To compensate for the lack of annotated examples, GUSP derives indirect supervision from a novel combination of three key sources. First, GUSP leverages the target database to constrain the search space. Specifically, it defines the semantic states based on the database schema, and derives lexical-trigger scores from database elements to bootstrap learning.

Second, in contrast to most existing approaches for semantic parsing, GUSP starts directly from dependency trees and focuses on translating them into semantic parses. While syntax may not always align perfectly with semantics, it is still highly informative about the latter. In particular, dependency edges are often indicative of semantic relations. On the other hand, syntax and semantic often diverge, and syntactic parsing errors abound. To combat this problem, GUSP introduces a novel dependency-based meaning representation with an augmented state space to account for semantic relations that are nonlocal in the dependency tree.

GUSP’s approach of starting directly from dependency tree is inspired by USP. However, GUSP uses a different meaning representation defined over individual nodes and edges, rather than partitions, which enables linear-time exact inference. GUSP also handles complex linguistic phenomena and syntax-semantics mismatch by explicitly augmenting the state space, whereas USP’s capability in handling such phenomena is indirect and more limited.

GUSP represents meaning by a semantic tree, which is similar to DCS (Liang et al., 2011). Their approach to semantic parsing, however, differs from GUSP in that it induced the semantic tree directly from a sentence, rather than starting from

a dependency tree and annotating it. Their approach alleviates some complexity in the meaning representation for handling syntax-semantics mismatch, but it has to search over a much larger search space involving exponentially many candidate trees. This might partially explain why it has not yet been scaled up to the ATIS dataset.

Finally, GUSP recognizes that certain aspects in semantic parsing may not be worth learning using precious annotated examples. These are domain-independent and closed-class expressions, such as times and dates (e.g., *before 5pm* and *July seventeenth*), logical connectives (e.g., *and*, *or*, *not*), and numerics (e.g., *200 dollars*). GUSP preprocesses the text to detect such expressions and restricts their interpretation to database elements of compatible types (e.g., *before 5pm* vs. `flight.departure_time` or `flight.arrival_time`). Short of training examples, GUSP also resolves quantifier scoping ambiguities deterministically by a fixed ordering. For example, in the phrase *cheapest flight to Seattle*, the scope of *cheapest* can be either *flight* or *flight to seattle*. GUSP always chooses to apply the superlative at last, amounting to choosing the most restricted scope (*flight to seattle*), which is usually the correct interpretation.

In the remainder of this section, we first formalize the problem setting and introduce the GUSP meaning representation. We then present the GUSP model and learning and inference algorithms. Finally, we describe how to convert a GUSP semantic parse into SQL.

### 3.1 Problem Formulation

Let  $d$  be a dependency tree,  $N(d)$  and  $E(d)$  be its nodes and edges. In GUSP, a semantic parse of  $d$  is an assignment  $z : N(d) \cup E(d) \rightarrow \mathcal{S}$  that maps its nodes and edges to semantic states in  $\mathcal{S}$ . For example, in the example in Figure 1,  $z(\textit{flight}) = E:\textit{flight}$ . At the core of GUSP is a joint probability distribution  $P_\theta(d, z)$  over the dependency tree and the semantic parse. Semantic parsing in GUSP amounts to finding the most probable parse  $z^* = \arg \max_z P_\theta(d, z)$ . Given a set of sentences and their dependency trees  $D$ , learning in GUSP maximizes the log-likelihood of  $D$  while summing out the latent parses  $z$ :

$$\begin{aligned} \theta^* &= \arg \max \log P_\theta(D) \\ &= \arg \max \sum_{d \in D} \log \sum_z P_\theta(d, z) \end{aligned}$$

### 3.2 Simple Semantic States

**Node states** GUSP creates a state  $E:X$  ( $E$  short for entity) for each database entity  $X$  (i.e., a database table), a state  $P:Y$  ( $P$  short for property) and  $V:Y$  ( $V$  short for value) for each database attribute  $Y$  (i.e., a database column). Node states are assigned to dependency nodes. Intuitively, they represent database entities, properties, and values. For example, the ATIS domain contains entities such as `flight` and `fare`, which may contain properties such as the departure time `flight.departure_time` or ticket price `fare.one_direction_cost`. The mentions of entities and properties are represented by entity and property states, whereas constants such as `9:25am` or `120 dollars` are represented by value states. In the semantic parse in Figure 1, for example, *flight* is assigned to entity state  $E:\textit{flight}$ , where *toronto* is assigned to value state  $V:\textit{city.name}$ . There is a special node state `NULL`, which signifies that the subtree headed by the word contributes no meaning to the semantic parse (e.g., an auxiliary verb).

**Edge states** GUSP creates an edge state for each valid relational join paths connecting two node states. Edge states are assigned to dependency edges. GUSP enforces the constraints that the node states of the dependency parent and child must agree with the node states in the edge state. For example,  $E:\textit{flight}-V:\textit{flight.departure_time}$  represents a natural join between the flight entity and the property value departure time. For a dependency edge  $e : a \rightarrow b$ , the assignment to  $E:\textit{flight}-V:\textit{flight.departure_time}$  signifies that  $a$  represents a flight entity, and  $b$  represents the value of its departure time. An edge state may also represent a relational path consisting of a serial of joins. For example, Zettlemoyer and Collins (2007) used a predicate `from(f, c)` to signify that flight  $f$  starts from city  $c$ . In the ATIS database, however, this amounts to a path of three joins:

```
flight.from-airport-airport
airport-airport-service
airport-service-city
```

In GUSP, this is represented by the edge state `flight-flight.from-airport-airport-service-city`.

GUSP only creates edge states for relational join paths up to length four, as longer paths rarely correspond to meaningful semantic relations.

**Composition** To handle compositions such as *American Airlines* and *New York City*, it helps to distinguish the head words (*Airlines* and *City*) from the rest. In GUSP, this is handled by introducing, for each node state such as `E:airline`, a new node state such as `E:airline:C`, where `C` signifies composition. For example, in Figure 1, *diego* is assigned to `V:city.name`, whereas *san diego* is assigned to `V:city.name:C`, since *san diego* forms a single meaning unit, and should be translated into SQL as a whole.

### 3.3 Domain-Independent States

These are for handling special linguistic phenomena that are not domain-specific, such as negation, superlatives, and quantifiers.

**Operator states** GUSP create node states for the logical and comparison operators (`OR`, `AND`, `NOT`, `MORE`, `LESS`, `EQ`). Additionally, to handle the cases when prepositions and logical connectives are collapsed into the label of a dependency edge, as in Stanford dependency, GUSP introduces an edge state for each triple of an operator and two node states, such as `E:flight-AND-E:fare`.

**Quantifier states** GUSP creates a node state for each of the standard SQL functions: `argmin`, `argmax`, `count`, `sum`. Additionally, it creates a node state for each pair of compatible function and property. For example, `argmin` can be applied to any numeric property, in particular `flight.departure_time`, and so the node state `P:flight.departure_time:argmin` is created and can be assigned to superlatives such as *earliest*.

### 3.4 Complex Semantic States

For sentences with a correct dependency tree and well-aligned syntax and semantics, the simple semantic states suffice for annotating the correct semantic parse. However, in complex sentences, syntax and semantic often diverge, either due to their differing goals or simply stemming from syntactic parsing errors. In Figure 1, the dependency tree contains multiple errors: *from toronto* and *to san diego* are mistakenly attached to *get*, which has no literal meaning here; *stopping in dtw* is also

wrongly attached to *diego* rather than *flight*. Annotating such a tree with only simple states will lead to incorrect semantic parses, e.g., by joining `V:city:san diego` with `V:airport:dtw` via `E:airport_service`, rather than joining `E:flight` with `V:airport:dtw` via `E:flight_stop`.

To overcome these challenges, GUSP introduces three types of complex states to handle syntax-semantics divergence. Figure 1 shows the correct semantic parse for the above sentence using the complex states.

**Raising** For each simple node state `N`, GUSP creates a “raised” state `N:R` (`R` short for raised). A raised state signifies a word that has little or none of its own meaning, but effectively takes one of its child states to be its own (“raises”). Correspondingly, GUSP creates a “raising” edge state `N-R-N`, which signifies that the parent is a raised state and its meaning is derived from the dependency child of state `N`. For all other children, the parent behaves just as state `N`. For example, in Figure 1, *get* is assigned to the raised state `E:flight:R`, and the edge between *get* and *flight* is assigned to the raising edge state `E:flight-R-E:flight`.

**Sinking** For simple node states `A`, `B` and an edge state `E` connecting the two, GUSP creates a “sinking” node state `A+E+B:S` (`S` for sinking). When a node `n` is assigned to such a sinking state, `n` can behave as either `A` or `B` for its children (i.e., the edge states can connect to either one), and `n`’s parent must be of state `B`. In Figure 1, for example, *diego* is assigned to a sinking state `V:city.name + E:flight` (the edge state is omitted for brevity). `E:flight` comes from its parent *get*. For child *san diego* behaves as in state `V:city.name`, and their edge state is a simple compositional join. For the other child *stopping diego* behaves as in state `E:flight`, and their edge state is a relational join connecting *flight* with *flight\_stop*. Effectively, this connects *stopping* with *get* and eventually with *flight* (due to raising), virtually correcting the syntax-semantics mismatch stemming from attachment errors.

**Implicit** For simple node states `A`, `B` and an edge state `E` connecting the two, GUSP also creates a node state `A+E+B:I` (`I` for implicit) with the “implicit” state `B`. In natural languages, an entity is often introduced implicitly, which the reader infers from shared world knowledge. For example,

to obtain the correct semantic parse for *Give me the fare from Seattle to Boston*, one needs to infer the existence of a *flight* entity, as in *Give me the fare (of a flight) from Seattle to Boston*. Implicit states offer candidates for addressing such needs. As in sinking, child nodes have access to either of the two simple states, but the implicit state is not visible to the parent node.

### 3.5 Lexical-Trigger Scores

GUSP uses the database elements to automatically derive a simple scoring scheme for lexical triggers. If a database element has a name of  $k$  words, each word is assigned score  $1/k$  for the corresponding node state. Similarly for property values and value node states. In a sentence, if a word  $w$  triggers a node state with score  $s$ , its dependency children and left and right neighbors all get a trigger score of  $0.1 \cdot s$  for the same state. To score relevant words not appearing in the database (due to incompleteness of the database or lexical variations), GUSP uses DASH (Pantel et al., 2009) to provide additional word-pair scoring based on lexical distributional similarity computed over general text corpora (Wikipedia in this case). In the case of multiple score assignments for the same word, the maximum score is used.

For multi-word values of property  $Y$ , and for a dependency edge connecting two collocated words, GUSP assigns a score 1.0 to the edge state joining the value node state  $V:Y$  to its composition state  $V:Y:C$ , as well as the edge state joining two composition states  $V:Y:C$ .

GUSP also uses a domain-independent list of superlatives with the corresponding data types and polarity (e.g., *first*, *last*, *earliest*, *latest*, *cheapest*) and assigns a trigger score of 1.0 for each property of a compatible data type (e.g., *cheapest* for properties of type MONEY).

### 3.6 The GUSP Model

In a nutshell, the GUSP model resembles a tree-HMM, which models the emission of words and dependencies by node and edge states, as well as transition between an edge state and the parent and child node states. In preliminary experiments on the development set, we found that the naïve model (with multinomials as conditional probabilities) did not perform well in EM. We thus chose to apply feature-rich EM (Berg-Kirkpatrick et al., 2010) in GUSP, which enabled the use of more generalizable features. Specifically, GUSP defines

a probability distribution over dependency tree  $d$  and semantic parse  $z$  by

$$P_{\theta}(d, z) = \frac{1}{Z} \exp \sum_i f_i(d, z) \cdot w_i(d, z)$$

where  $f_i$  and  $w_i$  are features and their weights, and  $Z$  is the normalization constant that sums over all possible  $d, z$  (over the same unlabeled tree). The features of GUSP are as follows:

**Lexical-trigger scores** These are implemented as emission features with fixed weights. For example, given a token  $t$  that triggers node state  $N$  with score  $s$ , there is a corresponding features  $1(\text{lemma} = t, \text{state} = N)$  with weight  $\alpha \cdot s$ , where  $\alpha$  is a parameter.

**Emission features for node states** GUSP uses two templates for emission of node states: for raised states,  $1(\text{token} = \cdot)$ , i.e., the emission weights for all raised states are tied; for non-raised states,  $1(\text{lemma} = \cdot, \text{state} = N)$ .

**Emission features for edge states** GUSP uses the following templates for emission of edge states:

Child node state is NULL, dependency=  $\cdot$ ;

Edge state is RAISING, dependency=  $\cdot$ ;

Parent node state is same as the child node state, dependency=  $\cdot$ ;

Otherwise, parent node state=  $\cdot$ , child node state=  $\cdot$ , edge state type=  $\cdot$ , dependency=  $\cdot$ .

**Transition features** GUSP uses the following templates for transition features, which are similar to the edge emission features except for the dependency label:

Child node state is NULL;

Edge state is RAISING;

Parent node state is same as the child node state;

Otherwise, parent node state=  $\cdot$ , child node state=  $\cdot$ , edge state type=  $\cdot$ .

**Complexity Prior** To favor simple semantic parses, GUSP imposes an exponential prior with weight  $\beta$  on nodes states that are not null or raised, and on each relational join in an edge state.

### 3.7 Learning and Inference

Since the GUSP model factors over nodes and edges, learning and inference can be done efficiently using EM and dynamic programming. Specifically, the MAP parse and expectations can

be computed by tree-Viterbi and inside-outside (Petrov and Klein, 2008). The parameters can be estimated by feature-rich EM (Berg-Kirkpatrick et al., 2010).

Because the Viterbi and inside-outside are applied to a fixed tree (i.e., the input dependency tree), their running times are only linear in the sentence length in GUSP.

### 3.8 Query Generation

Given a semantic parse, GUSP generates the SQL by a depth-first traversal that recursively computes the denotation of a node from the denotations of its children and its node state and edge states. Each denotation is a structured query that contains: a list of entities for projection (corresponding to the FROM statement in SQL); a computation tree where the leaves are simple joins or value comparisons, and the internal nodes are logical or quantifier operators (the WHERE statement); the salient database elements (the SELECT statement). Below, we illustrate this procedure using the semantic parse in Figure 1 as a running example.

**Value node state** GUSP creates a semantic object of the given type with a unique index and the word constant. For example, the denotation for node *toronto* is a `city.name` object with a unique index and constant “toronto”. The unique index is necessary in case the SQL involves multiple instances of the same entity. For example, the SQL in Figure 1 involves two instances of the entity `city`, corresponding to the departure and arrival cities, respectively. By default, such a semantic object will be translated into an equality constraint, such as `city.name = toronto`.

**Entity or property node state** GUSP creates a semantic object of the given type with a unique relation index. For example, the denotation for node *flight* is simply a `flight` object with a unique index. By default, such an object will contribute to the list of entities in SQL projection (the FROM statement), but not any constraints.

**NULL state** GUSP returns an empty denotation.

**Simple edge state** GUSP appends the child denotation to that of the parent, and appends equality constraints corresponding to the relational join path. In the case of composition, such as the join between *diego* and *san*, GUSP simply keeps the parent object, while adding to it the words from

the child. In the case of a more complex join, such as that between *stopping* and *dtw*, GUSP adds the relational constraints that join `flight_stop` with `airport`:

`flight_stop.stop_airport = airport.airport_id`.

**Raising edge state** GUSP simply takes the child denotation and sets that to the parent.

**Implicit and sinking states** GUSP maintains two separate denotations for the two simple states in the complex state, and processes their respective edge states accordingly. For example, the node *diego* contains two denotations, one for `V:city.name`, and one for `E:flight`, with the corresponding child being *san* and *stopping*, respectively.

**Domain-independent states** For comparator states such as `MORE` or `LESS`, GUSP changes the default equality constraints to an inequality one, such as `flight.depart_time < 600` for *before 6am*. For logical connectives, GUSP combines the projection and constraints accordingly. For quantifier states, GUSP applies the given function to the query.

**Resolve scoping ambiguities** GUSP delays applying quantifiers until the child semantic object differs from the parent one or when reaching the root. GUSP employs the following fixed ordering in evaluating quantifiers and operators: superlatives and other quantifiers are evaluated at last (i.e., after evaluating all other joins or operators for the given object), whereas negation is evaluated first, conjunctions and disjunctions are evaluated in their order of appearance.

## 4 Experiments

### 4.1 Task

We evaluated GUSP on the ATIS travel planning domain, which has been studied in He & Young (2005, 2006) and adapted for evaluating semantic parsing by Zettlemoyer & Collins (2007) (henceforth ZC07). The ZC07 dataset contains annotated logical forms for each sentence, which we do not use. Since our goal is not to produce a specific logical form, we directly evaluate on the end-to-end task of translating questions into database queries and measure question-answering accuracy. The ATIS distribution contains the original SQL annotations, which we used to compute gold answers

for evaluation only. The dataset is split into training, development, and test, containing 4500, 478, and 449 sentences, respectively. We used the development set for initial development and tuning hyperparameters. At test time, we ran GUSP over the test set to learn a semantic parser and output the MAP parses.<sup>2</sup>

## 4.2 Preprocessing

The ATIS sentences were originally derived from spoken dialog and were therefore in lower cases. Since case information is important for parsers and taggers, we first truecased the sentences using DASH (Pantel et al., 2009), which stores the case for each phrase in Wikipedia.

We then ran the sentences through SPLAT, a state-of-the-art NLP toolkit (Quirk et al., 2012), to conduct tokenization, part-of-speech tagging, and constituency parsing. Since SPLAT does not output dependency trees, we ran the Stanford parser over SPLAT parses to generate the dependency trees in Stanford dependency (de Marneffe et al., 2006).

## 4.3 Systems

For the GUSP system, we set the hyperparameters from initial experiments on the development set, and used them in all subsequent experiments. Specifically, we set  $\alpha = 50$  and  $\beta = -0.1$ , and ran three iterations of feature-rich EM with an  $L_2$  prior of 10 over the feature weights.

To evaluate the importance of complex states, we considered two versions of GUSP : **GUSP-SIMPLE** and **GUSP-FULL**, where **GUSP-SIMPLE** only admits simple states, whereas **GUSP-FULL** admits all states.

During development, we found that some questions are inherently ambiguous that cannot be solved except with some domain knowledge or labeled examples. In Section 3.2, we discuss an edge state that joins a flight with its starting city: `flight-flight.from.airport-airport-airport.service-city`. The ATIS database also contains another path of the same length: `flight-flight.from.airport-airport-ground.service-city`. The only difference is that `air.service` is replaced by `ground.service`. In some occasions, the

<sup>2</sup>This doesn't lead to overfitting since we did not use any labeled information in the test set.

Table 1: Comparison of semantic parsing accuracy on the ATIS test dataset. Both ZC07 and FUBL used annotated logical forms in training, whereas GUSP-FULL and GUSP++ did not. The numbers for GUSP-FULL and GUSP++ are end-to-end question answering accuracy, whereas the numbers for ZC07 and FUBL are recall on exact match in logical forms.

	Accuracy
ZC07	84.6
FUBL	82.8
GUSP-FULL	74.8
GUSP++	83.5

answers are identical whereas in others they are different. Without other information, neither the complexity prior nor EM can properly discriminate one against another. (Note that this ambiguity is not present in the ZC07 logical forms, which use a single predicate `from(f, c)` for the entire relation paths. In other words, to translate ZC07 logical forms into SQL, one also needs to decide on which path to use.)

Another type of domain-specific ambiguities involves sentences such as *give me information on flights after 4pm on wednesday*. There is no obvious information to disambiguate between `flight.departure.time` and `flight.arrival.time` for *4pm*.

Such ambiguities suggest opportunities for interactive learning,<sup>3</sup> but this is clearly out of the scope of this paper. Instead, we incorporated a simple disambiguation feature with a small weight of 0.01 that fires over the simple states of `flight.departure.time` and `airport.service`. We named the resulting system **GUSP++**.

To gauge the difficulty of the task and the quality of lexical-trigger scores, we also considered a deterministic baseline **LEXICAL**, which computed semantic parses using lexical-trigger scores alone.

<sup>3</sup>For example, after eliminating other much less likely alternatives, the system can present to the user with both choices and let the user to choose the correct one. The implicit feedback signal can then be used to train the system for future disambiguation.

Table 2: Comparison of question answering accuracy in ablation experiments.

	Accuracy
LEXICAL	33.9
GUSP-SIMPLE	66.5
GUSP-FULL	74.8
GUSP++	83.5
– RAISING	75.7
– SINKING	77.5
– IMPLICIT	76.2

#### 4.4 Results

We first compared the results of GUSP-FULL and GUSP++ with ZC07 and FUBL (Kwiatkowski et al., 2011).<sup>4</sup> Note that ZC07 and FUBL were evaluated on exact match in logical forms. We used their recall numbers which are the percentages of sentences with fully correct logical forms. Given that the questions are quite specific and generally admit nonzero number of answers, the question-answer accuracy should be quite comparable with these numbers.

Table 1 shows the comparison. Surprisingly, even without the additional disambiguation feature, GUSP-FULL already attained an accuracy broadly in range with supervised results. With the feature, GUSP++ effectively tied with the best supervised approach.

To evaluate the importance of various components in GUSP, we conducted ablation test to compare the variants of GUSP. Table 2 shows the results. LEXICAL can parse more than one third of the sentences correctly, which is quite remarkable in itself, considering that it only used the lexical scores. On the other hand, roughly two-third of the sentences cannot be correctly parsed in this way, suggesting that the lexical scores are noisy and ambiguous. In comparison, all GUSP variants achieved significant gains over LEXICAL. Additionally, GUSP-FULL substantially outperformed GUSP-SIMPLE, highlighting the challenges of syntax-semantics mismatch in ATIS, and demonstrating the importance and effectiveness of complex states for handling such mismatch. All three types of complex states produced significant contributions. For example, compared to GUSP++,

<sup>4</sup>We should note that while the more recent system of FUBL slightly trails ZC07, it is language-independent and can parse questions in multiple languages.

removing RAISING dropped accuracy by almost 8 points.

#### 4.5 Discussion

Upon manual inspection, many of the remaining errors are due to syntactic parsing errors that are too severe to fix. This is partly due to the fact that ATIS sentences are out of domain compared to the newswired text on which the syntactic parsers were trained. For example, *show*, *list* were regularly parsed as nouns, whereas *round* (as in *round trip*) were often parsed as a verb and *northwest* were parsed as an auxiliary verb. Another reason is that ATIS sentences are typically less formal or grammatical, which exacerbates the difficulty in parsing. In this paper, we used the 1-best dependency tree to produce semantic parse. An interesting future direction is to consider joint syntactic-semantic parsing, using  $k$ -best trees or even the parse forest as input and reranking the top parse using semantic information.<sup>5</sup>

#### 5 Conclusion

This paper introduces grounded unsupervised semantic parsing, which leverages available database for indirect supervision and uses a grounded meaning representation to account for syntax-semantics mismatch in dependency-based semantic parsing. The resulting GUSP system is the first unsupervised approach to attain an accuracy comparable to the best supervised systems in translating complex natural-language questions to database queries.

Directions for future work include: joint syntactic-semantic parsing, developing better features for learning; interactive learning in a dialog setting; generalizing distant supervision; application to knowledge extraction from database-rich domains such as biomedical sciences.

#### Acknowledgments

We would like to thank Kristina Toutanova, Chris Quirk, Luke Zettlemoyer, and Yoav Artzi for useful discussions, and Patrick Pantel and Michael Gammon for help with the datasets.

<sup>5</sup>Note that this is still different from the currently predominant approaches in semantic parsing, which learn to parse both syntax and semantics by training from the *semantic parsing datasets* alone, which are considerably smaller compared to resources available for syntactic parsing.

## Abstract

It is important that the testimony of children be admissible in court, especially given allegations of abuse. Unfortunately, children can be misled by interrogators or might offer false information, with dire consequences. In this work, we evaluate various parameterizations of five classifiers (including support vector machines, neural networks, and random forests) in deciphering truth from lies given transcripts of interviews with 198 victims of abuse between the ages of 4 and 7. These evaluations are performed using a novel set of syntactic features, including measures of complexity. Our results show that sentence length, the mean number of clauses per utterance, and the Stajner-Mitkov measure of complexity are highly informative syntactic features, that classification accuracy varies greatly by the age of the speaker, and that accuracy up to 91.7% can be achieved by support vector machines given a sufficient amount of data.

## 1 Introduction

The challenge of disambiguating between truth and deception is critical in determining the admissibility of court testimony. Unfortunately, the testimony of maltreated children is often not admitted in court due to concerns about truthfulness since children can be instructed to deny transgressions or misled to elicit false accusations (Lyon and Dorado, 2008). However, the child is often the only witness of the transgression (Undeutsch, 2008); automatically determining truthfulness in

such situations is therefore a paramount goal so that justice may be served effectively.

## 2 Related Work

Research in the detection of deception in adult speech has included analyses of verbal and non-verbal cues such as behavioral changes, facial expression, speech dysfluencies, and cognitive complexity (DePaulo et al., 2003). Despite statistically significant predictors of deception such as shorter talking time, fewer semantic details, and less coherent statements, DePaulo et al. (2003) found that the median effect size is very small. Deception without special motivation (e.g., everyday ‘white lies’) exhibited almost no discernible cues of deception. However, analysis of moderating factors showed that cues were significantly more numerous and salient when lies were about transgressions.

Literature on deception in children is relatively limited. In one study, Lewis et al. (1989) studied 3-year-olds and measured behavioral cues, such as facial expression and nervous body movement, before and after the elicitation of a lie. Verbal responses consisted of yes/no answers. Results suggested that 3-year-old children are capable of deception, and that non-verbal behaviors during deception include increases in ‘positive’ behaviors (e.g., smiling). However, verbal cues of deception were not analyzed. Crucially, Lewis et al. (1989) showed that humans are no more accurate in deciphering truth from deception in child speech than in adult speech, being only about 50% accurate.

More recently, researchers have used linguistic features to identify deception. Newman et al. (2003) inferred deception in transcribed, typed, and handwritten text by identifying features of linguistic style such as the use of personal pronouns

and exclusive words (e.g., *but*, *except*, *without*). These features were obtained with the Linguistic Inquiry and Word Count (LIWC) tool and used in a logistic regression classifier which achieved, on average, 61% accuracy on test data. Feature analysis showed that deceptive stories were characterized by fewer self-references, more negative emotion words, and lower cognitive complexity, compared to non-deceptive language.

Another recent stylistometric experiment in automatic identification of deception was performed by Mihalcea and Strapparava (2009). The authors used a dataset of truthful and deceptive typed responses produced by adult subjects on three different topics, collected through the Amazon Mechanical Turk service. Two classifiers, Naïve Bayes (NB) and a support vector machine (SVM), were applied on the tokenized and stemmed statements to obtain best classification accuracies of 70% (abortion topic, NB), 67.4% (death penalty topic, NB), and 77% (friend description, SVM), where the baseline was taken to be 50%. The large variability of classifier performance based on the topic of deception suggests that performance is context-dependent. The authors note this as well by demonstrating significantly lower results of 59.8% for NB and 57.8% for SVM when cross-topic classification is performed by training each classifier on two topics and testing on the third.

The Mihalcea-Strapparava mturk dataset was further used in a study by Feng et al. (2012) which employs lexicalized and unlexicalized production rules to obtain deep syntactic features. The cross-validation accuracy obtained on the three topics was improved to 77% (abortion topic), 71.5% (death penalty topic), and 85% (friend description). The results nevertheless varied with topic.

Another experiment using syntactic features for identifying sentences containing uncertain or unreliable information was conducted by Zheng et al. (2010) on an adult-produced dataset of abstracts and full articles from BioScope, and on paragraphs from Wikipedia. The results demonstrated that using syntactic dependency features extracted with the Stanford parser improved performance on the biological dataset, while an ensemble classifier combining a conditional random field (CRF) and a MaxEnt classifier performed better than individual classifiers on the Wikipedia dataset.

A meta-analysis of features used in deception detection was performed by Hauch et al. (2012)

and revealed that verbal cues based on lexical categories extracted using the LIWC tool show statistically significant, though small, differences between truth- and lie-tellers. Vartapetian and Gillam (2012) surveyed existing cues to verbal deception and demonstrated that features in LIWC are not indicative of deception in online content, recommending that the features used to identify deception and the thresholds between deception and truth be based on the specific data set.

In the speech community, analysis of deceptive speech has combined various acoustic, prosodic, and lexical features (Hirschberg et al., 2005). Gra-ciarena et al. (2006) combined two independent systems — an acoustic Gaussian mixture model based on Mel cepstral features, and a prosodic support vector machine based on features such as pitch, energy, and duration — and achieved an accuracy of 64.4% on a test subset of the Columbia-SRI-Colorado (CSC) corpus of deceptive and non-deceptive speech (Hirschberg et al., 2005).

While previous studies have achieved some promising results in detecting deception with lexical, acoustic, and prosodic features, syntax remains relatively unexplored compared to LIWC-based features. Syntactic complexity as a cue to deception is consistent with literature in social psychology which suggests that emotion suppression (e.g., inhibition of guilt and fear) consumes cognitive resources, which can influence the underlying complexity of utterances (Richards and Gross, 1999; Richards and Gross, 2000). Additionally, the use of syntactic features is motivated by their successful use on adult-produced datasets for detecting deceptive or uncertain utterances (Feng et al., 2012; Zheng et al., 2010), as well as in other applications, such as the evaluation of changes in text complexity (Stajner and Mitkov, 2012), the identification of personality in conversation and text (Mairesse et al., 2007), and the detection of dementia through syntactic changes in writing (Le et al., 2011).

Past work has focused on identifying deceptive speech produced by adults. The problem of determining validity of child testimony in high-stakes child abuse court cases motivates the analysis of child-produced deceptive language. Further, the use of binary classification schemes in previous work does not account for partial truths often encountered in real-life scenarios. Due to the rarity of real deceptive data, studies typically use arti-

ficially produced deceptive language which falls unambiguously in one of two classes: complete truth or complete deception (Newman et al., 2003; Mihalcea and Strapparava, 2009). Studies which make use of real high-stakes courtroom data containing partial truths, such as the Italian DECOUR corpus analyzed by Fornaciari and Poesio (2012), preprocess the dataset to eliminate any partially truthful utterances. Since utterances of this kind are common in real language, their elimination from the dataset is not ideal.

The present study evaluates the viability of a novel set of 17 syntactic features as markers of deception in five classifiers. Moreover, to our knowledge, it is the first application of automatic deception detection to a real-life dataset of deceptive speech produced by maltreated children. The data is scored using a gradient of truthfulness, which is used to represent completely true, partially true, and completely false statements. Descriptions of the data (section 3) and feature sets (section 4) precede experimental results (section 5) and the concluding discussion (section 6).

### 3 Data

The data used in this study were obtained from Lyon et al. (2008), who conducted and transcribed a truth-induction experiment involving maltreated children awaiting court appearances in the Los Angeles County Dependency Court. Subjects were children between the ages of 4 and 7 (99 boys and 99 girls) who were interviewed regarding an unambiguous minor transgression involving playing with a toy. To ensure an understanding of lying and its negative consequences, all children passed a preliminary oath-taking competency task, requiring each child to correctly identify a truth-teller and a lie-teller in an object labeling task, as well as to identify which of the two would be the target of negative consequences.

During data collection, a confederate first engaged each child individually in one of four conditions: a) *play*, b) *play and coach*, c) *no play*, and d) *no play and coach*. In the two *play* conditions, the confederate engaged the child in play with a toy house (in the *no play* conditions, they did not); in the two *coach* conditions, the confederate coached the child to lie (i.e., to deny playing if they played with the toy house, or to admit playing if they did not). The confederate then left and the child was interviewed by a second researcher who performed a truth-induction manipulation consisting

of one of: a) *control* — no manipulation, b) *oath* — the interviewer reminded the child of the importance of telling the truth and elicited a promise of truth-telling, and c) *reassurance* — the interviewer reassured the child that telling the truth will not lead to any negative consequences.

Each pre- and post-induction transcription may contain explicit statements of up to seven features: looking at toy-house, touching toy-house, playing with toy-house, opening toy-house doors or windows to uncover hidden toys, playing with these hidden toys, spinning the toy-house, and putting back or hiding a toy. All children in the *play* condition engaged in all seven actions, while children in the *no play* condition engaged in none. An eighth feature is the lack of explicit denial of touching or playing with the toy house, which is considered to be truthful in the *play* condition, and deceptive in the *no play* condition (see the examples in the appendix). A transcription is labeled as *truth* if at least half of these features are truthful (53.2% of all transcriptions) and *lie* otherwise (46.8% of transcriptions). Other thresholds for this binary discrimination are explored in section 5.4.

Each child's verbal response was recorded twice: at time  $T_1$  (prior to truth-induction), and at time  $T_2$  (after truth-induction). Each child was subject to one of the four confederate conditions and one of the three induction conditions. The raw data were pre-processed to remove subjects with blank transcriptions, resulting in a total of 173 subjects (87 boys and 86 girls) and 346 transcriptions.

### 4 Methods

Since the data consist of speech produced by 4- to 7-year-old children, the predictive features must depend on the level of syntactic competence of this age group. The “continuity assumption” states that children have a complete system of abstract syntactic representation and have the same set of abstract functional categories accessible to adults (Pinker, 1984). An experimental study with 3- to 8-year-old children showed that their syntactic competence is comparable to that of adults; specifically, children have a productive rule for passive forms which allows them to generalize to previously unheard predicates while following adult-like constraints to avoid over-generalization (Pinker et al., 1987). Recent experiments with syntactic priming showed that children's representations of abstract passive constructions are well-developed as early as age 3 or 4, and young

children are generally able to form passive constructions with both action and non-action verbs (Thatcher et al., 2007). These results suggest that measures of syntactic complexity that are typically used to evaluate adult language could be adapted to child speech, provided that the children are at least 3 or 4 years old.

Here, the complexity of speech is characterized by the length of utterances and by the frequency of dependent and coordinate clauses, with more complex speech consisting of longer utterances and a higher number of subordinate clauses. We segmented the transcriptions into sentences, clauses and *T-units*, which are “minimally terminable units” consisting of a main clause and its dependent clauses (Hunt, 1965; O’Donnell et al., 1967)<sup>1</sup>. Deceptive communication generally has shorter duration and is less detailed than non-deceptive speech (DePaulo et al., 2003), so the length of each type of segment was counted along with frequency features over segments. Here, the frequency of dependent and coordinate clauses per constituent approximate clause-based measures of complexity.

Our approach combines a set of features obtained from a functional dependency grammar (FDG) parser with another (non-overlapping) set of features obtained from a phrase-based grammar parser. We obtained FDG parses of the transcriptions using Connexor’s Machine Syntax parser (Tapanainen and Järvinen, 1997) and extracted the following 5 features:

**ARI** *Automated readability index*. Measures word and sentence difficulty,  $4.71 \frac{c}{w} + 0.5 \frac{w}{s} - 21.43$ , where  $c$  is the number of characters,  $w$  is the number of words, and  $s$  is the number of sentences (Smith and Senter, 1967).

**ASL** *Average sentence length*. The number of words over the number of sentences.

**COM** *Sentence complexity*. The ratio of sentences with  $\geq 2$  finite predicators to those with  $\leq 1$  finite predicator (Stajner and Mitkov, 2012).

**PAS** *Passivity*. The ratio of non-finite main predicators in a passive construction (@-

FMAINV %VP) to the total number of finite (@+FMAINV %VA) and non-finite (@-FMAINV %VA and @-FMAINV %VP) main predicators, including active constructions.

**MCU** Mean number of clauses per utterance.

Additionally, we searched for specific syntactic patterns in phrase-based parses of the data. We used the Stanford probabilistic natural language parser (Klein and Manning, 2003) for constructing these parse trees, the Stanford Tregex utility (Levy and Andrew, 2006) for searching the constructed parse trees, and a tool provided by Lu (2011) which extracts a set of 14 clause-based features in relation to sentence, clause and T-unit constituents.

#### 4.1 Feature analysis

Analysis of variance (ANOVA) was performed on the set of 17 features, shown in Table 1. A one-factor ANOVA across the *truth* and *lie* groups showed three significant feature variations: average sentence length (ASL), sentence complexity (COM), and mean clauses per utterance (MCU). Dependencies between some feature pairs that are positively correlated are shown in Figure 1.

As expected, the number of clauses (MCU) is dependent on sentence length (ASL) ( $r(344) = .92, p < .001$ ). Also, the number of T-units is dependent on the number of clauses: CN/C is correlated with CN/T ( $r(344) = .89, p < .001$ ), CP/C is correlated with CP/T ( $r(344) = .85, p < .001$ ), and DC/C is correlated with DC/T ( $r(344) = .92, p < .001$ ). Other features are completely uncorrelated. For example, the number of passive constructions is independent of sentence length ( $r(344) = -.0020, p > .05$ ), the number of complex nominals per clause is independent of clause length ( $r(344) = .076, p > .05$ ), and the density of dependent clauses is independent of the density of coordinate phrases ( $r(344) = -.027, p > .05$ ).

## 5 Results

We evaluate five classifiers: logistic regression (**LR**), a multilayer perceptron (**MLP**), naïve Bayes (**NB**), a random forest (**RF**), and a support vector machine (**SVM**). Here, naïve Bayes, which assumes conditional independence of the features, and logistic regression, which has a linear decision boundary, are baselines. The MLP includes a variable number of layers of hidden units, which

<sup>1</sup>T-units include single clauses, two or more phrases in apposition, or clause fragments. Generally, coordinate clauses are split into separate T-units, as are clauses interrupted by discourse boundary markers.

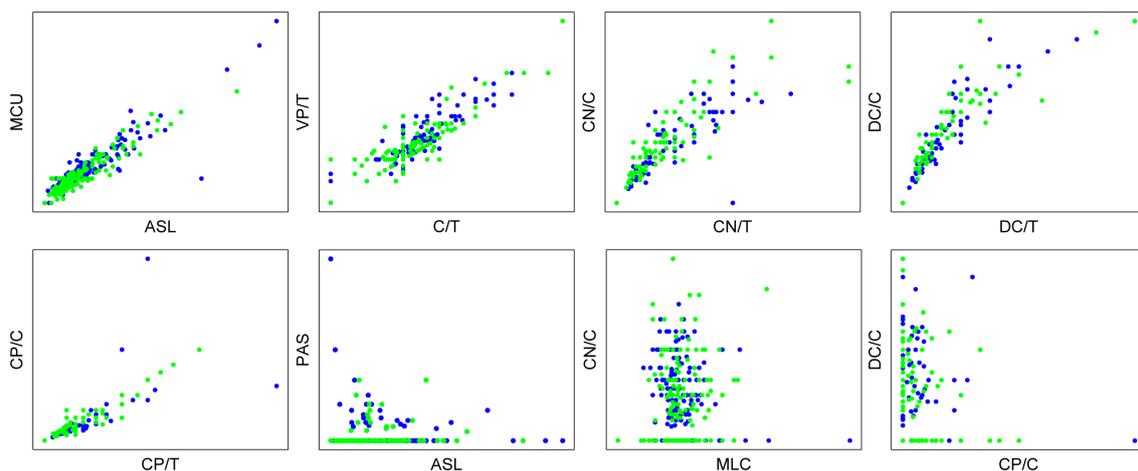

Figure 1: Independent and dependent feature pairs; data points are labeled as *truth* (blue) and *lie* (green).

Feature	$F_{1,344}$	$d$
Automated Readability Index ( <b>ARI</b> )	0.187	0.047
Average Sentence Length ( <b>ASL</b> )	3.870	<b>0.213</b>
Sentence Complexity ( <b>COM</b> )	10.93	<b>0.357</b>
Passive Sentences ( <b>PAS</b> )	1.468	0.131
Mean Clauses per Utterance ( <b>MCU</b> )	6.703	<b>0.280</b>
Mean Length of T-Unit ( <b>MLT</b> )	2.286	0.163
Mean Length of Clause ( <b>MLC</b> )	0.044	-0.023
Verb Phrases per T-Unit ( <b>VP/T</b> )	3.391	0.199
Clauses per T-Unit ( <b>C/T</b> )	2.345	0.166
Dependent Clauses per Clause ( <b>DC/C</b> )	1.207	0.119
Dependent Clauses per T-Unit ( <b>DC/T</b> )	1.221	0.119
T-Units per Sentence ( <b>T/S</b> )	3.692	0.208
Complex T-Unit Ratio ( <b>CT/T</b> )	2.103	0.157
Coordinate Phrases per T-Unit ( <b>CP/T</b> )	0.463	-0.074
Coordinate Phrases per Clause ( <b>CP/C</b> )	0.618	-0.085
Complex Nominals per T-Unit ( <b>CN/T</b> )	0.722	0.092
Complex Nominals per Clause ( <b>CN/C</b> )	0.087	0.032

Table 1: One-factor ANOVA ( $F$  statistics and Cohen’s  $d$ -values,  $\alpha = 0.05$ ) on all features across *truth* and *lie* groups. Statistically significant results are in bold.

apply non-linear activation functions on a linear combination of inputs. The SVM is a parametric binary classifier that provides highly non-linear decision boundaries given particular kernels. The random forest is an ensemble classifier that returns the mode of the class predictions of several decision trees.

### 5.1 Binary classification across all data

The five classifiers were evaluated on the entire pooled data set with 10-fold cross validation. Table 2 lists the parameters varied for each classifier, and Table 3 shows the cross-validation accuracy for the classifiers with the best parameter settings. The naïve Bayes classifier performs poorly, as could be expected given the assumption of conditional feature independence. The SVM classifier

performs best, with 59.5% cross-validation accuracy, which is a statistically significant improvement over the baselines of LR ( $t(4) = 22.25, p < .0001$ ), and NB ( $t(4) = 16.19, p < .0001$ ).

	Parameter	Values
LR	$R$ Ridge value	$10^{-10}$ to $10^{-2}$
	$L$ Learning rate	0.0003 to 0.3
MLP	$M$ Momentum	0 to 0.5
	$H$ Number of hidden layers	1 to 5
	$K$ Use kernel estimator	true, false
RF	$I$ Number of trees	1 to 20
	$K$ Maximum depth	unlimited, 1 to 10
SVM	$K$ Kernel	Linear, RBF, Polynomial
	$E$ Polynomial Exponent	2 to 5
	$G$ RBF Gamma	0.001 to 0.1
	$C$ Complexity constant	0.1 to 10

Table 2: Empirical parameter settings for each classifier

### 5.2 Binary classification by age group

Significant variation in syntactic complexity is expected across ages. To account for such variation, we segmented the dataset in four groups: 44 tran-

	Accuracy	Parameters
LR	0.5347	$R = 10^{-10}$
MLP	0.5838	$L = 0.003, M = 0.4$
NB	0.5173	$K = \text{false}$
RF	0.5809	$I = 10, K = 6$
SVM	0.5954	Polynomial, $E = 3, C = 1$

Table 3: Cross-validation accuracy of binary classification performed on entire dataset of 346 transcriptions.

criptions of 4-year-olds, 120 of 5-year-olds, 94 of 6-year-olds, and 88 of 7-year-olds. By comparison, Vrij et al. (2004) used data from only 35 children in their study of 5- and 6-year-olds. Classification of truthfulness was performed separately for each age, as shown in Table 4. In comparison with classification accuracy on pooled data, a paired  $t$ -test shows statistically significant improvement across all age groups using RF,  $t(3) = 10.37, p < .005$ .

	Age (years)			
	4	5	6	7
LR	0.6136	0.5333	0.5957*	0.4886
MLP	0.6136 <sup>†</sup>	0.5583	0.6170 <sup>†</sup>	0.5909*
NB	0.6136*	0.5250	0.5426	0.5682
RF	0.6364 <sup>†</sup>	<b>0.6333*</b>	<b>0.6383<sup>†</sup></b>	<b>0.6591<sup>†</sup></b>
SVM	<b>0.6591</b>	0.5583	0.6064	0.6250*

Table 4: Cross-validation accuracy of binary classification partitioned by age. The best classifier at each age is shown in bold. The classifiers showing statistically significant incremental improvement are marked: \* $p < .05$ , <sup>†</sup> $p < .001$  (paired  $t$ -test, d.f. 4)

### 5.3 Binary classification by age group, on verbose transcriptions

The length of speech, in number of words, varies widely ( $min = 1, max = 167, \mu = 36.83, \sigma = 28.34$ ) as a result of the unregulated nature of the interview interaction. To test the effect of verbosity, we segment the data by child age and select only the transcriptions with above-average word counts (i.e.,  $\geq 37$  words), resulting in four groups: 12 transcriptions of 4-year-olds, 48 of 5-year-olds, 39 of 6-year-olds, and 37 of 7-year-olds. This mimics the scenario in which some mini-

mum threshold is placed on the length of a child’s speech. In this verbose case, 63.3% of transcripts are labeled truth across age groups (using the same definition of truth as in section 3), with no substantial variation between ages; in the non-verbose case, 53.2% are marked truth. Fisher’s exact test on this contingency table reveals no significant difference between these distributions ( $p = 0.50$ ). Classification results are shown in Table 5. The size of the training set for the youngest age category is low compared to the other age groups, which may reduce the reliability of the higher accuracy achieved in that group. The other three age groups show a growing trend, which is consistent with expectations — older children exhibit greater syntactic complexity in speech, allowing greater variability of feature values across truth and deception. Here, both SVM and RF achieve 83.8% cross-validation accuracy in identifying deception in the speech of 7-year-old subjects.

	4	5	6	7
LR	0.7500 <sup>†</sup>	0.5417	0.6667 <sup>†</sup>	0.7297 <sup>†</sup>
MLP	0.8333 <sup>†</sup>	<b>0.6250<sup>†</sup></b>	0.6154	0.7838 <sup>†</sup>
NB	0.6667 <sup>†</sup>	0.4583	0.4103	0.7297*
RF	0.8333 <sup>†</sup>	0.5625	<b>0.7179<sup>†</sup></b>	<b>0.8378<sup>†</sup></b>
SVM	<b>0.9167*</b>	<b>0.6250<sup>†</sup></b>	0.6154*	<b>0.8378<sup>†</sup></b>

Table 5: Cross-validation accuracy of binary classification performed on transcriptions with above average word count (136 transcriptions), by age group. Rows represent classifiers, columns represent ages. The best classifier for each age is in bold. The classifiers showing statistically significant incremental improvement are marked: \* $p < .05$ , <sup>†</sup> $p < .001$  (paired  $t$ -test, d.f. 4)

### 5.4 Threshold variation

To study the effect of the threshold between the *truth* and *lie* classes, we vary the value of the threshold,  $\tau$ , from 1 to 8, requiring the admission of at least  $\tau$  truthful details (out of 8 possible details) in order to label a transcription as *truth*. The effect of  $\tau$  on classification accuracy over the entire pooled dataset for each of the 5 classifiers is shown in Figure 2. A one-factor ANOVA with  $\tau$  as the independent variable with 8 levels, and cross-validation accuracy as the dependent variable, confirms that the effect of the threshold is statistically significant ( $F_{7,40} = 220.69, p < .0001$ ) with  $\tau = 4$  being the most conservative setting.

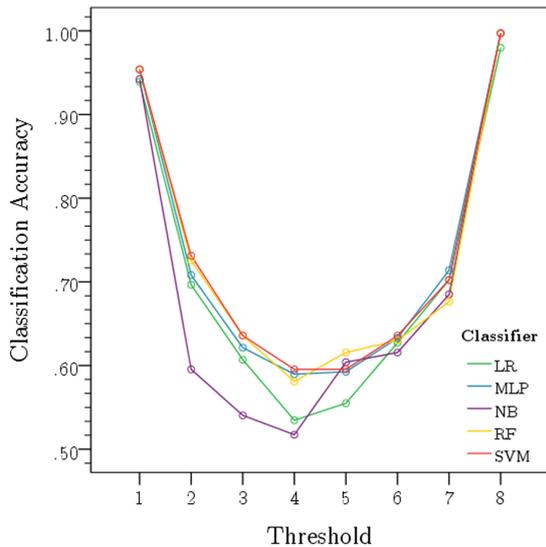

Figure 2: Effect of threshold and classifier choice on cross-validation accuracy. Threshold  $\tau = 0$  is not present, since all data would be labeled *truth*.

### 5.5 Linguistic Inquiry and Word Count

The Linguistic Inquiry and Word Count (LIWC) tool for generating features based on word category frequencies has been used in deception detection with adults, specifically: first-person singular pronouns (FP), exclusive words (EW), negative emotion words (NW), and motion verbs (MV) (Newman et al., 2003). We compare the performance of classifiers trained with our 17 syntactic features to those of classifiers trained with those LIWC-based features on the same data. To evaluate the four LIWC categories, we use the 86 words of the Pennebaker model (Little and Skillicorn, 2008; Vartapetian and Gillam, 2012). The performance of the classifiers trained with LIWC features is shown in Table 6.

The set of 17 syntactic features proposed here result in significantly higher accuracies across classifiers and experiments ( $\mu = 0.63$ ,  $\sigma = 0.10$ ) than with the LIWC features used in previous work ( $\mu = 0.58$ ,  $\sigma = 0.09$ ), as shown in Figure 3 ( $t(53) = -0.0691$ ,  $p < .0001$ ).

