lautemann's polynomial-time extension of CKY to HRGs has been known for some time, the desire to use graph grammars for large-scale NLP applications introduces some practical considerations not accounted for in Lautemann's original presentation. We have provided a detailed description of our refinement of his algorithm and its implementation. It runs in  $O((3^d n)^{k+1})$  time and requires  $O((2^d n)^{k+1})$  space, where  $n$  is the number of nodes in the input graph,  $d$  is its maximum degree, and  $k$  is the maximum treewidth of the rule right-hand sides in the grammar. We have also described how to extend this algorithm to synchronous parsing. The parsing algorithms described in this paper are implemented in the Bolinas toolkit.<sup>3</sup>

<sup>3</sup>The Bolinas toolkit can be downloaded from <http://www.isi.edu/licensed-sw/bolinas/>.

## Abstract

We present the first unsupervised approach for semantic parsing that rivals the accuracy of supervised approaches in translating natural-language questions to database queries. Our GUSP system produces a semantic parse by annotating the dependency-tree nodes and edges with latent states, and learns a probabilistic grammar using EM. To compensate for the lack of example annotations or question-answer pairs, GUSP adopts a novel grounded-learning approach to leverage database for indirect supervision. On the challenging ATIS dataset, GUSP attained an accuracy of 84%, effectively tying with the best published results by supervised approaches.

## 1 Introduction

Semantic parsing maps text to a formal meaning representation such as logical forms or structured queries. Recently, there has been a burgeoning interest in developing machine-learning approaches for semantic parsing (Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007; Mooney, 2007; Kwiatkowski et al., 2011), but the predominant paradigm uses supervised learning, which requires example annotations that are costly to obtain. More recently, several grounded-learning approaches have been proposed to alleviate the annotation burden (Chen and Mooney, 2008; Kim and Mooney, 2010; Börschinger et al., 2011; Clarke et al., 2010; Liang et al., 2011). In particular, Clarke et al. (2010) and Liang et al. (2011) proposed methods to learn from question-answer pairs alone, which represents a significant advance. However, although these methods exonerate annotators from mastering specialized logical forms, finding the answers for complex ques-

tions still requires non-trivial effort.<sup>1</sup>

Poon & Domingos (2009, 2010) proposed the USP system for unsupervised semantic parsing, which learns a parser by recursively clustering and composing synonymous expressions. While their approach completely obviates the need for direct supervision, their target logic forms are self-induced clusters, which do not align with existing database or ontology. As a result, USP can not be used directly to answer complex questions against an existing database. More importantly, it misses the opportunity to leverage database for indirect supervision.

In this paper, we present the GUSP system, which combines unsupervised semantic parsing with grounded learning from a database. GUSP starts with the dependency tree of a sentence and produces a semantic parse by annotating the nodes and edges with latent semantic states derived from the database. Given a set of natural-language questions and a database, GUSP learns a probabilistic semantic grammar using EM. To compensate for the lack of direct supervision, GUSP constrains the search space using the database schema, and bootstraps learning using lexical scores computed from the names and values of database elements.

Unlike previous grounded-learning approaches, GUSP does not require ambiguous annotations or oracle answers, but rather focuses on leveraging database contents that are readily available. Unlike USP, GUSP predetermines the target logical forms based on the database schema, which alleviates the difficulty in learning and ensures that the output semantic parses can be directly used in querying the database. To handle syntax-semantics mismatch, GUSP introduces a novel dependency-based meaning representation

---

<sup>1</sup>Clarke et al. (2010) and Liang et al. (2011) used the annotated logical forms to compute answers for their experiments.

by augmenting the state space to represent semantic relations beyond immediate dependency neighborhood. This representation also factorizes over nodes and edges, enabling linear-time exact inference in GUSP.

We evaluated GUSP on end-to-end question answering using the ATIS dataset for semantic parsing (Zettlemoyer and Collins, 2007). Compared to other standard datasets such as GEO and JOBS, ATIS features a database that is an order of magnitude larger in the numbers of relations and instances, as well as a more irregular language (ATIS questions were derived from spoken dialogs). Despite these challenges, GUSP attains an accuracy of 84% in end-to-end question answering, effectively tying with the state-of-the-art supervised approaches (85% by Zettlemoyer & Collins (2007), 83% by Kwiatkowski et al. (2011)).

## 2 Background

### 2.1 Semantic Parsing

The goal of semantic parsing is to map text to a complete and detailed meaning representation (Mooney, 2007). This is in contrast with semantic role labeling (Carreras and Marquez, 2004) and information extraction (Banko et al., 2007; Poon and Domingos, 2007), which have a more restricted goal of identifying local semantic roles or extracting selected information slots.

The standard language for meaning representation is first-order logic or a sublanguage, such as FunQL (Kate et al., 2005; Clarke et al., 2010) and lambda calculus (Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007). Poon & Domingos (2009, 2010) induce a meaning representation by clustering synonymous lambda-calculus forms stemming from partitions of dependency trees. More recently, Liang et al. (2011) proposed DCS for dependency-based compositional semantics, which represents a semantic parse as a tree with nodes representing database elements and operations, and edges representing relational joins.