## 6 Discussion and future work

This paper evaluates automatic estimation of truthfulness in the utterances of children using a novel set of lexical-syntactic features across five types of classifiers. While previous studies have favored word category frequencies extracted with LIWC (Newman et al., 2003; Little and Skillicorn, 2008; Hauch et al., 2012; Vartapetian and Gillam,

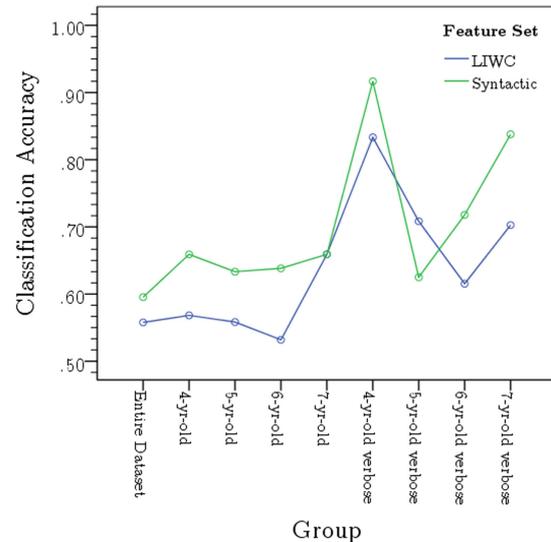

Figure 3: Effect of feature set choice on cross-validation accuracy.

2012; Almela et al., 2012; Fornaciari and Poesio, 2012), our results suggest that the set of syntactic features presented here perform significantly better than the LIWC feature set on our data, and across seven out of the eight experiments based on age groups and verbosity of transcriptions.

Statistical analyses showed that the average sentence length (ASL), the Stajner-Mitkov measure of sentence complexity (COM), and the mean number of clauses per utterance (MCU) are the features most predictive of truth and deception (see section 4.1). Further preliminary experiments are exploring two methods of feature selection, namely forward selection and minimum-Redundancy-Maximum-Relevance (mRMR). In forward selection, features are greedily added one-at-a-time (given an initially empty feature set) until the cross-validation error stops decreasing with the addition of new features (Deng, 1998). This results in a set of only two features: sentence complexity (COM) and T-units per sentence (T/S). Features are selected in mRMR by minimizing redundancy (i.e., the average mutual information between features) and maximizing the relevance (i.e., the mutual information between the given features and the class) (Peng et al., 2005). This approach selects five features: verb phrases per T-unit (VP/T), passive sentences (PAS), coordinate phrases per clause (CP/C), sentence complexity (COM), and complex nominals per clause (CN/C). These results confirm the predictive strength of sentence complexity. Further, preliminary classi-

Group	Accuracy	Best Classifier	Parameters

4-yr-olds	0.5682	MLP	$L = 0.005, M = 0.3, H = 1$
5-yr-olds	0.5583	RF	$I = 5, K = \text{unlimited}$
6-yr-olds	0.5319	MLP	$L = 0.005, M = 0.3, H = 1$
7-yr-olds	0.6591	RF	$I = 5, K = \text{unlimited}$
4-yr-olds, verbose	0.8333	SVM	PolyKernel, $E = 4, C = 10$
5-yr-olds, verbose	0.7083	SVM	NormalizedPolyKernel, $E = 1, C = 10$
6-yr-olds, verbose	0.6154	MLP	$L = 0.09, M = 0.2, H = 1$
7-yr-olds, verbose	0.7027	MLP	$L = 0.01, M = 0.5, H = 3$

Table 6: Best 10-fold cross-validation accuracies achieved on various subsets of the data, using the LIWC-based feature set.

fication results across all classifiers suggest that accuracies are significantly higher given forward selection ( $\mu = 0.58, \sigma = 0.02$ ) relative to the original feature set ( $\mu = 0.56, \sigma = 0.03$ );  $t(5) = -2.28, p < .05$  while the results given the mRMR features are not significantly different.

Generalized cross-validation accuracy increases significantly given partitioned age groups, which suggests that the importance of features may be moderated by age. A further incremental increase is achieved by considering only transcriptions above a minimum length. O’Donnell et al. (1967) examined syntactic complexity in the speech and writing of children aged 8 to 12, and found that speech complexity increases with age. This phenomenon appears to be manifested in the current study by the extent to which classification increases generally across the 5-, 6-, and 7-year-old groups, as shown in Table 5. Future examination of the effect of age on feature saliency may yield more appropriate age-dependent features.

While past research has used logistic regression as a binary classifier (Newman et al., 2003), our experiments show that the best-performing classifiers allow for highly non-linear class boundaries; SVM and RF models achieve between 62.5% and 91.7% accuracy across age groups — a significant improvement over the baselines of LR and NB, as well as over previous results. Moreover, since the performance of human judges in identifying deception is not significantly better than chance (Lewis et al., 1989; Newman et al., 2003), these results show promise in the use of automatic detection methods.

Partially truthful transcriptions were scored using a gradient of 0 to 8 truthful details, and a threshold  $\tau$  was used to perform binary classifica-

tion. Extreme values of  $\tau$  lead to poor F-scores despite high accuracy, since the class distribution of transcriptions is very skewed towards either class. Future work can explore the effect of threshold variation given sufficient data with even class distributions for each threshold setting. When such data is unavailable, experiments can make use of the most conservative setting ( $\tau = 4$ , or an equivalent mid-way setting) for analysis of real-life utterances containing partial truths.

Future work should consider measures of confidence for each classification, where possible, so that more ambiguous classifications are not treated on-par with more certain ones. For instance, confidence can be approximated in MLPs by the entropy across continuous-valued output nodes, and in RFs by the number of component decision trees that agree on a classification. Although acoustic data were not provided with this data set (Lyon and Dorado, 2008) (and, in practice, cannot be assured), future work should also examine the differences in the acoustics of children across truth conditions.

## Acknowledgments

The authors thank Kang Lee (Ontario Institute for Studies in Education, University of Toronto) and Angela Evans (Brock University) for sharing both this data set and their insight.

## Appendix

The following is an example of evasive deceptive speech from a 6-year-old after no truth induction (i.e., the *control* condition in which the interviewer merely states that he needs to ask more questions):

... Yeah yeah ok, I'm a tell you. We played that same game and I won and he won. I'm going to be in trouble if I tell you. It a secret. It's a secret 'cuz we're friends. ...

**Transcription excerpt labeled as *truth* by a threshold of  $\tau = 1$ :** 7-year-old child's response (*play, no coach* condition), in which the child does not explicitly deny playing with the toy house, and admits to looking at it but does not confess to any of the other six actions:

...I was playing, I was hiding the coin and I was trying to find the house... trying to see who was in there...

**Transcription excerpt labeled as *truth* by a threshold of  $\tau = 4$ :** 7-year-old child's response (*play, no coach* condition), in which the child does not explicitly deny playing, and admits to three actions:

...me and him was playing with it... we were just spinning it around and got the toys out...

## Abstract

A number of different notions, including subjectivity, have been proposed for distinguishing parts of documents that convey sentiment from those that do not. We propose a new concept, *sentiment relevance*, to make this distinction and argue that it better reflects the requirements of sentiment analysis systems. We demonstrate experimentally that sentiment relevance and subjectivity are related, but different. Since no large amount of labeled training data for our new notion of sentiment relevance is available, we investigate two semi-supervised methods for creating sentiment relevance classifiers: a distant supervision approach that leverages structured information about the domain of the reviews; and transfer learning on feature representations based on lexical taxonomies that enables knowledge transfer. We show that both methods learn sentiment relevance classifiers that perform well.

## 1 Introduction

It is generally recognized in sentiment analysis that only a subset of the content of a document contributes to the sentiment it conveys. For this reason, some authors distinguish the categories *subjective* and *objective* (Wilson and Wiebe, 2003). Subjective statements refer to the internal state of mind of a person, which cannot be observed. In contrast, objective statements can be verified by observing and checking reality. Some sentiment analysis systems filter out objective language and predict sentiment based on subjective language only because objective statements do not directly reveal sentiment.

Even though the categories subjective/objective are well-established in philosophy, we argue that

they are not optimal for sentiment analysis. We instead introduce the notion of *sentiment relevance* (*S-relevance* or *SR* for short). A sentence or linguistic expression is S-relevant if it contains information about the sentiment the document conveys; it is *S-nonrelevant* (*SNR*) otherwise.

Ideally, we would like to have at our disposal a large annotated training set for our new concept of sentiment relevance. However, such a resource does not yet exist. For this reason, we investigate two semi-supervised approaches to S-relevance classification that do not require S-relevance-labeled data. The first approach is distant supervision (DS). We create an initial labeling based on domain-specific metadata that we extract from a public database and show that this improves performance by 5.8%  $F_1$  compared to a baseline. The second approach is transfer learning (TL) (Thrun, 1996). We show that TL improves  $F_1$  by 12.6% for sentiment relevance classification when we use a feature representation based on lexical taxonomies that supports knowledge transfer.

In our approach, we classify *sentences* as S-(non)relevant because this is the most fine-grained level at which S-relevance manifests itself; at the word or phrase level, S-relevance classification is not possible because of scope and context effects. However, S-relevance is also a discourse phenomenon: authors tend to structure documents into S-relevant passages and S-nonrelevant passages. To impose this discourse constraint, we employ a sequence model. We represent each document as a graph of sentences and apply a minimum cut method.

The rest of the paper is structured as follows. Section 2 introduces the concept of sentiment relevance and relates it to subjectivity. In Section 3, we review previous work related to sentiment relevance. Next, we describe the methods applied in this paper (Section 4) and the features we extract (Section 5). Finally, we turn to the description and

results of our experiments on distant supervision (Section 6) and transfer learning (Section 7). We end with a conclusion in Section 8.

## 2 Sentiment Relevance

Sentiment Relevance is a concept to distinguish content informative for determining the sentiment of a document from uninformative content. This is in contrast to the usual distinction between subjective and objective content. Although there is overlap between the two notions, they are different. Consider the following examples for subjective and objective sentences:

(1) Subjective example: *Bruce Banner, a genetics researcher with a tragic past, suffers a horrible accident.*

(2) Objective example: *The movie won a Golden Globe for best foreign film and an Oscar.*

Sentence (1) is subjective because assessments like *tragic past* and *horrible accident* are subjective to the reader and writer. Sentence (2) is objective since we can check the truth of the statement. However, even though sentence (1) has negative subjective content, it is not S-relevant because it is about the plot of the movie and can appear in a glowingly positive review. Conversely, sentence (2) contributes to the positive opinion expressed by the author. Subjectivity and S-relevance are two distinct concepts that do not imply each other: Generally neutral and objective sentences can be S-relevant while certain subjective content is S-nonrelevant. Below, we first describe the annotation procedure for the sentiment relevance corpus and then demonstrate empirically that subjectivity and S-relevance differ.

### 2.1 Sentiment Relevance Corpus

For our initial experiments, we focus on sentiment relevance classification in the movie domain. To create a sentiment-relevance-annotated corpus, the SR corpus, we randomly selected 125 documents from the movie review data set (Pang et al., 2002).<sup>1</sup> Two annotators annotated the sentences for S-relevance, using the labels SR and SNR. If no decision can be made because a sentence contains both S-relevant and S-nonrelevant linguistic material, it is marked as *uncertain*. We excluded 360 sentences that were labeled *uncertain* from the

<sup>1</sup>We used the texts from the raw HTML files since the processed version does not have capitalization.

evaluation. In total, the SR corpus contains 2759 S-relevant and 728 S-nonrelevant sentences. Figure 1 shows an excerpt from the corpus. The full corpus is available online.<sup>2</sup>

First, we study agreement between human annotators. We had 762 sentences annotated for S-relevance by both annotators with an agreement (Fleiss'  $\kappa$ ) of .69. In addition, we obtained subjectivity annotations for the same data on Amazon Mechanical Turk, obtaining each label through a vote of three, with an agreement of  $\kappa = .61$ . However, the agreement of the subjectivity and relevance labelings after voting, assuming that subjectivity equals relevance, is only at  $\kappa = .48$ . This suggests that there is indeed a measurable difference between subjectivity and relevance. An annotator who we asked to examine the 225 examples where the annotations disagree found that 83.5% of these cases are true differences.

### 2.2 Contrastive Classification Experiment

We will now examine the similarities of S-relevance and an existing subjectivity dataset. Pang and Lee (2004) introduced subjectivity data (henceforth *P&L corpus*) that consists of 5000 highly subjective (*quote*) review snippets from rottentomatoes.com and 5000 objective (*plot*) sentences from IMDb plot descriptions.

We now show that although the P&L selection criteria (quotes, plot) bear resemblance to the definition of S-relevance, the two concepts are different.

We use *quote* as S-relevant and *plot* as S-nonrelevant data in TL. We divide both the SR and P&L corpora into training (50%) and test sets (50%) and train a Maximum Entropy (MaxEnt) classifier (Manning and Klein, 2003) with bag-of-word features. Macro-averaged  $F_1$  for the four possible training-test combinations is shown in Table 1. The results clearly show that the classes defined by the two labeled sets are different. A classifier trained on P&L performs worse by about 8% on SR than a classifier trained on SR (68.5 vs. 76.4). A classifier trained on SR performs worse by more than 20% on P&L than a classifier trained on P&L (67.4 vs. 89.7).

Note that the classes are not balanced in the S-relevance data while they are balanced in the subjectivity data. This can cause a misestimation

<sup>2</sup><http://www.ims.uni-stuttgart.de/forschung/ressourcen/korpora/sentimentrelevance/>

O	SNR	Braxton is a gambling addict in deep to Mook (Ellen Burstyn), a local bookie.
S	SNR	Kennesaw is bitter about his marriage to a socialite (Rosanna Arquette), believing his wife to be unfaithful.
S	SR	The plot is twisty and complex, with lots of lengthy flashbacks, and plenty of surprises.
S	SR	However, there are times when it is needlessly complex, and at least one instance the storytelling turns so muddled that the answers to important plot points actually get lost.
S	SR	Take a look at L. A. Confidential, or the film’s more likely inspiration, The Usual Suspects for how a complex plot can properly be handled.

Figure 1: Example data from the SR corpus with subjectivity (S/O) and S-relevance (SR/SNR) annotations

		<i>test</i>	
		P&L	SR
<i>train</i>	P&L	89.7	68.5
	SR	67.4	76.4

Table 1: TL/in-task  $F_1$  for P&L and SR corpora

vocabulary	$f_{\text{P&L}}$	$f_{\text{SNR}}$
{actor, director, story}	0	7.5
{good, bad, great}	11.5	4.8

Table 2: % incorrect sentences containing specific words

of class probabilities and lead to the experienced performance drops. Indeed, if we either balance the S-relevance data or unbalance the subjectivity data, we can significantly increase  $F_1$  to 74.8% and 77.9%, respectively, in the noisy label transfer setting. Note however that this step is difficult in practical applications if the actual label distribution is unknown. Also, in a real practical application the distribution of the data is what it is – it cannot be adjusted to the training set. We will show in Section 7 that using an unsupervised sequence model is superior to artificial manipulation of class-imbalances.

An error analysis for the classifier trained on P&L shows that many sentences misclassified as S-relevant ( $f_{\text{SR}}$ ) contain polar words; for example, *Then, the situation turns bad*. In contrast, sentences misclassified as S-nonrelevant ( $f_{\text{SNR}}$ ) contain named entities or plot and movie business vocabulary; for example, *Tim Roth delivers the most impressive acting job by getting the body language right*.

The word count statistics in Table 2 show this for three polar words and for three plot/movie business words. The P&L-trained classifier seems to have a strong bias to classify sentences with po-

lar words as S-relevant even if they are not, perhaps because most training instances for the category *quote* are highly subjective, so that there is insufficient representation of less emphatic S-relevant sentences. These snippets rarely contain plot/movie-business words, so that the P&L-trained classifier assigns almost all sentences with such words to the category S-nonrelevant.

### 3 Related Work

Many publications have addressed subjectivity in sentiment analysis. Two important papers that are based on the original philosophical definition of the term (internal state of mind vs. external reality) are (Wilson and Wiebe, 2003) and (Riloff and Wiebe, 2003). As we argue above, if the goal is to identify parts of a document that are useful/non-useful for sentiment analysis, then S-relevance is a better notion to use.

Researchers have implicitly deviated from the philosophical definition because they were primarily interested in satisfying the needs of a particular task. For example, Pang and Lee (2004) use a minimum cut graph model for review summarization. Because they do not directly evaluate the results of subjectivity classification, it is not clear to what extent their method is able to identify subjectivity correctly.

In general, it is not possible to know what the underlying concepts of a statistical classification are if no detailed annotation guidelines exist and no direct evaluation of manually labeled data is performed.

Our work is most closely related to (Taboada et al., 2009) who define a fine-grained classification that is similar to sentiment relevance on the highest level. However, unlike our study, they fail to experimentally compare their classification scheme to prior work in their experiments and

to show that this scheme is different. In addition, they work on the paragraph level. However, paragraphs often contain a mix of S-relevant and S-nonrelevant sentences. We use the minimum cut method and are therefore able to incorporate discourse-level constraints in a more flexible fashion, giving preference to “relevance-uniform” paragraphs without mandating them.

Täckström and McDonald (2011) develop a fine-grained annotation scheme that includes S-nonrelevance as one of five categories. However, they do not use the category S-nonrelevance directly in their experiments and do not evaluate classification accuracy for it. We do not use their data set as it would cause domain mismatch between the product reviews they use and the available movie review subjectivity data (Pang and Lee, 2004) in the TL approach. Changing both the domain (movies to products) and the task (subjectivity to S-relevance) would give rise to interactions that we would like to avoid in our study.

The notion of annotator rationales (Zaidan et al., 2007) has some overlap with our notion of sentiment relevance. Yessenalina et al. (2010) use rationales in a multi-level model to integrate sentence-level information into a document classifier. Neither paper presents a direct gold standard evaluation of the accuracy of rationale detection.

In summary, no direct evaluation of sentiment relevance has been performed previously. One contribution in this paper is that we provide a single-domain gold standard for sentiment relevance, created based on clear annotation guidelines, and use it for direct evaluation.

Sentiment relevance is also related to review mining (e.g., (Ding et al., 2008)) and sentiment retrieval techniques (e.g., (Eguchi and Lavrenko, 2006)) in that they aim to find phrases, sentences or snippets that are relevant for sentiment, either with respect to certain features or with a focus on high-precision retrieval (cf. (Liu, 2010)). However, finding a few S-relevant items with high precision is much easier than the task we address: exhaustive classification of all sentences.

Another contribution is that we show that generalization based on semantic classes improves S-relevance classification. While previous work has shown the utility of other types of feature generalization for sentiment and subjectivity analysis (e.g., syntax and part-of-speech (Riloff and Wiebe, 2003)), semantic classes have so far not been ex-

ploited.

Named-entity features in movie reviews were first used by Zhuang et al. (2006), in the form of feature-opinion pairs (e.g., a positive opinion about the acting). They show that recognizing plot elements (e.g., script) and classes of people (e.g., actor) benefits review summarization. We follow their approach by using IMDb to define named entity features. We extend their work by introducing methods for labeling partial uses of names and pronominal references. We address a different problem (S-relevance vs. opinions) and use different methods (graph-based and statistical vs. rule-based).

Täckström and McDonald (2011) also solve a similar sequence problem by applying a distantly supervised classifier with an unsupervised hidden sequence component. Their setup differs from ours as our focus lies on pattern-based distant supervision instead of distant supervision using documents for sentence classification.

Transfer learning has been applied previously in sentiment analysis (Tan and Cheng, 2009), targeting polarity detection.

## 4 Methods

Due to the sequential properties of S-relevance (cf. Taboada et al. (2009)), we impose the discourse constraint that an S-relevant (resp. S-nonrelevant) sentence tends to follow an S-relevant (resp. S-nonrelevant) sentence. Following Pang and Lee (2004), we use minimum cut (MinCut) to formalize this discourse constraint.

For a document with  $n$  sentences, we create a graph with  $n + 2$  nodes:  $n$  sentence nodes and source and sink nodes. We define source and sink to represent the classes S-relevance and S-nonrelevance, respectively, and refer to them as SR and SNR.

The individual weight  $\text{ind}(s, x)$  between a sentence  $s$  and the source/sink node  $x \in \{\text{SR}, \text{SNR}\}$  is weighted according to some confidence measure for assigning it to the corresponding class. The weight on the edge from the document’s  $i^{\text{th}}$  sentence  $s_i$  to its  $j^{\text{th}}$  sentence  $s_j$  is set to  $\text{assoc}(s_i, s_j) = c/(j - i)^2$  where  $c$  is a parameter (cf. (Pang and Lee, 2004)). The minimum cut is a tradeoff between the confidence of the classification decisions and “discourse coherence”. The discourse constraint often has the effect that high-confidence labels are propagated over the se-

quence. As a result, outliers with low confidence are eliminated and we get a “smoother” label sequence.

To compute minimum cuts, we use the push-relabel maximum flow method (Cherkassky and Goldberg, 1995).<sup>3</sup>

We need to find values for multiple free parameters related to the sequence model. Supervised optimization is impossible as we do not have any labeled data. We therefore resort to a proxy measure, the *run count*. A run is a sequence of sentences with the same label. We set each parameter  $p$  to the value that produces a median run count that is closest to the true median run count (or, in case of a tie, closest to the true mean run count). We assume that the optimal median/mean run count is known. In practice, it can be estimated from a small number of documents. We find the optimal value of  $p$  by grid search.

## 5 Features

Choosing features is crucial in situations where no high-quality training data is available. We are interested in features that are robust and support generalization. We propose two linguistic feature types for S-relevance classification that meet these requirements.

### 5.1 Generalization through Semantic Features

Distant supervision and transfer learning are settings where exact training data is unavailable. We therefore introduce generalization features which are more likely to support knowledge transfer. To generalize over concepts, we use knowledge from taxonomies. A set of generalizations can be induced by making a cut in the taxonomy and defining the concepts there as base classes. For nouns, the taxonomy is WordNet (Miller, 1995) for which CoreLex (Buitelaar, 1998) gives a set of basic types. For verbs, VerbNet (Kipper et al., 2008) already contains base classes.

We add for each verb in VerbNet and for each noun in CoreLex its base class or basic type as an additional feature where words tagged by the mate tagger (Bohnet, 2010) as NN . \* are treated as nouns and words tagged as VB . \* as verbs. For example, the verb *suggest* occurs in the VerbNet base class *say*, so we add a feature VN:say to the fea-

<sup>3</sup>using the HIPR tool ([www.avglab.com/andrew/soft.html](http://www.avglab.com/andrew/soft.html))

ture representation. We refer to these feature sets as *CoreLex (CX)* and *VerbNet (VN)* features and to their combination as *semantic features (SEM)*.

### 5.2 Named Entities

As standard named entity recognition (NER) systems do not capture categories that are relevant to the movie domain, we opt for a lexicon-based approach similar to (Zhuang et al., 2006). We use the IMDb movie metadata database<sup>4</sup> from which we extract names for the categories <ACTOR>, <PERSONNEL> (directors, screenwriters, and composers), and <CHARACTER> (movie characters). Many entries are unsuitable for NER, e.g., *dog* is frequently listed as a character. We filter out all words that also appear in lower case in a list of English words extracted from the dict.cc dictionary.<sup>5</sup>

A name  $n$  can be ambiguous between the categories (e.g., *John Williams*). We disambiguate by calculating the maximum likelihood estimate of  $p(c|n) = \frac{f(n,c)}{\sum_{c'} f(n,c')}$  where  $c$  is one of the three categories and  $f(n,c)$  is the number of times  $n$  occurs in the database as a member of category  $c$ . We also calculate these probabilities for all tokens that make up a name. While this can cause false positives, it can help in many cases where the name obviously belongs to a category (e.g., *Skywalker* in *Luke Skywalker* is very likely a character reference). We always interpret a name preceding an actor in parentheses as a character mention, e.g., *Reese Witherspoon* in *Tracy Flick (Reese Witherspoon) is an over-achiever [...]* This way, we can recognize character mentions for which IMDb provides insufficient information.

In addition, we use a set of simple rules to propagate annotations to related terms. If a capitalized word occurs, we check whether it is part of an already recognized named entity. For example, if we encounter *Robin* and we previously encountered *Robin Hood*, we assume that the two entities match. Personal pronouns will match the most recently encountered named entity. This rule has precedence over NER, so if a name matches a labeled entity, we do not attempt to label it through NER.

The aforementioned features are encoded as binary presence indicators for each sentence. This

<sup>4</sup>[www.imdb.com/interfaces/](http://www.imdb.com/interfaces/)

<sup>5</sup>[dict.cc](http://dict.cc)

feature set is referred to as *named entities (NE)*.

### 5.3 Sequential Features

Following previous sequence classification work with Maximum Entropy models (e.g., (Ratnaparkhi, 1996)), we use selected features of adjacent sentences. If a sentence contains a feature  $F$ , we add the feature  $F+1$  to the following sentence. For example, if a  $\langle \text{CHARACTER} \rangle$  feature occurs in a sentence,  $\langle \text{CHARACTER}+1 \rangle$  is added to the following sentence. For S-relevance classification, we perform this operation only for NE features as they are restricted to a few classes and thus will not enlarge the feature space notably. We refer to this feature set as *sequential features (SQ)*.

## 6 Distant Supervision

Since a large labeled resource for sentiment relevance classification is not yet available, we investigate semi-supervised methods for creating sentiment relevance classifiers. In this section, we show how to bootstrap a sentiment relevance classifier by distant supervision (DS).

Even though we do not have sentiment relevance annotations, there are sources of metadata about the movie domain that we can leverage for distant supervision. Specifically, movie databases like IMDb contain both metadata about the plot, in particular the characters of a movie, and metadata about the “creators” who were involved in the production of the movie: actors, writers, directors, and composers. On the one hand, statements about characters usually describe the plot and are not sentiment relevant and on the other hand, statements about the creators tend to be evaluations of their contributions – positive or negative – to the movie. We formulate a classification rule based on this observation: Count occurrences of NE features and label sentences that contain a majority of creators (and tied cases) as SR and sentences that contain a majority of characters as SNR. This simple labeling rule covers 1583 sentences with an  $F_1$  score of 67.2% on the SR corpus. We call these labels inferred from NE metadata *distant supervision (DS) labels*. This is a form of distant supervision in that we use the IMDb database as described in Section 5 to automatically label sentences based on which metadata from the database they contain.

To increase coverage, we train a Maximum Entropy (MaxEnt) classifier (Manning and Klein,

2003) on the labels. The MaxEnt model achieves an  $F_1$  of 61.2% on the SR corpus (Table 3, line 2). As this classifier uses training data that is biased towards a specialized case (sentences containing the named entity types creators and characters), it does not generalize well to other S-relevance problems and thus yields lower performance on the full dataset. This distant supervision setup suffers from two issues. First, the classifier only sees a subset of examples that contain named entities, making generalization to other types of expressions difficult. Second, there is no way to control the quality of the input to the classifier, as we have no confidence measure for our distant supervision labeling rule. We will address these two issues by introducing an intermediate step, the unsupervised sequence model introduced in Section 4.

As described in Section 4, each document is represented as a graph of sentences and weights between sentences and source/sink nodes representing SR/SNR are set to the confidence values obtained from the distantly trained MaxEnt classifier. We then apply MinCut as described in the following paragraphs and select the most confident examples as training material for a new classifier.

### 6.1 MinCut Setup

We follow the general MinCut setup described in Section 4. As explained above, we assume that creators and directors indicate relevance and characters indicate nonrelevance. Accordingly, we define  $n_{\text{SR}}$  to be the number of  $\langle \text{ACTOR} \rangle$  and  $\langle \text{PERSONNEL} \rangle$  features occurring in a sentence, and  $n_{\text{SNR}}$  the number of  $\langle \text{CHARACTER} \rangle$  features. We then set the individual weight between a sentence and the source/sink nodes to  $\text{ind}(s, x) = n_x$  where  $x \in \{\text{SR}, \text{SNR}\}$ . The MinCut parameter  $c$  is set to 1; we wish to give the association scores high weights as there might be long spans that have individual weights with zero values.

### 6.2 Confidence-based Data Selection

We use the output of the base classifier to train supervised models. Since the MinCut model is based on a weak assumption, it will make many false decisions. To eliminate incorrect decisions, we only use documents as training data that were labeled with high confidence. As the confidence measure for a document, we use the maximum flow value  $f$  – the “amount of fluid” flowing through the document. The max-flow min-cut theorem (Ford and Fulkerson, 1956) implies that if the flow value

	Model	Features	$F_{SR}$	$F_{SNR}$	$F_m$
1	Majority BL	–	88.3	0.0	44.2
2	MaxEnt (DSlabels)	NE	79.8	42.6	61.2 <sup>1</sup>
3	DSlabels+MinCut	NE	79.6	48.2	63.9 <sup>12</sup>
4	DS MaxEnt	NE	84.8	46.4	65.6 <sup>12</sup>
5	DS MaxEnt	NE+SEM	85.2	48.0	66.6 <sup>124</sup>
6	DS CRF	NE	83.4	49.5	66.4 <sup>12</sup>
7	DS MaxEnt	NE+SQ	84.8	49.2	67.0 <sup>1234</sup>
8	DS MaxEnt	NE+SQ+SEM	84.5	49.1	66.8 <sup>1234</sup>

Table 3: Classification results:  $F_{SR}$  (S-relevant  $F_1$ ),  $F_{SNR}$  (S-nonrelevant  $F_1$ ), and  $F_m$  (macro-averaged  $F_1$ ). Superscript numbers indicate a significant improvement over the corresponding line.

is low, then the cut was found more quickly and thus can be easier to calculate; this means that the sentence is more likely to have been assigned to the correct segment. Following this assumption, we train MaxEnt and Conditional Random Field (CRF, (McCallum, 2002)) classifiers on the  $k\%$  of documents that have the lowest maximum flow values  $f$ , where  $k$  is a parameter which we optimize using the run count method introduced in Section 4.

### 6.3 Experiments and Results

Table 3 shows S-relevant ( $F_{SR}$ ), S-nonrelevant ( $F_{SNR}$ ) and macro average ( $F_m$ )  $F_1$  values for different setups with this parameter. We compare the following setups: (1) The majority baseline (BL) i.e., choosing the most frequent label (SR). (2) a MaxEnt baseline trained on DS labels without application of MinCut; (3) the base classifier using MinCut (DSlabels+MinCut) as described above.

Conditions 4-8 train supervised classifiers based on the labels from DSlabels+MinCut: (4) MaxEnt with named entities (NE); (5) MaxEnt with NE and semantic (SEM) features; (6) CRF with NE; (7) MaxEnt with NE and sequential (SQ) features; (8) MaxEnt with NE, SQ, and SEM.

We test statistical significance using the approximate randomization test (Noreen, 1989) on documents with 10,000 iterations at  $p < .05$ . We achieve classification results above baseline using the MinCut base classifier (line 3) and a considerable improvement through distant supervision. We found that all classifiers using DS labels and MinCut are significantly better than MaxEnt trained on purely rule-based DS labels (line 2). Also, the MaxEnt models using SQ features (lines 7,8) are significantly better than the MinCut base classifier (line 3). For comparison to a chain-based se-

quence model, we train a CRF (line 6); however, the improvement over MaxEnt (line 4) is not significant.

We found that both semantic (lines 5,8) and sequential (lines 7,8) features help to improve the classifier. The best model (line 7) performs better than MinCut (3) by 3.1% and better than training on purely rule-generated DS labels (line 2) by 5.8%. However, we did not find a cumulative effect (line 8) of the two feature sets.

Generally, the quality of NER is crucial in this task. While IMDb is in general a thoroughly compiled database, it is not perfect. For example, all main characters in *Groundhog Day* are listed with their first name only even though the full names are given in the movie. Also, some entries are intentionally incomplete to avoid spoiling the plot. The data also contains ambiguities between characters and titles (e.g., *Forrest Gump*) that are impossible to resolve with our maximum likelihood method. In some types of movies, e.g., documentaries, the distinction between characters and actors makes little sense. Furthermore, ambiguities like occurrences of common names such as *John* are impossible to resolve if there is no earlier full referring expression (e.g., *John Williams*).

Feature analysis for the best model using DS labels (7) shows that NE features are dominant. This correlation is not surprising as the seed labels were induced based on NE features. Interestingly, some subjective features, e.g., *horrible* have high weights for S-nonrelevance, as they are associated with non-relevant content such as plot descriptions.

To summarize, the results of our experiments using distant supervision show that a sentiment relevance classifier can be trained successfully by labeling data with a few simple feature rules, with

MinCut-based input significantly outperforming the baseline. Named entity recognition, accomplished with data extracted from a domain-specific database, plays a significant role in creating an initial labeling.

## 7 Transfer Learning

To address the problem that we do not have enough labeled SR data we now investigate a second semi-supervised method for SR classification, transfer learning (TL). We will use the P&L data (introduced in Section 2.2) for training. This data set has labels that are intended to be subjectivity labels. However, they were automatically created using heuristics and the resulting labels can be either viewed as noisy SR labels or noisy subjectivity labels. Compared to distant supervision, the key advantage of training on P&L is that the training set is much larger, containing around 7 times as much data.

In TL, the key to success is to find a generalized feature representation that supports knowledge transfer. We use a semantic feature generalization method that relies on taxonomies to introduce such features.

We again use MinCut to impose discourse constraints. This time, we first classify the data using a supervised classifier and then use MinCut to smooth the sequences. The baseline (BL) uses a simple bag-of-words representation of sentences for classification which we then extend with semantic features.

### 7.1 MinCut Setup

We again implement the basic MinCut setup from Section 4. We set the individual weight  $\text{ind}(s, x)$  on the edge between sentence  $s$  and class  $x$  to the estimate  $p(x|s)$  returned by the supervised classifier. The parameter  $c$  of the MinCut model is tuned using the run count method described in Section 4.

### 7.2 Experiments and Results

As we would expect, the baseline performance of the supervised classifier on SR is low: 69.9% (Table 4, line 1). MinCut significantly boosts the performance by 7.9% to 77.5% (line 1), a result similar to (Pang and Lee, 2004). Adding semantic features improves supervised classification significantly by 5.7% (75.6% on line 4). When MinCut and both types of semantic features are used together, these improvements are partially cumula-

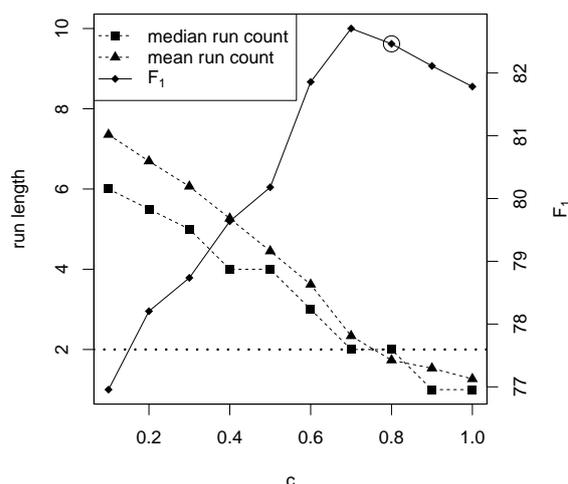

Figure 2:  $F_1$  measure for different values of  $c$ . Horizontal line: optimal median run count. Circle: selected point.

tive: an improvement over the baseline by 12.6% to 82.5% (line 4).

We also experiment with a training set where an artificial class imbalance is introduced, matching the 80:20 imbalance of SR:SNR in the S-relevance corpus. After applying MinCut, we find that while the results for BL with and without imbalances does not differ significantly. However, models using CX and VN features and imbalances are actually significantly inferior to the respective balanced versions. This result suggests that MinCut is more effective at coping with class imbalances than artificial balancing.

MinCut and semantic features are successful for TL because both impose constraints that are more useful in a setup where noise is a major problem. MinCut can exploit test set information without supervision as the MinCut graph is built directly on each test set review. If high-confidence information is “seeded” within a document and then spread to neighbors, mistakes with low confidence are corrected. This way, MinCut also leads to a compensation of different class imbalances.

The results are evidence that semantic features are robust to the differences between subjectivity and S-relevance (cf. Section 2). In the CX+VN model, meaningful feature classes receive high weights, e.g., the *human* class from CoreLex which contains professions that are frequently associated with non-relevant plot descriptions.

To illustrate the run-based parameter optimization criterion, we show  $F_1$  and median/mean run lengths for different values of  $c$  for the best TL

	Model	base classifier			MinCut		
		$F_{SR}$	$F_{SNR}$	$F_m$	$F_{SR}$	$F_{SNR}$	$F_m$
1	BL	81.1	58.6	69.9	87.2	67.8	77.5 <sup>B</sup>
2	CX	82.9	60.1	71.5 <sup>B</sup>	89.0	70.3	79.7 <sup>BM</sup>
3	VN	85.6	62.1	73.9 <sup>B</sup>	91.4	73.6	82.5 <sup>BM</sup>
4	CX+VN	88.3	62.9	75.6 <sup>B</sup>	92.7	72.2	82.5 <sup>BM</sup>

Table 4: Classification results:  $F_{SR}$  (S-relevant  $F_1$ ),  $F_{SNR}$  (S-nonrelevant  $F_1$ ), and  $F_m$  (macro-averaged  $F_1$ ). <sup>B</sup> indicates a significant improvement over the BL base classifier (69.9), <sup>M</sup> over BL MinCut (77.5).

setting (line 4) in Figure 2. Due to differences in the base classifier, the optimum of  $c$  may vary between the experiments. A weaker base classifier may yield a higher weight on the sequence model, resulting in a larger  $c$ . The circled point shows the data point selected through optimization. The optimization criterion does not always correlate perfectly with  $F_1$ . However, we find no statistically significant difference between the selected result and the highest  $F_1$  value.

These experiments demonstrate that S-relevance classification improves considerably through TL if semantic feature generalization and unsupervised sequence classification through MinCut are applied.

## 8 Conclusion

A number of different notions, including subjectivity, have been proposed for distinguishing parts of documents that convey sentiment from those that do not. We introduced *sentiment relevance* to make this distinction and argued that it better reflects the requirements of sentiment analysis systems. Our experiments demonstrated that sentiment relevance and subjectivity are related, but different. To enable other researchers to use this new notion of S-relevance, we have published the annotated S-relevance corpus used in this paper.

Since a large labeled sentiment relevance resource does not yet exist, we investigated semi-supervised approaches to S-relevance classification that do not require S-relevance-labeled data. We showed that a combination of different techniques gives us the best results: semantic generalization features, imposing discourse constraints implemented as the minimum cut graph-theoretic method, automatic “distant” labeling based on a domain-specific metadata database and transfer learning to exploit existing labels for a related classification problem.

In future work, we plan to use sentiment rele-

vance in a downstream task such as review summarization.

## Abstract

While there have been many attempts to estimate the emotion of an addresser from her/his utterance, few studies have explored how her/his utterance affects the emotion of the addressee. This has motivated us to investigate two novel tasks: predicting the emotion of the addressee and generating a response that elicits a specific emotion in the addressee's mind. We target Japanese Twitter posts as a source of dialogue data and automatically build training data for learning the predictors and generators. The feasibility of our approaches is assessed by using 1099 utterance-response pairs that are built by five human workers.

## 1 Introduction

When we have a conversation, we usually care about the emotion of the person to whom we speak. For example, we try to cheer her/him up if we find out s/he feels down, or we avoid saying things that would trouble her/him.

To date, the modeling of emotion in a dialogue has extensively been studied in NLP as well as related areas (Forbes-Riley and Litman, 2004; Ayadi et al., 2011). However, the past attempts are virtually restricted to estimating the emotion of an addresser<sup>1</sup> from her/his utterance. In contrast, few studies have explored how the emotion of the addressee is affected by the utterance. We consider the insufficiency of such research to be fatal for

<sup>1</sup>This work was conducted while the first author was a graduate student at the University of Tokyo.

<sup>2</sup>We use the terms *addresser/addressee* rather than a speaker/listener, because we target not spoken but online dialogue.

Figure 1: Two example pairs of utterances and responses. Those responses elicit certain emotions, JOY or SADNESS, in the addressee's mind. The addressee in this example refers to the left-hand user, who receives the response.

computers to support human-human communications or to provide a communicative man-machine interface.

With this motivation in mind, the paper investigates two novel tasks: (1) prediction of the addressee's emotion and (2) generation of the response that elicits a prespecified emotion in the addressee's mind.<sup>2</sup> In the prediction task, the system is provided with a dialogue history. For simplicity, we consider, as a history, an utterance and a response to it (Figure 1). Given the history, the system predicts the addressee's emotion that will be caused by the response. For example, the system outputs JOY when the response is *I hope you feel better soon*, while it outputs SADNESS when the response is *Sorry, but you can't join us today*

<sup>2</sup>We adopt Plutchik (1980)'s eight emotional categories in both tasks.

(Figure 1).

In the generation task, on the other hand, the system is provided with an utterance and an emotional category such as JOY or SADNESS, which is referred to as *goal emotion*. Then the system generates the response that elicits the goal emotion in the addressee’s mind. For example, *I hope you feel better soon* is generated as a response to *I have had a high fever for 3 days* when the goal emotion is specified as JOY, while *Sorry, but you can’t join us today* is generated for SADNESS (Figure 1).

Systems that can perform the two tasks not only serve as crucial components of dialogue systems but also have interesting applications of their own. Predicting the emotion of an addressee is useful for filtering flames or infelicitous expressions from online messages (Spertus, 1997). The response generator that is aware of the emotion of an addressee is also useful for text completion in online conversation (Hasselgren et al., 2003; Pang and Ravi, 2012).

This paper explores a data-driven approach to performing the two tasks. With the recent emergence of social media, especially microblogs, the amount of dialogue data available is rapidly increasing. Therefore, we are taking this opportunity to building large-scale training data from microblog posts automatically. This approach allows us to perform the two tasks in a large-scale with little human effort.

We employ standard classifiers for predicting the emotion of an addressee. Our contribution here is to investigate the effectiveness of new features that cannot be used in ordinary emotion recognition, the task of estimating the emotion of a speaker (or writer) from her/his utterance (or writing) (Ayadi et al., 2011; Bandyopadhyay and Okumura, 2011; Balahur et al., 2011; Balahur et al., 2012). We specifically extract features from the addressee’s last utterance (e.g., *I have had a high fever for 3 days* in Figure 1) and explore the effectiveness of using such features. Such information is characteristic of a dialogue situation.

To perform the generation task, we build a statistical response generator by following (Ritter et al., 2011). To improve on the previous study, we investigate a method for controlling the contents of the response for, in our case, eliciting the goal emotion. We achieve this by using a technique inspired by domain adaptation. We learn multiple models, each of which is adapted for eliciting one

specific emotion. Also, we perform model interpolation for addressing data sparseness.

In our experiment, we automatically build training data consisting of over 640 million dialogues from Japanese Twitter posts. Using this data set, we train the classifiers that predict the emotion of an addressee, and the response generators that elicit the goal emotion. We evaluate our methods on the test data that are built by five human workers, and confirm the feasibility of the proposed approaches.

## 2 Emotion-tagged Dialogue Corpus

The key in making a supervised approach to predicting and eliciting addressee’s emotion successful is to obtain large-scale, reliable training data effectually. We thus automatically build a large-scale emotion-tagged dialogue corpus from microblog posts, and use it as the training data in the prediction and generation tasks.

This section describes a method for constructing the emotion-tagged dialogue corpus. We first describe how to extract dialogues from posts in Twitter, a popular microblogging service. We then explain how to automatically annotate utterances in the extracted dialogues with the addressers’ emotions by using emotional expressions as clues.

### 2.1 Mining dialogues from Twitter

We have first crawled utterances (posts) from Twitter by using the Twitter REST API.<sup>3</sup> The crawled data consist of 5.5 billion utterances in Japanese tweeted by 770 thousand users from March 2011 to December 2012. We next cleaned up the crawled utterances by handling Twitter-specific expressions; we replaced all URL strings to ‘URL’, excluded utterances with the symbols that indicate the re-posting (RT) or quoting (QT) of others’ tweets, and erased @user\_name appearing at the head and tail of the utterances, since they are usually added to make a reply. We excluded utterances given by any user whose name included ‘bot.’

We then extracted dialogues from the resulting utterances, assuming that a series of utterances interchangeably made by two users form a dialogue. We here exploited ‘in\_reply\_to\_status\_id’ field of each utterance provided by Twitter REST API to link to the other, if any, utterance to which it replied.

<sup>3</sup><https://dev.twitter.com/docs/api/>

# users	672,937
# dialogues	311,541,839
# unique utterances	1,007,403,858
ave. # dialogues / user	463.0
ave. # utterances / user	1497.0
ave. # utterances / dialogue	3.2

Table 1: Statistics of dialogues extracted from Twitter.

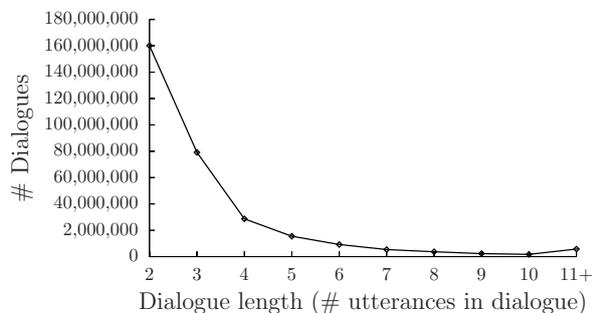

Figure 2: The number of dialogues plotted against the dialogue length.

Utterance	Emotion
A: Would you like to go for dinner with me?	
B: Sorry, I can't. I have a fever of 38 degrees.	
A: Oh dear. I hope you feel better soon.	SURPRISE
B: Thanks. I'm happy to hear you say that.	JOY

Table 2: An illustration of an emotion-tagged dialogue: The first column shows a dialogue (a series of utterances interchangeably made by two users), while the second column shows the addresser's emotion estimated from the utterance.

Table 1 lists the statistics of the extracted dialogues, while Figure 2 plots the number of dialogues plotted against the dialogue length (the number of utterances in dialogue). Most dialogues (98.2%) consist of at most 10 utterances, although the longest dialogue includes 1745 utterances and spans more than six weeks.

## 2.2 Tagging utterances with addressers' emotions

We then automatically labeled utterances in the obtained dialogues with the addressers' emotions by using emotional expressions as clues (Table 2). In this study, we have adopted Plutchik (1980)'s eight emotional categories (ANGER, ANTICIPATION, DISGUST, FEAR, JOY, SADNESS, SURPRISE, and TRUST) as the targets to label, and manually tailored around ten emotional expressions for each emotional category. Table 3 lists examples of the emotional expressions, while the

Emotion	Emotional expressions
ANGER	frustrating, irritating, nonsense
ANTICIPATION	exciting, expecting, looking forward
DISGUST	disgusting, unpleasant, hate
FEAR	afraid, anxious, scary
JOY	glad, happy, delighted
SADNESS	sad, lonely, unhappy
SURPRISE	surprised, oh dear, wow
TRUST	relieved, reliable, solid

Table 3: Example of clue emotional expressions.

Emotion	# utterances	Precision	
		Worker A	Worker B
ANGER	190,555	0.95	0.95
ANTICIPATION	2,548,706	0.99	0.99
DISGUST	475,711	0.93	0.93
FEAR	2,671,222	0.96	0.96
JOY	2,725,235	0.94	0.96

SURPRISE	975,433	0.97	0.97
TRUST	359,482	0.97	0.98

Table 4: Size and precision of utterances labeled with the addressers' emotions.

rest are mostly their spelling variations.<sup>4</sup>

Because precise annotation is critical in the supervised learning scenario, we annotate utterances with the addressers' emotions only when the emotional expressions do not:

1. modify content words.
2. accompany an expression of negation, conditional, imperative, interrogative, concession, or indirect speech in the same sentence.

For example, *I saw a frustrated teacher* is rejected by the first condition, while *I'll be happy if it rains* is rejected by the second condition. The second condition was judged by checking whether the sentence includes trigger expressions such as 'ない (*not/never*)', 'たら (*if-clause*)', '?', 'けど (*(al)though*)', and 'と (*that-clause*)'.

Table 4 lists the size and precision of the utterances labeled with the addressers' emotions. Two human workers measured the precision of the annotation by examining 100 labeled utterances randomly sampled for each emotional category. The inter-rater agreement was  $\kappa = 0.85$ , indicating almost perfect agreement. The precision of the annotation exceeded 0.95 for most of the emotional categories.

<sup>4</sup>Note that the clue emotional expressions are language-specific but can be easily tailored for other languages. Here, Japanese emotional expressions are translated into English to widen the potential readership of the paper.

### 3 Predicting Addressee’s Emotion

This section describes a method for predicting emotion elicited in an addressee when s/he receives a response to her/his utterance. The input to this task is a pair of an utterance and a response to it, e.g., the two utterances in Figure 1, while the output is the addressee’s emotion among the emotional categories of Plutchik (1980) (JOY and SADNESS for the top and bottom dialogues in Figure 1, respectively).

Although a response could elicit multiple emotions in the addressee, in this paper we focus on predicting the most salient emotion elicited in the addressee and cast the prediction as a single-label multi-class classification problem.<sup>5</sup> We then construct a one-versus-the-rest classifier<sup>6</sup> by combining eight binary classifiers, each of which predicts whether the response elicits each emotional category. We use online passive-aggressive algorithm to train the eight binary classifiers.

We exploit the emotion-tagged dialogue corpus constructed in Section 2 to collect training examples for the prediction task. For each emotion-tagged utterance in the corpus, we assume that the tagged emotion is elicited by the (last) response. We thereby extract the pair of utterances preceding the emotion-tagged utterance and the tagged emotion as one training example. Taking the dialogue in Table 2 as an example, we obtain one training example from the first two utterances and SURPRISE as the emotion elicited in user A.

We extract all the  $n$ -grams ( $n \leq 3$ ) in the response to induce (binary)  $n$ -gram features. The extracted  $n$ -grams could indicate a certain action that elicits a specific emotion (e.g., ‘have a fever’ in Table 2), or a style or tone of speaking (e.g., ‘Sorry’). Likewise, we extract word  $n$ -grams from the addressee’s utterance. The extracted  $n$ -grams activate another set of binary  $n$ -gram features.

Because word  $n$ -grams themselves are likely to be sparse, we estimate the addressers’ emotions from their utterances and exploit them to induce emotion features. The addresser’s emotion has been reported to influence the addressee’s emotion

<sup>5</sup>Because microblog posts are short, we expect emotions elicited by a response post not to be very diverse and a multi-class classification to be able to capture the essential crux of the prediction task.

<sup>6</sup>We should note that a one-versus-the-rest classifier can be used in the multi-label classification scenario, just by allowing the classifier to output more than one emotional category (Ghamrawi and McCallum, 2005).

strongly (Kim et al., 2012), while the addressee’s emotion just before receiving a response can be a reference to predict her/his emotion in question after receiving the response.

To induce emotion features, we exploit the rule-based approach used in Section 2.2 to estimate the addresser’s emotion. Since the rule-based approach annotates utterances with emotions only when they contain emotional expressions, we independently train for each emotional category a binary classifier that estimates the addresser’s emotion from her/his utterance and apply it to the unlabeled utterances. The training data for these classifiers are the emotion-tagged utterances obtained in Section 2, while the features are  $n$ -grams ( $n \leq 3$ )<sup>7</sup> in the utterance.

We should emphasize that the features induced from the addressee’s utterance are unique to this task and are hardly available in the related tasks that predicted the emotion of a reader of news articles (Lin and Hsin-Yih, 2008) or personal stories (Socher et al., 2011). We will later confirm the impact of these features on the prediction accuracy in the experiments.

### 4 Eliciting Addressee’s Emotion

This section presents a method for generating a response that elicits the goal emotion, which is one of the emotional categories of Plutchik (1980), in the addressee. In section 4.1, we describe a statistical framework for response generation proposed by (Ritter et al., 2011). In section 4.2, we present how to adapt the model in order to generate a response that elicits the goal emotion in the addressee.

#### 4.1 Statistical response generation

Following (Ritter et al., 2011), we apply the statistical machine translation model for generating a response to a given utterance. In this framework, a response is viewed as a translation of the input utterance. Similar to ordinary machine translation systems, the model is learned from pairs of an utterance and a response by using off-the-shelf tools for machine translation.

We use GIZA++<sup>8</sup> and SRILM<sup>9</sup> for learning translation model and 5-gram language model, re-

<sup>7</sup>We have excluded  $n$ -grams that matched the emotional expressions used in Section 2 to avoid overfitting.

<sup>8</sup><http://code.google.com/p/giza-pp/>

<sup>9</sup><http://www.speech.sri.com/projects/srilm/>

spectively. As post-processing, some phrase pairs are filtered out from the translation table as follows. When GIZA++ is directly applied to dialogue data, it frequently finds paraphrase pairs, learning to parrot back the input (Ritter et al., 2011). To avoid using such pairs for response generation, a phrase pair is removed if one phrase is the substring of the other.

We use Moses decoder<sup>10</sup> to search for the best response to a given utterance. Unlike machine translation, we do not use reordering models, because the positions of phrases are not considered to correlate strongly with the appropriateness of responses (Ritter et al., 2011). In addition, we do not use any discriminative training methods such as MERT for optimizing the feature weights (Och, 2003). They are set as default values provided by Moses (Ritter et al., 2011).

## 4.2 Model adaptation

The above framework allows us to generate appropriate responses to arbitrary input utterances. On top of this framework, we have developed a response generator that elicits a specific emotion.

We use the emotion-tagged dialogue corpus to learn eight translation models and language models, each of which is specialized in generating the response that elicits one of the eight emotions (Plutchik, 1980). Specifically, the models are learned from utterances preceding ones that are tagged with emotional category. As an example, let us examine to learn models for eliciting SURPRISE from the dialogue in Table 2. In this case, the first two utterances are used to learn the translation model, while only the second utterance is used to learn the language model.

However, this simple approach is prone to suffer from the data sparseness problem. Because not all the utterances are tagged with the emotion in emotion-tagged dialogue corpus, only a small fraction of utterances can be used for learning the adapted models.

We perform model interpolation for addressing this problem. In addition to the adapted models described above, we also use a general model, which is learned from the entire corpus. The two models are then merged as the weighted linear interpolation.

Specifically, we use `tmcombine.py` script provided by Moses for the interpolation of trans-

lation models (Sennrich, 2012). For all the four features (i.e., two phrase translation probabilities and two lexical weights) derived from translation model, the weights of the adapted model are equally set as  $\alpha$  ( $0 \leq \alpha \leq 1.0$ ). On the other hand, we use SRILM for the interpolation of language models. The weight of the adapted model is set as  $\beta$  ( $0 \leq \beta \leq 1.0$ ).

The parameters  $\alpha$  and  $\beta$  control the strength of the adapted models. Only adapted models are used when  $\alpha$  (or  $\beta$ ) = 1.0, while the adapted models are not at all used when  $\alpha$  (or  $\beta$ ) = 0. When both  $\alpha$  and  $\beta$  are specified as 0, the model becomes equivalent to the original one described in section 4.1.

## 5 Experiments

### 5.1 Test data

To evaluate the proposed method, we built, as test data, sets of an utterance paired with responses that elicit a certain goal emotion (Table 5). Note that they were used for evaluation in both of the two tasks. Each utterance in the test data has more than one responses that elicit the same goal emotion, because they are used to compute BLEU score (see section 5.3).

The data set was built in the following manner. We first asked five human worker to produce responses to 80 utterances (10 utterances for each goal emotion). Note that the 80 utterances do not have overlap between workers and that the worker produced only one response to each utterance.

To alleviate the burden on the workers, we actually provided each worker with the utterances in the emotion-tagged corpus. Then we asked each worker to select 80 utterances to which s/he thought s/he could easily respond. The selected utterances were removed from the corpus during training.

As a result, we obtained 400 utterance-response pairs (= 80 utterance-response pairs  $\times$  5 workers). For each of those 400 utterances, two additional responses are produced. We did not allow the same worker to produce more than one response to the same utterance. In this way, we obtained 1200 responses for the 400 utterances in total.

Finally, we assessed the data quality to remove responses that were unlikely to elicit the goal emotion. For each utterance-response pair, we asked two workers to judge whether the response elicited the goal emotion. If both workers regarded the

response as inappropriate, it was removed from the data. The resulting test data consist of 1099 utterance-response pairs for 396 utterances.

This data set is submitted as supplementary material to support the reproducibility of our experimental results.

## 5.2 Prediction task

We first report experimental results on predicting the addressee's emotion within a dialogue. Table 6 lists the number of utterance-response pairs used to train eight binary classifiers for individual emotional categories, which form a one-versus-the rest classifier for the prediction task. We used opal<sup>11</sup> as an implementation of online passive-aggressive algorithm to train the individual classifiers.

To investigate the impact of the features that are uniquely available in a dialogue data, we compared classifiers trained with the following two sets of features in terms of precision, recall, and F<sub>1</sub> for each emotional category.

**RESPONSE** The  $n$ -gram and emotion features induced from the response.

Table 8: Confusion matrix of predicting addressee's emotion, with mostly predicted emotions **bold-faced** and mostly confused emotions underlined for each emotional category.

**RESPONSE/UTTER.** The  $n$ -gram and emotion features induced from the response and the addressee's utterance.

Table 7 lists prediction results. We can see that the features induced from the addressee's utterance significantly improved the prediction performance, F<sub>1</sub>, for emotions other than FEAR. FEAR is elicited instantly by the response, and the features induced from the addressee's utterance thereby confused the classifier.

Table 8 shows a confusion matrix of the classifier using all the features, with mostly predicted emotions bold-faced and mostly confused emotions underlined for each emotional category. We can find some typical confusing pairs of emotions from this matrix. The classifier confuses DISGUST with ANGER and vice versa, while it confuses JOY with ANTICIPATION. These confusions conform to our expectation, since they are actually similar emotions. The classifier was less likely to confuse positive emotions (JOY and ANTICIPATION) with negative emotion (ANGER, DISGUST, FEAR, and SADNESS) vice versa.

<b>Goal emotion:</b> ANGER (predicted as SADNESS)
<b>U:</b> 毎日通話してるなんなの羨ましいわ (You have phone calls every day, I envy you.)
<b>R:</b> 君の方こそ誰からも電話こないから暇で羨ましいよ。 (I envy you have a lot of time 'cause no one calls you.)
<b>Goal emotion:</b> SURPRISE (predicted as FEAR)
<b>U:</b> 黒髪がモテるってマジか。 (Is it true that dark-haired girls are popular with boys?)
<b>R:</b> 80%くらいの男子は黒髪が好きらしい。 (About 80% of boys seem to prefer dark-haired girls.)

Table 9: Examples of utterance-response pairs to which the system predicted wrong emotions.

We have briefly examined the confusions and found the two major types of errors, each of which is exemplified in Table 9. The first (top) one is sarcasm or irony, which has been reported to be difficult to capture by lexical features alone (González-Ibáñez et al., 2011). The other (bottom) one is due to lack of information. In this example, only if the addressee does not know the fact provided by the response, s/he will surprise at it.

### 5.3 Generation task

We next demonstrate the experimental results for eliciting the emotion of the addressee.

We use the utterance pairs summarized in Table 6 to learn the translation models and language models for eliciting each emotional category. We also use the 640 million utterances pairs in the entire emotion-tagged corpus for learning general models. However, for learning the general translation models, we currently use 4 millions of utterance pairs sampled from the 640 millions of pairs due to the computational limitation.

#### Automatic evaluation

We first use BLEU score (Papineni et al., 2002) to perform automatic evaluation (Ritter et al., 2011). In this evaluation, the system is provided with the utterance and the goal emotion in the test data and the generated responses are evaluated through BLEU score. Specifically, we conducted two-fold cross-validation to optimize the weights of our method. We tried  $\alpha$  and  $\beta$  in  $\{0.0, 0.2, 0.4, 0.6, 0.8, 1.0\}$  and selected the weights that achieved the best BLEU score. Note that we adopted different values of the weights for different emotional categories.

Table 10 compares BLEU scores of three methods including the proposed one. The first row represents a method that does not perform model adaptation at all. It corresponds to the special case

System	BLEU
NO ADAPTATION	0.64
PROPOSED	1.05
OPTIMAL	1.57

Table 10: Comparison of BLEU scores.

(i.e.,  $\alpha = \beta = 0.0$ ) of the proposed method. The second row represents our method, while the last row represents the result of our method when the weights are set as optimal, i.e., those achieving the best BLEU on the test data. This result can be considered as an upper bound on BLEU score.

The results demonstrate that model adaptation is useful for generating the responses that elicit the goal emotion. We can clearly observe the improvement in the BLEU from 0.64 to 1.05.

On the other hand, there still remains a gap between the last two rows (i.e., proposed and optimal). We think this is partly because the current test data is too small to reliably tune parameters.

#### Human evaluation

We next asked two human workers to manually evaluate the generation results.

In this evaluation, the baseline (no adaptation in Table 10) and proposed method generated a response for each of the 396 utterances in the test data. For the resulting 792 utterance-response pairs, the two workers manually assessed the appropriateness of the response. Each response was judged whether it is grammatical and meaningful. If the response was regarded as so by either of the workers, it was further judged whether it elicits the goal emotion or not. To make the comparison fair, we did not expose to the workers which system generated the response. In addition, the responses generated by the two systems were presented in a random order.

As the result, 147 and 157 responses of the baseline and proposed method were regarded as appropriate, i.e., eliciting the goal emotion, by either of the workers; 74 and 92 responses were regarded as appropriate by both of the workers. These results suggest the effectiveness of the proposed method. Especially, we can confirm that the proposed method can generate responses that elicit addressee’s emotion more clearly. We investigated the agreement between the two workers in this evaluation. We found that the  $\kappa$  coefficient is 0.59, which indicates moderate agreement. This supports the reliability of our evaluation.

<b>Goal emotion:</b>	JOY
<b>Input:</b>	写真コンクールで優秀賞とったーーーー！2月7日表彰式！ (I woooooon the outstanding award at the photo competition! The ceremony is on Feb. 7!)
NO ADAPTATION:	残念ながら1日目だけですのー (Sorry to say, only the first day.)
PROPOSED:	金賞受賞おめでとう!!! おめでとうなのー (Congratulations on winning the gold prize!!! Congrats.)
<b>Goal emotion:</b>	TRUST
<b>Input:</b>	自暴自棄になっているの？ (Do you get desperate?)
NO ADAPTATION:	楽しみ！ (I'm looking forward to it!)
PROPOSED:	きっとまだ大丈夫 (Maybe still OK.)
<b>Goal emotion:</b>	ANTICIPATION
<b>Input:</b>	だよね！なんとかなるよね！ww (Huh! It's gonna be all right! lol) あ、わたしグッズ買わなきゃなのでその時間だけは取ってくれるとうれしい(´▽`) (I gotta buy the goods, so I'll be glad if you can take the time :-))
NO ADAPTATION:	私はグッズ買ってないから不安ですね (Since I've not bought it, I feel worried.)
PROPOSED:	いいですね！私も買いますね!!! (Good! I'll buy it too!!!)

Table 11: Examples of the responses generated by the two systems, NO ADAPTATION and PROPOSED.

## Examples

Table 11 illustrates examples of the responses generated by the no adaptation baseline and proposed method. In the first two examples, the proposed method successfully generates responses that elicit the goal emotions: JOY and TRUST. From these examples, we can consider that the adapted model assigns large probability to phrases such as *congratulations* or *OK*. In the last example, the system also succeeded in eliciting the goal emotion: ANTICIPATION. For this example, we can interpret that the speaker of the response (i.e., the system) feels anticipation, and consequently the emotion of the addressee is affected by the emotion of the speaker (i.e., the system). Interestingly, a similar phenomenon is also observed in real conversation (Kim et al., 2012).

## 6 Related Work

There have been a tremendous amount of studies on predicting the emotion from text or speech data (Ayadi et al., 2011; Bandyopadhyay and Okumura, 2011; Balahur et al., 2011; Balahur et al., 2012). Unlike our prediction task, most of them have exclusively focused on estimating the emotion of a speaker (or writer) from her/his utterance (or writing).

Analogous to our prediction task, Lin and Hsin-Yih (2008) and Socher et al. (2011) investigated predicting the emotion of a reader from the text that s/he reads. Our work differs from them in that we focus on dialogue data, and we exploit features that are not available within their task settings, e.g., the addressee's previous utterance.

Tokuhisa et al. (2008) proposed a method for

extracting pairs of an event (e.g., *It rained suddenly when I went to see the cherry blossoms*) and an emotion elicited by it (e.g., SADNESS) from the Web text. The extracted data are used for emotion classification. A similar technique would be useful for prediction the emotion of an addressee as well.

Response generation has a long research history (Weizenbaum, 1966), although it is only very recently that a fully statistical approach was introduced in this field (Ritter et al., 2011). At this moment, we are unaware of any statistical response generators that model the emotion of the user.

Some researchers have explored generating jokes or humorous text (Dybala et al., 2010; Labtov and Lipson, 2012). Those attempts are similar to our work in that they also aim at eliciting a certain emotion in the addressee. They are, however, restricted to elicit a specific emotion.

The linear interpolation of translation and/or language models is a widely-used technique for adapting machine translation systems to new domains (Sennrich, 2012). However, it has not been touched in the context of response generation.

## 7 Conclusion and Future Work

In this paper, we have explored predicting and eliciting the emotion of an addressee by using a large amount of dialogue data obtained from microblog posts. In the first attempt to model the emotion of an addressee in the field of NLP, we demonstrated that the response of the dialogue partner and the previous utterance of the addressee are useful for predicting the emotion. In the generation task, on the other hand, we showed that the

model adaptation approach successfully generates the responses that elicit the goal emotion.

For future work, we want to use longer dialogue history in both tasks. While we considered only two utterances as a history, a longer history would be helpful. We also plan to personalize the proposed methods, exploiting microblog posts made by users of a certain age, gender, occupation, or even character to perform model adaptation.

## Abstract

During real-life interactions, people are naturally gesturing and modulating their voice to emphasize specific points or to express their emotions. With the recent growth of social websites such as YouTube, Facebook, and Amazon, video reviews are emerging as a new source of multimodal and natural opinions that has been left almost untapped by automatic opinion analysis techniques. This paper presents a method for multimodal sentiment classification, which can identify the sentiment expressed in utterance-level visual datastreams. Using a new multimodal dataset consisting of sentiment annotated utterances extracted from video reviews, we show that multimodal sentiment analysis can be effectively performed, and that the joint use of visual, acoustic, and linguistic modalities can lead to error rate reductions of up to 10.5% as compared to the best performing individual modality.

## 1 Introduction

Video reviews represent a growing source of consumer information that gained increasing interest from companies, researchers, and consumers. Popular web platforms such as YouTube, Amazon, Facebook, and ExpoTV have reported a significant increase in the number of consumer reviews in video format over the past five years. Compared to traditional text reviews, video reviews provide a more natural experience as they allow the viewer to better sense the reviewer's emotions, beliefs, and intentions through richer channels such as intonations, facial expressions, and body language.

Much of the work to date on opinion analysis has focused on textual data, and a number of resources have been created including lexicons (Wiebe and

Riloff, 2005; Esuli and Sebastiani, 2006) or large annotated datasets (Maas et al., 2011). Given the accelerated growth of other media on the Web and elsewhere, which includes massive collections of videos (e.g., YouTube, Vimeo, VideoLectures), images (e.g., Flickr, Picasa), audio clips (e.g., podcasts), the ability to address the identification of opinions in the presence of diverse modalities is becoming increasingly important. This has motivated researchers to start exploring multimodal clues for the detection of sentiment and emotions in video content (Morency et al., 2011; Wagner et al., 2011).

In this paper, we explore the addition of speech and visual modalities to text analysis in order to identify the sentiment expressed in video reviews. Given the non homogeneous nature of full-video reviews, which typically include a mixture of positive, negative, and neutral statements, we decided to perform our experiments and analyses at the utterance level. This is in line with earlier work on text-based sentiment analysis, where it has been observed that full-document reviews often contain both positive and negative comments, which led to a number of methods addressing opinion analysis at sentence level. Our results show that relying on the joint use of linguistic, acoustic, and visual modalities allows us to better sense the sentiment being expressed as compared to the use of only one modality at a time.

Another important aspect of this paper is the introduction of a new multimodal opinion database annotated at the utterance level which is, to our knowledge, the first of its kind. In our work, this dataset enabled a wide range of multimodal sentiment analysis experiments, addressing the relative importance of modalities and individual features.

The following section presents related work in text-based sentiment analysis and audio-visual emotion recognition. Section 3 describes our new multimodal datasets with utterance-level sentiment annotations. Section 4 presents our multimodal sen-

timent analysis approach, including details about our linguistic, acoustic, and visual features. Our experiments and results on multimodal sentiment classification are presented in Section 5, with a detailed discussion and analysis in Section 6.

## 2 Related Work

In this section we provide a brief overview of related work in text-based sentiment analysis, as well as audio-visual emotion analysis.

### 2.1 Text-based Subjectivity and Sentiment Analysis

The techniques developed so far for subjectivity and sentiment analysis have focused primarily on the processing of text, and consist of either rule-based classifiers that make use of opinion lexicons, or data-driven methods that assume the availability of a large dataset annotated for polarity. These tools and resources have been already used in a large number of applications, including expressive text-to-speech synthesis (Alm et al., 2005), tracking sentiment timelines in on-line forums and news (Balog et al., 2006), analysis of political debates (Carvalho et al., 2011), question answering (Oh et al., 2012), conversation summarization (Carenini et al., 2008), and citation sentiment detection (Athar and Teufel, 2012).

One of the first lexicons used in sentiment analysis is the General Inquirer (Stone, 1968). Since then, many methods have been developed to automatically identify opinion words and their polarity (Hatzivassiloglou and McKeown, 1997; Turney, 2002; Hu and Liu, 2004; Taboada et al., 2011), as well as n-gram and more linguistically complex phrases (Yang and Cardie, 2012).

For data-driven methods, one of the most widely used datasets is the MPQA corpus (Wiebe et al., 2005), which is a collection of news articles manually annotated for opinions. Other datasets are also available, including two polarity datasets consisting of movie reviews (Pang and Lee, 2004; Maas et al., 2011), and a collection of newspaper headlines annotated for polarity (Strapparava and Mihalcea, 2007).

While difficult problems such as cross-domain (Blitzer et al., 2007; Li et al., 2012) or cross-language (Mihalcea et al., 2007; Wan, 2009; Meng et al., 2012) portability have been addressed, not much has been done in terms of extending the applicability of sentiment analysis to other modalities,

such as speech or facial expressions.

The only exceptions that we are aware of are the findings reported in (Somasundaran et al., 2006; Raaijmakers et al., 2008; Mairesse et al., 2012; Metze et al., 2009), where speech and text have been analyzed jointly for the purpose of subjectivity or sentiment identification, without, however, addressing other modalities such as visual cues; and the work reported in (Morency et al., 2011; Perez-Rosas et al., 2013), where multimodal cues have been used for the analysis of sentiment in product reviews, but where the analysis was done at the much coarser level of full videos rather than individual utterances as we do in our work.

### 2.2 Audio-Visual Emotion Analysis.

Also related to our work is the research done on emotion analysis. Emotion analysis of speech signals aims to identify the emotional or physical states of a person by analyzing his or her voice (Ververidis and Kotropoulos, 2006). Proposed methods for emotion recognition from speech focus both on what is being said and how is being said, and rely mainly on the analysis of the speech signal by sampling the content at utterance or frame level (Bitouk et al., 2010). Several researchers used prosody (e.g., pitch, speaking rate, Mel frequency coefficients) for speech-based emotion recognition (Polzin and Waibel, 1996; Tato et al., 2002; Ayadi et al., 2011).

There are also studies that analyzed the visual cues, such as facial expressions and body movements (Calder et al., 2001; Rosenblum et al., 1996; Essa and Pentland, 1997). Facial expressions are among the most powerful and natural means for human beings to communicate their emotions and intentions (Tian et al., 2001). Emotions can be also expressed unconsciously, through subtle movements of facial muscles such as smiling or eyebrow raising, often measured and described using the Facial Action Coding System (FACS) (Ekman et al., 2002).

De Silva et. al. (De Silva et al., 1997) and Chen et. al. (Chen et al., 1998) presented one of the early works that integrate both acoustic and visual information for emotion recognition. In addition to work that considered individual modalities, there is also a growing body of work concerned with multimodal emotion analysis (Silva et al., 1997; Sebe et al., 2006; Zhihong et al., 2009; Wollmer et al., 2010).

Pero el problema de estos labiales es que cuando uno se los aplica, te dejan un gusto asqueroso en la boca. But the problem with those lipsticks is that when you apply them, they leave a very nasty taste	neg
Sinceramente, es no es que sea el olor sino que es mas bien el gusto. Honestly, is not the smell, it is the taste.	neg

Table 1: Sample utterance-level annotations. The labels used are: pos(itive), neg(ative), neu(tral).

More recently, two challenges have been organized focusing on the recognition of emotions using audio and visual cues (Schuller et al., 2011a; Schuller et al., 2011b), which included sub-challenges on audio-only, video-only, and audio-video, and drew the participation of many teams from around the world. Note however that most of the previous work on audio-visual emotion analysis has focused exclusively on the audio and video modalities, and did not consider textual features, as we do in our work.

### 3 MOUD: Multimodal Opinion Utterances Dataset

For our experiments, we created a dataset of utterances (named MOUD) containing product opinions expressed in Spanish.<sup>1</sup> We chose to work with Spanish because it is a widely used language, and it is the native language of the main author of this paper.

We started by collecting a set of videos from the social media web site YouTube, using several keywords likely to lead to a product review or recommendation. Starting with the YouTube search page, videos were found using the following keywords: *mis products favoritos* (my favorite products), *products que no recomiendo* (non recommended products), *mis perfumes favoritos* (my favorite perfumes), *películas recomendadas* (recommended movies), *películas que no recomiendo* (non recommended movies) and *libros recomendados* (recommended books), *libros que no recomiendo* (non recommended books). Notice that the keywords are not targeted at a specific product type; rather, we used a variety of product names, so that the dataset has some degree of generality within the broad domain of product reviews.

<sup>1</sup>Publicly available from the authors webpage.

Among all the videos returned by the YouTube search, we selected only videos that respected the following guidelines: the speaker should be in front of the camera; her face should be clearly visible, with a minimum amount of face occlusion during the recording; there should not be any background music or animation. The final video set includes 80 videos randomly selected from the videos retrieved from YouTube that also met the guidelines above. The dataset includes 15 male and 65 female speakers, with their age approximately ranging from 20 to 60 years.

All the videos were first pre-processed to eliminate introductory titles and advertisements. Since the reviewers often switched topics when expressing their opinions, we manually selected a 30 seconds opinion segment from each video to avoid having multiple topics in a single review.

#### 3.1 Segmentation and Transcription

All the video clips were manually processed to transcribe the verbal statements and also to extract the start and end time of each utterance. Since the reviewers utter expressive sentences that are naturally segmented by speech pauses, we decided to use these pauses ( $>0.5$ seconds) to identify the beginning and the end of each utterance. The transcription and segmentation were performed using the Transcriber software.

Each video was segmented into an average of six utterances, resulting in a final dataset of 498 utterances. Each utterance is linked to the corresponding audio and video stream, as well as its manual transcription. The utterances have an average duration of 5 seconds, with a standard deviation of 1.2 seconds.

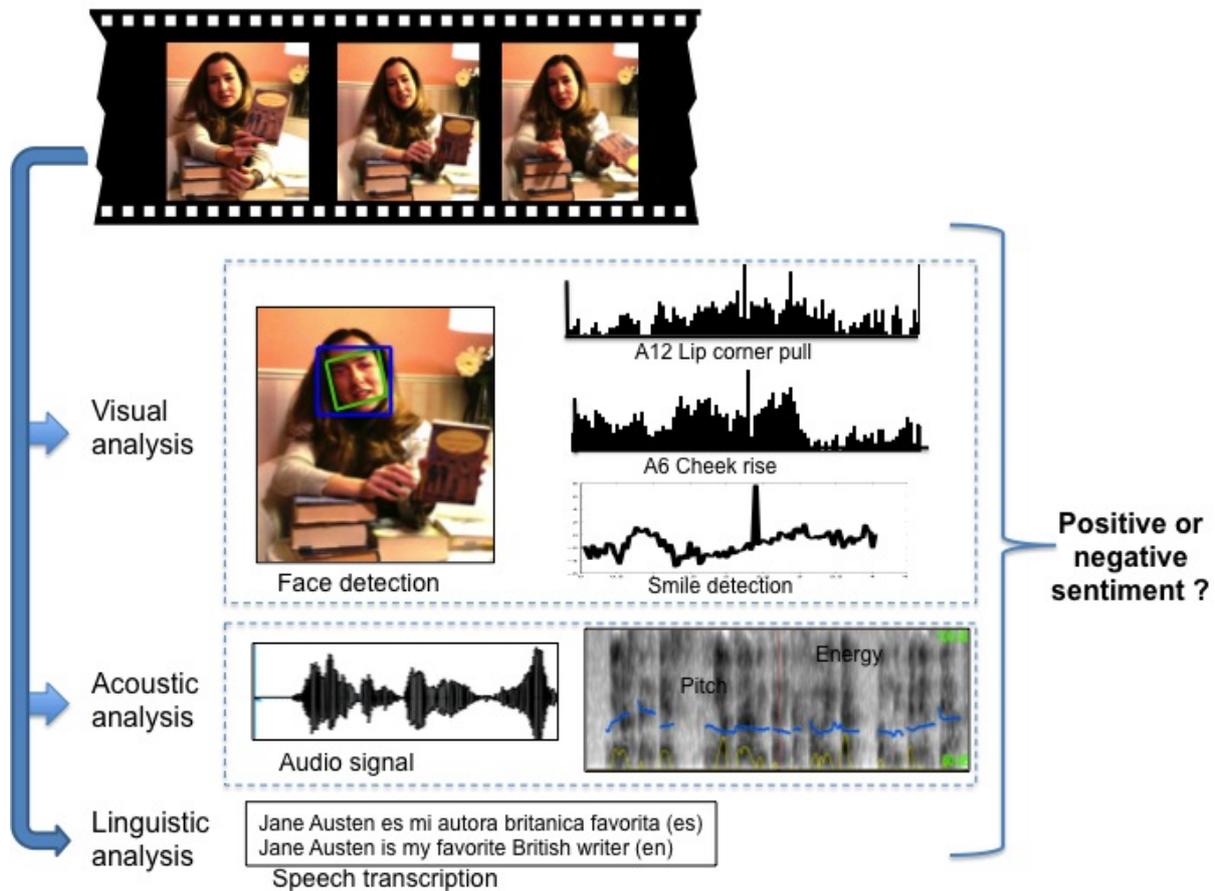

Figure 1: Multimodal feature extraction

### 3.2 Sentiment Annotation

To enable the use of this dataset for sentiment detection, we performed sentiment annotations at utterance level. Annotations were done using Elan,<sup>2</sup> which is a widely used tool for the annotation of video and audio resources. Two annotators independently labeled each utterance as positive, negative, or neutral. The annotation was done after seeing the video corresponding to an utterance (along with the corresponding audio source). The transcription of the utterance was also made available. Thus, the annotation process included all three modalities: visual, acoustic, and linguistic. The annotators were allowed to watch the video segment and their corresponding transcription as many times as needed.

The inter-annotator agreement was measured at 88%, with a Kappa of 0.81, which represents good agreement. All the disagreements were reconciled through discussions.

Table 1 shows the five utterances obtained from a video in our dataset, along with their corresponding

<sup>2</sup><http://tla.mpi.nl/tools/tla-tools/elan/>

sentiment annotations. As this example illustrates, a video can contain a mix of positive, negative, and neutral utterances. Note also that sentiment is not always explicit in the text: for example, the last utterance “Honestly, it is not the smell, it is the taste” has an implicit reference to the “nasty taste” expressed in the previous utterance, and thus it was also labeled as negative by both annotators.

## 4 Multimodal Sentiment Analysis

The main advantage that comes with the analysis of video opinions, as compared to their textual counterparts, is the availability of visual and speech cues. In textual opinions, the only source of information consists of words and their dependencies, which may sometime prove insufficient to convey the exact sentiment of the user. Instead, video opinions naturally contain multiple modalities, consisting of visual, acoustic, and linguistic datastreams. We hypothesize that the simultaneous use of these three modalities will help create a better opinion analysis model.

## 4.1 Feature Extraction

This section describes the process of automatically extracting linguistic, acoustic and visual features from the video reviews. First, we obtain the stream corresponding to each modality, followed by the extraction of a representative set of features for each modality, as described in the following subsections. These features are then used as cues to build a classifier of positive or negative sentiment. Figure 1 illustrates this process.

### 4.1.1 Linguistic Features

We use a bag-of-words representation of the video transcriptions of each utterance to derive unigram counts, which are then used as linguistic features. First, we build a vocabulary consisting of all the words, including stopwords, occurring in the transcriptions of the training set. We then remove those words that have a frequency below 10 (value determined empirically on a small development set). The remaining words represent the unigram features, which are then associated with a value corresponding to the frequency of the unigram inside each utterance transcription. These simple weighted unigram features have been successfully used in the past to build sentiment classifiers on text, and in conjunction with Support Vector Machines (SVM) have been shown to lead to state-of-the-art performance (Maas et al., 2011).

### 4.1.2 Acoustic Features

Acoustic features are automatically extracted from the speech signal of each utterance. We used the open source software OpenEAR (Schuller, 2009) to automatically compute a set of acoustic features. We include prosody, energy, voicing probabilities, spectrum, and cepstral features.

- Prosody features. These include intensity, loudness, and pitch that describe the speech signal in terms of amplitude and frequency.
- Energy features. These features describe the human loudness perception.
- Voice probabilities. These are probabilities that represent an estimate of the percentage of voiced and unvoiced energy in the speech.
- Spectral features. The spectral features are based on the characteristics of the human ear, which uses a nonlinear frequency unit to simulate the human auditory system. These features describe the speech formants, which

model spoken content and represent speaker characteristics.

- Cepstral features. These features emphasize changes or periodicity in the spectrum features measured by frequencies; we model them using 12 Mel-frequency cepstral coefficients that are calculated based on the Fourier transform of a speech frame.

Overall, we have a set of 28 acoustic features. During the feature extraction, we use a frame sampling of 25ms. Speaker normalization is performed using z-standardization. The voice intensity is thresholded to identify samples with and without speech, with the same threshold being used for all the experiments and all the speakers. The features are averaged over all the frames in an utterance, to obtain one feature vector for each utterance.

### 4.1.3 Facial Features

Facial expressions can provide important clues for affect recognition, which we use to complement the linguistic and acoustic features extracted from the speech stream.

The most widely used system for measuring and describing facial behaviors is the Facial Action Coding System (FACS), which allows for the description of face muscle activities through the use of a set of Action Units (AUs). According with (Ekman, 1993), there are 64 AUs that involve the upper and lower face, including several face positions and movements.<sup>3</sup> AUs can occur either by themselves or in combination, and can be used to identify a variety of emotions. While AUs are frequently annotated by certified human annotators, automatic tools are also available. In our work, we use the Computer Expression Recognition Toolbox (CERT) (Littlewort et al., 2011), which allows us to automatically extract the following visual features:

- Smile and head pose estimates. The smile feature is an estimate for smiles. Head pose detection consists of three-dimensional estimates of the head orientation, i.e., yaw, pitch, and roll. These features provide information about changes in smiles and face positions while uttering positive and negative opinions.
- Facial AUs. These features are the raw estimates for 30 facial AUs related to muscle movements for the eyes, eyebrows, nose, lips,

<sup>3</sup><http://www.cs.cmu.edu/afs/cs/project/face/www/facs.htm>

and chin. They provide detailed information about facial behaviors from which we expect to find differences between positive and negative states.

- Eight basic emotions. These are estimates for the following emotions: anger, contempt, disgust, fear, joy, sad, surprise, and neutral. These features describe the presence of two or more AUs that define a specific emotion. For example, the unit A12 describes the pulling of lip corners movement, which usually suggests a smile but when associated with a check raiser movement (unit A6), represents a marker for the emotion of happiness.

We extract a total of 40 visual features, each of them obtained at frame level. Since only one person is present in each video clip, most of the time facing the camera, the facial tracking was successfully applied for most of our data. For the analysis, we use a sampling rate of 30 frames per second. The features extracted for each utterance are averaged over all the valid frames, which are automatically identified using the output of CERT.<sup>4</sup> Segments with more than 60% of invalid frames are simply discarded.

## 5 Experiments and Results

We run our sentiment classification experiments on the MOUD dataset introduced earlier. From the dataset, we remove utterances labeled as neutral, thus keeping only the positive and negative utterances with valid visual features. The removal of neutral utterances is done for two main reasons. First, the number of neutral utterances in the dataset is rather small. Second, previous work in subjectivity and sentiment analysis has demonstrated that a layered approach (where neutral statements are first separated from opinion statements followed by a separation between positive and negative statements) works better than a single three-way classification. After this process, we are left with an experimental dataset of 412 utterances, 182 of which are labeled as positive, and 231 are labeled as negative.

From each utterance, we extract the linguistic, acoustic, and visual features described above, which are then combined using the early fusion (or feature-level fusion) approach (Hall and Llinas,

<sup>4</sup>There is a small number of frames that CERT could not process, mostly due to the brief occlusions that occur when the speaker is showing the product she is reviewing.

Modality	Accuracy
Baseline	55.93%
One modality at a time	
Linguistic	70.94%
Acoustic	64.85%
Visual	67.31%
Two modalities at a time	
Linguistic + Acoustic	72.88%
Linguistic + Visual	72.39%
Acoustic + Visual	68.86%
Three modalities at a time	
Linguistic+Acoustic+Visual	74.09%

Table 2: Utterance-level sentiment classification with linguistic, acoustic, and visual features.

1997; Atrey et al., 2010). In this approach, the features collected from all the multimodal streams are combined into a single feature vector, thus resulting in one vector for each utterance in the dataset which is used to make a decision about the sentiment orientation of the utterance.

We run several comparative experiments, using one, two, and three modalities at a time. We use the entire set of 412 utterances and run ten fold cross validations using an SVM classifier, as implemented in the Weka toolkit.<sup>5</sup> In line with previous work on emotion recognition in speech (Haq and Jackson, 2009; Anagnostopoulos and Vovoli, 2010) where utterances are selected in a speaker dependent manner (i.e., utterances from the same speaker are included in both training and test), as well as work on sentence-level opinion classification where document boundaries are not considered in the split performed between the training and test sets (Wilson et al., 2004; Wiegand and Klakow, 2009), the training/test split for each fold is performed at utterance level regardless of the video they belong to.

Table 2 shows the results of the utterance-level sentiment classification experiments. The baseline is obtained using the ZeroR classifier, which assigns the most frequent label by default, averaged over the ten folds.

## 6 Discussion

The experimental results show that sentiment classification can be effectively performed on multimodal datastreams. Moreover, the integration of

<sup>5</sup><http://www.cs.waikato.ac.nz/ml/weka/>

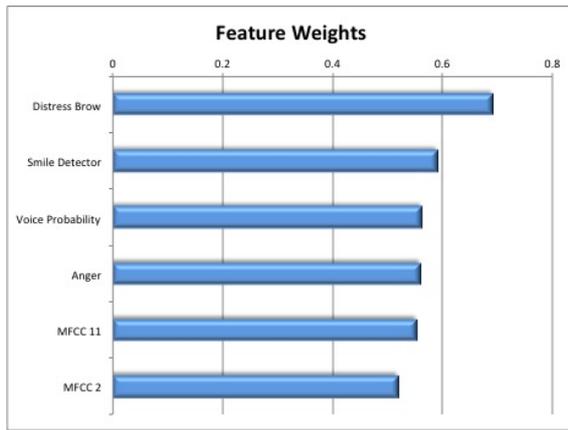

Figure 2: Visual and acoustic feature weights. This graph shows the relative importance of the information gain weights associated with the top most informative acoustic-visual features.

visual, acoustic, and linguistic features can improve significantly over the use of one modality at a time, with incremental improvements observed for each added modality.

Among the individual classifiers, the linguistic classifier appears to be the most accurate, followed by the classifier that relies on visual clues, and by the audio classifier. Compared to the best individual classifier, the relative error rate reduction obtained with the tri-modal classifier is 10.5%. The results obtained with this multimodal utterance classifier are found to be significantly better than the best individual results (obtained with the text modality), with significance being tested with a t-test ( $p=0.05$ ).

### Feature analysis.

To determine the role played by each of the visual and acoustic features, we compare the feature weights assigned by the learning algorithm, as shown in Figure 2. Interestingly, a distressed brow is the strongest indicator of sentiment, followed, this time not surprisingly, by the smile feature. Other informative features for sentiment classification are the voice probability, representing the energy in speech, the combined visual features that represent an angry face, and two of the cepstral coefficients.

To reach a better understanding of the relation between features, we also calculate the Pearson correlation between the visual and acoustic features. Table 3 shows a subset of these correlation figures. As we expected, correlations between features of the same type are higher. For example,

the correlation between features AU6 and AU12 or the correlation between intensity and loudness is higher than the correlation between AU6 and intensity. Nonetheless, we still find some significant correlations between features of different types, for instance AU12 and AU45 which are both significantly correlated with the intensity and loudness features. This give us confidence about using them for further analysis.

### Video-level sentiment analysis.

To understand the role played by the size of the video-segments considered in the sentiment classification experiments, as well as the potential effect of a speaker-independence assumption, we also run a set of experiments where we use full videos for the classification.

In these experiments, once again the sentiment annotation is done by two independent annotators, using the same protocol as in the utterance-based annotations. Videos that were ambivalent about the general sentiment were either labeled as neutral (and thus removed from the experiments), or labeled with the dominant sentiment. The inter-annotator agreement for this annotation was measured at 96.1%. As before, the linguistic, acoustic, and visual features are averaged over the entire video, and we use an SVM classifier in ten-fold cross validation experiments.

Table 4 shows the results obtained in these video-level experiments. While the combination of modalities still helps, the improvement is smaller than the one obtained during the utterance-level classification. Specifically, the combined effect of acoustic and visual features improves significantly over the individual modalities. However, the combination of linguistic features with other modalities does not lead to clear improvements. This may be due to the smaller number of feature vectors used in the experiments (only 80, as compared to the 412 used in the previous setup). Another possible reason is the fact that the acoustic and visual modalities are significantly weaker than the linguistic modality, most likely due to the fact that the feature vectors are now speaker-independent, which makes it harder to improve over the linguistic modality alone.

## 7 Conclusions

In this paper, we presented a multimodal approach for utterance-level sentiment classification. We introduced a new multimodal dataset consisting

	AU6	AU12	AU45	AUs 1,1+4	Pitch	Voice probability	Intensity	Loudness
AU6	1.00	0.46*	-0.03	-0.05	0.06	-0.14*	-0.04	-0.02
AU12		1.00	-0.23*	-0.33*	0.04	0.05	0.15*	0.16*
AU45			1.00	0.05	-0.05	-0.11*	-.163*	0.16*
AUs 1,1+4				1.00	-0.11*	-0.16*	0.06	0.07
Pitch					1.00	-0.04	-0.01	-0.08
Voice probability						1.00	0.19*	0.38*
Intensity							1.00	0.85*
Loudness								1.00

Table 3: Correlations between several visual and acoustic features. Visual features: AU6 Cheek raise, AU12 Lip corner pull, AU45 Blink eye and closure, AU1,1+4 Distress brow. Acoustic features: Pitch, Voice probability, Intensity, Energy. \*Correlation is significant at the 0.05 level (1-tailed)

Modality	Accuracy
Baseline	55.93%
One modality at a time	
Linguistic	73.33%
Acoustic	53.33%
Visual	50.66%
Two modalities at a time	
Linguistic + Acoustic	72.00%
Linguistic + Visual	74.66%
Acoustic + Visual	61.33%
Three modalities at a time	
Linguistic+Acoustic+Visual	74.66%

Table 4: Video-level sentiment classification with linguistic, acoustic, and visual features.

of sentiment annotated utterances extracted from video reviews, where each utterance is associated with a video, acoustic, and linguistic datastream. Our experiments show that sentiment annotation of utterance-level visual datastreams can be effectively performed, and that the use of multiple modalities can lead to error rate reductions of up to 10.5% as compared to the use of one modality at a time. In future work, we plan to explore alternative multimodal fusion methods, such as decision-level and meta-level fusion, to improve the integration of the visual, acoustic, and linguistic modalities.

## Acknowledgments

We would like to thank Alberto Castro for his help with the sentiment annotations. This material is based in part upon work supported by National Science Foundation awards #0917170 and #1118018, by DARPA-BAA-12-47 DEFT grant #12475008, and by a grant from U.S. RDECOM. Any opinions,

findings, and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of the National Science Foundation, the Defense Advanced Research Projects Agency, or the U.S. Army Research, Development, and Engineering Command.

## Abstract

*Sentiment Similarity* of word pairs reflects the distance between the words regarding their underlying sentiments. This paper aims to infer the sentiment similarity between word pairs with respect to their senses. To achieve this aim, we propose a probabilistic emotion-based approach that is built on a hidden emotional model. The model aims to predict a vector of basic human emotions for each sense of the words. The resultant emotional vectors are then employed to infer the sentiment similarity of word pairs. We apply the proposed approach to address two main NLP tasks, namely, *Indirect yes/no Question Answer Pairs* inference and *Sentiment Orientation* prediction. Extensive experiments demonstrate the effectiveness of the proposed approach.

## 1 Introduction

Sentiment similarity reflects the distance between words based on their underlying sentiments. Semantic similarity measures such as Latent Semantic Analysis (LSA) (Landauer et al., 1998) can effectively capture the similarity between semantically related words like "car" and "automobile", but they are less effective in relating words with similar sentiment orientation like "excellent" and "superior". For example, the following relations show the semantic similarity between some sentiment words computed by LSA:

$$\begin{aligned} \mathbf{E1}: \text{LSA}(\text{excellent}, \text{superior}) &= 0.40 \\ &< \text{LSA}(\text{excellent}, \text{good}) = 0.46 \\ &< \text{LSA}(\text{good}, \text{bad}) = 0.65 \end{aligned}$$

Clearly, the sentiment similarity between the above words should be in the reversed order. In fact, the sentiment intensity in "excellent" is closer to "superior" than "good". Furthermore,

sentiment similarity between "good" and "bad" should be 0.

In this paper, we propose a probabilistic approach to detect the sentiment similarity of words regarding their senses and underlying sentiments. For this purpose, we propose to model the hidden emotions of word senses. We show that our approach effectively outperforms the semantic similarity measures in two NLP tasks: *Indirect yes/no Question Answer Pairs (IQAPs) Inference* and *Sentiment Orientation (SO) prediction* that are described as follows:

In IQAPs, answers do not explicitly contain the *yes* or *no* keywords, but rather provide context information to infer the *yes* or *no* answer (e.g. **Q:** *Was she the **best** one on that old show?* **A:** *She was simply **funny**.*). Clearly, the sentiment words in IQAPs are the pivots to infer the *yes* or *no* answers. We show that sentiment similarity between such words (e.g., here the adjectives *best* and *Funny*) can be used effectively to infer the answers.

The second application (SO prediction) aims to determine the sentiment orientation of individual words. Previous research utilized the semantic relations between words obtained from WordNet (Hassan and Radev, 2010) and semantic similarity measures (e.g. Turney and Littman, 2003) for this purpose. In this paper, we show that sentiment similarity between word pairs can be effectively utilized to compute SO of words.

The contributions of this paper are follows:

- We propose an effective approach to predict the sentiment similarity between word pairs through hidden emotions at the sense level,
- We show the utility of sentiment similarity prediction in IQAP inference and SO prediction tasks, and
- Our hidden emotional model can infer the type and number of hidden emotions in a corpus.

## 2 Sentiment Similarity through Hidden Emotions

As we discussed above, semantic similarity measures are less effective to infer sentiment similarity between word pairs. In addition, different senses of sentiment words carry different human emotions. In fact, a sentiment word can be represented as a vector of emotions with *intensity* values from "very weak" to "very strong". For example, Table 1 shows several sentiment words and their corresponding emotion vectors based the following set of emotions:  $e = [\textit{anger}, \textit{disgust}, \textit{sadness}, \textit{fear}, \textit{guilt}, \textit{interest}, \textit{joy}, \textit{shame}, \textit{surprise}]$ . For example, "deceive" has 0.4 and 0.5 intensity values with respect to the emotions "disgust" and "sadness" with an overall -0.9 (i.e.  $-0.4-0.5$ ) value for sentiment orientation (Neviarouskaya et al., 2007; Neviarouskaya et al., 2009).

Word	Emotional Vector	SO
$e = [\textit{anger}, \textit{disgust}, \textit{sadness}, \textit{fear}, \textit{guilt}, \textit{interest}, \textit{joy}, \textit{shame}, \textit{surprise}]$		
<i>Rude</i>	[0.2, 0.4, 0, 0, 0, 0, 0, 0]	-0.6
<i>doleful</i>	[0, 0, 0.4, 0, 0, 0, 0, 0]	-0.4
<i>smashed</i>	[0, 0, 0.8, 0.6, 0, 0, 0, 0]	-1.4
<i>shamefully</i>	[0, 0, 0, 0, 0, 0, 0.7, 0]	-0.7
<i>deceive</i>	[0, 0.4, 0.5, 0, 0, 0, 0, 0]	-0.9

Table 1. Sample of emotional vectors

The difficulty of the sentiment similarity prediction task is evident when terms carry different types of emotions. For instance, all the words in Table 1 have negative sentiment orientation, but, they carry different emotions with different emotion vectors. For example, "rude" reflects the emotions "anger" and "disgust", while the word "doleful" only reflects the emotion "sadness". As such, the word "doleful" is closer to the words "smashed" and "deceive" involving the emotion "sadness" than others. We show that emotion vectors of the words can be effectively utilized to predict the sentiment similarity between them.

Previous research shows little agreement about the number and types of the basic emotions (Ortony and Turner 1990; Izard 1971). Thus, we assume that the number and types of basic emotions are hidden and not pre-defined and propose a Probabilistic Sense Sentiment Similarity (PSSS) approach to extract the hidden emotions of word senses to infer their sentiment similarity.

## 3 Hidden Emotional Model

Online review portals provide rating mechanisms (in terms of stars, e.g. 5- or 10-star rating) to al-

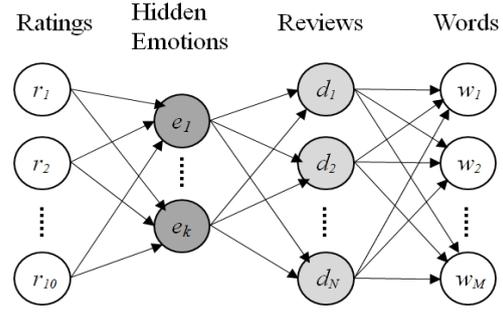

Figure 1. The structure of PSSS model

low users to attach ratings to their reviews. A rating indicates the summarized opinion of a user who ranks a product or service based on his feelings. There are various feelings and emotions behind such ratings with respect to the content of the reviews.