In this paper, we focus on semantic parsing for natural-language interface to database (Grosz et al., 1987). In this problem setting, a natural-language question is first translated into a meaning representation by semantic parsing, and then converted into a structured query such as SQL to obtain answer from the database.

### 2.2 Unsupervised Semantic Parsing

Unsupervised semantic parsing was first proposed by Poon & Domingos (2009, 2010) with their USP system. USP defines a probabilistic model over the dependency tree and semantic parse using Markov logic (Domingos and Lowd, 2009), and recursively clusters and composes synonymous dependency treelets using a hard EM-like procedure. Since USP uses nonlocal features (e.g., the argument-number feature) and operates over partitions, exact inference is intractable, and USP resorts to a greedy approach to find the MAP parse by searching over partitions. Titov & Klementiev (2011) proposed a Bayesian version of USP and Titov & Klementiev (2012) adapted it for semantic role induction. In USP, the meaning is represented by self-induced clusters. Therefore, to answer complex questions against a database, it requires an additional ontology matching step to resolve USP clusters with database elements.

Popescu et al. (2003, 2004) proposed the PRECISE system, which does not require labeled examples and can be directly applied to question answering with a database. The PRECISE system, however, requires substantial amount of engineering, including a domain-specific lexicon that specifies the synonyms for names and values of database elements, a restricted set of potential interpretations for domain verbs and prepositions, as well as a set of domain questions with manually labeled POS tags for retraining the tagger and parser. It also focuses on the subset of easy questions (“semantically tractable” questions), and sidesteps the problem of dealing with complex and nested structures, as well as ambiguous interpretations. Remarkably, while PRECISE can be very accurate on easy questions, it does not try to learn from these interpretations. In contrast, Goldwasser et al. (2011) proposed a self-supervised approach, which iteratively chose high-confidence parses to retrain the parser. Their system, however, still required a lexicon manually constructed for the given domain. Moreover, it was only applied to a small domain (a subset of GEO), and the result still trailed supervised systems by a wide margin.

### 2.3 Grounded Learning for Semantic Parsing

Grounded learning is motivated by alleviating the burden of direct supervision via interaction with the world, where the indirect supervision may take the form as ambiguous annotations (Chen

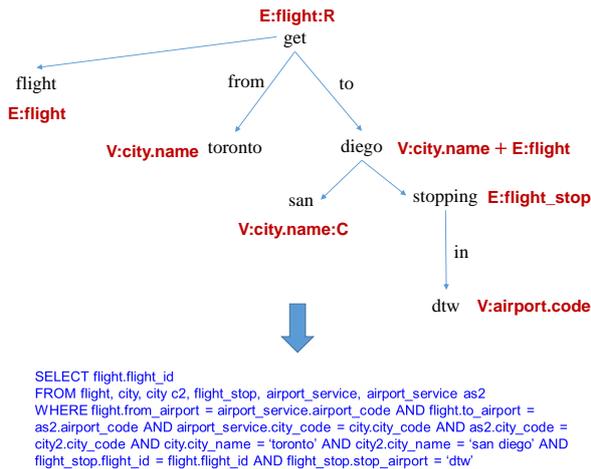

Figure 1: End-to-end question answering by GUSP for sentence *get flight from toronto to san diego stopping in dtw*. Top: the dependency tree of the sentence is annotated with latent semantic states by GUSP. For brevity, we omit the edge states. Raising occurs from *flight* to *get* and sinking occurs from *get* to *diego*. Bottom: the semantic tree is deterministically converted into SQL to obtain answer from the database.

and Mooney, 2008; Kim and Mooney, 2010; Börschinger et al., 2011) or example question-answer pairs (Clarke et al., 2010; Liang et al., 2011). In general, however, such supervision is not always available or easy to obtain. In contrast, databases are often abundantly available, especially for important domains.

The database community has considerable amount of work on leveraging databases in various tasks such as entity resolution, schema matching, and others. To the best of our knowledge, this approach is still underexplored in the NLP community. One notable exception is distant supervision (Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011; Krishnamurthy and Mitchell, 2012; Heck et al., 2013), which used database instances to derive training examples for relation extraction. This approach, however, still has considerable limitations. For example, it only handles binary relations, and the quality of the training examples is inherently noisy and hard to control. Moreover, this approach is not applicable to the question-answering setting considered in this paper, since entity pairs in questions need not correspond to valid relational instances in the database.

### 3 Grounded Unsupervised Semantic Parsing

In this section, we present the GUSP system for grounded unsupervised semantic parsing. GUSP is unsupervised and does not require example logical forms or question-answer pairs. Figure 1 shows an example of end-to-end question answering using GUSP. GUSP produces a semantic parse of the question by annotating its dependency tree with latent semantic states. The semantic tree can then be deterministically converted into SQL to obtain answer from the database. Given a set of natural-language questions and a database, GUSP learns a probabilistic semantic grammar using EM.