Figure 1 shows the intermediate layer of hidden emotions behind the ratings (sentiments) assigned to the documents (reviews) containing the words. This Figure indicates the general structure of our PSSS model. It shows that hidden emotions ( $e_i$ ) link the rating ( $r_j$ ) and the documents ( $d_k$ ). In this Section, we aim to employ ratings and the relations among ratings, documents, and words to extract the hidden emotions.

Figure 2 illustrates a simple graphical model using plate representation of Figure 1. As Figure 2 shows, the rating  $r$  from a set of ratings  $R = \{r_1, \dots, r_p\}$  is assigned to a hidden emotion set  $E = \{e_1, \dots, e_k\}$ . A document  $d$  from a set of documents  $D = \{d_1, \dots, d_N\}$  with vocabulary set  $W = \{w_1, \dots, w_M\}$  is associated with the hidden emotion set.

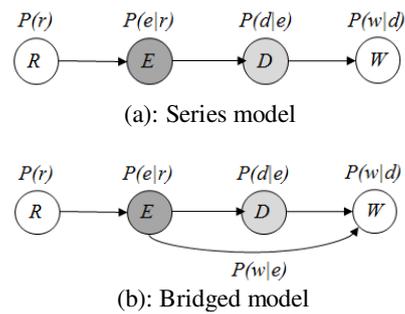

Figure 2. Hidden emotional model

The model presented in Figure 2(a) has been explored in (Mohtarami et al., 2013) and is called *Series Hidden Emotional Model* (SHEM). This representation assumes that *the word  $w$  is dependent to  $d$  and independent to  $e$*  (we refer to this Assumption as *A1*). However, in reality, a word  $w$  can inherit properties (e.g., emotions)

from the document  $d$  that contains  $w$ . Thus, we can assume that  $w$  is implicitly dependant on  $e$ . To account for this, we present *Bridged Hidden Emotional Model* (BHEM) shown in Figure 2(b). Our assumption, A2, in the BHEM model is as follows:  $w$  is dependent to both  $d$  and  $e$ .

Considering Figure 1, we represent the entire text collection as a set of  $(w,d,r)$  in which each observation  $(w,d,r)$  is associated with a set of unobserved emotions. If we assume that the observed tuples are independently generated, the whole data set is generated based on the joint probability of the observation tuples  $(w,d,r)$  as the follows (Mohtarami et al., 2013):

$$D = \prod_r \prod_d \prod_w P(w,d,r)^{n(w,d,r)} = \prod_r \prod_d \prod_w P(w,d,r)^{n(w,d)n(d,r)} \quad (1)$$

where,  $P(w,d,r)$  is the joint probability of the tuple  $(w,d,r)$ , and  $n(w,d,r)$  is the frequency of  $w$  in document  $d$  of rating  $r$  (note that  $n(w,d)$  is the term frequency of  $w$  in  $d$  and  $n(d,r)$  is one if  $r$  is assigned to  $d$ , and 0 otherwise). The joint probability for the BHEM is defined as follows considering hidden emotion  $e$ :

- regarding class probability of the hidden emotion  $e$  to be assigned to the observation  $(w,d,r)$ :

$$\begin{aligned} P(w,d,r) &= \sum_e P(w,d,r|e)P(e) = \\ &= \sum_e P(w,d|e)P(r|e)P(e) \\ - \text{regarding assumption A2 and Bayes' Rule:} \\ &= \sum_e P(w|d,e)P(d,e)P(r|e) \\ - \text{using Bayes' Rule:} \\ &= \sum_e P(d,e|w)P(w)P(r|e) \\ - \text{regarding A2 and conditional independency:} \\ &= \sum_e P(d|w)P(e|w)P(w)P(r|e) \\ &= P(d|w) \sum_e P(w|e)P(e)P(r|e) \end{aligned} \quad (2)$$

In the bridged model, the joint probability does not depend on the probability  $P(d|e)$  and the probabilities  $P(w|e)$ ,  $P(e)$  and  $P(r|e)$  are unknown, while in the SHEM model explained in (Mohtarami et al., 2013), the joint probability does not depend on  $P(w|e)$ , and probabilities  $P(d|e)$ ,  $P(e)$ , and  $P(r|e)$  are unknown.

We employ Maximum Likelihood approach to learn the probabilities and infer the possible hidden emotions. The log-likelihood of the whole

data set  $D$  in Equation (1) can be defined as follows:

$$L = \sum_r \sum_d \sum_w n(w,d)n(d,r) \log P(w,d,r) \quad (3)$$

Replacing  $P(w,d,r)$  by the values computed using the bridged model in Equation (2) results in:

$$L = \sum_r \sum_d \sum_w n(w,d)n(d,r) \log [P(d|w) \sum_e P(w|e)P(e)P(r|e)] \quad (4)$$

The above optimization problems are hard to compute due to the log of sum. Thus, *Expectation-maximization* (EM) is usually employed. EM consists of two following steps:

1. **E-step**: Calculates posterior probabilities for hidden emotions given the words, documents and ratings, and
2. **M-step**: Updates unknown probabilities (such as  $P(w|e)$  etc) using the posterior probabilities in the E-step.

The steps of EM can be computed for BHEM model. EM of the model employs assumptions A2 and Bayes Rule and is defined as follows:

**E-step**:

$$P(e|w,d,r) = \frac{P(r|e)P(e)P(w|e)}{\sum_e P(r|e)P(e)P(w|e)} \quad (5)$$

**M-step**:

$$\begin{aligned} P(r|e) &= \frac{\sum_d \sum_w n(w,d)n(d,r) P(e|w,d,r)}{\sum_r \sum_d \sum_w n(w,d)n(d,r) P(e|w,d,r)} \\ &= \frac{\sum_w n(w,r) P(e|w,d,r)}{\sum_r \sum_w n(w,r) P(e|w,d,r)} \end{aligned} \quad (6)$$

$$\begin{aligned} P(w|e) &= \frac{\sum_r \sum_d n(w,d)n(d,r) P(e|w,d,r)}{\sum_w \sum_r \sum_d n(w,d)n(d,r) P(e|w,d,r)} \\ &= \frac{\sum_r n(w,r) P(e|w,d,r)}{\sum_w \sum_r n(w,r) P(e|w,d,r)} \end{aligned} \quad (7)$$

$$\begin{aligned} P(e) &= \frac{\sum_r \sum_d \sum_w n(w,d)n(d,r) P(e|w,d,r)}{\sum_e \sum_d \sum_r \sum_w n(w,d)n(d,r) P(e|w,d,r)} \\ &= \frac{\sum_r \sum_w n(w,r) P(e|w,d,r)}{\sum_e \sum_r \sum_w n(w,r) P(e|w,d,r)} \end{aligned} \quad (8)$$

Note that in Equation (5), the probability  $P(e|w,d,r)$  does not depend on the document  $d$ . Also, in Equations (6)-(8) we remove the dependency on document  $d$  using the following Equation:

$$\sum_d n(w,d)n(d,r) = n(w,r) \quad (9)$$

where  $n(w,r)$  is the occurrence of  $w$  in all the documents in the rating  $r$ .

The EM steps computed by the bridged model do not depend on the variable document  $d$ , and discard  $d$  from the model. The reason is that  $w$  bypasses  $d$  to directly associate with the hidden emotion  $e$  in Figure 2(b).

Similar to BHEM, the EM steps for SHEM can be computed by considering assumptions *AI* and Bayes Rule as follows (Mohtarami et al., 2013):

**E-step:**

$$P(e|w, d, r) = \frac{P(r|e)P(e)P(d|e)}{\sum_e P(r|e)P(e)P(d|e)} \quad (10)$$

**M-step:**

$$P(r|e) = \frac{\sum_d \sum_w n(w, d)n(d, r)P(e|w, d, r)}{\sum_r \sum_d \sum_w n(w, d)n(d, r)P(e|w, d, r)} \quad (11)$$

$$P(d|e) = \frac{\sum_r \sum_w n(w, d)n(d, r)P(e|w, d, r)}{\sum_d \sum_r \sum_w n(w, d)n(d, r)P(e|w, d, r)} \quad (12)$$

$$P(e) = \frac{\sum_r \sum_d \sum_w n(w, d)n(d, r)P(e|w, d, r)}{\sum_e \sum_d \sum_r \sum_w n(w, d)n(d, r)P(e|w, d, r)} \quad (13)$$

Finally, we construct the emotional vectors using the algorithm presented in Table 2. The algorithm employs document-rating, term-document and term-rating matrices to infer the unknown probabilities. This algorithm can be used with both bridged or series models. Our goal is to infer the emotional vector for each word  $w$  that can be obtained by the probability  $P(w|e)$ . Note that, this probability can be simply computed for the SHEM model using  $P(d|e)$  as follows:

$$P(w|e) = \sum_d P(w|d)P(d|e) \quad (14)$$

### 3.1 Enriching Hidden Emotional Models

We enrich our emotional model by employing the requirement that the emotional vectors of two synonym words  $w_1$  and  $w_2$  should be similar. For this purpose, we utilize the semantic similarity between each two words and create an enriched matrix. Equation (15) shows how we compute this matrix. To compute the semantic similarity between word senses, we utilize their synsets as follows:

$$\begin{aligned} w_i w_j &= P(\text{syn}(w_i) | \text{syn}(w_j)) \\ &= \frac{1}{|\text{syn}(w_i)|} \sum_{\text{syn}(w_i)} \frac{1}{|\text{syn}(w_j)|} \sum_{\text{syn}(w_j)} P(w_i | w_j) \end{aligned} \quad (15)$$

where,  $\text{syn}(w)$  is the synset of  $w$ . Let  $\text{count}(w_i, w_j)$  be the co-occurrence of the  $w_i$  and  $w_j$ , and let  $\text{count}(w_j)$  be the total word count. The probability of  $w_i$  given  $w_j$  will then be  $P(w_i | w_j) = \text{count}(w_i, w_j) / \text{count}(w_j)$ . In addition, note that employing the synset of the words help to obtain different emotional vectors for each sense of a word.

The resultant enriched matrix  $W \times W$  is multiplied to the inputs of our hidden model (matrices  $W \times D$  or  $W \times R$ ). Note that this takes into account

**Input:**

*Series Model:* Document-Rate  $D \times R$ , Term-Document  $W \times D$   
*Bridged Model:* Term-Rate  $W \times R$

**Output:** Emotional vectors  $\{e_1, e_2, \dots, e_k\}$  for  $w$

**Algorithm:**

1. Enriching hidden emotional model:

*Series Model:* Update Term-Document  $W \times D$   
*Bridged Model:* Update Term-Rate  $W \times R$

2. Initialize unknown probabilities:

*Series Model:* Initialize  $P(d|e)$ ,  $P(r|e)$ , and  $P(e)$ , randomly  
*Bridged Model:* Initialize  $P(w|e)$ ,  $P(r|e)$ , and  $P(e)$

3. **while**  $L$  has not converged to a pre-specified value **do**

4. E-step;

*Series Model:* estimate the value of  $P(e|w, d, r)$  in Equation 10  
*Bridged Model:* estimate the value of  $P(e|w, d, r)$  in Equation 5

5. M-step;

*Series Model:* estimate the values of  $P(r|e)$ ,  $P(d|e)$ , and  $P(e)$  in Equations 11-13, respectively  
*Bridged Model:* estimate the values of  $P(r|e)$ ,  $P(w|e)$ , and  $P(e)$  in Equations 6-8, respectively

6. **end while**

7. **If** series hidden emotional model is used then

8. Infer word emotional vector: estimate  $P(w|e)$  in Equation 14.

9. **End if**

Table 2. Constructing emotional vectors via  $P(w|e)$

the senses of the words as well. The learning step of EM is done using the updated inputs. In this case, the correlated words can inherit the properties of each other. For example, if  $w_i$  does not occur in a document or rating involving another word (i.e.,  $w_j$ ), the word  $w_i$  can still be indirectly associated with the document or rating through the word  $w_j$ . However, the distribution of the opinion words in documents and ratings is not uniform. This may decrease the effectiveness of the enriched matrix.

The nonuniform distribution of opinion words has been also reported by Amiri et al. (2012) who showed that the positive words are frequently used in negative reviews. We also observed the same pattern in the development dataset. Figure 3 shows the overall occurrence of some positive and negative seeds in various ratings. As shown, in spite of the negative words, the positive words may frequently occur in both positive and negative documents. Such distribution of

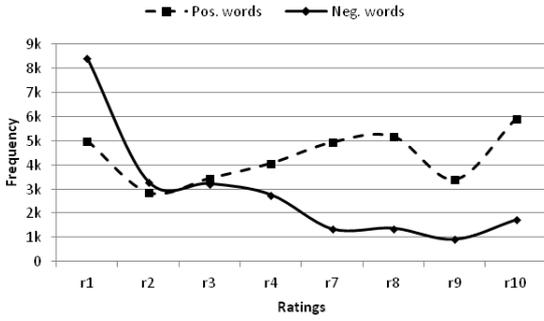

Figure 3. Nonuniform distribution of opinion words

positive words can mislead the enriched model.

To address this issue, we measure the confidence of an opinion word in the enriched matrix as follows.

$$Confidence_w = \frac{ABS[(TF_w^- \times DF_w^-) - (TF_w^+ \times DF_w^+)]}{(TF_w^- \times DF_w^-) + (TF_w^+ \times DF_w^+)} \quad (16)$$

where,  $TF_w^-$  ( $TF_w^+$ ) is the frequency of  $w$  in the ratings 1 to 4 (7 to 10), and  $DF_w^-$  ( $DF_w^+$ ) is the total number of documents with rating 1 to 4 (7 to 10) that contain  $w$ . The confidence value of  $w$  varies from 0 to 1, and it increases if:

- There is a large difference between the occurrences of  $w$  in positive and negative ratings.
- There is a large number of reviews involving  $w$  in the relative ratings.

To improve the efficiency of enriched matrix, the columns corresponding to each word in the matrix are multiplied by its confidence value.

#### 4 Predicting Sentiment Similarity

We utilize the approach proposed in (Mohtarami et al., 2013) to compute the sentiment similarity between two words. This approach compares the emotional vector of the given words. Let  $X$  and  $Y$  be the emotional vectors of two words. Equation (17) computes their correlation:

$$corr(X, Y) = \frac{\sum_{i=1}^n (X_i - \bar{X})(Y_i - \bar{Y})}{(n-1)S_X S_Y} \quad (17)$$

where,  $n$  is number of emotional categories,  $\bar{X}$ ,  $\bar{Y}$  and  $S_X$ ,  $S_Y$  are the mean and standard deviation values of  $X$  and  $Y$  respectively.  $corr(X, Y) = -1$  indicates that the two vectors are completely dissimilar, and  $corr(X, Y) = 1$  indicates that the vectors have perfect similarity.

The approach makes use of a thresholding mechanism to estimate the proper correlation value to find sentimentally similar words. For this, as in Mohtarami et al. (2013) we utilized the antonyms of the words. We consider two words,

#### Input:

$SAQ$ : The adjective in the question of given IQAP.  
 $SAA$ : The adjective in the answer of given IQAP.

**Output:** answer  $\in \{yes, no, uncertain\}$

#### Algorithm:

1. if  $SAQ$  or  $SAA$  are missing from our corpus then
2.     answer=*Uncertain*;
3. else if  $SS(SAQ, SAA) < 0$  then
4.     answer=*No*;
5.     else if  $SS(SAQ, SAA) > 0$  then
6.         answer=*yes*;

Figure 4. Sentiment similarity for IQAP inference

$w_i$  and  $w_j$  as similar in sentiment iff they satisfy both of the following conditions:

1.  $corr(w_i, w_j) > corr(w_i, \sim w_j)$ , and
2.  $corr(w_i, w_j) > corr(\sim w_i, w_j)$

where,  $\sim w_i$  is antonym of  $w_i$ , and  $corr(w_i, w_j)$  is obtained from Equation (17). Finally, we compute the sentiment similarity ( $SS$ ) as follows:

$$SS(w_i, w_j) = corr(w_i, w_j) - Max\{corr(w_i, \sim w_j), corr(\sim w_i, w_j)\} \quad (18)$$

Equation (18) enforces two sentimentally similar words to have weak correlation to the antonym of each others. A positive value of  $SS(...)$  indicates the words are sentimentally similar and a negative value shows that they are dissimilar.

## 5 Applications

We explain our approach in utilizing sentiment similarity between words to perform IQAP inference and SO prediction tasks respectively.

In IQAPs, we employ the sentiment similarity between the adjectives in questions and answers to interpret the indirect answers. Figure 4 shows the algorithm for this purpose.  $SS(...)$  indicates sentiment similarity computed by Equation (18). A positive  $SS$  means the words are sentimentally similar and thus the answer is *yes*. However, negative  $SS$  leads to a *no* response.

In SO-prediction task, we aim to compute more accurate SO using our sentiment similarity method. Turney and Littman (2003) proposed a method in which the SO of a word is calculated based on its semantic similarity with seven positive words minus its similarity with seven negative words as shown in Figure 5. As the similarity function,  $A(...)$ , they employed point-wise mutual information (PMI) to compute the similarity between the words. Here, we utilize the same approach, but instead of PMI we use our  $SS(...)$  measure as the similarity function.

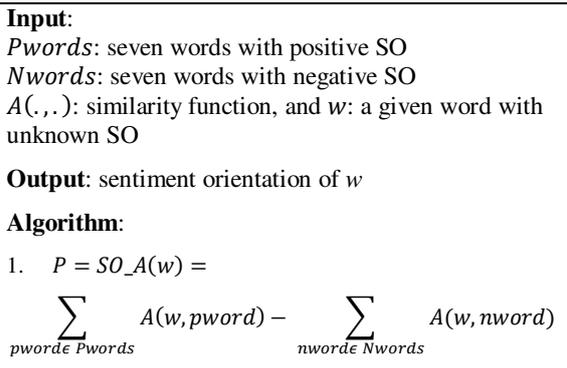

Figure 5. SO based on the similarity function *A*(.,.)

## 6 Evaluation and Results

### 6.1 Data and Settings

We used the review dataset employed by Maas et al. (2011) as the development dataset that contains movie reviews with star rating from one star (most negative) to 10 stars (most positive). We exclude the ratings 5 and 6 that are more neutral. We used this dataset to compute all the input matrices in Table 2 as well as the enriched matrix. The development dataset contains 50k movie reviews and 90k vocabulary.

We also used two datasets for the evaluation purpose: the MPQA (Wilson et al., 2005) and IQAPs (Marneffe et al., 2010) datasets. The MPQA dataset is used for SO prediction experiments, while the IQAP dataset is used for the IQAP experiments. We ignored the neutral words in MPQA dataset and used the remaining 4k opinion words. Also, the IQAPs dataset (Marneffe et al., 2010) contains 125 IQAPs and their corresponding *yes* or *no* labels as the ground truth.

### 6.2 Experimental Results

To evaluate our PSSS model, we perform experiments on the SO prediction and IQAPs inference tasks. Here, we consider six emotions for both bridged and series models. We study the effect of emotion numbers in Section 7.1. Also, we set a threshold of 0.3 for the confidence value in Equation (16), i.e. we set the confidence values smaller than the threshold to 0. We explain the effect of this parameter in Section 7.3.

#### Evaluation of SO Prediction

We evaluate the performance of our PSSS models in the SO prediction task using the algorithm explained in Figure 5 by setting our PSSS as similarity function (*A*). The results on SO prediction are presented in Table 3. The first and se-

Method	Precision	Recall	F1
PMI	56.20	56.36	55.01
ER	65.68	65.68	63.27
PSSS-SHEM	68.51	69.19	67.96
PSSS-BHEM	<b>69.39</b>	<b>70.07</b>	<b>68.68</b>

Table 3. Performance on SO prediction task

cond rows present the results of our baselines, PMI (Turney and Littman, 2003) and Expected Rating (ER) (Potts, 2011) of words respectively.

PMI extracts the semantic similarity between words using their co-occurrences. As Table 3 shows, it leads to poor performance. This is mainly due to the relatively small size of the development dataset which affects the quality of the co-occurrence information used by the PMI.

ER computes the expected rating of a word based on the distribution of the word across rating categories. The value of ER indicates the SO of the word. As shown in the two last rows of the table, the results of PSSS approach are higher than PMI and ER. The reason is that PSSS is based on the combination between sentiment space (through using ratings, and matrices  $W \times R$  in BHEM,  $D \times R$  in SHEM) and semantic space (through the input  $W \times D$  in SHEM and enriched matrix  $W \times W$  in both hidden models). However, the PMI employs only the semantic space (i.e., the co-occurrence of the words) and ER uses occurrence of the words in rating categories.

Furthermore, the PSSS model achieves higher performance with BHEM rather than SHEM. This is because the emotional vectors of the words are directly computed from the EM steps of BHEM. However, the emotional vectors of SHEM are computed after finishing the EM steps using Equation (14). This causes the SHEM model to estimate the number and type of the hidden emotions with a lower performance as compared to BHEM, although the performances of SHEM and BHEM are comparable as explained in Section 7.1.

#### Evaluation of IQAPs Inference

To apply our PSSS on IQAPs inference task, we use it as the sentiment similarity measure in the algorithm explained in Figure 4. The results are presented in Table 4. The first and second rows are baselines. The first row is the result obtained by Marneffe et al. (2010) approach. This approach is based on the similarity between the SO of the adjectives in question and answer. The second row of Table 4 show the results of using a popular semantic similarity measure, PMI, as the sentiment similarity (SS) measure in Figure 4.

Method	Prec.	Rec.	F1
Marneffe et al. (2010)	60.00	60.00	60.00
PMI	60.61	58.70	59.64
PSSS-SHEM	62.55	61.75	61.71
PSSS-BHEM (w/o WSD)	65.90	66.11	63.74
SS-BHEM (with WSD)	<b>66.95</b>	<b>67.15</b>	<b>65.66</b>

Table 4. Performance on IQAP inference task

The result shows that PMI is less effective to capture the sentiment similarity.

Our PSSS approach directly infers *yes* or *no* responses using SS between the adjectives and does not require computing SO of the adjectives. In Table 4, *PSSS-SHEM* and *PSSS-BHEM* indicate the results when we use our PSSS with SHEM and BHEM respectively. Table 4 shows the effectiveness of our sentiment similarity measure. Both models improve the performance over the baselines, while the bridged model leads to higher performance than the series model.

Furthermore, we employ Word Sense Disambiguation (WSD) to disambiguate the adjectives in the question and its corresponding answer. For example, **Q:** ... *Is that true?* **A:** *This is extraordinary and preposterous.* In the answer, the correct sense of the *extraordinary* is *unusual* and as such answer *no* can be correctly inferred. In the table, (*w/o WSD*) is based on the first sense (most common sense) of the words, whereas (*with WSD*) utilizes the real sense of the words. As Table 4 shows, WSD increases the performance. WSD could have higher effect, if more IQAPs contain adjectives with senses different from the first sense.

## 7 Analysis and Discussions

### 7.1 Number and Types of Emotions

In our PSSS approach, there is no limitation on the number and types of emotions as we assumed emotions are hidden. In this Section, we perform experiments to predict the number and type of hidden emotions.

Figure 6 and 7 show the results of the hidden models (SHEM and BHEM) on SO prediction and IQAPs inference tasks respectively with different number of emotions. As the Figures show, in both tasks, SHEM achieved high performances with 11 emotions. However, BHEM achieved high performances with six emotions. Now, the question is which emotion number should be considered? To answer this question, we further study the results as follows.

First, for SHEM, there is no significant difference between the performances with six and 11 emotions in the SO prediction task. This is the

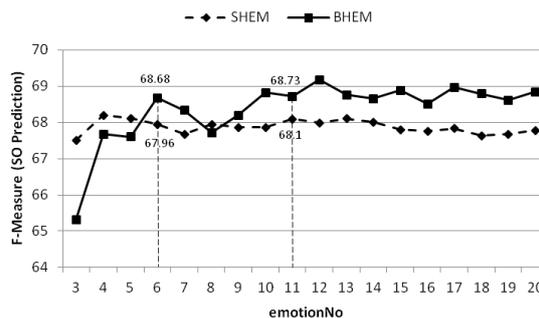

Figure 6. Performance of BHEM and SHEM on SO prediction through different #of emotions

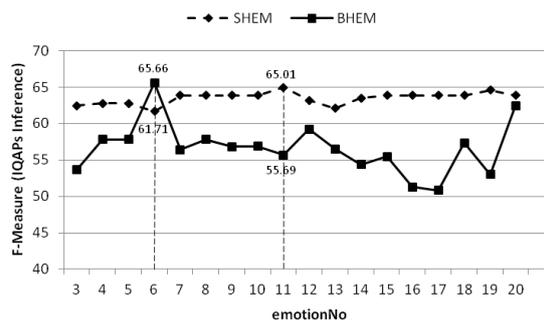

Figure 7. Performance of BHEM and SHEM on IQAPs inference through different #of emotions

same for BHEM. Also, the performances of SHEM on the IQAP inference task with six and 11 emotions are comparable. However, there is a significant difference between the performances of BHEM in six and 11 emotions. So, we consider the dimension in which both hidden emotional models present a reasonable performance over both tasks. This dimension is six here.

Second, as shown in the Figures 6 and 7, in contrast to BHEM, the performance of SHEM does not considerably change with different number of emotions over both tasks. This is because, in SHEM, the emotional vectors of the words are derived from the emotional vectors of the documents after the EM steps, see Equation (14). However, in BHEM, the emotional vectors are directly obtained from the EM steps. Thus, the bridged model is more sensitive than series model to the number of emotions. This could indicate that the bridged model is more accurate than the series model to estimate the number of emotions.

Therefore, based on the above discussion, the estimated number of emotions is six in our development dataset. This number may vary using different development datasets.

In addition to the number of emotions, their types can also be interpreted using our approach. To achieve this aim, we sort the words based on their probability values,  $P(w|e)$ , with respect to

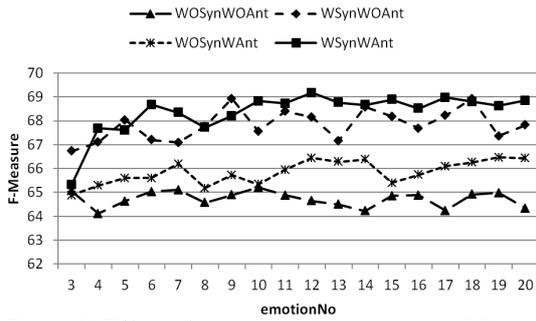

Figure 8. Effect of synonyms & antonyms in SO prediction task with different emotion numbers in BHEM

Emotion#1	Emotion#2	Emotion#3
excellent (1)	unimpressive (1)	disreputable (1)
magnificently(1)	humorlessly (1)	villian (1)
blessed (1)	paltry (1)	onslaught (1)
sublime (1)	humiliating (1)	ugly (1)
affirmation (1)	uncreative (1)	old (1)
tremendous (2)	lackluster (1)	disrupt (1)

Table 5. Sample words in three emotions

each emotion. Then, the type of the emotions can be interpreted by observing the top  $k$  words in each emotion. For example, Table 5 shows the top 6 words for three out of six emotions obtained for BHEM. The numbers in parentheses show the sense of the words. The corresponding emotions for these categories can be interpreted as "wonderful", "boring" and "disreputable", respectively.

We also observed that, in SHEM with eleven emotion numbers, some of the emotion categories have similar top  $k$  words such that they can be merged to represent the same emotion. Thus, it indicates that the BHEM is better than SHEM to estimates the number of emotions than SHEM.

## 7.2 Effect of Synsets and Antonyms

We show the important effect of synsets and antonyms in computing the sentiment similarity of words. For this purpose, we repeat the experiment for SO prediction by computing sentiment similarity of word pairs with and without using synonyms and antonyms. Figure 8 shows the results of obtained from BHEM. As the Figure shown, the highest performance can be achieved when synonyms and antonyms are used, while the lowest performance is obtained without using them. Note that, when the synonyms are not used, the entries of enriched matrix are computed using  $P(w_i|w_j)$  instead of  $P(\text{syn}(w_i)|\text{syn}(w_j))$  in the Equation (15). Also, when the antonyms are not used, the  $\text{Max}(\cdot)$  in Equation (18) is 0 and SS is computed using only correlation between words.

The results show that synonyms can improve the performance. As Figure 8 shows, the two

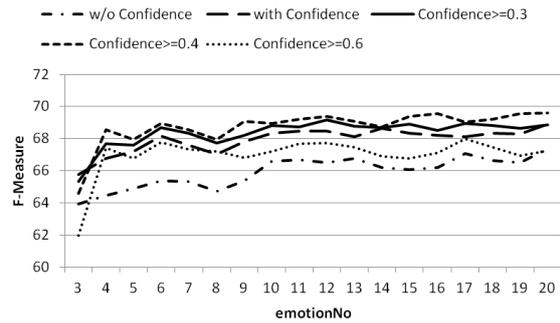

Figure 9. Effect of confidence values in SO prediction with different emotion numbers in BHEM

highest performances are obtained when we use synonyms and the two lowest performances are achieved when we don't use synonyms. This is indicates that the synsets of the words can improve the quality of the enriched matrix. The results also show that the antonyms can improve the result (compare WOSynWAnt with WOSynWOAnt). However, synonyms lead to greater improvement than antonyms (compare WSynWOAnt with WOSynWAnt).

## 7.3 Effect of Confidence Value

In Section 3.1, we defined a confidence value for each word to improve the quality of the enriched matrix. To illustrate the utility of the confidence value, we repeat the experiment for SO prediction by BHEM using all the words appears in enriched matrix with different confidence thresholds. The results are shown in Figure 9, "w/o confidence" shows the results when we don't use the confidence values, while "with confidence" shows the results when use the confidence values. Also, "confidence>x" indicates the results when we set all the confidence value smaller than x to 0. The thresholding helps to eliminate the effect of low confident words.

As Figure 9 shows, "w/o confidence" leads to the lowest performance, while "with confidence" improves the performance with different number of emotions. The thresholding is also effective. For example, a threshold like 0.3 or 0.4 improves the performance. However, if a large value (e.g., 0.6) is selected as threshold, the performance decreases. This is because a large threshold filters a large number of words from enriched model that decreases the effect of the enriched matrix.

## 7.4 Convergence Analysis

The PSSS approach is based on the EM algorithm for the BHEM (or SHEM) presented in Table 2. This algorithm performs a predefined

number of iterations or until convergence. To study the convergence of the algorithm, we repeat our experiments for SO prediction and IQAPs inference tasks using BHEM with different number of iterations. Figure 10 shows that after the first 15 iterations the performance does not change dramatically and is nearly constant when more than 30 iterations are performed. This shows that our algorithm will converge in less than 30 iterations for BHEM. We observed the same pattern in SHEM.

### 7.5 Bridged Vs. Series Model

The bridged and series models are both based on the hidden emotions that were developed to predict the sense sentiment similarity. Although their best results on the SO prediction and IQAPs inference tasks are comparable, they have some significant differences as follows:

- BHEM is considerably faster than SHEM. The reason is that, the input matrix of BHEM (i.e.,  $W \times R$ ) is significantly smaller than the input matrix of SHEM (i.e.,  $W \times D$ ).
- In BHEM, the emotional vectors are directly computed from the EM steps. However, the emotional vector of a word in SHEM is computed using the emotional vectors of the documents containing the word. This adds noises to the emotional vectors of the words.
- BHEM gives more accurate estimation over type and number of emotions versus SHEM. The reason is explained in Section 7.1.

## 8 Related Works

Sentiment similarity has not received enough attention to date. Most previous works employed semantic similarity of word pairs to address SO prediction and IQAP inference tasks. Turney and Littman (2003) proposed to compute pair-wised mutual information (PMI) between a target word and a set of seed positive and negative words to infer the SO of the target word. They also utilized Latent Semantic Analysis (LSA) (Landauer et al., 1998) as another semantic similarity measure. However, both PMI and LSA are semantic similarity measure. Similarly, Hassan and Radev (2010) presented a graph-based method for predicting SO of words. They constructed a lexical graph where nodes are words and edges connect two words with semantic similarity obtained from Wordnet (Fellbaum 1998). They propagated the SO of a set of seeds through this graph. However, such approaches did not take into account the sentiment similarity between words.

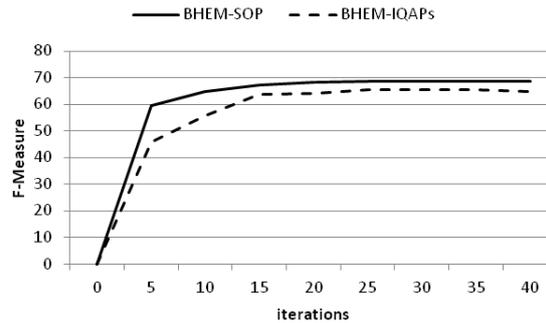

Figure 10. Convergence of BHEM

In IQAPs, Marneffe et al. (2010) inferred the *yes/no* answers using SO of the adjectives. If SO of the adjectives have different signs, then the answer conveys *no*, and Otherwise, if the absolute value of SO for the adjective in question is smaller than the absolute value of the adjective in answer, then the answer conveys *yes*, and otherwise *no*. In Mohtarami et al. (2012), we used two semantic similarity measures (PMI and LSA) for the IQAP inference task. We showed that measuring the sentiment similarities between the adjectives in question and answer leads to higher performance as compared to semantic similarity measures.

In Mohtarami et al. (2012), we proposed an approach to predict the sentiment similarity of words using their emotional vectors. We assumed that the type and number of emotions are pre-defined and our approach was based on this assumption. However, in previous research, there is little agreement about the number and types of basic emotions. Furthermore, the emotions in different dataset can be varied. We relaxed this assumption in Mohtarami et al., (2013) by considering the emotions as hidden and presented a hidden emotional model called SHEM. This paper also consider the emotions as hidden and presents another hidden emotional model called BHEM that gives more accurate estimation of the numbers and types of the hidden emotions.

## 9 Conclusion

We propose a probabilistic approach to infer the sentiment similarity between word senses with respect to automatically learned hidden emotions. We propose to utilize the correlations between reviews, ratings, and words to learn the hidden emotions. We show the effectiveness of our method in two NLP tasks. Experiments show that our sentiment similarity models lead to effective emotional vector construction and significantly outperform semantic similarity measures for the two NLP task.

# A user-centric model of voting intention from Social Media

Vasileios Lampos, Daniel Preotiuc-Pietro and Trevor Cohn

Computer Science Department

University of Sheffield, UK

{v.lampos,d.preotiuc,t.cohn}@dcs.shef.ac.uk

## Abstract

Social Media contain a multitude of user opinions which can be used to predict real-world phenomena in many domains including politics, finance and health. Most existing methods treat these problems as linear regression, learning to relate word frequencies and other simple features to a known response variable (*e.g.*, voting intention polls or financial indicators). These techniques require very careful filtering of the input texts, as most Social Media posts are irrelevant to the task. In this paper, we present a novel approach which performs high quality filtering automatically, through modelling not just words but also users, framed as a bilinear model with a sparse regulariser. We also consider the problem of modelling groups of related output variables, using a structured multi-task regularisation method. Our experiments on voting intention prediction demonstrate strong performance over large-scale input from Twitter on two distinct case studies, outperforming competitive baselines.

## 1 Introduction

Web Social Media platforms have ushered a new era in human interaction and communication. The main by-product of this activity is vast amounts of user-generated content, a type of information that has already attracted the interest of both marketers and scientists because it offers – for the first time at a large-scale – unmediated access to people’s observations and opinions.

One exciting avenue of research concentrates on mining interesting signals automatically from this stream of text input. For example, by exploiting Twitter posts, it is possible to infer time series

that correlate with financial indicators (Bollen et al., 2011), track infectious diseases (Lampos and Cristianini, 2010; Lampos et al., 2010; Paul and Dredze, 2011) and, in general, nowcast the magnitude of events emerging in real-life (Sakaki et al., 2010; Lampos and Cristianini, 2012). Other studies suggest ways for modelling opinions encapsulated in this content in order to forge branding strategies (Jansen et al., 2009) or understand various socio-political trends (Tumasjan et al., 2010; O’Connor et al., 2010; Lansdall-Welfare et al., 2012). The main theme of the aforementioned works is linear regression between word frequencies and a real-world quantity. They also tend to incorporate hand-crafted lists of search terms to filter irrelevant content and use sentiment analysis lexicons for extracting opinion bias. Consequently, they are quite often restricted to a specific application and therefore, generalise poorly to new data sets (Gayo-Avello et al., 2011).

In this paper, we propose a generic method that aims to be independent of the characteristics described above (use of search terms or sentiment analysis tools). Our approach is able to explore not only word frequencies, but also the space of users by introducing a **bilinear** formulation for this learning task. Regularised regression on both spaces allows for an automatic selection of the most important terms and users, performing at the same time an improved noise filtering. In addition, more advanced regularisation functions enable **multi-task learning** schemes that can exploit shared structure in the feature space. The latter property becomes very useful in **multi-output regression** scenarios, where selected features are expected to have correlated as well as anti-correlated impact on each output (*e.g.*, when inferring voting intentions for competing political parties).

We evaluate our methods on the domain of politics using data from the microblogging service of Twitter to infer voting trends. Our pro-

posed framework is able to successfully predict voting intentions for the top-3 and top-4 parties in the United Kingdom (UK) and Austria respectively. In both case studies – bound by different characteristics (including language, time-span and number of users) – the average prediction error is smaller than 1.5% for our best model using multi-task learning. Finally, our qualitative analysis shows that the models uncover interesting and semantically interpretable insights from the data.

## 2 Data

For the evaluation of the proposed methodologies we have created two data sets of Social Media content with different characteristics based in the UK and Austria respectively. They are used for performing regression aiming to infer voting intention polls in those countries. Data processing is performed using the TrendMiner architecture for Social Media analysis (Preoțiuc-Pietro et al., 2012).

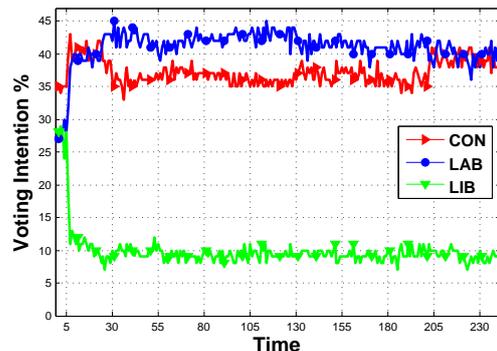

### 2.1 Tweets from users in the UK

The first data set (we refer to it as  $C_{uk}$ ) used in our experimental process consists of approx. 60 million tweets produced by approx. 42K UK Twitter users from 30/04/2010 to 13/02/2012. We assumed each user to be from the UK, if the location field in their profile matched with a list of common UK locations and their time zone was set to G.M.T. In this way, we were able to extract hundreds of thousands of UK users, from which we sub-sampled 42K users to be distributed across the UK geographical regions proportionally to their population figures.<sup>1</sup>

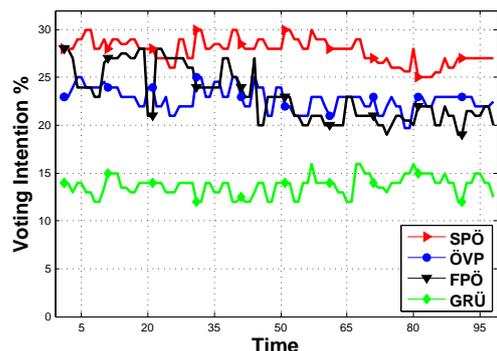

### 2.2 Tweets for Austria

The second data set ( $C_{au}$ ) is shorter in terms of the number of users involved (1.1K), its time span (25/01 to 01/12/2012) and, consequently, of the total number of tweets considered (800K). However, this time the selection of users has been made by Austrian political experts who decided which accounts to monitor by subjectively assessing the value of information they may provide towards political-oriented topics. Still, we assume that the different users will produce information of varying quality, and some should be eliminated entirely. However, we emphasise that there may be smaller

<sup>1</sup>Data collection was performed using Twitter API, <http://dev.twitter.com/>, to extract all posts for our target users.

(a) 240 voting intention polls for the 3 major parties in the UK (April 2010 to February 2012)

(b) 98 voting intention polls for the 4 major parties in Austria (January to December 2012)

Figure 1: Voting intention polls for the UK and Austria.

potential gains from user modelling compared to the UK case study. Another important distinction is language, which for this data set is primarily German with some English.

### 2.3 Ground Truth

The ground truth for training and evaluating our regression models is formed by voting intention polls from YouGov (UK) and a collection of Austrian pollsters<sup>2</sup> – as none performed high frequency polling – for the Austrian case study. We focused on the three major parties in the UK, namely Conservatives (CON), Labour (LAB) and Liberal Democrats (LBD) and the four major parties in Austria, namely the Social Democratic Party (SPÖ), People’s Party (ÖVP), Freedom Party (FPÖ) and the Green Alternative Party (GRÜ). Matching with the time spans of the data sets described in the previous sections, we have acquired 240 unique polls for the UK and 65 polls for Austria. The latter have been expanded to 98 polls by replicating the poll of day  $i$  for day

<sup>2</sup>Wikipedia, [http://de.wikipedia.org/wiki/Nationalratswahl\\_in\\_%D6sterreich\\_2013](http://de.wikipedia.org/wiki/Nationalratswahl_in_%D6sterreich_2013).

$i - 1$  where possible.<sup>3</sup> There exists some interesting variability towards the end for the UK polls (Fig. 1a), whereas for the Austrian case, the main changing point is between the second and the third party (Fig. 1b).

### 3 Methods

The textual content posted on Social Media platforms unarguably contains valuable information, but quite often it is hidden under vast amounts of unstructured user generated input. In this section, we propose a set of methods that build on one another, which aim to filter the non desirable noise and extract the most informative features not only based on word frequencies, but also by incorporating users in this process.

#### 3.1 The bilinear model

There exist a number of different possibilities for incorporating user information into a regression model. A simple approach is to expand the feature set, such that each user’s effect on the response variable can be modelled separately. Although flexible, this approach would be doomed to failure due to the sheer size of the resulting feature set, and the propensity to overfit all but the largest of training sets. One solution is to group users into different types, such as journalist, politician, activist, etc., but this presupposes a method for classification or clustering of users which is a non-trivial undertaking. Besides, these naïve approaches fail to account for the fact that most users use similar words to express their opinions, by separately parameterising the model for different users or user groups.

We propose to account for individual users while restricting all users to share the same vocabulary. This is formulated as a bilinear predictive model,

$$f(X) = \mathbf{u}^T X \mathbf{w} + \beta, \quad (1)$$

where  $X$  is an  $m \times p$  matrix of user-word frequencies and  $\mathbf{u}$  and  $\mathbf{w}$  are the model parameters. Let  $\mathcal{Q} \in \mathbb{R}^{n \times m \times p}$  be a tensor which captures our training inputs, where  $n$ ,  $m$  and  $p$  denote the considered number of samples (each sample usually refers to a day), terms and users respectively;  $\mathcal{Q}$  can simply be interpreted as  $n$  versions of  $X$  (denoted by  $\mathcal{Q}_i$  in the remainder of the script), a different one for each day, put together. Each element

<sup>3</sup>This has been carried out to ensure an adequate number of training points in the experimental process.

$\mathcal{Q}_{ijk}$  holds the frequency of term  $j$  for user  $k$  during the day  $i$  in our sample. If a user  $k$  has posted  $c_{i,k}$  tweets during day  $i$ , and  $c_{ijk} \leq c_{i,k}$  of them contain a term  $j$ , then the frequency of  $j$  for this day and user is defined as  $\mathcal{Q}_{ijk} = \frac{c_{ijk}}{c_{i,k}}$ .

Aiming to learn sparse sets of users and terms that are representative of the voting intention signal, we formulate our optimisation task as follows:

$$\{\mathbf{w}^*, \mathbf{u}^*, \beta^*\} = \underset{\mathbf{w}, \mathbf{u}, \beta}{\operatorname{argmin}} \sum_{i=1}^n (\mathbf{u}^T \mathcal{Q}_i \mathbf{w} + \beta - y_i)^2 + \psi(\mathbf{w}, \rho_1) + \psi(\mathbf{u}, \rho_2), \quad (2)$$

where  $\mathbf{y} \in \mathbb{R}^n$  is the response variable (voting intention),  $\mathbf{w} \in \mathbb{R}^m$  and  $\mathbf{u} \in \mathbb{R}^p$  denote the term and user weights respectively,  $\mathbf{u}^T \mathcal{Q}_i \mathbf{w}$  expresses the bilinear term,  $\beta \in \mathbb{R}$  is a bias term and  $\psi(\cdot)$  is a regularisation function with parameters  $\rho_1$  or  $\rho_2$ . The first term in Eq. 2 is the standard regularisation loss function, namely the sum squared error over the training instances.<sup>4</sup>

In the main formulation of our bilinear model, as the regularisation function  $\psi(\cdot)$  we use the **elastic net** (Zou and Hastie, 2005), an extension of the well-studied  $\ell_1$ -norm regulariser, known as the LASSO (Tibshirani, 1996). The  $\ell_1$ -norm regularisation has found many applications in several scientific fields as it encourages sparse solutions which reduce the possibility of overfitting and enhance the interpretability of the inferred model (Hastie et al., 2009). The elastic net applies an extra penalty on the  $\ell_2$ -norm of the weight vector, and can resolve instability issues of LASSO which arise when correlated predictors exist in the input data (Zhao and Yu, 2006). Its regularisation function  $\psi_{\text{el}}(\cdot)$  is defined by:

$$\psi_{\text{el}}(\mathbf{w}, \lambda, \alpha) = \lambda \left( \frac{1 - \alpha}{2} \|\mathbf{w}\|_2^2 + \alpha \|\mathbf{w}\|_1 \right), \quad (3)$$

where  $\lambda > 0$  and  $\alpha \in [0, 1)$ ; setting parameter  $\alpha$  to its extremes transforms elastic net to ridge regression ( $\alpha = 0$ ) or vanilla LASSO ( $\alpha = 1$ ).

Eq. 2 can be treated as a biconvex learning task (Al-Khayyal and Falk, 1983), by observing that for a fixed  $\mathbf{w}$ , learning  $\mathbf{u}$  is a convex problem and vice versa. Biconvex functions and possible applications have been well studied in the optimisation literature (Quesada and Grossmann, 1995;

<sup>4</sup>Note that other loss functions could be used here, such as logistic loss for classification, or more generally bilinear variations of Generalised Linear Models (Nelder and Wedderburn, 1972).

Pirsiavash et al., 2009). Their main advantage is the ability to solve efficiently non-convex problems by a repeated application of two convex processes, *i.e.*, a form of coordinate ascent. In our case, the bilinear technique makes it possible to explore both word and user spaces, while maintaining a modest training complexity.

Therefore, in our bilinear approach we divide learning in two phases, where we learn word and user weights respectively. For the first phase we produce the term-scores matrix  $\mathcal{V} \in \mathbb{R}^{n \times m}$  with elements given by:

$$\mathcal{V}_{ij} = \sum_{z=1}^p u_z \mathcal{Q}_{ijz}. \quad (4)$$

$\mathcal{V}$  contains weighted sums of term frequencies over all users for the considered set of days. The weights are held in  $\mathbf{u}$  and are representative of each user. The initial optimisation task is formulated as:

$$\{\mathbf{w}^*, \beta^*\} = \underset{\mathbf{w}, \beta}{\operatorname{argmin}} \|\mathcal{V}\mathbf{w} + \beta - \mathbf{y}\|_2^2 + \psi_{\text{el}}(\mathbf{w}, \lambda_1, \alpha_1), \quad (5)$$

where we aim to learn a sparse but consistent set of weights  $w^*$  for the terms of our vocabulary.

In the second phase, we are using  $\mathbf{w}^*$  to form the user-scores matrix  $\mathcal{D} \in \mathbb{R}^{n \times p}$ :

$$\mathcal{D}_{ik} = \sum_{z=1}^m w_z^* \mathcal{Q}_{izk}, \quad (6)$$

which now contains weighted sums over all terms for the same set of days. The optimisation task becomes:

$$\{\mathbf{u}^*, \beta^*\} = \underset{\mathbf{u}, \beta}{\operatorname{argmin}} \|\mathcal{D}\mathbf{u} + \beta - \mathbf{y}\|_2^2 + \psi_{\text{el}}(\mathbf{u}, \lambda_2, \alpha_2). \quad (7)$$

This process continues iteratively by inserting the weights of the second phase back to phase one, and so on until convergence. We cannot claim that a global optimum will be reached, but biconvexity guarantees that our global objective (Eq. 2) will decrease in each step of this iterative process. In the remainder of this paper, we refer to the method described above as Bilinear Elastic Net (**BEN**).

### 3.2 Exploiting term-target or user-target relationships

The previous model assumes that the response variable  $\mathbf{y}$  holds information about a single infer-

ence target. However, the task that we are addressing in this paper usually implies the existence of several targets, *i.e.*, different political parties or politicians. An important property, therefore, is the ability to perform multiple output regression. A simple way of adapting the model to the multiple output scenario is by framing a separate learning problem for each output, but tying together some of the parameters. Here we consider tying together the user weights  $\mathbf{u}$ , to enforce that the same set of users are relevant to all tasks, while learning different term weights. Note that the converse situation, where  $\mathbf{w}$ 's are tied and  $\mathbf{u}$ 's are independent, can be formulated in an equivalent manner.

Suppose that our target variable  $\mathbf{y} \in \mathbb{R}^{\tau n}$  refers now to  $\tau$  political entities,  $\mathbf{y} = [\mathbf{y}_1^T \mathbf{y}_2^T \dots \mathbf{y}_\tau^T]^T$ ; in this formation the top  $n$  elements of  $\mathbf{y}$  match to the first political entity, the next  $n$  elements to the second and so on. In the first phase of the bilinear model, we would have to solve the following optimisation task:

$$\{\mathbf{w}^*, \beta^*\} = \underset{\mathbf{w}, \beta}{\operatorname{argmin}} \sum_{i=1}^{\tau} \|\mathcal{V}\mathbf{w}_i + \beta_i - \mathbf{y}_i\|_2^2 + \sum_{i=1}^{\tau} \psi_{\text{el}}(\mathbf{w}_i, \lambda_1, \alpha_1), \quad (8)$$

where  $\mathcal{V}$  is given by Eq. 4 and  $\mathbf{w}^* \in \mathbb{R}^{\tau m}$  denotes the vector of weights which can be sliced into  $\tau$  sub-vectors  $\{\mathbf{w}_1^*, \dots, \mathbf{w}_\tau^*\}$  each one representing a political entity. In the second phase, sub-vectors  $\mathbf{w}_i^*$  are used to form the input matrices  $\mathcal{D}_i$ ,  $i \in \{1, \dots, \tau\}$  with elements given by Eq. 6. The input matrix  $\mathcal{D}'$  is formed by the vertical concatenation of all  $\mathcal{D}_i$  user score matrices, *i.e.*,  $\mathcal{D}' = [\mathcal{D}_1^T \dots \mathcal{D}_\tau^T]^T$ , and the optimisation target is equivalent to the one expressed in Eq. 7. Since  $\mathcal{D}' \in \mathbb{R}^{\tau n \times p}$ , the user weight vector  $\mathbf{u}^* \in \mathbb{R}^p$  and thus, we are learning a single weight per user and not one per political party as in the previous step.

The method described above allows learning different term weights per response variable and then binds them under a shared set of user weights. As mentioned before, one could also try the opposite (*i.e.*, start by expanding the user space); both those models can also be optimised in an iterative process. However, our experiments revealed that those approaches did not improve on the performance of BEN. Still, this behaviour could be problem-specific, *i.e.*, learning different words

from a shared set of users (and the opposite) may not be a good modelling practice for the domain of politics. Nevertheless, this observation served as a motivation for the method described in the next section, where we extract a consistent set of words and users that are weighted differently among the considered political entities.

### 3.3 Multi-task learning with the $\ell_1/\ell_2$ regulariser

All previous models – even when combining all inference targets – were not able to explore relationships across the different task domains; in our case, a task domain is defined by a specific political label or party. Ideally, we would like to make a sparse selection of words and users but with a regulariser that promotes inter-task sharing of structure, so that many features may have a positive influence towards one or more parties, but negative towards the remaining one(s). It is possible to achieve this multi-task learning property by introducing a different set of regularisation constraints in the optimisation function.

We perform multi-task learning using an extension of group LASSO (Yuan and Lin, 2006), a method known as  $\ell_1/\ell_2$  regularisation (Argyriou et al., 2008; Liu et al., 2009). Group LASSO exploits a predefined group structure on the feature space and tries to achieve sparsity in the group-level, *i.e.*, it does not perform feature selection (unlike the elastic net), but group selection. The  $\ell_1/\ell_2$  regulariser extends this notion for a  $\tau$ -dimensional response variable. The global optimisation target is now formulated as:

$$\begin{aligned} \{W^*, U^*, \beta^*\} = \\ \underset{W, U, \beta}{\operatorname{argmin}} \sum_{t=1}^{\tau} \sum_{i=1}^n (\mathbf{u}_t^T Q_i \mathbf{w}_t + \beta_t - y_{ti})^2 \quad (9) \\ + \lambda_1 \sum_{j=1}^m \|W_j\|_2 + \lambda_2 \sum_{k=1}^p \|U_k\|_2, \end{aligned}$$

where the input matrix  $Q_i$  is defined in the same way as earlier,  $W = [\mathbf{w}_1 \dots \mathbf{w}_\tau]$  is the term weight matrix (each  $\mathbf{w}_t$  refers to the  $t$ -th political entity or task), equivalently  $U = [\mathbf{u}_1 \dots \mathbf{u}_\tau]$ ,  $W_j$  and  $U_j$  denote the  $j$ -th rows of weight matrices  $W$  and  $U$  respectively, and vector  $\beta \in \mathbb{R}^\tau$  holds the bias terms per task. In this optimisation process, we aim to enforce sparsity in the feature space but in a structured manner. Notice that we are now regularising the  $\ell_{2,1}$  mixed norm of  $W$  and  $U$ , which is

defined as the sum of the row  $\ell_2$ -norms for those matrices. As a result, we expect to encourage the activation of a sparse set of features (corresponding to the rows of  $W$  and  $U$ ), but with nonzero weights across the  $\tau$  tasks (Argyriou et al., 2008). Consequently, we are performing filtering (many users and words will have zero weights) and, at the same time, assign weights of different magnitude and sign on the selected features, something that suits a political opinion mining application, where pro-A often means anti-B.

Eq. 9 can be broken into two convex tasks (following the same notion as in Eqs. 5 and 7), where we individually learn  $\{W, \beta\}$  and then  $\{U, \beta\}$ ; each step of the process is a standard linear regression problem with an  $\ell_1/\ell_2$  regulariser. Again, we are able to iterate this bilinear process and in each step convexity is guaranteed. We refer to this method as Bilinear Group  $\ell_1/\ell_2$  (BGL).

## 4 Experiments

The proposed models are evaluated on  $C_{uk}$  and  $C_{au}$  which have been introduced in Section 2. We measure predictive performance, compare it to the performance of several competitive baselines, and provide a qualitative analysis of the parameters learned by the models.

### 4.1 Data preprocessing

Basic preprocessing has been applied on the vocabulary index of  $C_{uk}$  and  $C_{au}$  aiming to filter out some of the word features and partially reduce the dimensionality of the problem. Stop words and web links were removed in both sets, together with character sequences of length  $<4$  and  $<3$  for  $C_{uk}$  and  $C_{au}$  respectively.<sup>5</sup> As the vocabulary size of  $C_{uk}$  was significantly larger, for this data set we have additionally merged Twitter hashtags (*i.e.*, words starting with ‘#’) with their exact non topic word match, where possible (by dropping the ‘#’ when the word existed in the index). After performing the preprocessing routines described above, the vocabulary sizes for  $C_{uk}$  and  $C_{au}$  were set to 80,976 and 22,917 respectively.

### 4.2 Predictive accuracy

To evaluate the predictive accuracy of our methods, we have chosen to emulate a real-life scenario

<sup>5</sup>Most of the times those character sequences were not valid words. This pattern was different in each language and thus, a different filtering threshold was applied in each data set.

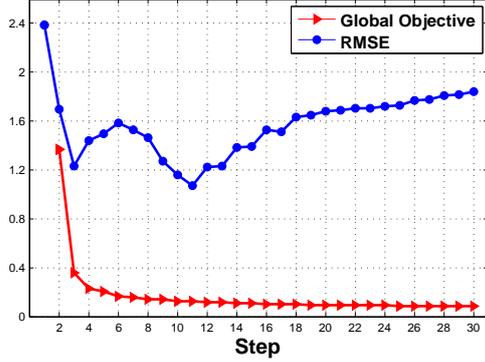

Figure 2: Global objective function and RMSE on a validation set for **BEN** in 15 iterations (30 steps) of the model.

of voting intention prediction. The evaluation process starts by using a fixed set of polls matching to consecutive time points in the past for training and validating the parameters of each model. Testing is performed on the following  $\delta$  (unseen) polls of the data set. In the next step of the evaluation process, the training/validation set is increased by merging it with the previously used test set ( $\delta$  polls), and testing is now performed on the next  $\delta$  unseen polls. In our experiments, the number of steps in this evaluation process is set to 10 and in each step the size of the test set is set to  $\delta = 5$  polls. Hence, each model is tested on 50 unseen and consecutive in time samples. The loss function in our evaluation is the standard Mean Square Error (**MSE**), but to allow a better interpretation of the results, we display its root (**RMSE**) in tables and figures.<sup>6</sup>

The parameters of each model ( $\alpha_i$  for **BEN** and  $\lambda_i$  for **BEN** and **BGL**,  $i \in \{1, 2\}$ ) are optimised using a held-out validation set by performing grid search. Note that it may be tempting to adapt the regularisation parameters in each phase of the iterative training loop, however this would change the global objective (see Eqs. 2 and 9) and thus convergence will not be guaranteed. A key question is how many iterations of training are required to reach convergence. Figure 2 illustrates how the **BEN** global objective function (Eq. 2) converges during this iterative process and the model’s performance on an unseen validation set. Notice that there is a large performance improvement after the first step (which alone is a linear solver), but overfitting occurs after step 11. Based on this result, for subsequent experiments we run the training process for two iterations (4 steps), and take the

<sup>6</sup>RMSE has the same metric units as the response variable.

Table 2: Austrian case study — Average RMSEs for the 10-step validation process.

best performing model on the held-out validation set.

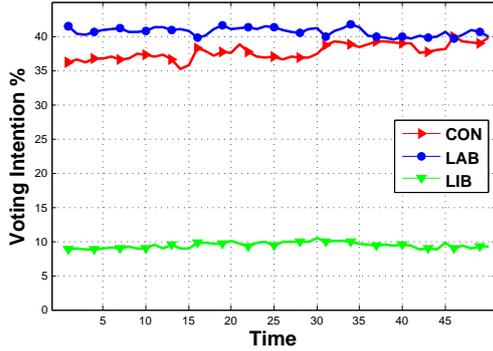

We compare the performance of our methods with three baselines. The first makes a constant prediction of the mean value of the response variable  $\mathbf{y}$  in the training set (**B $_{\mu}$** ); the second predicts the last value of  $\mathbf{y}$  (**B $_{last}$** ); and the third baseline (**LEN**) is a linear regression over the terms using elastic net regularisation. Recalling that each test set is made of 5 polls, **B $_{last}$**  should be considered as a hard baseline to beat<sup>7</sup> given that voting intentions tend to have a smooth behaviour. Moreover, improving on **LEN** partly justifies the usefulness of a bilinear approach compared to a linear one.

Performance results comparing inferred voting intention percentages and polls for  $C_{uk}$  and  $C_{au}$  are presented in Tables 1 and 2 respectively. For the UK case study, both **BEN** and **BGL** are able to beat all baselines in average performance across all parties. However in the Austrian case study, **LEN** performs better than **BEN**, something that could be justified by the fact that the users in  $C_{au}$  were selected by domain experts, and consequently there was not much gain to be had by filtering them further. Nevertheless, the difference in performance was rather small (approx. 0.26% error) and the in-

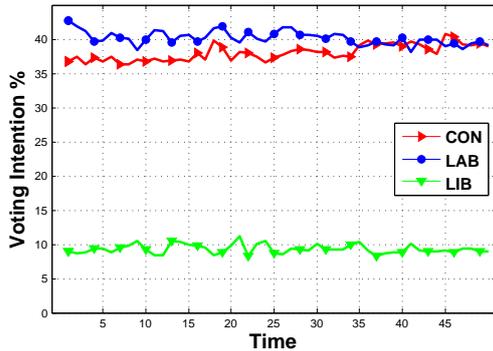

<sup>7</sup>The last response value could be easily included as a feature in the model, and would likely improve predictive performance.

(a) Ground Truth (polls)

ferences of LEN and BEN followed a very similar pattern ( $\bar{\rho} = .94$  with  $p < 10^{-10}$ ).<sup>8</sup> Multi-task learning (BGL) delivered the best inference performance in both case studies, which was on average smaller than 1.48% (RMSE).

Inferences for both BEN and BGL have been plotted on Figures 3 and 4. They are presented as continuous lines of 50 inferred points (per party) which are created by concatenating the inferences

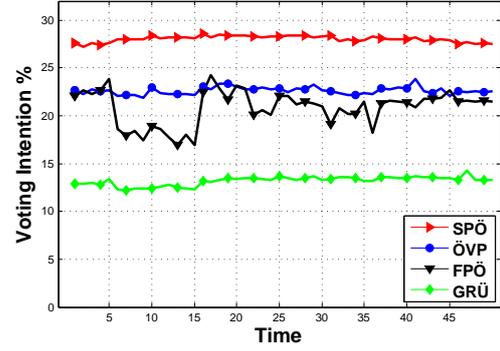

<sup>8</sup>Pearson’s linear correlation averaged across the four Austrian parties.

on all test sets.<sup>9</sup> For the UK case study, one may observe that BEN (Fig. 3b) cannot register any change – with the exception of one test point – in the leading party fight (CON versus LAB); BGL (Fig. 3c) performs much better in that aspect. In the Austrian case study this characteristic becomes more obvious. BEN (Fig. 4b) consistently predicts the wrong ranking of ÖVP and FPÖ, whereas BGL (Fig. 4c) does much better. Most importantly, a

<sup>9</sup>Voting intention polls were plotted separately to allow a better presentation.

Table 3: Examples of tweets amongst the ones with top positive and negative scores per party for both  $C_{uk}$  and  $C_{au}$  data sets (tweets in Austrian have been translated in English as well). Notice that weight magnitude may differ per case study and party as they are based on the range of the response variable and the total number of selected features.

general observation is that BEN's predictions are smooth and do not vary significantly with time. This might be a result of overfitting the model to a single response variable which usually has a smooth behaviour. On the contrary, the multi-task learning property of BGL reduces this type of overfitting providing more statistical evidence for the terms and users and thus, yielding not only a better inference performance, but also a more accurate model.

### 4.3 Qualitative Analysis

In this section, we refer to features that have been selected and weighted as significant by our bi-

linear learning functions. Based on the weights for the word and the user spaces that we retrieve after the application of BGL in the last step of the evaluation process (see the previous section), we compute a score (weighted sum) for each tweet in our training data sets for both  $C_{uk}$  and  $C_{au}$ . Table 3 shows examples of interesting tweets amongst the top weighted ones (positively as well as negatively) per party. Together with their text (anonymised for privacy reasons) and scores, we also provide an attribute for the author (if present). In the displayed tweets for the UK study, the only possible outlier is the 'Art Fanzine'; still, it seems to register a consistent behaviour (positive towards

LAB, negative towards LBD) and, of course, hidden, indirect relationships may exist between political opinion and art. The Austrian case study revealed even more interesting tweets since training was conducted on data from a very active pre-election period (we made an effort to translate those tweets in English language as well). For a better interpretation of the presented tweets, it may be useful to know that ‘*Johannes Voggenhuber*’ (who receives a positive comment for his book) and ‘*Peter Pilz*’ (whose comment is questioned) are members of GRÜ, ‘*Krone*’ (or *Kronen Zeitung*) is the major newspaper in Austria<sup>10</sup> and that FPÖ is labelled as a far right party, something that may cause various reactions from ‘*Human Rights*’ organisations.

## 5 Related Work

The topic of political opinion mining from Social Media has been the focus of various recent research works. Several papers have presented methods that aim to predict the result of an election (Tumasjan et al., 2010; Bermingham and Smeaton, 2011) or to model voting intention and other kinds of socio-political polls (O’Connor et al., 2010; Lampos, 2012). Their common feature is a methodology based on a meta-analysis of word frequencies using off-the-shelf sentiment tools such as LIWC (Pennebaker et al., 2007) or Senti-WordNet (Esuli and Sebastiani, 2006). Moreover, the proposed techniques tend to incorporate posting volume figures as well as hand-crafted lists of words relevant to the task (*e.g.*, names of politicians or parties) in order to filter the content successfully.

Such papers have been criticised as their methods do not generalise when applied on different data sets. According to the work in (Gayo-Avello et al., 2011), the methods presented in (Tumasjan et al., 2010) and (O’Connor et al., 2010) failed to predict the result of US congressional elections in 2009. We disagree with the arguments supporting the statement “you cannot predict elections with Twitter” (Gayo-Avello, 2012), as many times in the past actual voting intention polls have also failed to predict election outcomes, but we agree that most methods that have been proposed so far were not entirely generic. It is a fact that the

<sup>10</sup>“Accused of abusing its near monopoly to manipulate public opinion in Austria”, Wikipedia, 19/02/2013, [http://en.wikipedia.org/wiki/Kronen\\_Zeitung](http://en.wikipedia.org/wiki/Kronen_Zeitung).

majority of sentiment analysis tools are English-specific (or even American English) and, most importantly, political word lists (or ontologies) change in time, per country and per party; hence, generalisable methods should make an effort to limit reliance from such tools.

Furthermore, our work – indirectly – meets the guidelines proposed in (Metaxas et al., 2011) as we have developed a framework of “well-defined” algorithms that are “Social Web aware” (since the bilinear approach aims to improve noise filtering) and that have been tested on two evaluation scenarios with distinct characteristics.

## 6 Conclusions and Future Work

We have presented a novel method for text regression that exploits both word and user spaces by solving a bilinear optimisation task, and an extension that applies multi-task learning for multi-output inference. Our approach performs feature selection – hence, noise filtering – on large-scale user-generated inputs automatically, generalises across two languages without manual adaptations and delivers some significant improvements over strong performance baselines (< 1.5% error when predicting polls). The application domain in this paper was politics, though the presented methods are generic and could be easily applied on various other domains, such as health or finance.

Future work may investigate further modelling improvements achieved by applying different regularisation functions as well as the adaptation of the presented models to classification problems. Finally, in the application level, we aim at an in-depth analysis of patterns and characteristics in the extracted sets of features by collaborating with domain experts (*e.g.*, political analysts).

## Acknowledgments

This work was funded by the TrendMiner project (EU-FP7-ICT n.287863). All authors would like to thank the political analysts (and especially Paul Ringler) from SORA<sup>11</sup> for their useful insights on politics in Austria.

# Using Supervised Bigram-based ILP for Extractive Summarization

Chen Li, Xian Qian, and Yang Liu

The University of Texas at Dallas

Computer Science Department

chenli, qx, yangl@hlt.utdallas.edu

## Abstract

In this paper, we propose a bigram based supervised method for extractive document summarization in the integer linear programming (ILP) framework. For each bigram, a regression model is used to estimate its frequency in the reference summary. The regression model uses a variety of indicative features and is trained discriminatively to minimize the distance between the estimated and the ground truth bigram frequency in the reference summary. During testing, the sentence selection problem is formulated as an ILP problem to maximize the bigram gains. We demonstrate that our system consistently outperforms the previous ILP method on different TAC data sets, and performs competitively compared to the best results in the TAC evaluations. We also conducted various analysis to show the impact of bigram selection, weight estimation, and ILP setup.

## 1 Introduction

Extractive summarization is a sentence selection problem: identifying important summary sentences from one or multiple documents. Many methods have been developed for this problem, including supervised approaches that use classifiers to predict summary sentences, graph based approaches to rank the sentences, and recent global optimization methods such as integer linear programming (ILP) and submodular methods. These global optimization methods have been shown to be quite powerful for extractive summarization, because they try to select important sentences and remove redundancy at the same time under the length constraint.

Gillick and Favre (Gillick and Favre, 2009) introduced the concept-based ILP for summariza-

tion. Their system achieved the best result in the TAC 09 summarization task based on the ROUGE evaluation metric. In this approach the goal is to maximize the sum of the weights of the language concepts that appear in the summary. They used bigrams as such language concepts. The association between the language concepts and sentences serves as the constraints. This ILP method is formally represented as below (see (Gillick and Favre, 2009) for more details):

$$\max \quad \sum_i w_i c_i \quad (1)$$

$$s.t. \quad s_j Occ_{ij} \leq c_i \quad (2)$$

$$\sum_j s_j Occ_{ij} \geq c_i \quad (3)$$

$$\sum_j l_j s_j \leq L \quad (4)$$

$$c_i \in \{0, 1\} \forall i \quad (5)$$

$$s_j \in \{0, 1\} \forall j \quad (6)$$

$c_i$  and  $s_j$  are binary variables (shown in (5) and (6)) that indicate the presence of a concept and a sentence respectively.  $w_i$  is a concept's weight and  $Occ_{ij}$  means the occurrence of concept  $i$  in sentence  $j$ . Inequalities (2)(3) associate the sentences and concepts. They ensure that selecting a sentence leads to the selection of all the concepts it contains, and selecting a concept only happens when it is present in at least one of the selected sentences.

There are two important components in this concept-based ILP: one is how to select the concepts ( $c_i$ ); the second is how to set up their weights ( $w_i$ ). Gillick and Favre (Gillick and Favre, 2009) used bigrams as concepts, which are selected from a subset of the sentences, and their document frequency as the weight in the objective function.

In this paper, we propose to find a candidate summary such that the language concepts (e.g., bigrams) in this candidate summary and the reference summary can have the same frequency. We expect this restriction is more consistent with the

ROUGE evaluation metric used for summarization (Lin, 2004). In addition, in the previous concept-based ILP method, the constraints are with respect to the appearance of language concepts, hence it cannot distinguish the importance of different language concepts in the reference summary. Our method can decide not only which language concepts to use in ILP, but also the frequency of these language concepts in the candidate summary. To estimate the bigram frequency in the summary, we propose to use a supervised regression model that is discriminatively trained using a variety of features. Our experiments on several TAC summarization data sets demonstrate this proposed method outperforms the previous ILP system and often the best performing TAC system.

## 2 Proposed Method

### 2.1 Bigram Gain Maximization by ILP

We choose bigrams as the language concepts in our proposed method since they have been successfully used in previous work. In addition, we expect that the bigram oriented ILP is consistent with the ROUGE-2 measure widely used for summarization evaluation.

We start the description of our approach for the scenario where a human abstractive summary is provided, and the task is to select sentences to form an extractive summary. Then Our goal is to make the bigram frequency in this system summary as close as possible to that in the reference. For each bigram  $b$ , we define its gain:

$$\text{Gain}(b, \text{sum}) = \min\{n_{b,ref}, n_{b,sum}\} \quad (7)$$

where  $n_{b,ref}$  is the frequency of  $b$  in the reference summary, and  $n_{b,sum}$  is the frequency of  $b$  in the automatic summary. The gain of a bigram is no more than its frequency in the reference summary, hence adding redundant bigrams will not increase the gain.

The total gain of an extractive summary is defined as the sum of every bigram gain in the summary:

$$\begin{aligned} \text{Gain}(\text{sum}) &= \sum_b \text{Gain}(b, \text{sum}) \\ &= \sum_b \min\{n_{b,ref}, \sum_s z(s) * n_{b,s}\} \end{aligned} \quad (8)$$

where  $s$  is a sentence in the document,  $n_{b,s}$  is the frequency of  $b$  in sentence  $s$ ,  $z(s)$  is a binary variable, indicating whether  $s$  is selected in the

summary. The goal is to find  $z$  that maximizes  $\text{Gain}(\text{sum})$  (formula (8)) under the length constraint  $L$ .

This problem can be casted as an ILP problem. First, using the fact that

$$\min\{a, x\} = 0.5(-|x - a| + x + a), \quad x, a \geq 0$$

we have

$$\begin{aligned} \sum_b \min\{n_{b,ref}, \sum_s z(s) * n_{b,s}\} &= \\ \sum_b 0.5 * (-|n_{b,ref} - \sum_s z(s) * n_{b,s}| + & \\ n_{b,ref} + \sum_s z(s) * n_{b,s}) & \end{aligned}$$

Now the problem is equivalent to:

$$\begin{aligned} \max_z \quad & \sum_b (-|n_{b,ref} - \sum_s z(s) * n_{b,s}| + \\ & n_{b,ref} + \sum_s z(s) * n_{b,s}) \\ \text{s.t.} \quad & \sum_s z(s) * |S| \leq L; \quad z(s) \in \{0, 1\} \end{aligned}$$

This is equivalent to the ILP:

$$\max \quad \sum_b (\sum_s z(s) * n_{b,s} - C_b) \quad (9)$$

$$\text{s.t.} \quad \sum_s z(s) * |S| \leq L \quad (10)$$

$$z(s) \in \{0, 1\} \quad (11)$$

$$-C_b \leq n_{b,ref} - \sum_s z(s) * n_{b,s} \leq C_b \quad (12)$$

where  $C_b$  is an auxiliary variable we introduce that is equal to  $|n_{b,ref} - \sum_s z(s) * n_{b,s}|$ , and  $n_{b,ref}$  is a constant that can be dropped from the objective function.

### 2.2 Regression Model for Bigram Frequency Estimation

In the previous section, we assume that  $n_{b,ref}$  is at hand (reference abstractive summary is given) and propose a bigram-based optimization framework for extractive summarization. However, for the summarization task, the bigram frequency is unknown, and thus our first goal is to estimate such frequency. We propose to use a regression model for this.

Since a bigram's frequency depends on the summary length ( $L$ ), we use a normalized frequency

in our method. Let  $n_{b,ref} = N_{b,ref} * L$ , where  $N_{b,ref} = \frac{n(b,ref)}{\sum_b n(b,ref)}$  is the normalized frequency in the summary. Now the problem is to automatically estimate  $N_{b,ref}$ .

Since the normalized frequency  $N_{b,ref}$  is a real number, we choose to use a logistic regression model to predict it:

$$N_{b,ref} = \frac{\exp\{w'f(b)\}}{\sum_j \exp\{w'f(b_j)\}} \quad (13)$$

where  $f(b_j)$  is the feature vector of bigram  $b_j$  and  $w'$  is the corresponding feature weight. Since even for identical bigrams  $b_i = b_j$ , their feature vectors may be different ( $f(b_i) \neq f(b_j)$ ) due to their different contexts, we sum up frequencies for identical bigrams  $\{b_i | b_i = b\}$ :

$$\begin{aligned} N_{b,ref} &= \sum_{i, b_i=b} N_{b_i,ref} \\ &= \frac{\sum_{i, b_i=b} \exp\{w'f(b_i)\}}{\sum_j \exp\{w'f(b_j)\}} \end{aligned} \quad (14)$$

To train this regression model using the given reference abstractive summaries, rather than trying to minimize the squared error as typically done, we propose a new objective function. Since the normalized frequency satisfies the probability constraint  $\sum_b N_{b,ref} = 1$ , we propose to use KL divergence to measure the distance between the estimated frequencies and the ground truth values. The objective function for training is thus to minimize the KL distance:

$$\min \sum_b \tilde{N}_{b,ref} \log \frac{\tilde{N}_{b,ref}}{N_{b,ref}} \quad (15)$$

where  $\tilde{N}_{b,ref}$  is the true normalized frequency of bigram  $b$  in reference summaries.

Finally, we replace  $N_{b,ref}$  in Formula (15) with Eq (14) and get the objective function below:

$$\max \sum_b \tilde{N}_{b,ref} \log \frac{\sum_{i, b_i=b} \exp\{w'f(b_i)\}}{\sum_j \exp\{w'f(b_j)\}} \quad (16)$$

This shares the same form as the contrastive estimation proposed by (Smith and Eisner, 2005). We use gradient decent method for parameter estimation, initial  $w$  is set with zero.

## 2.3 Features

Each bigram is represented using a set of features in the above regression model. We use two types of features: word level and sentence level features. Some of these features have been used in previous work (Aker and Gaizauskas, 2009; Brandow et al., 1995; Edmundson, 1969; Radev, 2001):

- Word Level:

- **1. Term frequency1:** The frequency of this bigram in the given topic.
- **2. Term frequency2:** The frequency of this bigram in the selected sentences<sup>1</sup>.
- **3. Stop word ratio:** Ratio of stop words in this bigram. The value can be  $\{0, 0.5, 1\}$ .
- **4. Similarity with topic title:** The number of common tokens in these two strings, divided by the length of the longer string.
- **5. Similarity with description of the topic:** Similarity of the bigram with topic description (see next data section about the given topics in the summarization task).

- Sentence Level: (information of sentence containing the bigram)

- **6. Sentence ratio:** Number of sentences that include this bigram, divided by the total number of the selected sentences.
- **7. Sentence similarity:** Sentence similarity with topic's query, which is the concatenation of topic title and description.
- **8. Sentence position:** Sentence position in the document.
- **9. Sentence length:** The number of words in the sentence.
- **10. Paragraph starter:** Binary feature indicating whether this sentence is the beginning of a paragraph.

## 3 Experiments

### 3.1 Data

We evaluate our method using several recent TAC data sets, from 2008 to 2011. The TAC summarization task is to generate at most 100 words summaries from 10 documents for a given topic query (with a title and more detailed description). For model training, we also included two years' DUC data (2006 and 2007). When evaluating on one TAC data set, we use the other years of the TAC data plus the two DUC data sets as the training data.

<sup>1</sup>See next section about the sentence selection step

### 3.2 Summarization System

We use the same system pipeline described in (Gillick et al., 2008; McDonald, 2007). The key modules in the ICSI ILP system (Gillick et al., 2008) are briefly described below.

- Step 1: Clean documents, split text into sentences.
- Step 2: Extract bigrams from all the sentences, then select those bigrams with document frequency equal to more than 3. We call this subset as initial bigram set in the following.
- Step 3: Select relevant sentences that contain at least one bigram from the initial bigram set.
- Step 4: Feed the ILP with sentences and the bigram set to get the result.
- Step 5: Order sentences identified by ILP as the final result of summary.

The difference between the ICSI and our system is in the 4th step. In our method, we first extract all the bigrams from the selected sentences and then estimate each bigram’s  $N_{b,ref}$  using the regression model. Then we use the top-n bigrams with their  $N_{b,ref}$  and all the selected sentences in our proposed ILP module for summary sentence selection. When training our bigram regression model, we use each of the 4 reference summaries separately, i.e., the bigram frequency is obtained from one reference summary. The same pre-selection of sentences described above is also applied in training, that is, the bigram instances used in training are from these selected sentences and the reference summary.

## 4 Experiment and Analysis

### 4.1 Experimental Results

Table 1 shows the ROUGE-2 results of our proposed system, the ICSI system, and also the best performing system in the NIST TAC evaluation. We can see that our proposed system consistently outperforms ICSI ILP system (the gain is statistically significant based on ROUGE’s 95% confidence interval results). Compared to the best reported TAC result, our method has better performance on three data sets, except 2011 data. Note that the best performing system for the 2009 data is the ICSI ILP system, with an additional compression step. Our ILP method is purely extrac-

tive. Even without using compression, our approach performs better than the full ICSI system. The best performing system for the 2011 data also has some compression module. We expect that after applying sentence compression and merging, we will have even better performance, however, our focus in this paper is on the bigram-based extractive summarization.

	ICSI ILP	Proposed System	TAC Rank1 System
2008	0.1023	<b>0.1076</b>	0.1038
2009	0.1160	<b>0.1246</b>	0.1216
2010	0.1003	<b>0.1067</b>	0.0957
2011	0.1271	0.1327	<b>0.1344</b>

Table 1: ROUGE-2 summarization results.

There are several differences between the ICSI system and our proposed method. First is the bigrams (concepts) used. We use the top 100 bigrams from our bigram estimation module; whereas the ICSI system just used the initial bigram set described in Section 3.2. Second, the weights for those bigrams differ. We used the estimated value from the regression model; the ICSI system just uses the bigram’s document frequency in the original text as weight. Finally, two systems use different ILP setups. To analyze which factors (or all of them) explain the performance difference, we conducted various controlled experiments for these three factors (bigrams, weights, ILP). All of the following experiments use the TAC 2009 data as the test set.

### 4.2 Effect of Bigram Weights

In this experiment, we vary the weighting methods for the two systems: our proposed method and the ICSI system. We use three weighting setups: the estimated bigram frequency value in our method, document frequency, or term frequency from the original text. Table 2 and 3 show the results using the top 100 bigrams from our system and the initial bigram set from the ICSI system respectively. We also evaluate using the two different ILP configurations in these experiments.

First of all, we can see that for both ILP systems, our estimated bigram weights outperform the other frequency-based weights. For the ICSI ILP system, using bigram document frequency achieves better performance than term frequency (which verified why document frequency is used in their system). In contrast, for our ILP method,

#	Weight	ILP	ROUGE-2
1	Estimated value	Proposed	<b>0.1246</b>
2		ICSI	0.1178
3	Document freq	Proposed	0.1109
4		ICSI	0.1132
5	Term freq	Proposed	0.1116
6		ICSI	0.1080

Table 2: Results using different weighting methods on the top 100 bigrams generated from our proposed system.

#	Weight	ILP	ROUGE-2
1	Estimated value	Proposed	0.1157
2		ICSI	<b>0.1161</b>
3	Document freq	Proposed	0.1101
4		ICSI	0.1160
5	Term freq	Proposed	0.1109
6		ICSI	0.1072

Table 3: Results using different weighting methods based on the initial bigram sets. The average number of bigrams is around 80 for each topic.

the bigram’s term frequency is slightly more useful than its document frequency. This indicates that our estimated value is more related to bigram’s term frequency in the original text. When the weight is document frequency, the ICSI’s result is better than our proposed ILP; whereas when using term frequency as the weights, our ILP has better results, again suggesting term frequency fits our ILP system better. When the weight is estimated value, the results depend on the bigram set used. The ICSI’s ILP performs slightly better than ours when it is equipped with the initial bigram, but our proposed ILP has much better results using our selected top100 bigrams. This shows that the size and quality of the bigrams has an impact on the ILP modules.

### 4.3 The Effect of Bigram Set’s size

In our proposed system, we use 100 top bigrams. There are about 80 bigrams used in the ICSI ILP system. A natural question to ask is the impact of the number of bigrams and their quality on the summarization system. Table 4 shows some statistics of the bigrams. We can see that about one third of bigrams in the reference summary are in the original text (127.3 out of 321.93), verifying that people do use different words/bigram when

writing abstractive summaries. We mentioned that we only use the top- $N$  ( $n$  is 100 in previous experiments) bigrams in our summarization system. On one hand, this is to save computational cost for the ILP module. On the other hand, we see from the table that only 127 of these more than 2K bigrams are in the reference summary and are thus expected to help the summary responsiveness. Including all the bigrams would lead to huge noise.

# bigrams in ref summary	321.93
# bigrams in text and ref summary	127.3
# bigrams used in our regression model (i.e., in selected sentences)	2140.7

Table 4: Bigram statistics. The numbers are the average ones for each topic.

Fig 1 shows the bigram coverage (number of bigrams used in the system that are also in reference summaries) when we vary  $N$  selected bigrams. As expected, we can see that as  $n$  increases, there are more reference summary bigrams included in the system. There are 25 summary bigrams in the top-50 bigrams and about 38 in top-100 bigrams. Compared with the ICSI system that has around 80 bigrams in the initial bigram set and 29 in the reference summary, our estimation module has better coverage.

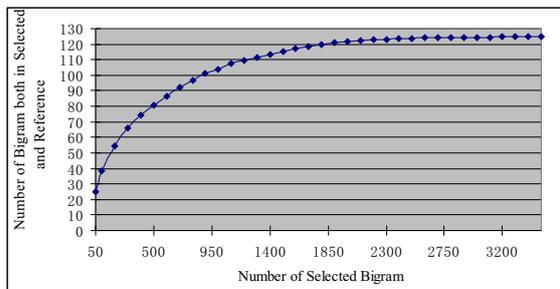

Figure 1: Coverage of bigrams (number of bigrams in reference summary) when varying the number of bigrams used in the ILP systems.

Increasing the number of bigrams used in the system will lead to better coverage, however, the incorrect bigrams also increase and have a negative impact on the system performance. To examine the best tradeoff, we conduct the experiments by choosing the different top- $N$  bigram set for the two ILP systems, as shown in Fig 2. For both the ILP systems, we used the estimated weight value for the bigrams.

We can see that the ICSI ILP system performs better when the input bigrams have less noise (those bigrams that are not in summary). However, our proposed method is slightly more robust to this kind of noise, possibly because of the weights we use in our system – the noisy bigrams have lower weights and thus less impact on the final system performance. Overall the two systems have similar trends: performance increases at the beginning when using more bigrams, and after certain points starts degrading with too many bigrams. The optimal number of bigrams differs for the two systems, with a larger number of bigrams in our method. We also notice that the ICSI ILP system achieved a ROUGE-2 of 0.1218 when using top 60 bigrams, which is better than using the initial bigram set in their method (0.1160).

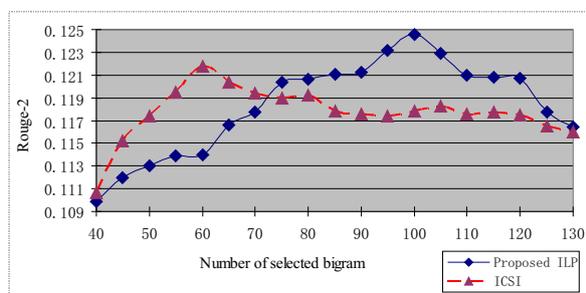

Figure 2: Summarization performance when varying the number of bigrams for two systems.

#### 4.4 Oracle Experiments

Based on the above analysis, we can see the impact of the bigram set and their weights. The following experiments are designed to demonstrate the best system performance we can achieve if we have access to good quality bigrams and weights. Here we use the information from the reference summary.

The first is an oracle experiment, where we use all the bigrams from the reference summaries that are also in the original text. In the ICSI ILP system, the weights are the document frequency from the multiple reference summaries. In our ILP module, we use the term frequency of the bigram. The oracle results are shown in Table 5. We can see these are significantly better than the automatic systems.

From Table 5, we notice that ICSI’s ILP performs marginally better than our proposed ILP. We hypothesize that one reason may be that many bigrams in the summary reference only appear once. Table 6 shows the frequency of the bigrams in the summary. Indeed 85% of bigram only appear once

ILP System	ROUGE-2
Our ILP	0.2124
ICSI ILP	0.2128

Table 5: Oracle experiment: using bigrams and their frequencies in the reference summary as weights.

and no bigrams appear more than 9 times. For the majority of the bigrams, our method and the ICSI ILP are the same. For the others, our system has slight disadvantage when using the reference term frequency. We expect the high term frequency may need to be properly smoothed/normalized.

Freq	1	2	3	4	5	6	7	8	9
Ave#	277	32	7.5	3.2	1.1	0.3	0.1	0.1	0.04

Table 6: Average number of bigrams for each term frequency in one topic’s reference summary.

We also treat the oracle results as the gold standard for extractive summarization and compared how the two automatic summarization systems differ at the sentence level. This is different from the results in Table 1, which are the ROUGE results comparing to human written abstractive summaries at the n-gram level. We found that among the 188 sentences in this gold standard, our system hits 31 and ICSI only has 23. This again shows that our system has better performance, not just at the word level based on ROUGE measures, but also at the sentence level. There are on average 3 different sentences per topic between these two results.

In the second experiment, after we obtain the estimated  $N_{b,ref}$  for every bigram in the selected sentences from our regression model, we only keep those bigrams that are in the reference summary, and use the estimated weights for both ILP modules. Table 7 shows the results. We can consider these as the upper bound the system can achieve if we use the automatically estimated weights for the correct bigrams. In this experiment ICSI ILP’s performance still performs better than ours. This might be attributed to the fact there is less noise (all the bigrams are the correct ones) and thus the ICSI ILP system performs well. We can see that these results are worse than the previous oracle experiments, but are better than using the automatically generated bigrams, again showing the bigram and weight estimation is critical for

summarization.

#	Weight	ILP	ROUGE-2
1	Estimated value	Proposed	0.1888
2		ICSI	0.1942

Table 7: Summarization results when using the estimated weights and only keeping the bigrams that are in the reference summary.

#### 4.5 Effect of Training Set

Since our method uses supervised learning, we conduct the experiment to show the impact of training size. In TAC’s data, each topic has two sets of documents. For set A, the task is a standard summarization, and there are 4 reference summaries, each 100 words long; for set B, it is an update summarization task – the summary includes information not mentioned in the summary from set A. There are also 4 reference summaries, with 400 words in total. Table 8 shows the results on 2009 data when using the data from different years and different sets for training. We notice that when the training data only contains set A, the performance is always better than using set B or the combined set A and B. This is not surprising because of the different task definition. Therefore, for the rest of the study on data size impact, we only use data set A from the TAC data and the DUC data as the training set. In total there are about 233 topics from the two years’ DUC data (06, 07) and three years’ TAC data (08, 10, 11). We incrementally add 20 topics every time (from DUC06 to TAC11) and plot the learning curve, as shown in Fig 3. As expected, more training data results in better performance.

Training Set	# Topics	ROUGE-2
08 Corpus (A)	48	0.1192
08 Corpus (B)	48	0.1178
08 Corpus (A+B)	96	0.1188
10 Corpus (A)	46	0.1174
10 Corpus (B)	46	0.1167
10 Corpus (A+B)	92	0.1170
11 Corpus (A)	44	0.1157
11 Corpus (B)	44	0.1130
11 Corpus (A+B)	88	0.1140

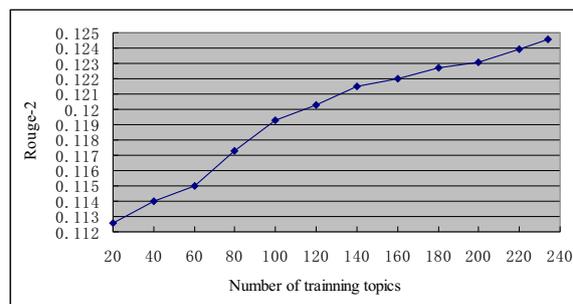

Figure 3: Learning curve

#### 4.6 Summary of Analysis

The previous experiments have shown the impact of the three factors: the quality of the bigrams themselves, the weights used for these bigrams, and the ILP module. We found that the bigrams and their weights are critical for both the ILP setups. However, there is negligible difference between the two ILP methods.

An important part of our system is the supervised method for bigram and weight estimation. We have already seen for the previous ILP method, when using our bigrams together with the weights, better performance can be achieved. Therefore we ask the question whether this is simply because we use supervised learning, or whether our proposed regression model is the key. To answer this, we trained a simple supervised binary classifier for bigram prediction (positive means that a bigram appears in the summary) using the same set of features as used in our bigram weight estimation module, and then used their document frequency in the ICSI ILP system. The result for this method is 0.1128 on the TAC 2009 data. This is much lower than our result. We originally expected that using the supervised method may outperform the unsupervised bigram selection which only uses term frequency information. Further experiments are needed to investigate this. From this we can see that it is not just the supervised methods or using annotated data that yields the overall improved system performance, but rather our proposed regression setup for bigrams is the main reason.

### 5 Related Work

We briefly describe some prior work on summarization in this section. Unsupervised methods have been widely used. In particular, recently several optimization approaches have demonstrated

competitive performance for extractive summarization task. Maximum marginal relevance (MMR) (Carbonell and Goldstein, 1998) uses a greedy algorithm to find summary sentences. (McDonald, 2007) improved the MMR algorithm to dynamic programming. They used a modified objective function in order to consider whether the selected sentence is globally optimal. Sentence-level ILP was also first introduced in (McDonald, 2007), but (Gillick and Favre, 2009) revised it to concept-based ILP. (Woodsend and Lapata, 2012) utilized ILP to jointly optimize different aspects including content selection, surface realization, and rewrite rules in summarization. (Galanis et al., 2012) uses ILP to jointly maximize the importance of the sentences and their diversity in the summary. (Berg-Kirkpatrick et al., 2011) applied a similar idea to conduct the sentence compression and extraction for multiple document summarization. (Jin et al., 2010) made a comparative study on sentence/concept selection and pairwise and list ranking algorithms, and concluded ILP performed better than MMR and the diversity penalty strategy in sentence/concept selection. Other global optimization methods include submodularity (Lin and Bilmes, 2010) and graph-based approaches (Erkan and Radev, 2004; Leskovec et al., 2005; Mihalcea and Tarau, 2004). Various unsupervised probabilistic topic models have also been investigated for summarization and shown promising. For example, (Celikyilmaz and Hakkani-Tür, 2011) used it to model the hidden abstract concepts across documents as well as the correlation between these concepts to generate topically coherent and non-redundant summaries. (Darling and Song, 2011) applied it to separate the semantically important words from the low-content function words.

In contrast to these unsupervised approaches, there are also various efforts on supervised learning for summarization where a model is trained to predict whether a sentence is in the summary or not. Different features and classifiers have been explored for this task, such as Bayesian method (Kupiec et al., 1995), maximum entropy (Osborne, 2002), CRF (Galley, 2006), and recently reinforcement learning (Ryang and Abekawa, 2012). (Aker et al., 2010) used discriminative reranking on multiple candidates generated by A\* search. Recently, research has also been performed to address some issues in the supervised setup, such as the class

data imbalance problem (Xie and Liu, 2010).

In this paper, we propose to incorporate the supervised method into the concept-based ILP framework. Unlike previous work using sentence-based supervised learning, we use a regression model to estimate the bigrams and their weights, and use these to guide sentence selection. Compared to the direct sentence-based classification or regression methods mentioned above, our method has an advantage. When abstractive summaries are given, one needs to use that information to automatically generate reference labels (a sentence is in the summary or not) for extractive summarization. Most researchers have used the similarity between a sentence in the document and the abstractive summary for labeling. This is not a perfect process. In our method, we do not need to generate this extra label for model training since ours is based on bigrams – it is straightforward to obtain the reference frequency for bigrams by simply looking at the reference summary. We expect our approach also paves an easy way for future automatic abstractive summarization. One previous study that is most related to ours is (Conroy et al., 2011), which utilized a Naive Bayes classifier to predict the probability of a bigram, and applied ILP for the final sentence selection. They used more features than ours, whereas we use a discriminatively trained regression model and a modified ILP framework. Our proposed method performs better than their reported results in TAC 2011 data. Another study closely related to ours is (Davis et al., 2012), which leveraged Latent Semantic Analysis (LSA) to produce term weights and selected summary sentences by computing an approximate solution to the Budgeted Maximal Coverage problem.

## 6 Conclusion and Future Work

In this paper, we leverage the ILP method as a core component in our summarization system. Different from the previous ILP summarization approach, we propose a supervised learning method (a discriminatively trained regression model) to determine the importance of the bigrams fed to the ILP module. In addition, we revise the ILP to maximize the bigram gain (which is expected to be highly correlated with ROUGE-2 scores) rather than the concept/bigram coverage. Our proposed method yielded better results than the previous state-of-the-art ILP system on different TAC data

sets. From a series of experiments, we found that there is little difference between the two ILP modules, and that the improved system performance is attributed to the fact that our proposed supervised bigram estimation module can successfully gather the important bigram and assign them appropriate weights. There are several directions that warrant further research. We plan to consider the context of bigrams to better predict whether a bigram is in the reference summary. We will also investigate the relationship between concepts and sentences, which may help move towards abstractive summarization.

## Abstract

We propose a new optimization framework for summarization by generalizing the submodular framework of (Lin and Bilmes, 2011). In our framework the summarization desideratum is expressed as a sum of a submodular function and a non-submodular function, which we call *dispersion*; the latter uses inter-sentence dissimilarities in different ways in order to ensure non-redundancy of the summary. We consider three natural dispersion functions and show that a greedy algorithm can obtain an approximately optimal summary in all three cases. We conduct experiments on two corpora—DUC 2004 and user comments on news articles—and show that the performance of our algorithm outperforms those that rely only on submodularity.

## 1 Introduction

Summarization is a classic text processing problem. Broadly speaking, given one or more documents, the goal is to obtain a concise piece of text that contains the most salient points in the given document(s). Thanks to the omnipresent information overload facing all of us, the importance of summarization is gaining; semi-automatically summarized content is increasingly becoming user-facing: many newspapers equip editors with automated tools to aid them in choosing a subset of user comments to show. Summarization has been studied for the past in various settings—a large single document, multiple documents on the same topic, and user-generated content.

Each domain throws up its own set of idiosyncrasies and challenges for the summarization task. On one hand, in the multi-document case (say, different news reports on the same event), the text is

often very long and detailed. The precision/recall requirements are higher in this domain and a semantic representation of the text might be needed to avoid redundancy. On the other hand, in the case of user-generated content (say, comments on a news article), even though the text is short, one is faced with a different set of problems: volume (popular articles generate more than 10,000 comments), noise (most comments are vacuous, linguistically deficient, and tangential to the article), and redundancy (similar views are expressed by multiple commenters). In both cases, there is a delicate balance between choosing the salient, relevant, popular, and diverse points (e.g., sentences) versus minimizing syntactic and semantic redundancy.

While there have been many approaches to automatic summarization (see Section 2), our work is directly inspired by the recent elegant framework of (Lin and Bilmes, 2011). They employed the powerful theory of submodular functions for summarization: submodularity embodies the “diminishing returns” property and hence is a natural vocabulary to express the summarization desiderata. In this framework, each of the constraints (relevance, redundancy, etc.) is captured as a submodular function and the objective is to maximize their sum. A simple greedy algorithm is guaranteed to produce an approximately optimal summary. They used this framework to obtain the best results on the DUC 2004 corpus.

Even though the submodularity framework is quite general, it has limitations in its expressivity. In particular, it cannot capture redundancy constraints that depend on pairwise dissimilarities between sentences. For example, a natural constraint on the summary is that the sum or the minimum of pairwise dissimilarities between sentences chosen in the summary should be maximized; this, unfortunately, is not a submodular function. We call functions that depend on inter-sentence pair-

wise dissimilarities in the summary as *dispersion* functions. Our focus in this work is on significantly furthering the submodularity-based summarization framework to incorporate such dispersion functions.

We propose a very general graph-based summarization framework that combines a submodular function with a non-submodular dispersion function. We consider three natural dispersion functions on the sentences in a summary: sum of all-pair sentence dissimilarities, the weight of the minimum spanning tree on the sentences, and the minimum of all-pair sentence dissimilarities. These three functions represent three different ways of using the sentence dissimilarities. We then show that a greedy algorithm can obtain approximately optimal summary in each of the three cases; the proof exploits some nice combinatorial properties satisfied by the three dispersion functions. We then conduct experiments on two corpora: the DUC 2004 corpus and a corpus of user comments on news articles. On DUC 2004, we obtain performance that matches (Lin and Bilmes, 2011), without any serious parameter tuning; note that their framework does not have the dispersion function. On the comment corpus, we outperform their method, demonstrating that value of dispersion functions. As part of our methodology, we also use a new structured representation for summaries.

## 2 Related Work

Automatic summarization is a well-studied problem in the literature. Several methods have been proposed for single- and multi-document summarization (Carbonell and Goldstein, 1998; Conroy and O’Leary, 2001; Takamura and Okumura, 2009; Shen and Li, 2010).

Related concepts have also been used in several other scenarios such as query-focused summarization in information retrieval (Daumé and Marcu, 2006), microblog summarization (Sharifi et al., 2010), event summarization (Filatova, 2004), and others (Riedhammer et al., 2010; Qazvinian et al., 2010; Yatani et al., 2011).

Graph-based methods have been used for summarization (Ganesan et al., 2010), but in a different context—using paths in graphs to produce very short abstractive summaries. For a detailed survey on existing automatic summarization techniques and other related topics, see (Kim et al.,

2011; Nenkova and McKeown, 2012).

## 3 Framework

In this section we present the summarization framework. We start by describing a generic objective function that can be widely applied to several summarization scenarios. This objective function is the sum of a monotone submodular *coverage* function and a non-submodular *dispersion* function. We then describe a simple greedy algorithm for optimizing this objective function with provable approximation guarantees for three natural dispersion functions.

### 3.1 Preliminaries

Let  $C$  be a collection of texts. Depending on the summarization application,  $C$  can refer to the set of documents (e.g., newswire) related to a particular topic as in standard summarization; in other scenarios (e.g., user-generated content), it is a collection of comments associated with a news article or a blog post, etc. For each document  $c \in C$ , let  $S(c)$  denote the set of sentences in  $c$ . Let  $U = \cup_{c \in C} S(c)$  be the universe of all sentences; without loss of generality, we assume each sentence is unique to a document. For a sentence  $u \in U$ , let  $C(u)$  be the document corresponding to  $u$ .

Each  $u \in U$  is associated with a *weight*  $w(u)$ , which might indicate, for instance, how similar  $u$  is to the main article (and/or the query, in query-dependent settings). Each pair  $u, v \in U$  is associated with a *similarity*  $s(u, v) \in [0, 1]$ . This similarity can then be used to define an inter-sentence distance  $d(\cdot, \cdot)$  as follows: let  $d'(u, v) = 1 - s(u, v)$  and define  $d(u, v)$  to be the shortest path distance from  $u$  to  $v$  in the graph where the weight of each edge  $(u, v)$  is  $d'(u, v)$ . Note that  $d(\cdot, \cdot)$  is a metric unlike  $d'(\cdot, \cdot)$ , which may not be a metric. (In addition to being intuitive,  $d(\cdot, \cdot)$  being a metric helps us obtain guarantees on the algorithm’s output.) For a set  $S$ , and a point  $u \notin S$ , define  $d(u, S) = \min_{v \in S} d(u, v)$ .

Let  $k > 0$  be fixed. A *summary* of  $U$  is a subset  $S \subseteq U$ ,  $|S| = k$ . Our aim is to find a summary that maximizes

$$f(S) = g(S) + \delta h(S), \quad (1)$$

where  $g(S)$  is the *coverage* function that is non-negative, monotone, and submodular<sup>1</sup>,  $h(S)$  is a

<sup>1</sup>A function  $f : U \rightarrow \Re$  is *submodular* if for every

dispersion function, and  $\delta \geq 0$  is a parameter that can be used to scale the range of  $h(\cdot)$  to be comparable to that of  $g(\cdot)$ .

For two sets  $S$  and  $T$ , let  $P$  be the set of unordered pairs  $\{u, v\}$  where  $u \in S$  and  $v \in T$ . Our focus is on the following dispersion functions: the *sum* measure  $h_s(S, T) = \sum_{\{u, v\} \in P} d(u, v)$ , the *spanning tree* measure  $h_t(S, T)$  given by the cost of the minimum spanning tree of the set  $S \cup T$ , and the *min* measure  $h_m(S, T) = \min_{\{u, v\} \in P} d(u, v)$ . Note that these functions span from considering the entire set of distances in  $S$  to considering only the minimum distance in  $S$ ; also it is easy to construct examples to show that none of these functions is submodular. Define  $h_*(u, S) = h_*(\{u\}, S)$  and  $h_*(S) = h_*(S, S)$ .

Let  $O$  be the optimal solution of the function  $f$ . A summary  $\tilde{S}$  is a  $\gamma$ -approximation if  $f(\tilde{S}) \geq \gamma f(O)$ .

### 3.2 Algorithm

Maximizing (1) is NP-hard even if  $\delta = 0$  or if  $g(\cdot) = 0$  (Chandra and Halldórsson, 2001). For the special case  $\delta = 0$ , since  $g(\cdot)$  is submodular, a classical greedy algorithm obtains a  $(1 - 1/e)$ -approximation (Nemhauser et al., 1978). But if  $\delta > 0$ , since the dispersion function  $h(\cdot)$  is not submodular, the combined objective  $f(\cdot)$  is not submodular as well. Despite this, we show that a simple greedy algorithm achieves a provable approximation factor for (1). This is possible due to some nice structural properties of the dispersion functions we consider.

---

**Algorithm 2** Greedy algorithm, parametrized by the dispersion function  $h$ ; here,  $U, k, g, \delta$  are fixed.

---

```

 $S_0 \leftarrow \emptyset; i \leftarrow 0$ 
for  $i = 0, \dots, k - 1$  do
     $v \leftarrow \arg \max_{u \in U \setminus S_i} g(S_i + u) + \delta h(S_i + u)$ 
     $S_{i+1} \leftarrow S_i \cup \{v\}$ 
end for

```

---

### 3.3 Analysis

In this section we obtain a provable approximation for the greedy algorithm. First, we show that a greedy choice is well-behaved with respect to the dispersion function  $h(\cdot)$ .

**Lemma 1.** *Let  $O$  be any set with  $|O| = k$ . If  $S$  is such that  $|S| = \ell < k$ , then*

$$(i) \sum_{u \in O \setminus S} h_s(u, S) \geq |O \setminus S| \frac{\ell h_s(O)}{k(k-1)};$$

---

$A, B \subseteq U$ , we have  $f(A) + f(B) \geq f(A \cup B) + f(A \cap B)$ .

- (ii)  $\sum_{u \in O \setminus S} d(u, S) \geq \frac{1}{2} h_t(O) - h_t(S)$ ; and  
(iii) *there exists  $u \in O \setminus S$  such that  $h_m(u, S) \geq h_m(O)/2$ .*

*Proof.* The proof for (i) follows directly from Lemma 1 in (Borodin et al., 2012).

To prove (ii) let  $T$  be the tree obtained by adding all points of  $O \setminus S$  directly to their respective closest points on the minimum spanning tree of  $S$ .  $T$  is a spanning tree, and hence a Steiner tree, for the points in set  $S \cup O$ . Hence,  $\text{cost}(T) = h_t(S) + \sum_{u \in O \setminus S} d(u, S)$ . Let  $\text{smt}(S)$  denote the cost of a minimum Steiner tree of  $S$ . Thus,  $\text{cost}(T) \geq \text{smt}(O \cup S)$ . Since a Steiner tree of  $O \cup S$  is also a Steiner tree of  $O$ ,  $\text{smt}(O \cup S) \geq \text{smt}(O)$ . Since this is a metric space,  $\text{smt}(O) \geq \frac{1}{2} h_t(O)$  (see, for example, (Cieslik, 2001)). Thus,

$$\begin{aligned} h_t(S) + \sum_{u \in O \setminus S} d(u, S) &\geq \frac{1}{2} h_t(O) \\ \Rightarrow \sum_{u \in O \setminus S} d(u, S) &\geq \frac{1}{2} h_t(O) - h_t(S). \end{aligned}$$

To prove (iii), let  $O = \{u_1, \dots, u_k\}$ . By definition, for every  $i \neq j$ ,  $d(u_i, u_j) \geq h_m(O)$ . Consider the (open) ball  $B_i$  of radius  $h_m(O)/2$  around each element  $u_i$ . By construction for each  $i$ ,  $B_i \cap O = \{u_i\}$  and for each pair  $i \neq j$ ,  $B_i \cap B_j = \emptyset$ . Since  $|S| < k$ , and there are  $k$  balls  $B_i$ , there exists  $k - \ell$  balls  $B_i$  such that  $S \cap B_i = \emptyset$ , proving (iii).  $\square$

We next show that the tree created by the greedy algorithm for  $h = h_t$  is not far from the optimum.

**Lemma 2.** *Let  $u_1, \dots, u_k$  be a sequence of points and let  $S_i = \{u_j, j \leq i\}$ . Then,  $h_t(S_k) \geq \frac{1}{\log k} \sum_{2 \leq j \leq k} d(u_j, S_{j-1})$ .*

*Proof.* The proof follows by noting that we get a spanning tree by connecting each  $u_i$  to its closest point in  $S_{i-1}$ . The cost of this spanning tree is  $\sum_{2 \leq j \leq k} d(u_j, S_{j-1})$  and this tree is also the result of the greedy algorithm run in an online fashion on the input sequence  $\{u_1, \dots, u_k\}$ . Using the result of (Imase and Waxman, 1991), the competitive ratio of this algorithm is  $\log k$ , and hence the proof.  $\square$

We now state and prove the main result about the quality of approximation of the greedy algorithm.

**Theorem 3.** For  $k > 1$ , there is a polynomial-time algorithm that obtains a  $\gamma$ -approximation to  $f(S)$ , where  $\gamma = 1/2$  for  $h = h_s$ ,  $\gamma = 1/4$  for  $h = h_m$ , and  $\gamma = 1/3 \log k$  for  $h = h_t$ .

*Proof.* For  $h_s$  and  $h_t$ , we run Algorithm 1 using a new dispersion function  $h'$ , which is a slightly modified version of  $h$ . In particular, for  $h = h_s$ , we use  $h'(S) = 2h_s(S)$ . For  $h = h_t$ , we abuse notation and define  $h'$  to be a function over an ordered set  $S = \{u_1, \dots, u_k\}$  as follows:  $h'(S) = \sum_{j \leq |S|} d(u_j, S_{j-1})$ , where  $S_{j-1} = \{u_1, \dots, u_{j-1}\}$ . Let  $f'(S) = g(S) + \delta h'(S)$ .

Consider the  $i$ th iteration of the algorithm. By the submodularity of  $g(\cdot)$ ,

$$\begin{aligned} & \sum_{u \in O \setminus S_i} g(S_i \cup \{u\}) - g(S_i) \\ & \geq g(O \cup S_i) - g(S_i) \geq g(O) - g(S_k), \end{aligned} \quad (2)$$

where we use monotonicity of  $g(\cdot)$  to infer  $g(O \cup S_i) \geq g(O)$  and  $g(S_i) \leq g(S_k)$ .

For  $h = h_s$ , the proof follows by Lemma 1(i) and by Theorem 1 in (Borodin et al., 2012).

For  $h_t$ , using the above argument of submodularity and monotonicity of  $g$ , and the result from Lemma 1(ii), we have

$$\begin{aligned} & \sum_{u \in O \setminus S_i} g(S_i \cup u) - g(S_i) + \delta d(u, S_i) \\ & \geq g(O) - g(S_i) + \delta(h_t(O)/2 - h_t(S_i)) \\ & \geq (g(O) + \delta h_t(O)/2) - (g(S_i) + \delta h_t(S_i)) \\ & \geq f(O)/2 - (g(S_i) + \delta h_t(S_i)). \end{aligned}$$

Also,  $h_t(S_i) \leq 2 \text{smt}(S_i)$  since this is a metric space. Using the monotonicity of the Steiner tree cost,  $\text{smt}(S_i) \leq \text{smt}(S_k) \leq h_t(S_k)$ . Hence,  $h_t(S_i) \leq 2h_t(S_k)$ . Thus,

$$\begin{aligned} & \sum_{u \in O \setminus S_i} g(S_i \cup u) - g(S_i) + \delta d(u, S_i) \\ & \geq f(O)/2 - (g(S_i) + \delta h_t(S_i)) \\ & \geq f(O)/2 - (g(S_k) + 2\delta h_t(S_k)) \\ & \geq f(O)/2 - 2f(S_k). \end{aligned} \quad (3)$$

By the greedy choice of  $u_{i+1}$ ,

$$\begin{aligned} & f'(S_i \cup u_{i+1}) - f'(S_i) \\ & = g(S_i \cup u_{i+1}) - g(S_i) + \delta d(u_{i+1}, S_i) \\ & \geq (f(O)/2 - 2f(S_k))/|O \setminus S_i| \\ & \geq \frac{1}{k} (f(O)/2 - 2f(S_k)). \end{aligned}$$

Summing over all  $i \in [1, k-1]$ ,

$$f'(S_k) \geq (k-1)/k (f(O)/2 - 2f(S_k)). \quad (4)$$

Using Lemma 2 we obtain

$$\begin{aligned} f(S_k) & = g(S_k) + \delta h_t(S_k) \geq \frac{f'(S_k)}{\log k} \\ & \geq \frac{1 - 1/k}{\log k} (f(O)/2 - 2f(S_k)). \end{aligned}$$

By simplifying, we obtain  $f(S_k) \geq f(O)/3 \log k$ .

Finally for  $h_m$ , we run Algorithm 1 twice: once with  $g$  as given and  $h \equiv 0$ , and the second time with  $g \equiv 0$  and  $h \equiv h_m$ . Let  $S_g$  and  $S_h$  be the solutions in the two cases. Let  $O_g$  and  $O_h$  be the corresponding optimal solutions. By the submodularity and monotonicity of  $g(\cdot)$ ,  $g(S_g) \geq (1 - 1/e)g(O_g) \geq g(O_g)/2$ . Similarly, using Lemma 1(iii),  $h_m(S_h) \geq h_m(O_h)/2$  since in any iteration  $i < k$  we can choose an element  $u_{i+1}$  such that  $h_m(u_{i+1}, S_i) \geq h_m(O_h)/2$ . Let  $S = \arg \max_{X \in \{S_g, S_h\}} f(X)$ . Using an averaging argument, since  $g$  and  $h_m$  are both non-negative,

$$f(X) \geq (f(S_g) + f(S_h))/2 \geq (g(O_g) + \delta h_m(O_h))/4.$$

Since by definition  $g(O_g) \geq g(O)$  and  $h_m(O_h) \geq h_m(O)$ , we have a  $1/4$ -approximation.  $\square$

### 3.4 A universal constant-factor approximation

Using the above algorithm that we used for  $h_m$ , it is possible to give a universal algorithm that gives a constant-factor approximation to each of the above objectives. By running the Algorithm 1 once for  $g \equiv 0$  and next for  $h \equiv 0$  and taking the best of the two solutions, we can argue that the resulting set gives a constant factor approximation to  $f$ . We do not use this algorithm in our experiments, as it is oblivious of the actual dispersion functions used.

## 4 Using the Framework

Next, we describe how the framework described in Section 3 can be applied to our tasks of interest, i.e., summarizing documents or user-generated content (in our case, comments). First, we represent the elements of interest (i.e., sentences within comments) in a structured manner by using dependency trees. We then use this representation to

generate a graph and instantiate our summarization objective function with specific components that capture the desiderata of a given summarization task.

#### 4.1 Structured representation for sentences

In order to instantiate the summarization graph (nodes and edges), we first need to model each sentence (in multi-document summarization) or comment (i.e., set of sentences) as nodes in the graph. Sentences have been typically modeled using standard ngrams (unigrams or bigrams) in previous summarization work. Instead, we model sentences using a structured representation, i.e., its syntax structure using dependency parse trees. We first use a dependency parser (de Marneffe et al., 2006) to parse each sentence and extract the set of dependency relations associated with the sentence. For example, the sentence “I adore tennis” is represented by the dependency relations (nsubj: adore, I) and (dobj: adore, tennis).

Each sentence represents a single node  $u$  in the graph (unless otherwise specified) and is comprised of a set of dependency relations (or ngrams) present in the sentence. Furthermore, the edge weights  $s(u, v)$  represent pairwise similarity between sentences or comments (e.g., similarity between views expressed in different comments). The edge weights are then used to define the inter-sentence distance metric  $d(u, v)$  for the different dispersion functions. We identify similar views/opinions by computing semantic similarity rather than using standard similarity measures (such as cosine similarity based on exact lexical matches between different nodes in the graph). For each pair of nodes  $(u, v)$  in the graph, we compute the semantic similarity score (using WordNet) between every pair of dependency relation (rel:  $a, b$ ) in  $u$  and  $v$  as:

$$s(u, v) = \sum_{\substack{\text{rel}_i \in u, \text{rel}_j \in v \\ \text{rel}_i = \text{rel}_j}} \text{WN}(a_i, a_j) \times \text{WN}(b_i, b_j),$$

where rel is a relation type (e.g., nsubj) and  $a, b$  are the two arguments present in the dependency relation ( $b$  does not exist for some relations).  $\text{WN}(w_i, w_j)$  is defined as the WordNet similarity score between words  $w_i$  and  $w_j$ .<sup>2</sup> The edge weights are then normalized across all edges in the

<sup>2</sup>There exists various semantic relatedness measures based on WordNet (Patwardhan and Pedersen, 2006). In our experiments, for WN we pick one that is based on the path length between the two words in the WordNet graph.

graph.

This allows us to perform approximate matching of syntactic treelets obtained from the dependency parses using semantic (WordNet) similarity. For example, the sentences “I adore tennis” and “Everyone likes tennis” convey the same view and should be assigned a higher similarity score as opposed to “I hate tennis”. Using the syntactic structure along with semantic similarity helps us identify useful (valid) nuggets of information within comments (or documents), avoid redundancies, and identify similar views in a semantic space.

#### 4.2 Components of the coverage function

Our coverage function is a linear combination of the following.

(i) *Popularity*. One of the requirements for a good summary (especially, for user-generated content) is that it should include (or rather not miss) the popular views or opinions expressed by several users across multiple documents or comments. We model this property in our objective function as follows.

For each node  $u$ , we define  $w(u)$  as the number of documents  $|C_{u_{\text{rel}}} \subseteq C|$  from the collection such that at least one of the dependency relations  $\text{rel} \in u$  appeared in a sentence within some document  $c \in C_{u_{\text{rel}}}$ . The popularity scores are then normalized across all nodes in the graph. We then add this component to our objective function as  $w(S) = \sum_{u \in S} w(u)$ .

(ii) *Cluster contribution*. This term captures the fact that we do not intend to include multiple sentences from the same comment (or document). Define  $\mathcal{B}$  to be the clustering induced by the sentence to comment relation, i.e., two sentences in the same comment belong to the same cluster. The corresponding contribution to the objective function is  $\sum_{B \in \mathcal{B}} |S \cap B|^{1/2}$ .

(iii) *Content contribution*. This term promotes the diversification of content. We look at the graph of sentences where the weight of each edge is  $s(u, v)$ . This graph is then partitioned based on a local random walk based method to give us clusters  $\mathcal{D} = \{D_1, \dots, D_n\}$ . The corresponding contribution to the objective function is  $\sum_{D \in \mathcal{D}} |S \cap D|^{1/2}$ .

(iv) *Cover contribution*. We also measure the cover of the set  $S$  as follows: for each element  $s$  in  $U$  first define cover of an element  $u$  by a set  $S'$  as  $\text{cov}(u, S') = \sum_{v \in S'} s(u, v)$ . Then, the

cover value of the set  $S$  is defined as  $\text{cov}(S) = \sum_{u \in S} \min(\text{cov}(u, S), 0.25\text{cov}(u, U))$ .<sup>3</sup>

Thus, the final coverage function is:  $g(S) = w(S) + \alpha \sum_{B \in \mathcal{B}} |S \cap B|^{1/2} + \beta \sum_{D \in \mathcal{D}} |S \cap D|^{1/2} + \lambda \text{cov}(S)$ , where  $\alpha, \beta, \lambda$  are non-negative constants. By using the monotone submodularity of each of the component functions, and the fact that addition preserves submodularity, the following is immediate.

**Fact 4.**  $g(S)$  is a monotone, non-negative, sub-modular function.

We then apply Algorithm 1 to optimize (1).

## 5 Experiments

### 5.1 Data

**Multi-document summarization.** We use the DUC 2004 corpus<sup>4</sup> that comprises 50 clusters (i.e., 50 different summarization tasks) with 10 documents per cluster on average. Each document contains multiple sentences and the goal is to produce a summary of all the documents for a given cluster.

**Comments summarization.** We extracted a set of news articles and corresponding user comments from Yahoo! News website. Our corpus contains a set of 34 articles and each article is associated with anywhere from 100–500 comments. Each comment contains more than three sentences and 36 words per sentence on average.

### 5.2 Evaluation

For each summarization task, we compare the system output (i.e., summaries automatically produced by the algorithm) against the human-generated summaries and evaluate the performance in terms of ROUGE score (Lin, 2004), a standard recall-based evaluation measure used in summarization. A system that produces higher ROUGE scores generates better quality summary and vice versa.

We use the following evaluation settings in our experiments for each summarization task:

(1) For multi-document summarization, we compute the ROUGE-1<sup>5</sup> scores that was the main evaluation criterion for DUC 2004 evaluations.

<sup>3</sup>The choice of the value 0.25 in the cover component is inspired by the observations made by (Lin and Bilmes, 2011) for the  $\alpha$  value used in their cover function.

<sup>4</sup><http://duc.nist.gov/duc2004/tasks.html>

<sup>5</sup>ROUGE v1.5.5 with options: -a -c 95 -b 665 -m -n 4 -w 1.2

(2) For comment summarization, the collection of user comments associated with a given article is typically much larger. Additionally, individual comments are noisy, wordy, diverse, and informally written. Hence for this task, we use a slightly different evaluation criterion that is inspired from the DUC 2005-2007 summarization evaluation tasks.

We represent the content within each comment  $c$  (i.e., all sentences  $S(c)$  comprising the comment) as a single node in the graph. We then run our summarization algorithm on the instantiated graph to produce a summary for each news article. In addition, each news article and corresponding set of comments were presented to three human annotators. They were asked to select a subset of comments (at most 20 comments) that best represented a summary capturing the most popular as well as diverse set of views and opinions expressed by different users that are relevant to the given news article. We then compare the automatically generated comment summaries against the human-generated summaries and compute the ROUGE-1 and ROUGE-2 scores.<sup>6</sup>

This summarization task is particularly hard for even human annotators since user-generated comments are typically noisy and there are several hundreds of comments per article. Similar to existing work in the literature (Sekine and Nobata, 2003), we computed inter-annotator agreement for the humans by comparing their summaries against each other on a small held-out set of articles. The average ROUGE-1 F-scores observed for humans was much higher (59.7) than that of automatic systems measured against the human-generated summaries (our best system achieved a score of 28.9 ROUGE-1 on the same dataset). This shows that even though this is a new type of summarization task, humans tend to generate more consistent summaries and hence their annotations are reliable for evaluation purposes as in multi-document summarization.

### 5.3 Results

**Multi-document summarization.** (1) Table 1 compares the performance of our system with the previous best reported system that participated in the DUC 2004 competition. We also include for comparison another baseline—a version

<sup>6</sup>ROUGE v1.5.5 with options: -a -n 2 -x -m -2 4 -u -c 95 -r 1000 -f A -p 0.5 -t 0 -d -l 150

of our system that approximates the submodular objective function proposed by (Lin and Bilmes, 2011).<sup>7</sup> As shown in the results, our best system<sup>8</sup> which uses the  $h_s$  dispersion function achieves a better ROUGE-1 F-score than all other systems.

(2) We observe that the  $h_m$  and  $h_t$  dispersion functions produce slightly lower scores than  $h_s$ , which may be a characteristic of this particular summarization task. We believe that the empirical results achieved by different dispersion functions depend on the nature of the summarization tasks and there are task settings under which  $h_m$  or  $h_t$  perform better than  $h_s$ . For example, we show later how using the  $h_t$  dispersion function yields the best performance on the comments summarization task. Regardless, the theoretical guarantees presented in this paper cover all these cases.

(3) We also analyze the contributions of individual components of the new objective function towards summarization performance by selectively setting certain parameters to 0. Table 2 illustrates these results. We clearly see that each component (popularity, cluster contribution, dispersion) individually yields a reasonable summarization performance but the best result is achieved by the combined system (row 5 in the table). We also contrast the performance of the full system with and without the dispersion component (row 4 versus row 5). The results show that optimizing for dispersion yields an improvement in summarization performance.

(4) To understand the effect of utilizing syntactic structure and semantic similarity for constructing the summarization graph, we ran the experiments using just the unigrams and bigrams; we obtained a ROUGE-1 F-score of 37.1. Thus, modeling the syntactic structure (using relations extracted

from dependency parse tree) along with computing similarity in semantic spaces (using WordNet) clearly produces an improvement in the summarization quality (+1.4 improvement in ROUGE-1 F-score). However, while the structured representation is beneficial, we observed that dispersion (and other individual components) contribute similar performance gains even when using ngrams alone. So the improvements obtained from the structured representation and dispersion are complementary.

System	ROUGE-1 F
Best system in DUC 2004 (Lin and Bilmes, 2011), no tuning	37.9 37.4 <sup>7</sup>
Our algorithm with $h = h_m$	37.5
$h = h_s$	<b>38.5</b>
$h = h_t$	36.8

Table 1: Performance on DUC 2004.

**Comments summarization.** (1) Table 3 compares the performance of our system against a baseline system that is constructed by picking comments in order of decreasing length, i.e., we first pick the longest comment (comprising the most number of characters), then the next longest comment and so on, to create an ordered set of comments. The intuition behind this baseline is that longer comments contain more content and possibly cover more topics than short ones.

From the table, we observe that the new system (using either dispersion function) outperforms the baseline by a huge margin (+44% relative improvement in ROUGE-1 and much bigger improvements in ROUGE-2 scores). One reason behind the lower ROUGE-2 scores for the baseline might be that while long comments provide more content (in terms of size), they also add noise and irrelevant information to the generated summaries. Our system models sentences using the syntactic structure and semantics and jointly optimizes for multiple summarization criteria (including dispersion) which helps weed out the noise and identify relevant, useful information within the comments thereby producing better quality summaries. The 95% confidence interval scores for the best system on this task is [36.5–46.9].

(2) Unlike the multi-document summarization, here we observe that the  $h_t$  dispersion function yields the best empirical performance for this task. This observation supports our claim that the choice of the specific dispersion function depends

<sup>7</sup>Note that Lin & Bilmes (2011) report a slightly higher ROUGE-1 score (F-score 38.90) on DUC 2004. This is because their system was tuned for the particular summarization task using the DUC 2003 corpus. On the other hand, even without any parameter tuning our method yields good performance, as evidenced by results on the two different summarization tasks. However, since individual components within our objective function are parametrized it is easy to tune them for a specific task or genre.

<sup>8</sup>For the full system, we weight certain parameters pertaining to cluster contributions and dispersion higher ( $\alpha = \beta = \delta = 5$ ) compared to the rest of the objective function ( $\lambda = 1$ ). Lin & Bilmes (2011) also observed a similar finding (albeit via parameter tuning) where weighting the cluster contribution component higher yielded better performance. If the maximum number of sentences/comments chosen were  $k$ , we brought both  $h_s$  and  $h_t$  to the same approximate scale as  $h_m$  by dividing  $h_s$  by  $k(k-1)/2$  and  $h_t$  by  $k-1$ .

Objective function components	ROUGE-1 F
$\alpha = \beta = \lambda = \delta = 0$	35.7
$w(S) = \beta = \lambda = \delta = 0$	35.1
$h = h_s, w(S) = \alpha = \beta = \lambda = 0$	37.1
$\delta = 0$	37.4
$w(S), \alpha, \beta, \lambda, \delta > 0$	<b>38.5</b>

Table 2: Performance with different parameters (DUC).

on the summarization task and that the dispersion functions proposed in this paper have a wider variety of use cases.

(3) Results showing contributions from individual components of the new summarization objective function are listed in Table 4. We observe a similar pattern as with multi-document summarization. The full system using all components outperform all other parameter settings, achieving the best ROUGE-1 and ROUGE-2 scores. The table also shows that incorporating dispersion into the objective function yields an improvement in summarization quality (row 4 versus row 5).

System	ROUGE-1	ROUGE-2
Baseline (decreasing length)	28.9	2.9
Our algorithm with $h = h_m$	39.2	13.2
$h = h_s$	40.9	15.0
$h = h_t$	<b>41.6</b>	<b>16.2</b>

Table 3: Performance on comments summarization.

Objective function components	ROUGE-1	ROUGE-2
$\alpha = \beta = \lambda = \delta = 0$	36.1	9.4
$w(S) = \beta = \lambda = \delta = 0$	32.1	4.9
$h = h_t, w(S) = \alpha = \beta = \lambda = 0$	37.8	11.2
$\delta = 0$	38.0	11.6
$w(S), \alpha, \beta, \lambda, \delta > 0$	<b>41.6</b>	<b>16.2</b>

Table 4: Performance with different parameters (comments).

## 6 Conclusions

We introduced a new general-purpose graph-based summarization framework that combines a submodular coverage function with a non-submodular dispersion function. We presented three natural dispersion functions that represent three different ways of ensuring non-redundancy (using sentence dissimilarities) for summarization and proved that a simple greedy algorithm can obtain an approximately optimal summary in all these cases. Experiments on two different summarization tasks show

that our algorithm outperforms algorithms that rely only on submodularity. Finally, we demonstrated that using a structured representation to model sentences in the graph improves summarization quality.

For future work, it would be interesting to investigate other related developments in this area and perhaps combine them with our approach to see if further improvements are possible. Firstly, it would interesting to see if dispersion offers similar improvements over a tuned version of the submodular framework of Lin and Bilmes (2011). In a very recent work, Lin and Bilmes (2012) demonstrate a further improvement in performance for document summarization by using mixtures of submodular shells. This is an interesting extension of their previous submodular framework and while the new formulation permits more complex functions, the resulting function is still submodular and hence can be combined with the dispersion measures proposed in this paper. A different body of work uses determinantal point processes (DPP) to model subset selection problems and adapt it for document summarization (Kulesza and Taskar, 2011). Note that DPPs use similarity kernels for performing inference whereas our measures are combinatorial and not kernel-representable. While approximation guarantees for DPPs are open, it would be interesting to investigate the empirical gains by combining DPPs with dispersion-like functions.

## Abstract

This study proposes a text summarization model that simultaneously performs sentence extraction and compression. We translate the text summarization task into a problem of extracting a set of dependency subtrees in the document cluster. We also encode obligatory case constraints as must-link dependency constraints in order to guarantee the readability of the generated summary. In order to handle the subtree extraction problem, we investigate a new class of submodular maximization problem, and a new algorithm that has the approximation ratio  $\frac{1}{2}(1 - e^{-1})$ . Our experiments with the NTCIR ACLIA test collections show that our approach outperforms a state-of-the-art algorithm.

## 1 Introduction

Text summarization is often addressed as a task of simultaneously performing sentence extraction and sentence compression (Berg-Kirkpatrick et al., 2011; Martins and Smith, 2009). Joint models of sentence extraction and compression have a great benefit in that they have a large degree of freedom as far as controlling redundancy goes. In contrast, conventional two-stage approaches (Zajic et al., 2006), which first generate candidate compressed sentences and then use them to generate a summary, have less computational complexity than joint models. However, two-stage approaches are suboptimal for text summarization. For example, when we compress sentences first, the compressed sentences may fail to contain important pieces of information due to the length limit imposed on each sentence. On the other

hand, when we extract sentences first, an important sentence may fail to be selected, simply because it is long. Enumerating a huge number of compressed sentences is also infeasible. Joint models can prune unimportant or redundant descriptions without resorting to enumeration.

Meanwhile, *submodular maximization* has recently been applied to the text summarization task, and the methods thereof have performed very well (Lin and Bilmes, 2010; Lin and Bilmes, 2011; Morita et al., 2011). Formalizing summarization as a submodular maximization problem has an important benefit in that the problem can be solved by using a greedy algorithm with a performance guarantee.

We therefore decided to formalize the task of simultaneously performing sentence extraction and compression as a submodular maximization problem. That is, we extract subsentences for making the summary directly from all available subsentences in the documents and not in a stepwise fashion. However, there is a difficulty with such a formalization. In the past, the resulting maximization problem has been often accompanied by thousands of linear constraints representing logical relations between words. The existing greedy algorithm for solving submodular maximization problems cannot work in the presence of such numerous constraints although monotone and non-monotone submodular maximization with constraints other than budget constraints have been studied (Lee et al., 2009; Kulik et al., 2009; Gupta et al., 2010). In this study, we avoid this difficulty by reducing the task to one of extracting dependency subtrees from sentences in the source documents. The reduction replaces the difficulty of numerous linear constraints with another difficulty wherein two subtrees can share the same word to-

ken when they are selected from the same sentence, and as a result, the cost of the union of the two subtrees is not always the mere sum of their costs. We can overcome this difficulty by tackling a new class of submodular maximization problem: a budgeted monotone nondecreasing submodular function maximization with a cost function, where the cost of an extraction unit varies depending on what other extraction units are selected. By formalizing the subtree extraction problem as this new maximization problem, we can treat the constraints regarding the grammaticality of the compressed sentences in a straightforward way and use an arbitrary monotone submodular word score function for words including our word score function (shown later). We also propose a new greedy algorithm that solves this new class of maximization problem with a performance guarantee  $\frac{1}{2}(1 - e^{-1})$ .

We evaluated our method on by using it to perform query-oriented summarization (Tang et al., 2009). Experimental results show that it is superior to state-of-the-art methods.

## 2 Related Work

*Submodularity* is formally defined as a property of a set function for a finite universe  $V$ . The function  $f : 2^V \rightarrow \mathbb{R}$  maps a subset  $S \subseteq V$  to a real value. If for any  $S, T \subseteq V$ ,  $f(S \cup T) + f(S \cap T) \leq f(S) + f(T)$ ,  $f$  is called *submodular*. This definition is equivalent to that of *diminishing returns*, which is well known in the field of economics:  $f(S \cup \{u\}) - f(S) \leq f(T \cup \{u\}) - f(T)$ , where  $T \subseteq S \subseteq V$  and  $u$  is an element of  $V$ . Diminishing returns means that the value of an element  $u$  remains the same or decreases as  $S$  becomes larger. This property is suitable for summarization purposes, because the gain of adding a new sentence to a summary that already contains sufficient information should be small. Therefore, many studies have formalized text summarization as a submodular maximization problem (Lin and Bilmes, 2010; Lin and Bilmes, 2011; Morita et al., 2011). Their approaches, however, have been based on sentence extraction. To our knowledge, there is no study that addresses the joint task of simultaneously performing compression and extraction through an approximate submodular maximization with a performance guarantee.

In the field of constrained maximization problems, Kulik et al. (2009) proposed an algorithm that solves the submodular maximization problem

under multiple linear constraints with a performance guarantee  $1 - e^{-1}$  in polynomial time. Although their approach can represent more flexible constraints, we cannot use their algorithm to solve our problem, because their algorithm needs to enumerate many combinations of elements. Integer linear programming (ILP) formulations can represent such flexible constraints, and they are commonly used to model text summarization (McDonald, 2007). Berg-Kirkpatrick et al. (2011) formulated a unified task of sentence extraction and sentence compression as an ILP. However, it is hard to solve large-scale ILP problems exactly in a practical amount of time.

## 3 Budgeted Submodular Maximization with Cost Function

### 3.1 Problem Definition

Let  $V$  be the finite set of all *valid* subtrees in the source documents, where *valid* subtrees are defined to be the ones that can be regarded as grammatical sentences. In this paper, we regard subtrees containing the root node of the sentence as valid. Accordingly,  $V$  denotes a set of all rooted subtrees in all sentences. A subtree contains a set of elements that are units in a dependency structure (e.g., morphemes, words or clauses). Let us consider the following problem of budgeted monotone nondecreasing submodular function maximization with a cost function:  $\max_{S \subseteq V} \{f(S) : c(S) \leq L\}$ , where  $S$  is a summary represented as a set of subtrees,  $c(\cdot)$  is the cost function for the set of subtrees,  $L$  is our budget, and the submodular function  $f(\cdot)$  scores the summary quality. The cost function is not always the sum of the costs of the covered subtrees, but depends on the set of the covered elements by the subtrees. Here, we will assume that the generated summary has to be as long as or shorter than the given summary length limit, as measured by the number of characters. This means the cost of a subtree is the integer number of characters it contains.

$V$  is partitioned into exclusive subsets  $\mathbb{B}$  of valid subtrees, and each subset corresponds to the original sentence from which the valid subtrees derived. However, the cost of a union of subtrees from different sentences is simply the sum of the costs of subtrees, while the cost of a union of subtrees from the same sentence is smaller than the sum of the costs. Therefore, the problem can be represented as follows:

$$\max_{S \subseteq V} \left\{ f(S) : \sum_{B \in \mathbb{B}} c(B \cap S) \leq L \right\}. \quad (1)$$

For example, if we add a subtree  $t$  containing words  $\{w_a, w_b, w_c\}$  to a summary that already covers words  $\{w_a, w_b, w_d\}$  from the same sentence, the additional cost of  $t$  is only  $c(\{w_c\})$  because  $w_a$  and  $w_b$  are already covered<sup>1</sup>.

The problem has two requirements. The first requirement is that the union of valid subtrees is also a valid subtree. The second requirement is that the union of subtrees and a single valid subtree have the same score and the same cost if they cover the same elements. We will refer to the single valid subtree as the *equivalent* subtree of the union of subtrees. These requirements enable us to represent sentence compression as the extraction of subtrees from a sentence. This is because the requirements guarantee that the extracted subtrees represent a sentence.

### 3.2 Greedy Algorithm

We propose Algorithm 1 that solves the maximization problem (Eq.1). The algorithm is based on ones proposed by Khuller et al. (1999) and Krause et al. (2005). Instead of enumerating all candidate subtrees, we use a *local search* to extract the element that has the highest gain per cost. In the algorithm,  $G_i$  indicates a summary set obtained by adding element  $s_i$  to  $G_{i-1}$ .  $U$  means the set of subtrees that are not extracted. The algorithm iteratively adds to the current summary the element  $s_i$  that has the largest ratio of the objective function gain to the additional cost, unless adding it violates the budget constraint. We set a parameter  $r$  that is the scaling factor proposed by Lin and Bilmes (2010). After the loop, the algorithm compares  $G_i$  with the  $\{s^*\}$  that has the largest value of the objective function among all subtrees that are under the budget, and it outputs the summary candidate with the largest value.

Let us analyze the performance guarantee of Algorithm 1<sup>2</sup>.

<sup>1</sup>Each subset  $B$  corresponds to a kind of greedoid constraint.  $V$  implicitly constrains the model such that it can only select valid subtrees from a set of nodes and edges.

<sup>2</sup>Our performance guarantee is lower than that reported by Lin and Bilmes (2010). However, their proof is erroneous. In their proof of Lemma 2, they derive  $\forall u \in S^* \setminus G_{i-1}, \frac{\rho_u(G_{i-1})}{C_u^r} \leq \frac{\rho_{v_i}(G_{i-1})}{C_{v_i}^r}$ , for any  $i(1 \leq i \leq |G|)$ , from line 4 of their Algorithm 1, which selects the densest element out of all available elements. However, the inequality does not hold for  $i$ , for which element  $u$  selected on line 4 is discarded on line 5 of their algorithm. The performance guarantee of their algorithm is actually the same as ours, since

```

1:  $G_0 \leftarrow \phi$ 
2:  $U \leftarrow V$ 
3:  $i \leftarrow 1$ 
4: while  $U \neq \phi$  do
5:    $s_i \leftarrow \arg \max_{s \in U} \frac{f(G_{i-1} \cup \{s\}) - f(G_{i-1})}{c(G_{i-1} \cup \{s\}) - c(G_{i-1})^r}$ 
6:   if  $c(\{s_i\} \cup G_{i-1}) \leq L$  then
7:      $G_i \leftarrow G_{i-1} \cup \{s_i\}$ 
8:      $i \leftarrow i + 1$ 
9:   end if
10:   $U \leftarrow U \setminus \{s_i\}$ 
11: end while
12:  $\bar{s} \leftarrow \arg \max_{s \in V, c(s) \leq L} f(\{s\})$ 
13: return  $G_f = \arg \max_{S \in \{\bar{s}, G_i\}} f(S)$ 

```

---

**Theorem 1** For a normalized monotone submodular function  $f(\cdot)$ , Algorithm 1 has a constant approximation factor when  $r = 1$  as follows:

$$f(G_f) \geq \left( \frac{1}{2}(1 - e^{-1}) \right) f(S^*), \quad (2)$$

where  $S^*$  is the optimal solution and,  $G_f$  is the solution obtained by Greedy Algorithm 1.

**Proof.** See appendix.

### 3.3 Relation with Discrete Optimization

We argue that our optimization problem can be regarded as an extraction of subtrees rooted at a given node from a directed graph, instead of from a tree. Let  $D$  be the set of edges of the directed graph,  $\mathcal{F}$  be a subset of  $D$  that is a subtree. In the field of combinatorial optimization, a pair  $(D, \mathcal{F})$  is a kind of greedoid: *directed branching greedoid* (Schmidt, 1991). A greedoid is a generalization of the matroid concept. However, while matroids are often used to represent constraints on submodular maximization problems (Conforti and Cornuéjols, 1984; Calinescu et al., 2011), greedoids have not been used for that purpose, in spite of their high representation ability. To our knowledge, this is the first study that gives a constant performance guarantee for the submodular maximization under greedoid (non-matroid) constraints.

---

the guarantee  $\frac{1}{2}(1 - e^{-1})$  was already proved by Krause and Guestrin (2005). We show a counterexample. Suppose that  $V$  is  $\{e_1(\text{density } 4:\text{cost } 6), e_2(\text{density } 2:\text{cost } 4), e_3(\text{density } 3:\text{cost } 1), e_4(\text{density } 1:\text{cost } 1)\}$ , and cost limit  $K$  is 10. The optimal solution is  $S^* = \{e_1, e_2\}$ . Their algorithm selects  $e_1, e_3, e_4$  in this order. However the algorithm selects  $e_2$  on line 4 after selecting  $e_3$ , and it drops  $e_2$  on line 5. As a result,  $e_4$  selected by the algorithm does not satisfy the inequality  $\forall u \in S^* \setminus G_{i-1}, \frac{\rho_u(G_{i-1})}{C_u^r} \leq \frac{\rho_{v_i}(G_{i-1})}{C_{v_i}^r}$ .

## 4 Joint Model of Extraction and Compression

We will formalize the unified task of sentence compression and extraction as a budgeted monotone nondecreasing submodular function maximization with a cost function. In this formalization, a valid subtree of a sentence represents a candidate of a compressed sentence. We will refer to all valid subtrees of a given sentence as a *valid set*. A valid set corresponds to all candidates of the compression of a sentence. Note that although we use the valid set in the formalization, we do not have to enumerate all the candidates for each sentence. Since, from the requirements, the union of valid subtrees is also a valid subtree in the valid set, the model can extract one or more subtrees from one sentence, and generate a compressed sentence by merging those subtrees to generate an equivalent subtree. Therefore, the joint model can extract an arbitrarily compressed sentence as a subtree without enumerating all candidates. The joint model can remove the redundant part as well as the irrelevant part of a sentence, because the model simultaneously extracts and compresses sentences. We can approximately solve the subtree extraction problem by using Algorithm 1. On line 5 of the algorithm, the subtree extraction is performed as a local search that finds *maximal density subtrees* from the whole documents. The maximal density subtree is a subtree that has the highest score per cost of subtree. We use a cost function to represent the cost, which indicates the length of word tokens in the subtree.

In this paper, we address the task of summarization of Japanese text by means of sentence compression and extraction. In Japanese, syntactic subtrees that contain the root of the dependency tree of the original sentence often make grammatical sentences. This means that the requirements mentioned in Section 3.1 that a union of valid subtrees is a valid and equivalent tree is often true for Japanese. The root indicates the predicate of a sentence, and it is syntactically modified by other prior words. Some modifying words can be pruned. Therefore, sentence compression can be represented as edge pruning. The linguistic units we extract are *bunsetsu* phrases, which are syntactic chunks often containing a functional word after one or more content words. We will refer to *bunsetsu* phrases as *phrases* for simplicity. Since Japanese syntactic dependency is generally

defined between two phrases, we use the phrases as the nodes of subtrees.

In this joint model, we generate a compressed sentence by extracting an arbitrary subtree from a dependency tree of a sentence. However, not all subtrees are always valid. The sentence generated by a subtree can be unnatural even though the subtree contains the root node of the sentence. To avoid generating such ungrammatical sentences, we need to detect and retain the obligatory dependency relations in the dependency tree. We address this problem by imposing must-link constraints if a phrase corresponds to an obligatory case of the main predicate. We merge obligatory phrases with the predicate beforehand so that the merged nodes make a single large node.

Although we focus on Japanese in this paper, our approach can be applied to English and other languages if certain conditions are satisfied. First, we need a dependency parser of the language in order to represent sentence compression as dependency tree pruning. Moreover, although, in Japanese, obligatory cases distinguish which edges of the dependency tree can be pruned or not, we need another technique to distinguish them in other languages. For example we can distinguish obligatory phrases from optional ones by using semantic role labeling to detect arguments of predicates. The adaptation to other languages is left for future work.

### 4.1 Objective Function

We extract subtrees from sentences in order to solve the query-oriented summarization problem as a unified one consisting of sentence compression and extraction. We thus need to allocate a query relevance score to each node. Off-the-shelf similarity measures such as the cosine similarity of bag-of-words vectors with query terms would allocate scores to the terms that appear in the query, but would give no scores to terms that do not appear in it. With such a similarity, sentence compression extracts nearly only the query terms and fails to contain important information. Instead, we used Query SnowBall (QSB) (Morita et al., 2011) to calculate the query relevance score of each phrase. QSB is a method for query-oriented summarization, which calculates the similarity between query terms and each word by using co-occurrences within the source documents. Although the authors of QSB also provided scores of word pairs to avoid putting excessive penalties

on word overlaps, we do not score word pairs. The score function is *supermodular* as a score function of subtree extraction<sup>3</sup>, because the union of two subtrees can have extra word pairs that are not included in either subtree. If the extra pair has a positive score, the score of the union is greater than the sum of the score of the subtrees. This violates the definition of submodularity, and invalidates the performance guarantee of our algorithms.

We designed our objective function by combining this relevance score with a penalty for redundancy and too-compressed sentences. Important words that describe the main topic should occur multiple times in a good summary. However, excessive overlap undermines the quality of a summary, as do irrelevant words. Therefore, the scores of overlapping words should be lower than those of new words. The behavior can be represented by a submodular objective function that reduces word scores depending on those already included in the summary. Furthermore, a summary consisting of many too-compressed sentences would lack readability. We thus give a positive reward to long sentences. The positive reward leads to a natural summary being generated with fewer sentences and indirectly penalizes too short sentences. Our positive reward for long sentences is represented as

$$reward(S) = c(S) - |S|, \quad (3)$$

where  $c(S)$  is the cost of summary  $S$ , and  $|S|$  is the number of sentences in  $S$ . Since a sentence must contain more than one character, the reward consistently gives a positive score, and gives a higher score to a summary that consists of fewer sentences.

Let  $d$  be the damping rate,  $count_S(w)$  be the number of sentences containing word  $w$  in summary  $S$ ,  $words(S)$  be the set of words included in summary  $S$ ,  $qsb(w)$  be the query relevance score of word  $w$ , and  $\gamma$  be a parameter that adjusts the rate of sentence compression. Our score function for a summary  $S$  is as follows:

$$f(S) = \sum_{w \in words(S)} \left\{ \sum_{i=0}^{count_S(w)-1} qsb(w)d^i \right\} + \gamma reward(S). \quad (4)$$

An optimization problem with this objective function cannot be regarded as an ILP problem because it contains non-linear terms. It is also ad-

<sup>3</sup>The score is still submodular for the purpose of sentence extraction.

vantageous that the submodular maximization can deal with such objective functions. Note that the objective function is such that it can be calculated according to the type of word. Due to the nature of the objective function, we can use dynamic programming to effectively search for the subtree with the maximal density.

## 4.2 Local Search for Maximal Density Subtree

Let us now discuss the local search used on line 5 of Algorithm 1. We will use a fast algorithm to find the maximal density subtree (MDS) of a given sentence for each cost in Algorithm 1.

Consider the objective function Eq. 4. We can ignore the second term of the reward function while looking for the MDS in a sentence because the number of sentences is the same for every MDS in a sentence. That is, the gain function of adding a subtree to a summary can be represented as the sum of gains for words:

$$g(t) = \sum_{w \in t} \{gain_S(w) + freq_t(w)c(w)\gamma\},$$

$$gain_S(w) = qsb(w)d^{count_S(w)},$$

where  $freq_t(w)$  is the number of  $w$ s in subtree  $t$ , and  $gain_S(w)$  is the gain of adding the word  $w$  to the summary  $S$ . Our algorithm is based on *dynamic programming*, and it selects a subtree that maximizes the gain function per cost.

When the word gain is a constant, the algorithm proposed by Hsieh et al. (2010) can be used to find the MDS. We extended this algorithm to work for submodular word gain functions that are not constant. Note that the gain of a word that occurs only once in the sentence, can be treated as a constant. In what follows, we will describe an extended algorithm to find the MDS even if there is word overlap.

For example, let us describe how to obtain the MDS in the case of a binary tree. First let us tackle the case in which the gain is always constant. Let  $n$  be a node in the tree,  $a$  and  $b$  be child nodes of  $n$ ,  $c(n)$  be the cost of  $n$ ,  $mds_a^c$  be the MDS rooted at  $a$  and have cost  $c$ .  $mds_n = \{mds_n^{c(n)}, \dots, mds_n^L\}$  denotes the set of MDSs for each cost and its root node  $n$ . The valid subtrees rooted at  $n$  can be obtained by taking unions of  $n$  with one or both of  $t_1 \in mds_a$  and  $t_2 \in mds_b$ .  $mds_n^c$  is the union that has the largest gain over the union with the cost of  $c$  (by enumerating all the unions). The MDS for

the sentence root can be found by calculating each  $mds_n^c$  from the bottom of the tree to the top.

Next, let us consider the objective function that returns the sum of values of submodular word gain functions. When there is no word overlap within the union, we can obtain  $mds_n^c$  in the same manner as for the constant gain. In contrast, if the union includes word overlap, the gain is less than the sum of gains:  $g(mds_n^c) \leq g(n) + g(mds_a^k) + g(mds_b^{c-k-c(n)})$ , where  $k$  and  $c$  are variables. The score reduction can change the order of the gains of the union. That is, it is possible that another union without word overlaps will have a larger gain. Therefore, the algorithm needs to know whether each  $t \in mds_n$  has the potential to have word overlaps with other MDSs. Let  $\mathcal{O}$  be the set of words that occur twice or more in the sentence on which the local search focuses. The algorithm stores MDS for each  $o \subseteq \mathcal{O}$ , as well as each cost. By storing MDS for each  $o$  and cost as shown in Fig. 1, the algorithm can find MDS with the largest gain over the combinations of subtrees.

Algorithm 2 shows the procedure. In it,  $t$  and  $m$  denote subtrees,  $words(t)$  returns a set of words in the subtree,  $g(t)$  returns the gain of  $t$ ,  $tree(n)$  means a tree consisting of node  $n$ , and  $t \cup m$  denotes the union of subtrees:  $t$  and  $m$ .  $subt$  indicates a set of current maximal density subtrees among the combinations calculated before.  $newt$  indicates a set of temporary maximal density subtrees for the combinations calculated from line 4 to 8.  $subt_{[cost,ws]}$  indicates a element of  $subt$  that has a cost  $cost$  and contains a set of words  $ws$ .  $newt_{[cost,ws]}$  is defined similarly. Line 1 sets  $subt$  to a set consisting of a subtree that indicates node  $n$  itself. The algorithm calculates maximal density subtrees within combinations of the root node  $n$  and MDSs rooted at child nodes of  $n$ . Line 3 iteratively adds MDSs rooted at a next child node to the combinations; the algorithm then calculates MDSs  $newt$  between  $subt$  and the MDSs of the child node. The procedure from line 6 to 8 selects a subtree that has a larger gain from the temporary maximal subtree and the union of  $t$  and  $m$ . The computational complexity of this algorithm is  $O(NC^2)$  when there is no word overlap within the sentence, where  $C$  denotes the cost of the whole sentence, and  $N$  denotes the number of nodes in the sentence. The complexity order is the same as that of the algorithm of Hsieh et al. (2010). When we treat word overlaps, we need to count

all unions of combinations of the stored MDSs. There are at most  $(C2^{|\mathcal{O}|})$  MDSs that the algorithm needs to store at each node. Therefore the total computational complexity is  $O(NC^22^{2|\mathcal{O}|})$ . Since it is unlikely that a sentence contains many word tokens of one type, the computational cost may not be so large in practical situations.

## 5 Experimental Settings

We evaluate our method on Japanese QA test collections from NTCIR-7 ACLIA1 and NTCIR-8 ACLIA2 (Mitamura et al., 2008; Mitamura et al., 2010). The collections contain questions and weighted answer nuggets. Our experimental settings followed the settings of (Morita et al., 2011), except for the maximum summary length. We generated summaries consisting of 140 Japanese characters or less, with the question as the query terms. We did this because our aim is to use our method in mobile situations. We used “ACLIA1 test data” to tune the parameters, and evaluated our method on “ACLIA2 test” data.

We used JUMAN (Kurohashi and Kawahara, 2009a) for word segmentation and part-of-speech tagging, and we calculated  $idf$  over Mainichi newspaper articles from 1991 to 2005. For the de-

	POURPRE	Precision	Recall	F1	F3
Lin and Bilmes (2011)	0.215	0.126	0.201	0.135	0.174
Subtree extraction (SbE)	0.268	0.238	0.213	<b>0.159</b>	<b>0.190</b>
Sentence extraction (NC)	0.278	0.206	0.215	0.139	0.183

Table 1: Results on ACLIA2 test data.

pendency parsing, we used KNP (Kurohashi and Kawahara, 2009b). Since KNP internally has a flag that indicates either an “obligatory case” or an “adjacent case”, we regarded dependency relations flagged by KNP as obligatory in the sentence compression. KNP utilizes Kyoto University’s case frames (Kawahara and Kurohashi, 2006) as the resource for detecting obligatory or adjacent cases.

To evaluate the summaries, we followed the practices of the TAC summarization tasks (Dang, 2008) and NTCIR ACLIA tasks, and computed pyramid-based precision with the allowance parameter, recall, and  $F_\beta$  (where  $\beta$  is 1 or 3) scores. The allowance parameter was determined from the average nugget length for each question type of the ACLIA2 collection (Mitamura et al., 2010). Precision and recall are computed from the nuggets that the summary covered along with their weights. One of the authors of this paper manually evaluated whether each nugget matched the summary. We also used the automatic evaluation measure, POURPRE (Lin and Demner-Fushman, 2006). POURPRE is based on word matching of reference nuggets and system outputs. We regarded as stopwords the most frequent 100 words in Mainichi articles from 1991 to 2005 (the document frequency was used to measure the frequency). We also set the threshold of nugget matching as 0.5 and binarized the nugget matching, following the previous study (Mitamura et al., 2010). We tuned the parameters by using POURPRE on the development dataset.

Lin and Bilmes (2011) designed a monotone submodular function for query-oriented summarization. Their succinct method performed well in DUC from 2004 to 2007. They proposed a positive diversity reward function in order to define a monotone submodular objective function for generating a non-redundant summary. The diversity reward gives a smaller gain for a biased summary, because it consists of gains based on three clusters and calculates a square root score with respect to each sentence. The reward also contains a score for the similarity of a sentence to the query, for purposes of query-oriented summa-

	Recall	Length	# of nuggets
Subtree extraction	0.213	11,143	100
Reconstructed (RC)	0.228	13,797	108

Table 2: Effect of sentence compression.

riziation. Their objective function also includes a coverage function based on the similarity  $w_{i,j}$  between sentences. In the coverage function min function limits the maximum gain  $\alpha \sum_{i \in V} w_{i,j}$ , which is a small fraction  $\alpha$  of the similarity between a sentence  $j$  and the all source documents. The objective function is the sum of the positive reward  $\mathcal{R}$  and the coverage function  $\mathcal{L}$  over the source documents  $V$ , as follows:

$$\begin{aligned} \mathcal{F}(S) &= \mathcal{L}(S) + \sum_{k=1}^3 \lambda_k \mathcal{R}_{Q,k}(S), \\ \mathcal{L}(S) &= \sum_{i \in V} \min \left\{ \sum_{j \in S} w_{i,j}, \alpha \sum_{k \in V} w_{i,k} \right\}, \\ \mathcal{R}_{Q,k} &= \sum_{c \in C_k} \sqrt{\sum_{j \in S \cup c} \left( \frac{\beta}{N} \sum_{i \in V} w_{i,j} + (1 - \beta) r_{j,Q} \right)}, \end{aligned}$$

where  $\alpha$ ,  $\beta$  and  $\lambda_k$  are parameters, and  $r_{j,Q}$  represents the similarity between sentence  $j$  and query  $Q$ . We tuned the parameters on the development dataset. Lin and Bilmes (2011) used three clusters  $C_k$  with different granularities, which were calculated in advance. We set the granularity to  $(0.2N, 0.15N, 0.05N)$  according to the settings of them, where  $N$  is the number of sentences in a document.

We also regarded as stopwords “教える (tell),” “知る (know),” “何 (what)” and their conjugated forms, which are excessively common in questions. For the query expansion in the baseline, we used Japanese WordNet to obtain synonyms and hypernyms of query terms.

## 6 Results

Table 1 summarizes our results. “Subtree extraction (SbE)” is our method, and “Sentence extraction (NC)” is a version of our method without compression. The NC has the same objective function but only extracts sentences. The F1-measure and F3-measure of our method are 0.159 and 0.190 respectively, while those of the state-of-

the-art baseline are 0.135 and 0.174 respectively. Unfortunately, since the document set is small, the difference is not statistically significant. Comparing our method with the one without compression, we can see that there are improvements in the F1 and F3 scores of the human evaluation, whereas the POURPRE score of the version of our method without compression is higher than that of our method with compression. The compression improved the precision of our method, but slightly decreased the recall.

For the error analyses, we reconstructed the original sentences from which our method extracted the subtrees. Table 2 shows the statistics of the summaries of SbE and reconstructed summaries (RC). The original sentences covered 108 answer nuggets in total, and 8 of these answer nuggets were dropped by the sentence compression. Comparing the results of SbE and RC, we can see that the sentence compression caused the recall of SbE to be 7% lower than that of RC. However, the drop is relatively small in light of the fact that the sentence compression can discard 19% of the original character length with SbE. This suggests that the compression can efficiently prune words while avoiding pruning informative content.

Since the summary length is short, we can select only two or three sentences for a summary. As Morita et al. (2011) mentioned, answer nuggets overlap each other. The baseline objective function  $\mathcal{R}$  tends to extract sentences from various clusters. If the answer nuggets are present in the same cluster, the objective function does not fit the situation. However, our methods (SbE and NC) have a parameter  $d$  that can directly adjust overlap penalty with respect to word importance as well as query relevance. This may help our methods to cover similar answer nuggets. In fact, the development data resulted in a relatively high parameter  $d$  (0.8) for NC compared with 0.2 for SbE.

## 7 Conclusions and Future Work

We formalized a query-oriented summarization, which is a task in which one simultaneously performs sentence compression and extraction, as a new optimization problem: budgeted monotone nondecreasing submodular function maximization with a cost function. We devised an approximate algorithm to solve the problem in a reasonable computational time and proved that its approximation rate is  $\frac{1}{2}(1 - e^{-1})$ . Our approach achieved

an F3-measure of 0.19 on the ACLIA2 Japanese test collection, which is 9.2 % improvement over a state-of-the-art method using a submodular objective function.

Since our algorithm requires that the objective function is the sum of word score functions, our proposed method has a restriction that we cannot use an arbitrary monotone submodular function as the objective function for the summary. Our future work will improve the local search algorithm to remove this restriction. As mentioned before, we also plan to adapt of our system to other languages.

## Appendix

Here, we analyze the performance guarantee of Algorithm 1. We use the following notation.  $S^*$  is the optimal solution,  $c_u(S)$  is the residual cost of subtree  $u$  when  $S$  is already covered, and  $i^*$  is the last step before the algorithm discards a subtree  $s \in S^*$  or a part of the subtree  $s$ . This is because the subtree does not belong to either the approximate solution or the optimal solution. We can remove the subtree  $s'$  from  $V$  without changing the approximate rate.  $s_i$  is the  $i$ -th subtree obtained by line 5 of Algorithm 1.  $G_i$  is the set obtained after adding subtree  $s_i$  to  $G_{i-1}$  from the valid set  $B_i$ .  $G_f$  is the final solution obtained by Algorithm 1.  $f(\cdot) : 2^V \rightarrow \mathbb{R}$  is a monotone submodular function.

We assume that there is an equivalent subtree with any union of subtrees in a valid set  $B$ :  $\forall t_1, t_2, \exists t_e, t_e \equiv \{t_1, t_2\}$ . Note that for any order of the set, the cost or profit of the set is fixed:  $\sum_{u_i \in S = \{u_1, \dots, u_{|S|}\}} c_{u_i}(S_{i-1}) = c(S)$ .

**Lemma 1**  $\forall X, Y \subseteq V, f(X) \leq f(Y) + \sum_{u \in X \setminus Y} \rho_u(Y)$ , where  $\rho_u(S) = f(S \cup \{u\}) - f(S)$ .

The inequality can be derived from the definition of submodularity.  $\square$

**Lemma 2** For  $i = 1, \dots, i^* + 1$ , when  $0 \leq r \leq 1$ ,

$$f(S^*) - f(G_{i-1}) \leq \frac{L^r |S^*|^{1-r}}{c_{s_i}(G_{i-1})} (f(G_{i-1} \cup \{s_i\}) - f(G_{i-1})),$$

where  $c_u(S) = c(S \cup \{u\}) - c(S)$ .

*Proof.* From line 5 of Algorithm 1, we have

$$\forall u \in S^* \setminus G_{i-1}, \frac{\rho_u(G_{i-1})}{c_u(G_{i-1})^r} \leq \frac{\rho_{s_i}(G_{i-1})}{c_{s_i}(G_{i-1})^r}.$$

Let  $B$  be a valid set, and  $union$  be a function that returns the union of subtrees. We have

$\forall T \subseteq B, \exists b \in B, b = \text{union}(T)$ , because we have an equivalent tree  $b \in B$  for each union of trees  $T$  in a valid set  $B$ . That is, for any set of subtrees, we have an equivalent set of subtrees, where  $b_i \in B_i$ . Without loss of generality, we can replace the difference set  $S^* \setminus G_{i-1}$  with a set  $T'_{i-1} = \{b_0, \dots, b_{|T'_{i-1}|}\}$  that does not contain any two elements extracted from the same valid set. Thus when  $0 \leq r \leq 1$  and  $0 \leq i \leq i^* + 1$ ,  $\frac{\rho_{S^* \setminus G_{i-1}}(G_{i-1})}{c_{S^* \setminus G_{i-1}}(G_{i-1})^r} = \frac{\rho_{T'_{i-1}}(G_{i-1})}{c_{T'_{i-1}}(G_{i-1})^r}$ , and  $\forall b_j \in T'_{i-1}, \frac{\rho_{b_j}(G_{i-1})}{c_{b_j}(G_{i-1})^r} \leq \frac{\rho_{s_i}(G_{i-1})}{c_{s_i}(G_{i-1})^r}$ . Thus,

$$\begin{aligned} \rho_{T'_{i-1}}(G_{i-1}) &= \sum_{u \in T'_{i-1}} \rho_u(G_{i-1}) \\ &\leq \frac{\rho_{s_i}(G_{i-1})}{c_{s_i}(G_{i-1})^r} \sum_{u \in T'_{i-1}} c_u(G_{i-1})^r \\ &\leq \frac{\rho_{s_i}(G_{i-1})}{c_{s_i}(G_{i-1})^r} |T'_{i-1}| \left( \frac{\sum_{u \in T'_{i-1}} c_u(G_{i-1})}{|T'_{i-1}|} \right)^r \\ &\leq \frac{\rho_{s_i}(G_{i-1})}{c_{s_i}(G_{i-1})^r} |T'_{i-1}|^{1-r} \left( \sum_{u \in T'_{i-1}} c_u(\phi) \right)^r \\ &\leq \frac{\rho_{s_i}(G_{i-1})}{c_{s_i}(G_{i-1})^r} |S^*|^{1-r} L^r, \end{aligned}$$

where the second inequality is from Hölder's inequality. The third inequality uses the submodularity of the cost function,

$$c_u(G_{i-1}) = c(\{u\} \cup G_{i-1}) - c(G_{i-1}) \leq c_u(\phi)$$

and the fact that  $|S^*| \geq |S^* \setminus G_{i-1}| \geq |T'_{i-1}|$ , and  $\sum_{u \in T'_{i-1}} c_u(\phi) = c(T'_{i-1}) \leq L$ .

As a result, we have

$$\begin{aligned} \rho_{S^* \setminus G_{i-1}}(G_{i-1}) &= \rho_{T'_{i-1}}(G_{i-1}) \\ &\leq \frac{\rho_{s_i}(G_{i-1})}{c_{s_i}(G_{i-1})^r} |S^*|^{1-r} L^r. \end{aligned}$$

Let  $X = S^*$  and  $Y = G_{i-1}$ . Applying Lemma 1 yields

$$\begin{aligned} f(S^*) &\leq f(G_{i-1}) + \rho_{u \in S^* \setminus G_{i-1}}(G_{i-1}). \\ &\leq f(G_{i-1}) + \frac{\rho_{s_i}(G_{i-1})}{c_{s_i}(G_{i-1})^r} |S^*|^{1-r} L^r. \end{aligned}$$

The lemma follows as a result.

**Lemma 3** For a normalized monotone submodular  $f(\cdot)$ , for  $i = 1, \dots, i^* + 1$  and  $0 \leq r \leq 1$  and letting  $s_i$  be the  $i$ -th unit added into  $G$  and  $G_i$  be the set after adding  $s_i$ , we have

$$f(G_i) \geq \left( 1 - \prod_{k=1}^i \left( 1 - \frac{c_{s_k}(G_{k-1})^r}{L^r |S^*|^{1-r}} \right) \right) f(S^*).$$

*Proof.* This is proved similarly to Lemma 3 of (Krause and Guestrin, 2005) using Lemma 2.

*Proof of Theorem 1.* This is proved similarly to Theorem 1 of (Krause and Guestrin, 2005) using Lemma 3.

## Abstract

Probabilistic context-free grammars have the unusual property of not always defining tight distributions (i.e., the sum of the “probabilities” of the trees the grammar generates can be less than one). This paper reviews how this non-tightness can arise and discusses its impact on Bayesian estimation of PCFGs. We begin by presenting the notion of “almost everywhere tight grammars” and show that linear CFGs follow it. We then propose three different ways of reinterpreting non-tight PCFGs to make them tight, show that the Bayesian estimators in Johnson et al. (2007) are correct under one of them, and provide MCMC samplers for the other two. We conclude with a discussion of the impact of tightness empirically.

## 1 Introduction

Probabilistic Context-Free Grammars (PCFGs) play a special role in computational linguistics because they are perhaps the simplest probabilistic models of hierarchical structures. Their simplicity enables us to mathematically analyze their properties to a detail that would be difficult with linguistically more accurate models. Such analysis is useful because it is reasonable to expect more complex models to exhibit similar properties as well.

The problem of inferring PCFG rule probabilities from training data consisting of yields or strings alone is interesting from both cognitive and engineering perspectives. Cognitively it is implausible that children can perceive the parse trees of the language they are learning, but it is more reasonable to assume that they can obtain the terminal strings or yield of these trees. Unsupervised methods for learning a grammar from terminal strings alone is also interesting from an engineering perspective because such training data is cheap and

plentiful, while the manually parsed data required by supervised methods are expensive to produce and relatively rare.

Cohen and Smith (2012) show that inferring PCFG rule probabilities from strings alone is computationally intractable, so we should not expect to find an efficient, general-purpose algorithm for the unsupervised problem. Instead, approximation algorithms are standardly used. For example, the Inside-Outside (IO) algorithm efficiently implements the Expectation-Maximization (EM) procedure for approximating a Maximum Likelihood estimator (Lari and Young, 1990). Bayesian estimators for PCFG rule probabilities have also been attracting attention because they provide a theoretically-principled way of incorporating prior information. Kurihara and Sato (2006) proposed a Variational Bayes estimator based on a mean-field approximation, and Johnson et al. (2007) proposed MCMC samplers for the posterior distribution over rule probabilities and the parse trees of the training data strings.

PCFGs have the interesting property (which we expect most linguistically more realistic models to also possess) that the distributions they define are not always properly normalized or “tight”. In a non-tight PCFG the partition function (i.e., sum of the “probabilities” of all the trees generated by the PCFG) is less than one. (Booth and Thompson, 1973, called such non-tight PCFGs “inconsistent”, but we follow Chi and Geman (1998) in calling them “non-tight” to avoid confusion with the consistency of statistical estimators). Chi (1999) showed that renormalized non-tight PCFGs (which he called “Gibbs CFGs”) define the same class of distributions over trees as do tight PCFGs with the same rules, and provided an algorithm for mapping any PCFG to a tight PCFG with the same rules that defines the same distribution over trees.

An obvious question is then: how does tightness affect the inference of PCFGs? Chi and Geman (1998) studied the question for Maximum Likelihood (ML) estimation, and showed that ML es-

timates are always tight for both the supervised case (where the input consists of parse trees) and the unsupervised case (where the input consists of yields or terminal strings). This means that ML estimators can simply ignore issues of tightness, and rest assured that the PCFGs they estimate are in fact tight.

The situation is more subtle with Bayesian estimators. We show that for the special case of linear PCFGs (which include HMMs) with non-degenerate priors the posterior puts zero mass on non-tight PCFGs, so tightness is not an issue with Bayesian estimation of such grammars. However, because all of the commonly used priors (such as the Dirichlet or the logistic normal) assign non-zero probability across the whole probability simplex, in general the posterior may assign non-zero probability to non-tight PCFGs. We discuss three different possible approaches to this in this paper:

1. the *only-tight* approach, where we modify the prior so it only assigns non-zero probability to tight PCFGs,
2. the *renormalization* approach, where we renormalize non-tight PCFGs so they define a probability distribution over trees, and
3. the *sink-element* approach, where we reinterpret non-tight PCFGs as assigning non-zero probability to a “sink element”, so both tight and non-tight PCFGs are properly normalized.

We show how to modify the Gibbs sampler described by Johnson et al. (2007) so it produces samples from the posterior distributions defined by the only-tight and renormalization approaches. Perhaps surprisingly, we show that Gibbs sampler as defined by Johnson et al. actually produces samples from the posterior distributions defined by the sink-element approach.

We conclude by studying the effect of requiring tightness on the estimation of some simple PCFGs. Because the Bayesian posterior converges around the (tight) ML estimate as the size of the data grows, requiring tightness only seems to make a difference with highly biased priors or with very small training corpora.

## 2 PCFGs and tightness

Let  $G = (T, N, S, R)$  be a Context-Free Grammar in Chomsky normal form with no useless productions, where  $T$  is a finite set of *terminal symbols*,

$N$  is a finite set of *nonterminal symbols* (disjoint from  $T$ ),  $S \in N$  is a distinguished nonterminal called the *start symbol*, and  $R$  is a finite set of *productions* of the form  $A \rightarrow BC$  or  $A \rightarrow w$ , where  $A, B, C \in N$  and  $w \in T$ . In what follows we use  $\beta$  as a variable ranging over  $(N \times N) \cup T$ .

A *Probabilistic Context-Free Grammar*  $(G, \Theta)$  is a pair consisting of a context-free grammar  $G$  and a real-valued vector  $\Theta$  of length  $|R|$  indexed by productions, where  $\theta_{A \rightarrow \beta}$  is the *production probability* associated with the production  $A \rightarrow \beta \in R$ . We require that  $\theta_{A \rightarrow \beta} \geq 0$  and that for all nonterminals  $A \in N$ ,  $\sum_{A \rightarrow \beta \in R_A} \theta_{A \rightarrow \beta} = 1$ , where  $R_A$  is the subset of rules  $R$  expanding the nonterminal  $A$ .

A PCFG  $(G, \Theta)$  defines a measure  $\mu_\Theta$  over trees  $t$  as follows:

$$\mu_\Theta(t) = \prod_{r \in R} \theta_r^{f_r(t)}$$

where  $f_r(t)$  is the number of times the production  $r = A \rightarrow \beta \in R$  is used in the derivation of  $t$ .

The *partition function*  $Z$  or measure of all possible trees is:

$$Z(\Theta) = \sum_{t' \in \mathcal{T}} \prod_{r \in R} \theta_r^{f_r(t')}$$

where  $\mathcal{T}$  is the set of all (finite) trees generated by  $G$ . A PCFG is *tight* iff the partition function  $Z(\Theta) = 1$ . In this paper we use  $\Theta^\perp$  to denote the set of rule probability vectors  $\Theta$  for which  $G$  is non-tight. Nederhof and Satta (2008) survey several algorithms for computing  $Z(\Theta)$ , and hence for determining whether a PCFG is tight.<sup>1</sup>

Non-tightness can arise in very simple PCFGs, such as the “Catalan” PCFG  $S \rightarrow SS \mid a$ . This grammar produces binary trees where all internal nodes are labeled as  $S$  and the yield of these trees is a sequence of  $as$ . If the probability of the rule  $S \rightarrow SS$  is greater than 0.5 then this PCFG is non-tight.

Perhaps the most straight-forward way to understand this non-tightness is to view this grammar as defining a branching process where an  $S$  can either “reproduce” with probability  $\theta_{S \rightarrow SS}$  or “die out”

<sup>1</sup>We found out that finding whether a PCFG is tight by directly inspecting the partition function value is less stable than using the method in Wetherell (1980). For this reason, we used Wetherell’s approach, which is based on finding the principal eigenvalue of the matrix  $M$ .

with probability  $\theta_{S \rightarrow a}$ . When  $\theta_{S \rightarrow S} > \theta_{S \rightarrow a}$  the  $S$  nodes reproduce at a faster rate than they die out, so the derivation has a non-zero probability of endlessly rewriting (Atherya and Ney, 1972).

### 3 Bayesian inference for PCFGs

The goal of Bayesian inference for PCFGs is to infer a posterior distribution over the rule probability vectors  $\Theta$  given observed data  $D$ . This posterior distribution is obtained by combining the likelihood  $P(D | \Theta)$  with a prior distribution  $P(\Theta)$  over  $\Theta$  using Bayes Rule.

$$P(\Theta | D) \propto P(D | \Theta) P(\Theta)$$

We now formally define the three approaches to handling non-tightness mentioned earlier:

**the only-tight approach:** we only permit priors where  $P(\Theta^\perp) = 0$ , i.e., we insist that the prior assign zero mass to non-tight rule probability vectors, so  $Z = 1$ . This means we can define:

$$P(t | \Theta) = \mu_\Theta(t)$$

**the renormalization approach:** we renormalize non-tight PCFGs by dividing by the partition function:

$$P(t | \Theta) = \frac{1}{Z(\Theta)} \mu_\Theta(t) \quad (1)$$

**the sink-element approach:** we redefine our probability distribution so its domain is a set  $\mathcal{T}' = \mathcal{T} \cup \{\perp\}$ , where  $\mathcal{T}$  is the set of (finite) trees generated by  $G$  and  $\perp \notin \mathcal{T}$  is a new element that serves as a “sink state” to which the “missing mass”  $1 - Z(\Theta)$  is assigned. Then we define:<sup>2</sup>

$$P(t | \Theta) = \begin{cases} \mu_\Theta(t) & \text{if } t \in \mathcal{T} \\ 1 - Z(\Theta) & \text{if } t = \perp \end{cases}$$

<sup>2</sup>This definition of a distribution over trees can be induced by a tight PCFG with a special  $\perp$  symbol in its vocabulary. Given  $G$ , the first step is to create a tight grammar  $G_0$  using the renormalization approach. Then, a new start symbol is added to  $G_0$ ,  $S_0$ , and also rules  $S_0 \rightarrow S$  (where  $S$  is the old start symbol in  $G_0$ ) and  $S_0 \rightarrow \perp$ . The first rule is given probability  $Z(\Theta)$  and the second rule is given probability  $1 - Z(\Theta)$ . It can be then readily shown that the new tight PCFG  $G_0$  induces a distribution over trees just like in Eq. 3, only with additional  $S_0$  on top of all trees.

With this in hand, we can now define the likelihood term. We consider two types of data  $D$  here. In the *supervised setting* the data  $D$  consists of a corpus of parse trees  $D = (t_1, \dots, t_n)$  where each tree  $t_i$  is generated by the PCFG  $G$ , so

$$P(D | \Theta) = \prod_{i=1}^n P(t_i | \Theta)$$

In the *unsupervised setting* the data  $D$  consists of a corpus of strings  $D = (w_1, \dots, w_n)$  where each string  $w_i$  is the yield of one or more trees generated by  $G$ . In this setting

$$P(D | \Theta) = \prod_{i=1}^n P(w_i | \Theta), \text{ where:}$$

$$P(w | \Theta) = \sum_{t \in \mathcal{T}: \text{yield}(t)=w} P(t | \Theta)$$

### 4 The special case of linear PCFGs

One way to handle the issue of tightness is to identify a family of CFGs for which practically any parameter setting will yield a tight PCFG. This is the focus of this section, in which we identify a subset of CFGs, which are “almost everywhere” tight. This family of CFGs includes many of the CFGs used in NLP applications.

We cannot expect that a CFG will yield a tight PCFG for *any* assignment to the rule probabilities (i.e. that  $\Theta^\perp = \emptyset$ ). Even in simple cases, such as the grammar  $S \rightarrow S|a$ , the assignment of probability 1 to  $S \rightarrow S$  and 0 to the other rule renders the  $S$  nonterminal useless, and places all of the probability mass on infinite structures of the form  $S \rightarrow S \rightarrow S \rightarrow \dots$

However, we can weaken our requirement so that the cases in which parameter assignment yields a non-tight PCFG are rare, or have measure zero. To put it more formally, we say that a prior  $P(\Theta)$  is “tight almost everywhere for  $G$ ” if

$$P(\Theta^\perp) = \int_{\Theta \in \Theta^\perp} P(\Theta) d\Theta = 0.$$

We now provide a sufficient condition (linearity) for CFGs under which they are tight almost everywhere with any continuous prior.

For a nonterminal  $A \in N$  and  $\beta \in (N \cup T)^*$ , we use  $A \Rightarrow^k \beta$  to denote that  $A$  can be re-written using a sequence of rules from  $R$  to the sentential form  $\beta$  in  $k$  derivation steps. We use  $A \Rightarrow^+ \beta$  to denote that there exists a  $k > 0$  such that  $A \Rightarrow^k \beta$ .

**Definition 1** A context-free grammar  $G$  is linear if there are no  $A \in N$  such that

$$A \Rightarrow^+ \dots A \dots A \dots$$

**Definition 2** A nonterminal  $A \in N$  in a probabilistic context-free grammar  $G$  with parameters  $\Theta$  is nonterminating if

$$P_G(A \Rightarrow^+ \dots A \dots | \Theta) = 1.$$

Here  $P(A \Rightarrow^+ \dots A \dots | \Theta)$  is defined as:

$$\sum_{\beta: \beta = \dots A \dots} P_G(A \Rightarrow^+ \beta | \Theta).$$

**Lemma 1** A linear PCFG  $G$  with parameters  $\Theta$  which does not have any nonterminating nonterminals is tight.

*Proof:* Our proof relies on the properties of a certain  $|N| \times |N|$  matrix  $M$  where:

$$M_{AB} = \sum_{A \rightarrow \beta \in R_A} n(\beta, B) \theta_{A \rightarrow \beta}$$

where  $n(\beta, B)$  is the number of appearances of the nonterminal  $B$  in the sequence  $\beta$ .  $M_{AB}$  is the expected number of  $B$  nonterminals generated from an  $A$  nonterminal in one single derivational step, so  $[M^k]_{AB}$  is the expected number of  $B$  nonterminals generated from an  $A$  nonterminal in a  $k$ -step derivation (Wetherell, 1980).

Since  $M$  is a non-negative matrix, under some regularity conditions, the Frobenius-Perron theorem states that the largest eigenvalue of this matrix (in absolute value) is a real number. Let this eigenvalue be denoted by  $\lambda$ .

A PCFG is called “subcritical” if  $\lambda < 1$  and supercritical if  $\lambda > 1$ . Then, in turn, a PCFG is tight if it is subcritical. It is not tight if it is supercritical. The case of  $\lambda = 1$  is a borderline case that does not give sufficient information to know whether the PCFG is tight or not. In the Bayesian case, for a continuous prior such as the Dirichlet prior, this borderline case will have measure zero under the prior.

Now let  $A \in N$ . Since the grammar is linear, there is no derivation  $A \Rightarrow^+ \dots A \dots A \dots$ . Therefore, any derivation of the form  $A \Rightarrow^+ \dots A \dots$  includes  $A$  on the right hand-side exactly once. Because the grammar has no useless nonterminals, the probability of such a derivation is strictly smaller than 1.

For each  $A \in N$ , define:

$$p_A = \sum_{\beta = \dots A \dots} P(A \Rightarrow^{|\beta|} \beta | \Theta).$$

Since  $A$  is not useless, then  $p_A < 1$ . Therefore  $q = \max_A p_A < 1$ . Since any derivation of length  $k$  of the form  $A \Rightarrow \dots A \dots$  can be decomposed to at least  $\frac{k}{2^{|N|}}$  cycles that start at a terminal  $B \in N$  and end in the same nonterminal  $B \in N$ , it holds that:

$$[M^k]_{AA} \leq q^{\frac{k}{2^{|N|}}} \xrightarrow{k \rightarrow \infty} 0.$$

This means that  $\text{trace}(M^k) \xrightarrow{k \rightarrow \infty} 0$ . This means that the eigenvalue of  $M$  is strictly smaller than 1 (linear algebra), and therefore the PCFG is tight. ■

**Proposition 1** Any continuous prior  $P(\Theta)$  on a linear grammar  $G$  is tight almost everywhere for  $G$ .

*Proof:* Let  $G$  be a linear grammar. With a continuous prior, the probability of  $G$  getting parameters from the prior which yield a useless non-terminal is 0 – it would require setting at least one rule in the grammar with rule probability which is exactly 1. Therefore, with probability 1, the parameters taken from the prior yield a PCFG which is linear and does not have nonterminating nonterminals. According to Lemma 1, this means the PCFG is tight. ■

Deciding whether a grammar  $G$  is linear can be done in polynomial time using the construction from Bar-Hillel et al. (1964). We can first eliminate the differences between nonterminals and terminal symbols by adding a rule  $A \rightarrow c_A$  for each nonterminal  $A \in N$ , after extending the set of terminal symbols  $A$  with  $\{c_A | A \in N\}$ . Let  $G_A$  be the grammar  $G$  with the start symbol being replaced with  $A$ . We can then intersect the grammar  $G_A$  with the regular language  $T^*c_A T^*c_A T^*$  (for each nonterminal  $A \in N$ ). If for any nonterminal  $A$  the intersection is not the empty set (with respect to the language that the intersection generates), then the grammar is not linear. Checking whether the intersection is the empty set or not can be done in polynomial time.

We conclude this section by remarking that many of the models used in computational linguistics are in fact equivalent to linear PCFGs, so continuous Bayesian priors are almost everywhere tight. For example, HMMs and many kinds of “stacked” finite-state machines are equivalent to

linear PCFGs, as are the example PCFGs given in Johnson et al. (2007) to motivate the MCMC estimation procedures.

## 5 Dirichlet priors

The first step in Bayesian inference is to specify a prior on  $\Theta$ . In the rest of this paper we take  $P(\Theta)$  to be a product of Dirichlet distributions, with one distribution for each non-terminal  $A \in N$ , as this turns out to simplify the computations considerably. The prior is parameterized by a positive real valued vector  $\alpha$  indexed by productions  $R$ , so each production probability  $\theta_{A \rightarrow \beta}$  has a corresponding Dirichlet parameter  $\alpha_{A \rightarrow \beta}$ . As before, let  $R_A$  be the set of productions in  $R$  with left-hand side  $A$ , and let  $\theta_A$  and  $\alpha_A$  refer to the component subvectors of  $\theta$  and  $\alpha$  respectively indexed by productions in  $R_A$ . The Dirichlet prior  $P(\Theta | \alpha)$  is:

$$P(\Theta | \alpha) = \prod_{A \in N} P_D(\Theta_A | \alpha_A),$$

where

$$P_D(\Theta_A | \alpha_A) = \frac{1}{C(\alpha_A)} \prod_{r \in R_A} \theta_r^{\alpha_r - 1} \quad \text{and}$$

$$C(\alpha_A) = \frac{\prod_{r \in R_A} \Gamma(\alpha_r)}{\Gamma(\sum_{r \in R_A} \alpha_r)}$$

where  $\Gamma$  is the generalized factorial function and  $C(\alpha)$  is a normalization constant that does not depend on  $\Theta_A$ .

Dirichlet priors are useful because they are *conjugate* to the multinomial distribution, which is the building block of PCFGs. Ignoring issues of tightness for the moment and setting  $P(t | \Theta) = \mu_\Theta(t)$ , this means that in the supervised setting the posterior distribution  $P(\Theta | \mathbf{t}, \alpha)$  given a set of parse trees  $\mathbf{t} = (t_1, \dots, t_n)$  is also a product of Dirichlets distribution.

$$P(\Theta | \mathbf{t}, \alpha) \propto P(\mathbf{t} | \Theta) P(\Theta | \alpha)$$

$$\propto \left( \prod_{r \in R} \theta_r^{f_r(\mathbf{t})} \right) \left( \prod_{r \in R} \theta_r^{\alpha_r - 1} \right)$$

$$= \prod_{r \in R} \theta_r^{f_r(\mathbf{t}) + \alpha_r - 1}$$

which is a product of Dirichlet distributions with parameters  $\mathbf{f}(\mathbf{t}) + \alpha$ , where  $\mathbf{f}(\mathbf{t})$  is the vector of rule counts in  $\mathbf{t}$  indexed by  $r \in R$ . We can thus write:

$$P(\Theta | \mathbf{t}, \alpha) = P(\Theta | \mathbf{f}(\mathbf{t}) + \alpha)$$

**Input:** Grammar  $G$ , vector of trees  $\mathbf{t}$ , vector of hyperparameters  $\alpha$ , previous parameters  $\Theta_0$ .

**Result:** A vector of parameters  $\Theta$

**repeat**

    draw  $\theta$  from products of Dirichlet with hyperparameters  $\alpha + \mathbf{f}(\mathbf{t})$

**until**  $\Theta$  is tight for  $G$ ;

return  $\Theta$

**Algorithm 1:** An algorithm for generating samples from  $P(\Theta | \mathbf{t}, \alpha)$  for the only-tight approach.

**Input:** Grammar  $G$ , vector of trees  $\mathbf{t}$ , vector of hyperparameters  $\alpha$ , previous rule parameters  $\Theta_0$ .

**Result:** A vector of parameters  $\Theta$

draw a proposal  $\Theta^*$  from a product of Dirichlets with parameters  $\alpha + \mathbf{f}(\mathbf{t})$ .

draw a uniform number  $u$  from  $[0, 1]$ .

if  $u < \min\{1, (Z(\Theta^{(i-1)})/Z(\Theta^*))^n\}$  return  $\Theta^*$ .

return  $\Theta_0$ .

**Algorithm 2:** One step of Metropolis-Hastings algorithm for generating samples from  $P(\Theta | \mathbf{t}, \alpha)$  for the renormalization approach.

which makes it clear that the rule counts are directly added to the parameters of the prior to produce the parameters of the posterior.

## 6 Inference in the supervised setting

We first discuss Bayesian inference in the supervised setting, as inference in the unsupervised setting is based on inference for the supervised setting. For each of the three approaches to non-tightness we provide an algorithm that characterizes the posterior  $P(\Theta | \mathbf{t})$ , where  $\mathbf{t} = (t_1, \dots, t_n)$  is a sequence of trees, by generating samples from that posterior. Our MCMC algorithms for the unsupervised setting build on these samplers for the supervised setting.

### 6.1 The only-tight approach

The ‘‘only-tight’’ approach requires that the prior assign zero mass to non-tight rule probability vectors  $\Theta^\perp$ . One way to define such a distribution is to restrict the domain of an existing prior distribution with the set of tight  $\Theta$  and renormalize. In more detail, if  $P(\Theta)$  is a prior over rule probabilities, then its renormalization is the prior  $P'$  defined as:

$$P'(\Theta) = \frac{P(\Theta)I(\Theta \notin \Theta^\perp)}{Z(\Theta^\perp)}. \quad (2)$$

where  $Z(\Theta^\perp) = \int_{\Theta} P(\Theta)I(\Theta \notin \Theta^\perp)d\Theta$ .

**Input:** Grammar  $G$ , vector of trees  $\mathbf{t}$ , vector of hyperparameters  $\alpha$ , previous parameters  $\Theta_0$ .

**Result:** A vector of parameters  $\Theta$   
draw  $\Theta$  from products of Dirichlet with hyperparameters  $\alpha + \mathbf{f}(\mathbf{t})$   
return  $\Theta$

**Algorithm 3:** An algorithm for generating samples from  $P(\Theta | \mathbf{t}, \alpha)$  for the sink-state approach.

Perhaps surprisingly, it turns out that if  $P(\Theta)$  belongs to a family of conjugate priors, then  $P'(\Theta)$  also belongs to a (different) family of conjugate priors as well.

**Proposition 2** *Let  $P(\Theta|\alpha)$  be a prior with hyperparameters  $\alpha$  over the parameters of  $G$  such that  $P$  is conjugate to the grammar likelihood. Then  $P'$ , defined in Eq. 2, is conjugate to the grammar likelihood as well.*

*Proof:* Assume that trees  $\mathbf{t}$  are observed, and the prior over the grammar parameters is the prior defined in Eq. 2. Therefore, the posterior is:

$$\begin{aligned} P(\Theta|\mathbf{t}, \alpha) &\propto P'(\Theta|\alpha)p(\mathbf{t}|\Theta) \\ &= \frac{P(\Theta|\alpha)p(\mathbf{t}|\Theta)I(\Theta \notin \Theta^\perp)}{Z(\Theta^\perp)} \\ &\propto \frac{P(\Theta|\mathbf{t}, \alpha)I(\Theta \notin \Theta^\perp)}{Z(\Theta^\perp)}. \end{aligned}$$

Since  $P(\Theta|\alpha)$  is a conjugate prior to the PCFG likelihood, then there exists  $\alpha' = \alpha'(\mathbf{t})$  such that  $P(\Theta|\mathbf{t}, \alpha) = P'(\Theta|\alpha')$ . Therefore:

$$P(\Theta|\mathbf{t}, \alpha) \propto \frac{P(\Theta|\alpha')I(\Theta \notin \Theta^\perp)}{Z(\Theta^\perp)}.$$

which exactly equals  $P'(\Theta|\alpha')$ . ■

Sampling from the posterior over the parameters given a set of trees  $\mathbf{t}$  is therefore quite simple when assuming the base prior being renormalized is a product of Dirichlets. Algorithm 1 samples from a product of Dirichlets distribution with hyperparameters  $\alpha + \mathbf{f}(\mathbf{t})$  repeatedly, each time checking and rejecting the sample until we obtain a tight PCFG.

The more mass the Dirichlet distribution with hyperparameters  $\alpha + \mathbf{f}(\mathbf{t})$  puts on non-tight PCFGs, the more rejections will happen. In general, if the probability mass on non-tight PCFGs is  $q_\perp$ , then it would require, on average  $1/(1 - q_\perp)$  samples from this distribution in order to obtain a tight PCFG.

## 6.2 The renormalization approach

The renormalization approach modifies the likelihood function instead of the prior. Here we use a product of Dirichlets prior  $P(\Theta | \alpha)$  on rule probability vectors  $\Theta$ , but the presence of the partition function  $Z(\Theta)$  in Eq. 1 means that the likelihood is no longer conjugate to the prior. Instead we have:

$$\begin{aligned} P(\Theta | \mathbf{t}) &= \prod_{i=1}^n \frac{\mu_\Theta(t_i)}{Z(\Theta)} P(\Theta | \alpha) \\ &\propto \frac{1}{Z(\Theta)^n} P(\Theta | \alpha + \mathbf{f}(\mathbf{t})). \end{aligned} \quad (3)$$

Note that the factor  $Z(\Theta)$  depends on  $\Theta$ , and therefore cannot be absorbed into the constant. Algorithm 2 describes a Metropolis-Hastings sampler for sampling from the posterior in Eq. 3 that uses a product of Dirichlets with parameters  $\alpha + \mathbf{f}(\mathbf{t})$  as a proposal distribution.

In our experiments, we use the algorithm from Nederhof and Satta (2008) to compute the partition function which is needed in Algorithm 2.

## 6.3 The “sink element” approach

The “sink element” approach does not affect the likelihood (since the probability of a tree  $t$  is just the product of the probabilities of the rules used to generate it), nor does it require a change to the prior. (The sink element  $\perp$  is not a member of the set of trees  $\mathcal{T}$ , so it cannot appear in the data  $\mathbf{t}$ ).

This means that the conjugacy argument given at the bottom of section 5 holds in this approach, so the posterior  $P(\Theta | \mathbf{t}, \alpha)$  is a product of Dirichlets with parameters  $\mathbf{f}(\mathbf{t}) + \alpha$ . Algorithm 3 gives a sampler for  $P(\Theta | \mathbf{t}, \alpha)$  for the sink element approach.

## 7 Inference in the unsupervised setting

Johnson et al. (2007) provide two Markov chain Monte Carlo algorithms for Bayesian inference for PCFG rule probabilities in the unsupervised setting (i.e., where the data consists of a corpus of strings  $\mathbf{w} = (w_1, \dots, w_n)$  alone). The algorithms we give here are based on their Gibbs sampler, which in each iteration first samples parse trees  $\mathbf{t} = (t_1, \dots, t_n)$ , where each  $t_i$  is a parse for  $w_i$ , from  $P(\mathbf{t} | \mathbf{w}, \Theta)$ , and then samples  $\Theta$  from  $P(\Theta | \mathbf{t}, \alpha)$ .

Notice that the conditional distribution  $P(t | \mathbf{w}, \Theta)$  is unaffected in each of our three approaches (the partition functions cancel in the

**Input:** Grammar  $G$ , vector of hyperparameters  $\alpha$ , vector of strings  $\mathbf{w} = (w_1, \dots, w_n)$ , previous rule parameters  $\Theta_0$ .

**Result:** A vector of parameters  $\Theta$

use Algorithm 2 to sample  $\Theta$  given  $G, \mathbf{t}, \alpha$  and  $\Theta_0$

return  $\Theta$

**Algorithm 4:** One step of the Metropolis-within-Gibbs sampler for the renormalization approach.

renormalization approach), so the algorithm for sampling from  $P(\mathbf{t} \mid \mathbf{w}, \Theta)$  given by Johnson et al. applies in each of our three approaches as well.

Johnson et al. ignored tightness and assumed that  $P(\Theta \mid \mathbf{t}, \alpha)$  is a product of Dirichlets with parameters  $\mathbf{f}(\mathbf{t}) + \alpha$ . As we noted in section 6.3, this assumption holds for the sink-state approach to non-tightness, so their sampler is in fact correct for the sink-state approach.

In fact, we obtain samplers for the unsupervised setting for each of our approaches by “plugging in” the corresponding sampling algorithm (Eq. 1–3) for  $P(\Theta \mid \mathbf{t}, \alpha)$  into the generic Gibbs sampler framework of Johnson et al.

The one complication is that because we use a Metropolis-Hastings procedure to generate samples from  $P(\Theta \mid \mathbf{t}, \alpha)$  in the renormalization approach, we use the Metropolis-within-Gibbs procedure given in Algorithm 4 (Robert and Casella, 2004).

## 8 The expressive power of the three approaches

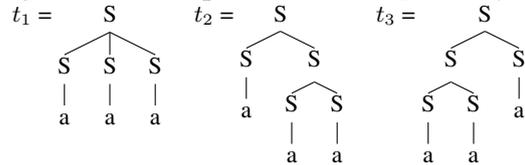

Probably the most important question to ask with respect to the three different approaches to non-tightness is whether they differ in terms of expressive power. Clearly the three approaches differ in terms of the grammars they admit (the only-tight approach requires the prior to only assign non-zero probability to tight PCFGs, while the other two approaches permit the prior to assign non-zero probability to non-tight PCFGs as well). However, if we regard a grammar as merely a device for defining a distribution over trees and a prior as defining a distribution over distributions over trees, it is reasonable to ask whether the class of distributions over distributions of trees that each of these approaches define are the same or differ. We believe, but have not proved, that all three approaches define the same class of distributions over distribu-

tions of trees in the following sense: any prior used with one of the approaches can be transformed into a different prior that can be used with one of the other approaches, and yield the same posterior over trees conditioned on a string, marginalizing out the parameters.

This does not mean that the three approaches are equivalent, however. In this section we provide a grammar such that with a uniform prior over rule probabilities, the conditional distribution over trees given a fixed string varies under each of the three different approaches.

The grammar we consider has three rules  $S \rightarrow S S S \mid S S \mid a$  with probabilities  $\theta_1, \theta_2$  and  $1 - \theta_1 - \theta_2$ , respectively. The  $\Theta$  parameters are required to satisfy  $\theta_1 + \theta_2 \leq 1$  and  $\theta_i \geq 0$  for  $i = 1, 2$ .

We compute the posterior distribution over parse trees for the string  $w = a a a$ . The grammar generates three parse trees for  $w_1$ , namely:

The partition function  $Z$  for this grammar is the smallest positive root of the cubic equation:

$$Z = \theta_1 Z^3 + \theta_2 Z^2 + (1 - \theta_1 - \theta_2)$$

We used Mathematica to find an analytic solution for  $Z$  in this equation, obtaining not only an expression for the partition function  $Z(\Theta)$  but also identifying the non-tight region  $\Theta^\perp$ .

In order to compute  $P(t_i|w)$ , we used Mathematica to first compute the following quantities:

$$q_{\text{sinkElement}}(t_i) = \int_{\Theta} \mu_{\Theta}(t_i) d\Theta$$

$$q_{\text{tightOnly}}(t_i) = \int_{\Theta} \mu_{\Theta}(t_i) I(\Theta \notin \Theta^\perp) d\Theta$$

$$q_{\text{renormalization}}(t_i) = \int_{\Theta} \mu_{\Theta}(t_i) / Z(\Theta) d\Theta$$

where  $i \in \{1, 2, 3\}$ . We used Mathematica to analytically compute  $q(t_i)$  for each approach and each  $i \in \{1, 2, 3\}$ . Then it’s easy to show that:

$$P(t_i \mid w) = \frac{q(t_i)}{\sum_{i'=1}^3 q(t_{i'})}$$

where the  $q$  used is based on the approach to tightness desired. For the sink-element approach,

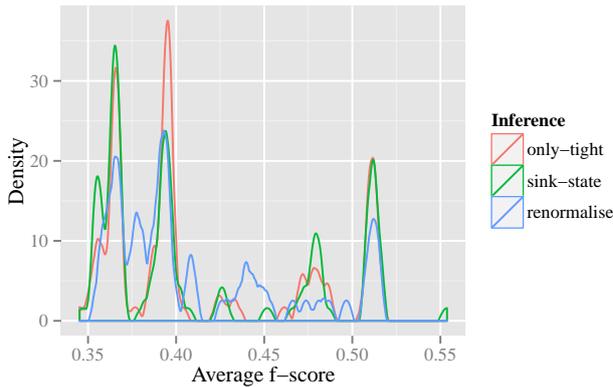

Figure 1: The density of the  $F_1$ -scores with the three approaches. The prior used is a symmetric Dirichlet with  $\alpha = 0.1$ .

$P(t_1|w) = \frac{7}{11} \approx 0.636364$ . For the only-tight approach  $P(t_1|w) = \frac{11179}{17221} \approx 0.649149$ . For the renormalization approach the analytic expression is too complex to include in this paper, but it approximately equals 0.619893. A log of our Mathematica calculations is available at <http://www.cs.columbia.edu/~scohen/acl13tightness-mathematica.pdf>, and we confirmed these results to three decimal places using the samplers described above (which required  $10^7$  samples per approach).

While the differences between these conditional probabilities are not great, the conditional probabilities are clearly different, so the three approaches do in fact define different distributions over trees under a uniform prior on rule probabilities.

## 9 Empirical effects of the three approaches in unsupervised grammar induction

In this section we present experiments using the three samplers just described in an unsupervised grammar induction problem. Our goal here is not to improve the state-of-the-art in unsupervised grammar induction, but to try to measure empirical differences in the estimates produced by the three different approaches to tightness just described. The bottom line of our experiments is that we could not detect any significant difference in the estimates produced by samplers for these three different approaches.

In our experiments we used the English Penn treebank (Marcus et al., 1993). We use the part-

of-speech tag sequences of sentences shorter than 11 words in sections 2–21. The grammar we use is the PCFG version of the dependency model with valence (Klein and Manning, 2004), as it appears in Smith (2006).

We used a symmetric Dirichlet prior with hyperparameter  $\alpha = 0.1$ . For each of the three approaches for handling tightness, we ran 100 times the samplers in §7, each for 1,000 iterations. We discarded the first 900 sweeps of each run, and calculated the  $F_1$ -scores of the sampled trees every 10th sweep from the last 100 sweeps. For each run we calculated the average  $F_1$ -score over the 10 sweeps we evaluated. We thus have 100 average  $F_1$ -scores for each of the samplers.

Figure 1 plots the density of  $F_1$  scores (compared to the gold standard) resulting from the Gibbs sampler, using all three approaches. The mean value for each of the approaches is 0.41 with standard deviation 0.06 (only-tight), 0.41 with standard deviation 0.05 (renormalization) and 0.42 with standard deviation 0.06 (sink element). In addition, the only-tight approach results in an average of 437 (s.d., 142) rejected proposals in 1,000 samples, while the renormalization approach results in an average of 232 (s.d., 114) rejected proposals in 1,000 samples. (It’s not surprising that the only-tight approach results in more rejections as it keeps proposing new  $\Theta$  until a tight proposal is found, while the renormalization approach simply uses the old  $\Theta$ ).

We performed two-sample Kolmogorov-Smirnov tests (which are non-parametric tests designed to determine if two distributions are different; see DeGroot, 1991) on each of the three pairs of 100  $F_1$ -scores. None of the tests were close to significant; the p-values were all above 0.5. Thus our experiments provided no evidence that the samplers produced different distributions over trees, although it’s reasonable to expect that these distributions do indeed differ.

In terms of running time, our implementation of the renormalization approach was several times slower than our implementations of the other two approaches because we used the naive fixed-point algorithm to compute the partition function: perhaps this could be improved using one of the more sophisticated partition function algorithms described in Nederhof and Satta (2008).

## 10 Conclusion

In this paper we characterized the notion of an almost everywhere tight grammar in the Bayesian setting and showed it holds for linear CFGs. For non-linear CFGs, we described three different approaches to handle non-tightness. The “only-tight” approach restricts attention to tight PCFGs, and perhaps surprisingly, we showed that conjugacy still obtains when the domain of a product of Dirichlets prior is restricted to the subset of tight grammars. The renormalization approach involves renormalizing the PCFG measure  $\mu$  over trees when the grammar is non-tight, which destroys conjugacy with a product of Dirichlets prior. Perhaps most surprisingly of all, the sink-element approach, which assigns the missing mass in non-tight PCFG to a sink element  $\perp$ , turns out to be equivalent to existing practice where tightness is ignored.

We studied the posterior distributions over trees induced by the three approaches under a uniform prior for a simple grammar and showed that they differ. We leave for future work the important question of whether the classes of distributions over distributions over trees that the three approaches define are the same or different.

We described samplers for the supervised and unsupervised settings for each of these approaches, and applied them to an unsupervised grammar induction problem. (The code for the unsupervised samplers is available from <http://web.science.mq.edu.au/~mjohnson>).

We could not detect any difference in the posterior distributions over trees produced by these samplers, despite devoting considerable computational resources to the problem. This suggests that for these kinds of problems at least, tightness is not of practical concern for Bayesian inference of PCFGs.

## Abstract

This paper describes a method of inducing wide-coverage CCG resources for Japanese. While deep parsers with corpus-induced grammars have been emerging for some languages, those for Japanese have not been widely studied, mainly because most Japanese syntactic resources are dependency-based. Our method first integrates multiple dependency-based corpora into phrase structure trees and then converts the trees into CCG derivations. The method is empirically evaluated in terms of the coverage of the obtained lexicon and the accuracy of parsing.

## 1 Introduction

Syntactic parsing for Japanese has been dominated by a dependency-based pipeline in which chunk-based dependency parsing is applied and then semantic role labeling is performed on the dependencies (Sasano and Kurohashi, 2011; Kawahara and Kurohashi, 2011; Kudo and Matsumoto, 2002; Iida and Poesio, 2011; Hayashibe et al., 2011). This dominance is mainly because chunk-based dependency analysis looks most appropriate for Japanese syntax due to its morphosyntactic typology, which includes agglutination and scrambling (Bekki, 2010). However, it is also true that this type of analysis has prevented us from deeper syntactic analysis such as deep parsing (Clark and Curran, 2007) and logical inference (Bos et al., 2004; Bos, 2007), both of which have been surpassing shallow parsing-based approaches in languages like English.

In this paper, we present our work on inducing wide-coverage Japanese resources based on

combinatory categorial grammar (CCG) (Steedman, 2001). Our work is basically an extension of a seminal work on CCGbank (Hockenmaier and Steedman, 2007), in which the phrase structure trees of the Penn Treebank (PTB) (Marcus et al., 1993) are converted into CCG derivations and a wide-coverage CCG lexicon is then extracted from these derivations. As CCGbank has enabled a variety of outstanding works on wide-coverage deep parsing for English, our resources are expected to significantly contribute to Japanese deep parsing.

The application of the CCGbank method to Japanese is not trivial, as resources like PTB are not available in Japanese. The widely used resources for parsing research are the Kyoto corpus (Kawahara et al., 2002) and the NAIST text corpus (Iida et al., 2007), both of which are based on the dependency structures of chunks. Moreover, the relation between chunk-based dependency structures and CCG derivations is not obvious.

In this work, we propose a method to integrate multiple dependency-based corpora into phrase structure trees augmented with predicate argument relations. We can then convert the phrase structure trees into CCG derivations. In the following, we describe the details of the integration method as well as Japanese-specific issues in the conversion into CCG derivations. The method is empirically evaluated in terms of the quality of the corpus conversion, the coverage of the obtained lexicon, and the accuracy of parsing with the obtained grammar. Additionally, we discuss problems that remain in Japanese resources from the viewpoint of developing CCG derivations.

There are three primary contributions of this paper: 1) we show the first comprehensive results for Japanese CCG parsing, 2) we present a methodology for integrating multiple dependency-based re-

sources to induce CCG derivations, and 3) we investigate the possibility of further improving CCG analysis by additional resources.

## 2 Background

### 2.1 Combinatory Categorial Grammar

CCG is a syntactic theory widely accepted in the NLP field. A grammar based on CCG theory consists of *categories*, which represent syntactic categories of words and phrases, and *combinatory rules*, which are rules to combine the categories. Categories are either *ground categories* like  $S$  and  $NP$  or *complex categories* in the form of  $X/Y$  or  $X \backslash Y$ , where  $X$  and  $Y$  are the categories. Category  $X/Y$  intuitively means that it becomes category  $X$  when it is combined with another category  $Y$  to its right, and  $X \backslash Y$  means it takes a category  $Y$  to its left. Categories are combined by applying combinatory rules (Fig. 2) to form categories for larger phrases. Figure 1 shows a CCG analysis of a simple English sentence, which is called a *derivation*. The verb *give* is assigned category  $S \backslash NP / NP / NP$ , which indicates that it takes two NPs to its right, one NP to its left, and finally becomes  $S$ . Starting from lexical categories assigned to words, we can obtain categories for phrases by applying the rules recursively.

An important property of CCG is a clear interface between syntax and semantics. As shown in Fig. 1, each category is associated with a lambda term of semantic representations, and each combinatory rule is associated with rules for semantic composition. Since these rules are universal, we can obtain different semantic representations by switching the semantic representations of lexical categories. This means that we can plug in a vari-

Sentence	$S$	Verb	$S \backslash \$$ (e.g. $S \backslash NP_{ga}$ )
Noun phrase	$NP$	Post particle	$NP_{ga o ni to} \backslash NP$
Auxiliary verb	$S \backslash S$		

Table 1: Typical categories for Japanese syntax.

Cat.	Feature	Value	Interpretation

ety of semantic theories with CCG-based syntactic parsing (Bos et al., 2004).

### 2.2 CCG-based syntactic theory for Japanese

Bekki (2010) proposed a comprehensive theory for Japanese syntax based on CCG. While the theory is based on Steedman (2001), it provides concrete explanations for a variety of constructions of Japanese, such as agglutination, scrambling, long-distance dependencies, etc. (Fig. 3).

The ground categories in his theory are  $S$ ,  $NP$ , and  $CONJ$  (for conjunctions). Table 1 presents typical lexical categories. While most of them are obvious from the theory of CCG, categories for auxiliary verbs require an explanation. In Japanese, auxiliary verbs are extensively used to express various semantic information, such as tense and modality. They agglutinate to the main verb in a sequential order. This is explained in Bekki’s theory by the category  $S \backslash S$  combined with a main verb via the function composition rule ( $<B$ ). Syntactic features are assigned to categories  $NP$  and  $S$  (Table 2). The feature *case* represents a syntactic case of a noun phrase. The feature *form* denotes an inflection form, and is necessary for constraining the grammaticality of agglutination.

Our implementation of the grammar basically follows Bekki (2010)’s theory. However, as a first step in implementing a wide-coverage Japanese parser, we focused on the frequent syntactic constructions that are necessary for computing predicate argument relations, including agglutination, inflection, scrambling, case alternation, etc. Other details of the theory are largely simplified (Fig. 3),

and Bender, 2002) is a large-scale Japanese grammar based on HPSG, but its semantics is tightly embedded in the grammar and it is not as easy to systematically switch them as it is in CCG. Yoshida (2005) proposed methods for extracting a wide-coverage lexicon based on HPSG from a phrase structure treebank of Japanese. We largely extended their work by exploiting the standard chunk-based Japanese corpora and demonstrated the first results for Japanese deep parsing with grammar induced from large corpora.

Corpus-based acquisition of wide-coverage CCG resources has enjoyed great success for English (Hockenmaier and Steedman, 2007). In that method, PTB was converted into CCG-based derivations from which a wide-coverage CCG lexicon was extracted. CCGbank has been used for the development of wide-coverage CCG parsers (Clark and Curran, 2007). The same methodology has been applied to German (Hockenmaier, 2006), Italian (Bos et al., 2009), and Turkish (Çakıcı, 2005). Their treebanks are annotated with dependencies of *words*, the conversion of which into phrase structures is not a big concern. A notable contribution of the present work is a method for inducing CCG grammars from chunk-based dependency structures, which is not obvious, as we discuss later in this paper.

CCG parsing provides not only predicate argument relations but also CCG derivations, which can be used for various semantic processing tasks (Bos et al., 2004; Bos, 2007). Our work constitutes a starting point for such deep linguistic processing for languages like Japanese.

### 3 Corpus integration and conversion

For wide-coverage CCG parsing, we need a) a wide-coverage CCG lexicon, b) combinatory rules, c) training data for parse disambiguation, and d) a parser (e.g., a CKY parser). Since d) is grammar- and language-independent, all we have to develop for a new language is a)–c).

As we have adopted the method of CCGbank, which relies on a source treebank to be converted into CCG derivations, a critical issue to address is the absence of a Japanese counterpart to PTB. We only have chunk-based dependency corpora, and their relationship to CCG analysis is not clear.

Our solution is to first integrate multiple dependency-based resources and convert them into a phrase structure treebank that is independent

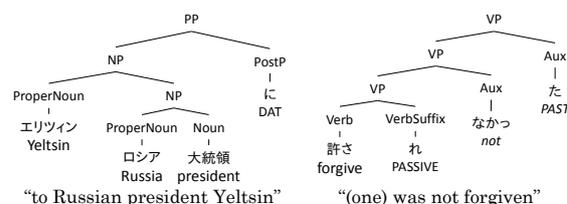

Figure 6: Internal structures of a nominal chunk (left) and a verbal chunk (right).

of CCG analysis (Step 1). Next, we translate the treebank into CCG derivations (Step 2). The idea of Step 2 is similar to what has been done with the English CCGbank, but obviously we have to address language-specific issues.

#### 3.1 Dependencies to phrase structure trees

We first integrate and convert available Japanese corpora—namely, the Kyoto corpus, the NAIST text corpus, and the JP corpus—into a phrase structure treebank, which is similar in spirit to PTB. Our approach is to convert the dependency structures of the Kyoto corpus into phrase structures and then augment them with syntactic/semantic roles from the other two corpora.

The conversion involves two steps: 1) recognizing the chunk-internal structures, and 2) converting inter-chunk dependencies into phrase structures. For 1), we don’t have any explicit information in the Kyoto corpus although, in principle, each chunk has internal structures (Vadas and Curran, 2007; Yamada et al., 2010). The lack of a chunk-internal structure makes the dependency-to-constituency conversion more complex than a similar procedure by Bos et al. (2009) that converts an Italian dependency treebank into constituency trees since their dependency trees are annotated down to the level of each word. For the current implementation, we abandon the idea of identifying exact structures and instead basically rely on the following generic rules (Fig. 6):

**Nominal chunks** Compound nouns are first formed as a right-branching phrase and post-positions are then attached to it.

**Verbal chunks** Verbal chunks are analyzed as left-branching structures.

The rules amount to assume that all but the last word in a compound noun modify the head noun (i.e., the last word) and that a verbal chunk is typically in a form  $V A_1 \dots A_n$ , where  $V$  is a verb

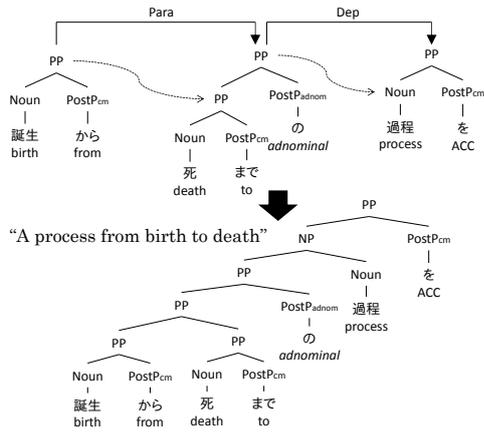

Figure 7: From inter-chunk dependencies to a tree.

(or other predicative word) and  $A_i$ s are auxiliaries (see Fig. 6). We chose the left-branching structure as default for verbal chunks because the semantic scopes of the auxiliaries are generally in that order (i.e.,  $A_1$  has the narrowest scope). For both cases, phrase symbols are percolated upward from the right-most daughters of the branches (except for a few cases like punctuation) because in almost all cases the syntactic head of a Japanese phrase is the right-most element.

In practice, we have found several patterns of exceptions for the above rules. We implemented exceptional patterns as a small CFG and determined the chunk-internal structures by deterministic parsing with the generic rules and the CFG. For example, two of the rules we came up with are

- rule A: Number  $\rightarrow$  PrefixOfNumber Number
- rule B: ClassifierPhrase  $\rightarrow$  Number Classifier

in the precedence: rule A  $>$  B  $>$  generic rules. Using the above, we bracket a compound noun

約            千            人            死亡  
*approximately   thousand   people   death*  
 PrefixOfNumber   Number   Classifier   CommonNoun  
 “death of approximately one thousand people”

as in

(((約            千)            人)            死亡)  
 (((approximately   thousand)   people)   death)

We can improve chunk-internal structures to some extent by refining the CFG rules. A complete solution like the manual annotation by Vadas and Curran (2007) is left for future work.

The conversion of inter-chunk dependencies into phrase structures may sound trivial, but it is not necessarily easy when combined with chunk-internal structures. The problem is to which node in the internal structure of the head the dependent

dep	modifier-type	precedence
Para	から/PostP <sub>cm</sub>	まで/PostP <sub>cm</sub> , */(Verb Aux), ...
Dep	*/PostP <sub>cm</sub>	*/(Verb Aux), */Noun, ...
Dep	*/PostP <sub>adnom</sub>	*/Noun, */(Verb Aux), ...

Table 3: Rules to determine adjoin position.

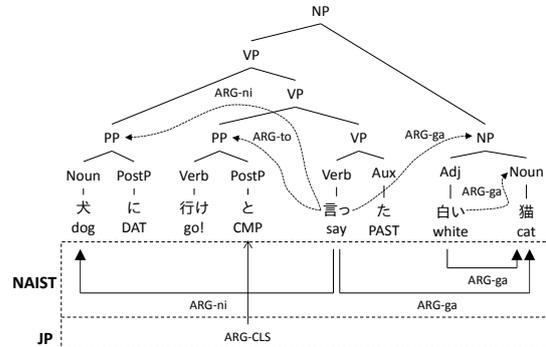

Figure 8: Overlay of pred-arg structure annotation (“The white cat who said “Go!” to the dog.”).

tree is adjoined (Fig. 7). In the case shown in the figure, three chunks are in the dependency relation indicated by arrows on the top. The dotted arrows show the nodes to which the subtrees are adjoined.

Without any human-created resources, we cannot always determine the adjoin positions correctly. Therefore, as a compromise, we wound up implementing approximate heuristic rules to determine the adjoin positions. Table 3 shows examples of such rules. A rule specifies a precedence of the possible adjoin nodes as an ordered list of patterns on the lexical head of the subtree under an adjoin position. The precedence is defined for each combination of the type of the dependent phrase, which is determined by its lexical head, and the dependency type in the Kyoto corpus.

To select the adjoin position for the left-most subtree in Fig. 7, for instance, we look up the rule table using the dependency type, “Para”, and the lexical head of the modifier subtree, “から/PostP<sub>cm</sub>”, as the key, and find the precedence “まで/PostP<sub>cm</sub>, \*/(Verb|Aux), ...”. We thus select the PP-node on the middle subtree indicated by the dotted arrow because its lexical head (the right-most word), “まで/PostP<sub>cm</sub>”, matches the first pattern in the precedence list. In general, we seek for an adjoin node for each pattern  $p$  in the precedence list, until we find a first match.

The semantic annotation given in the NAIST corpus and the JP corpus is overlaid on the phrase structure trees with slight modifications (Fig. 8).

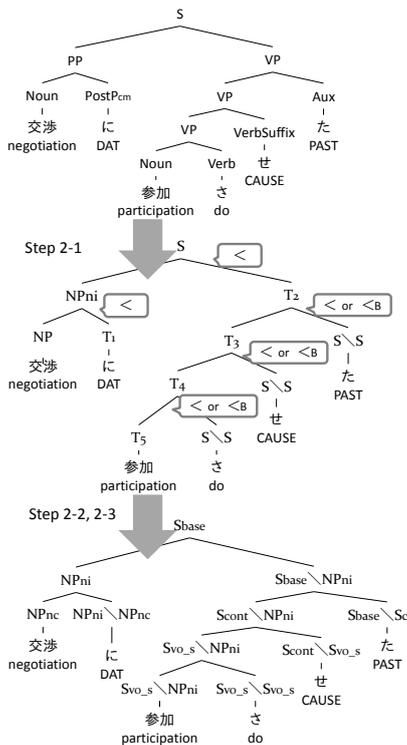

Figure 9: A phrase structure into a CCG derivation.

In the figure, the annotation given in the two corpora is shown inside the dotted box at the bottom. We converted the predicate-argument annotations given as labeled word-to-word dependencies into the relations between the predicate words and their argument *phrases*. The results are thus similar to the annotation style of PropBank (Palmer et al., 2005). In the NAIST corpus, each pred-arg relation is labeled with the argument-type (*ga/o/ni*) and a flag indicating that the relation is mediated by either a syntactic dependency or a zero anaphora. For a relation of a predicate  $w_p$  and its argument  $w_a$  in the NAIST corpus, the boundary of the argument phrase is determined as follows:

1. If  $w_a$  precedes  $w_p$  and the relation is mediated by a syntactic dep., select the maximum PP that is formed by attaching one or more postpositions to the NP headed by  $w_a$ .
2. If  $w_p$  precedes  $w_a$  or the relation is mediated by a zero anaphora, select the maximum NP headed by  $w_a$  that does not include  $w_p$ .

In the figure, “犬/dog に/DAT” is marked as the ni-argument of the predicate “言つ/say” (Case 1), and “白い/white 猫/cat” is marked as its *ga*-argument (Case 2). Case 1 is for the most basic construction, where an argument PP precedes its predicate. Case

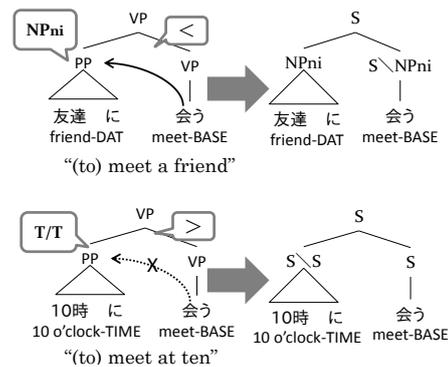

Figure 10: An argument post particle phrase (PP) (upper) and an adjunct PP (lower).

2 covers the relative clause construction, where a relative clause precedes the head NP, the modification of a noun by an adjective, and the relations mediated by zero anaphora.

The JP corpus provides only the function label to each particle “to” in the text. We determined the argument phrases marked by the “to” particles labeled as (nominal or clausal) argument-markers in a similar way to Case 1 above and identified the predicate words as the lexical heads of the phrases to which the  $PP_{to}$  phrases attach.

### 3.2 Phrase structures to CCG derivations

This step consists of three procedures (Fig. 9):

1. Add constraints on categories and features to tree nodes as far as possible and assign a combinatory rule to each branching.
2. Apply combinatory rules to all branching and obtain CCG derivations.
3. Add feature constraints to terminal nodes.

#### 3.2.1 Local constraint on derivations

According to the phrase structures, the first procedure in Step 2 imposes restrictions on the resulting CCG derivations. To describe the restrictions, we focus on some of the notable constructions and illustrate the restrictions for each of them.

**Phrases headed by case marker particles** A phrase of this type must be either an argument (Fig. 10, upper) or a modifier (Fig. 10, lower) of a predicative. Distinction between the two is made based on the pred-arg annotation of the predicative. If a phrase is found to be an argument, 1) category NP is assigned to the corresponding node, 2) the case feature of the category is given according to the particle (in the case of Fig. 10 (upper)),

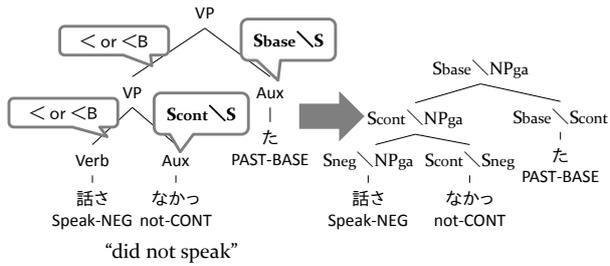

Figure 11: An auxiliary verb and its conversion.

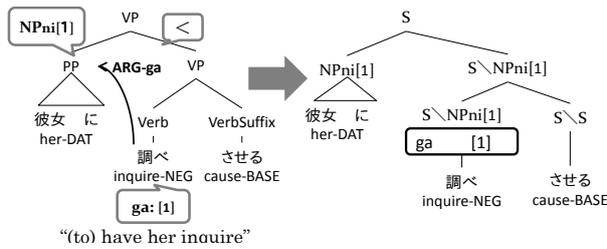

Figure 12: A causative construction.

*ni* for dative), and 3) the combinatory rule that combines the particle phrase and the predicative phrase is assigned *backward function application rule* (<). Otherwise, a category  $T/T$  is assigned to the corresponding modifier node and the rule will be *forward function application* (>).

**Auxiliary verbs** As described in Sec. 2.2, an auxiliary verb is always given the category  $S\backslash S$  and is combined with a verbal phrase via < or <B (Fig. 11). Furthermore, we assign the *form* feature value of the returning category  $S$  according to the inflection form of the auxiliary. In the case shown in the figure,  $S_{base}\backslash S$  is assigned for “た/PAST-BASE” and  $S_{cont}\backslash S$  for “なかつ/not-CONT”. As a result of this restriction, we can obtain conditions for every auxiliary agglutination because the two *form* values in  $S\backslash S$  are both restricted after applying combinatory rules (Sec. 3.2.2).

**Case alternations** In addition to the argument/adjunct distinction illustrated above, a process is needed for argument phrases of predicates involving case alternation. Such predicates are either causative (see Fig. 12) or passive verbs and can be detected by voice annotation from the NAIST corpus. For an argument of that type of verb, its *deep* case (*ga* for Fig. 12) must be used to construct the semantic representation, namely the PAS. As well as assigning the shallow case value (*ni* in Fig. 12) to the argument’s category NP, as usual, we assign a restriction to the PAS

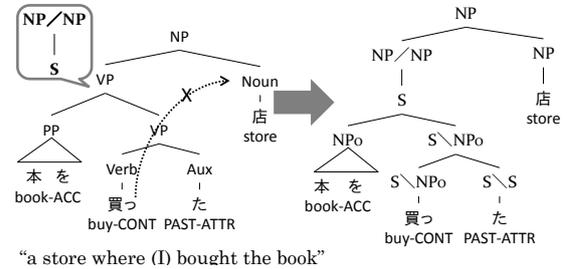

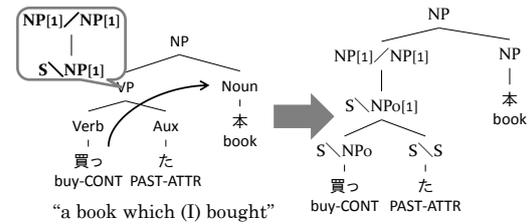

Figure 13: A relative clause with/without argument extraction (upper/lower, respectively).

of the verb so that the semantic argument corresponding to the deep case is co-indexed with the argument NP. These restrictions are then utilized for PAS construction in Sec. 3.2.3.

**Relative clauses** A relative clause can be detected as a subtree that has a VP as its left child and an NP as its right child, as shown in Fig. 13. The conversion of the subtree consists of 1) inserting a node on the top of the left VP (see the right-hand side of Fig. 13), and 2) assigning the appropriate unary rule to make the new node. The difference between candidate rules RelExt and RelIn (see Fig. 4) is whether the right-hand NP is an obligatory argument of the VP or not, which can be determined by the pred-arg annotation on the predicate in the VP. In the upper example in Fig. 13, RelIn is assigned because the right NP “book” is annotated as an accusative argument of the predicate “buy”. In contrast, RelExt is assigned in the lower side in the figure because the right NP “store” is not annotated as an argument.

**Continuous clauses** A continuous clause can be detected as a subtree with a VP of continuous form as its left child and a VP as its right child. Its conversion is similar to that of a relative clause, and only differs in that the candidate rules are Con and ConCoord. ConCoord generates a continuous clause that shares arguments with the main clause while Con produces one without shared arguments. Rule assignment is done by comparing the pred-arg annotations of the two phrases.

	Training	Develop.	Test
#Sentences	24,283	4,833	9,284
#Chunks	234,685	47,571	89,874
#Words	664,898	136,585	255,624

Table 4: Statistics of input linguistic resources.

### 3.2.2 Inverse application of rules

The second procedure in Step 2 begins with assigning a category  $S$  to the root node. A combinatorial rule assigned to each branching is then “inversely” applied so that the constraint assigned to the parent transfers to the children.

### 3.2.3 Constraints on terminal nodes

The final process consists of a) imposing restrictions on the terminal category in order to instantiate all the feature values, and b) constructing a PAS for each verbal terminal. An example of process a) includes setting the *form* features in the verb category, such as  $S \backslash NP_{ni}$ , according to the inflection form of the verb. As for b), arguments in a PAS are given according to the category and the partial restriction. For instance, if a category  $S \backslash NP_{ni}$  is obtained for “調べ/inquire” (Fig. 12), the PAS for “inquire” is unary because the category has one argument category ( $NP_{ni}$ ), and the category is co-indexed with the semantic argument *ga* in the PAS due to the partial restriction depicted in Sec. 3.2.1. As a result, a lexical entry is obtained as 調べ  $\vdash S \backslash NP_{ni}[1]: inquire([1])$ .

### 3.3 Lexical entries

Finally, lexical rules are applied to each of the obtained lexical entries in order to reduce them to the canonical form. Since words in the corpus (especially verbs) often involve pro-drop and scrambling, there are a lot of obtained entries that have slightly varied categories yet share a PAS. We assume that an obtained entry is a variation of the canonical one and register the canonical entries in the lexicon. We treat only subject deletion for pro-drop because there is not sufficient information to judge the deletion of other arguments. Scrambling is simply treated as permutation of arguments.

## 4 Evaluation

We used the following for the implementation of our resources: Kyoto corpus ver. 4.0<sup>2</sup>, NAIST text

<sup>2</sup><http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?Kyoto%20University%20Text%20Corpus>

	Training		Develop.		Test	
	St.1	St.2	St.1	St.2	St.1	St.2
Sent.	24,283	24,116	4,833	4,803	9,284	9,245
Converted	24,116	22,820	4,803	4,559	9,245	8,769
Con. rate	99.3	94.6	99.4	94.9	99.6	94.9

Table 5: Statistics of corpus conversion.

Sentential Coverage				
	Covered	Uncovered	Cov. (%)	
Devel.	3,920	639	85.99	
Test	7,610	1,159	86.78

			combi.	cat. word
Devel.	127,144	126,383	682	79
Test	238,083	236,651	1,242	145

Table 6: Sentential and lexical coverage.

corpus ver. 1.5<sup>3</sup>, and JP corpus ver. 1.0<sup>4</sup>. The integrated corpus is divided into training, development, and final test sets following the standard data split in previous works on Japanese dependency parsing (Kudo and Matsumoto, 2002). The details of these resources are shown in Table 4.

### 4.1 Corpus conversion and lexicon extraction

Table 5 shows the number of successful conversions performed by our method. In total, we obtained 22,820 CCG derivations from 24,283 sentences (in the training set), resulting in the total conversion rate of 93.98%. The table shows we lost more sentences in Step 2 than in Step 1. This is natural because Step 2 imposed more restrictions on resulting structures and therefore detected more discrepancies including compounding errors. Our conversion rate is about 5.5 points lower than the English counterpart (Hockenmaier and Steedman, 2007). Manual investigation of the sampled derivations would be beneficial for the conversion improvement.

For the lexicon extraction from the CCGbank, we obtained 699 types of lexical categories from 616,305 word tokens. After lexical reduction, the number of categories decreased to 454, which in turn may produce 5,342 categories by lexical expansion. The average number of categories for a word type was 11.68 as a result.

### 4.2 Evaluation of coverage

Following the evaluation criteria in (Hockenmaier and Steedman, 2007), we measured the coverage

<sup>3</sup><http://cl.naist.jp/nldata/corpus/>

<sup>4</sup><https://alaginrc.nict.go.jp/resources/tocorpus/tocorpusabstract.html>

of the grammar on unseen texts. First, we obtained CCG derivations for evaluation sets by applying our conversion method and then used these derivations as gold standard. Lexical coverage indicates the number of words to which the grammar assigns a gold standard category. Sentential coverage indicates the number of sentences in which all words are assigned gold standard categories <sup>5</sup>.

Table 6 shows the evaluation results. Lexical coverage was 99.40% with rare word treatment, which is in the same level as the case of the English CCG parser C&C (Clark and Curran, 2007). We also measured coverage in a “weak” sense, which means the number of sentences that are given at least one analysis (not necessarily correct) by the obtained grammar. This number was 99.12 % and 99.06 % for the development and the test set, respectively, which is sufficiently high for wide-coverage parsing of real-world texts.

### 4.3 Evaluation of parsing accuracy

Finally, we evaluated the parsing accuracy. We employed the parser and the supertagger of (Miyao and Tsujii, 2008), specifically, its generalized modules for lexicalized grammars. We trained log-linear models in the same way as (Clark and Curran, 2007) using the training set as training data. Feature sets were simply borrowed from an English parser; no tuning was performed. Following conventions in research on Japanese dependency parsing, gold morphological analysis results were input to a parser. Following C&C, the evaluation measure was precision and recall over dependencies, where a dependency is defined as a 4-tuple: a head of a functor, a functor category, an argument slot, and a head of an argument.

Table 7 shows the parsing accuracy on the development and the test sets. The supertagging accuracy is presented in the upper table. While our coverage was almost the same as C&C, the performance of our supertagger and parser was lower. To improve the performance, tuning disambiguation models for Japanese is a possible approach. Comparing the parser’s performance with previous works on Japanese dependency parsing is difficult as our figures are not directly comparable to theirs. Sassano and Kurohashi (2009) reported the accuracy of their parser as 88.48 and 95.09

<sup>5</sup>Since a gold derivation can logically be obtained if gold categories are assigned to all words in a sentence, sentential coverage means that the obtained lexicon has the ability to produce exactly correct derivations for those sentences.

<b>Supertagging accuracy</b>						
	Lex. Cov.		Cat. Acc.			
Devel.	99.40		90.86			
Test	99.40		90.69			
C&C	99.63		94.32			
<b>Overall performance</b>						
	LP	LR	LF	UP	UR	UF
Devel.	82.55	82.73	82.64	90.02	90.22	90.12
Test	82.40	82.59	82.50	89.95	90.15	90.05
C&C	88.34	86.96	87.64	93.74	92.28	93.00

Table 7: Parsing accuracy. LP, LR and LF refer to labeled precision, recall, and F-score respectively. UP, UR, and UF are for unlabeled.

in unlabeled chunk-based and word-based F1 respectively. While our score of 90.05 in unlabeled category dependency seems to be lower than their word-based score, this is reasonable because our category dependency includes more difficult problems, such as whether a subject PP is shared by coordinated verbs. Thus, our parser is expected to be capable of real-world Japanese text analysis as well as dependency parsers.

## 5 Conclusion

In this paper, we proposed a method to induce wide-coverage Japanese resources based on CCG that will lead to deeper syntactic analysis for Japanese and presented empirical evaluation in terms of the quality of the obtained lexicon and the parsing accuracy. Although our work is basically in line with CCGbank, the application of the method to Japanese is not trivial due to the fact that the relationship between chunk-based dependency structures and CCG derivations is not obvious.

Our method integrates multiple dependency-based resources to convert them into an integrated phrase structure treebank. The obtained treebank is then transformed into CCG derivations. The empirical evaluation in Sec. 4 shows that our corpus conversion successfully converts 94 % of the corpus sentences and the coverage of the lexicon is 99.4 %, which is sufficiently high for analyzing real-world texts. A comparison of the parsing accuracy with previous works on Japanese dependency parsing and English CCG parsing indicates that our parser can analyze real-world Japanese texts fairly well and that there is room for improvement in disambiguation models.

## Abstract

We present a novel approach, called selectional branching, which uses confidence estimates to decide when to employ a beam, providing the accuracy of beam search at speeds close to a greedy transition-based dependency parsing approach. Selectional branching is guaranteed to perform a fewer number of transitions than beam search yet performs as accurately. We also present a new transition-based dependency parsing algorithm that gives a complexity of  $O(n)$  for projective parsing and an expected linear time speed for non-projective parsing. With the standard setup, our parser shows an unlabeled attachment score of 92.96% and a parsing speed of 9 milliseconds per sentence, which is faster and more accurate than the current state-of-the-art transition-based parser that uses beam search.

## 1 Introduction

Transition-based dependency parsing has gained considerable interest because it runs fast and performs accurately. Transition-based parsing gives complexities as low as  $O(n)$  and  $O(n^2)$  for projective and non-projective parsing, respectively (Nivre, 2008).<sup>1</sup> The complexity is lower for projective parsing because a parser can deterministically skip tokens violating projectivity, while this property is not assumed for non-projective parsing. Nonetheless, it is possible to perform non-projective parsing in expected linear time because the amount of non-projective dependencies is notably smaller (Nivre and Nilsson, 2005) so a parser can assume projectivity for most cases while recognizing ones for which projectivity should not be assumed (Nivre, 2009; Choi and Palmer, 2011).

<sup>1</sup>We refer parsing approaches that produce only projective dependency trees as projective parsing and both projective and non-projective dependency trees as non-projective parsing.

Greedy transition-based dependency parsing has been widely deployed because of its speed (Cer et al., 2010); however, state-of-the-art accuracies have been achieved by globally optimized parsers using beam search (Zhang and Clark, 2008; Huang and Sagae, 2010; Zhang and Nivre, 2011; Bohnet and Nivre, 2012). These approaches generate multiple transition sequences given a sentence, and pick one with the highest confidence. Coupled with dynamic programming, transition-based dependency parsing with beam search can be done very efficiently and gives significant improvement to parsing accuracy.

One downside of beam search is that it always uses a fixed size of beam even when a smaller size of beam is sufficient for good results. In our experiments, a greedy parser performs as accurately as a parser that uses beam search for about 64% of time. Thus, it is preferred if the beam size is not fixed but proportional to the number of low confidence predictions that a greedy parser makes, in which case, fewer transition sequences need to be explored to produce the same or similar parse output.

We first present a new transition-based parsing algorithm that gives a complexity of  $O(n)$  for projective parsing and an expected linear time speed for non-projective parsing. We then introduce selectional branching that uses confidence estimates to decide when to employ a beam. With our new approach, we achieve a higher parsing accuracy than the current state-of-the-art transition-based parser that uses beam search and a much faster speed.

## 2 Transition-based dependency parsing

We introduce a transition-based dependency parsing algorithm that is a hybrid between Nivre’s arc-eager and list-based algorithms (Nivre, 2003; Nivre, 2008). Nivre’s arc-eager is a projective parsing algorithm showing a complexity of  $O(n)$ . Nivre’s list-based algorithm is a non-projective parsing algorithm showing a complexity of  $O(n^2)$ . Table 1 shows transitions in our algorithm. The top 4 and

Transition	Current state	⇒	Resulting state
LEFT <sub>l</sub> -REDUCE	$([\sigma i], \delta, [j \beta], A)$	⇒	$(\sigma, \delta, [j \beta], A \cup \{i \xleftarrow{l} j\})$
RIGHT <sub>l</sub> -SHIFT	$([\sigma i], \delta, [j \beta], A)$	⇒	$([\sigma i\delta]j, [], \beta, A \cup \{i \xrightarrow{l} j\})$
NO-SHIFT	$([\sigma i], \delta, [j \beta], A)$	⇒	$([\sigma i\delta]j, [], \beta, A)$
NO-REDUCE	$([\sigma i], \delta, [j \beta], A)$	⇒	$(\sigma, \delta, [j \beta], A)$
LEFT <sub>l</sub> -PASS	$([\sigma i], \delta, [j \beta], A)$	⇒	$(\sigma, [i \delta], [j \beta], A \cup \{i \xleftarrow{l} j\})$
RIGHT <sub>l</sub> -PASS	$([\sigma i], \delta, [j \beta], A)$	⇒	$(\sigma, [i \delta], [j \beta], A \cup \{i \xrightarrow{l} j\})$
NO-PASS	$([\sigma i], \delta, [j \beta], A)$	⇒	$(\sigma, [i \delta], [j \beta], A)$

Table 1: Transitions in our dependency parsing algorithm.

Transition	Preconditions
LEFT <sub>l</sub> -*	$[i \neq 0] \wedge \neg[\exists k. (i \leftarrow k) \in A] \wedge \neg[(i \rightarrow^* j) \in A]$
RIGHT <sub>l</sub> -*	$\neg[\exists k. (k \rightarrow j) \in A] \wedge \neg[(i \leftarrow^* j) \in A]$
*-SHIFT	$\neg[\exists k \in \sigma. (k \neq i) \wedge ((k \leftarrow j) \vee (k \rightarrow j))]$
*-REDUCE	$[\exists h. (h \rightarrow i) \in A] \wedge \neg[\exists k \in \beta. (i \rightarrow k)]$

Table 2: Preconditions of the transitions in Table 1 (\* is a wildcard representing any transition).

the bottom 3 transitions are inherited from Nivre’s arc-eager and list-based algorithms, respectively.<sup>2</sup>

Each parsing state is represented as a tuple  $(\sigma, \delta, \beta, A)$ , where  $\sigma$  is a stack containing processed tokens,  $\delta$  is a deque containing tokens popped out of  $\sigma$  but will be pushed back into  $\sigma$  in later parsing states to handle non-projectivity, and  $\beta$  is a buffer containing unprocessed tokens.  $A$  is a set of labeled arcs.  $(i, j)$  represent indices of their corresponding tokens ( $w_i, w_j$ ),  $l$  is a dependency label, and the 0 identifier corresponds to  $w_0$ , introduced as the root of a tree. The initial state is  $([0], [], [1, \dots, n], \emptyset)$ , and the final state is  $(\sigma, \delta, [], A)$ . At any parsing state, a decision is made by comparing the top of  $\sigma$ ,  $w_i$ , and the first element of  $\beta$ ,  $w_j$ . This decision is consulted by gold-standard trees during training and a classifier during decoding.

LEFT<sub>l</sub>-\* and RIGHT<sub>l</sub>-\* are performed when  $w_j$  is the head of  $w_i$  with a dependency label  $l$ , and vice versa. After LEFT<sub>l</sub>-\* or RIGHT<sub>l</sub>-, an arc is added to  $A$ . NO-\* is performed when no dependency is found for  $w_i$  and  $w_j$ . \*-SHIFT is performed when no dependency is found for  $w_j$  and any token in  $\sigma$  other than  $w_i$ . After \*-SHIFT, all tokens in  $\delta$  as well as  $w_j$  are pushed into  $\sigma$ . \*-REDUCE is performed when  $w_i$  already has the head, and  $w_i$  is not the head of any token in  $\beta$ . After \*-REDUCE,  $w_i$  is popped out of  $\sigma$ . \*-PASS is performed when neither \*-SHIFT nor \*-REDUCE can be performed. After \*-PASS,  $w_i$  is moved to the front of  $\delta$  so it

can be compared to other tokens in  $\beta$  later. Each transition needs to satisfy certain preconditions to ensure the properties of a well-formed dependency graph (Nivre, 2008); they are described in Table 2.  $(i \leftarrow j)$  and  $(i \leftarrow^* j)$  indicate that  $w_j$  is the head and an ancestor of  $w_i$  with any label, respectively.

When a parser is trained on only projective trees, our algorithm learns only the top 4 transitions and produces only projective trees during decoding. In this case, it performs at most  $2n - 1$  transitions per sentence so the complexity is  $O(n)$ . When a parser is trained on a mixture of projective and non-projective trees, our algorithm learns all transitions and produces both kinds of trees during decoding. In this case, it performs at most  $\frac{n(n+1)}{2}$  transitions so the complexity is  $O(n^2)$ . However, because of the presence of \*-SHIFT and \*-REDUCE, our algorithm is capable of skipping or removing tokens during non-projective parsing, which allows it to show a linear time parsing speed in practice.

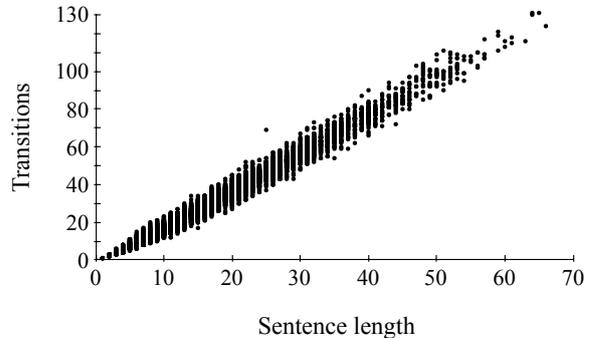

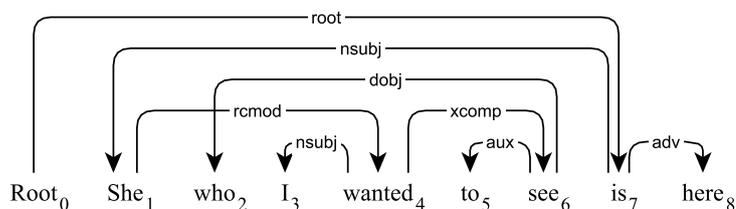

Figure 1: The # of transitions performed during training with respect to sentence lengths for Dutch.

<sup>2</sup>The parsing complexity of a transition-based dependency parsing algorithm is determined by the number of transitions performed with respect to the number of tokens in a sentence, say  $n$  (Kübler et al., 2009).

Table 3: A transition sequence generated by our parsing algorithm using gold-standard decisions.

Figure 1 shows the total number of transitions performed during training with respect to sentence lengths for Dutch. Among all languages distributed by the CoNLL-X shared task (Buchholz and Marsi, 2006), Dutch consists of the highest number of non-projective dependencies (5.4% in arcs, 36.4% in trees). Even with such a high number of non-projective dependencies, our parsing algorithm still shows a linear growth in transitions.

Table 3 shows a transition sequence generated by our parsing algorithm using gold-standard decisions. After  $w_3$  and  $w_4$  are compared,  $w_3$  is popped out of  $\sigma$  (state 4) so it is not compared to any other token in  $\beta$  (states 9 and 13). After  $w_2$  and  $w_4$  are compared,  $w_2$  is moved to  $\delta$  (state 5) so it can be compared to other tokens in  $\beta$  (state 10). After  $w_4$  and  $w_6$  are compared, RIGHT-PASS is performed (state 9) because there is a dependency between  $w_6$  and  $w_2$  in  $\sigma$  (state 10). After  $w_6$  and  $w_7$  are compared,  $w_6$  is popped out of  $\sigma$  (state 12) because it is not needed for later parsing states.

### 3 Selectional branching

#### 3.1 Motivation

For transition-based parsing, state-of-the-art accuracies have been achieved by parsers optimized on multiple transition sequences using beam search,

which can be done very efficiently when it is coupled with dynamic programming (Zhang and Clark, 2008; Huang and Sagae, 2010; Zhang and Nivre, 2011; Huang et al., 2012; Bohnet and Nivre, 2012). Despite all the benefits, there is one downside of this approach; it generates a fixed number of transition sequences no matter how confident the one-best sequence is.<sup>3</sup> If every prediction leading to the one-best sequence is confident, it may not be necessary to explore more sequences to get the best output. Thus, it is preferred if the beam size is not fixed but proportional to the number of low confidence predictions made for the one-best sequence.

The selectional branching method presented here performs at most  $d \cdot t - e$  transitions, where  $t$  is the maximum number of transitions performed to generate a transition sequence,  $d = \min(b, |\lambda| + 1)$ ,  $b$  is the beam size,  $|\lambda|$  is the number of low confidence predictions made for the one-best sequence, and  $e = \frac{d(d-1)}{2}$ . Compared to beam search that always performs  $b \cdot t$  transitions, selectional branching is guaranteed to perform fewer transitions given the same beam size because  $d \leq b$  and  $e > 0$  except for  $d = 1$ , in which case, no branching happens. With selectional branching, our parser shows slightly

<sup>3</sup>The ‘one-best sequence’ is a transition sequence generated by taking only the best prediction at each parsing state.

higher parsing accuracy than the current state-of-the-art transition-based parser using beam search, and performs about 3 times faster.

### 3.2 Branching strategy

Figure 2 shows an overview of our branching strategy.  $s_{ij}$  represents a parsing state, where  $i$  is the index of the current transition sequence and  $j$  is the index of the current parsing state (e.g.,  $s_{12}$  represents the 2nd parsing state in the 1st transition sequence).  $p_{kj}$  represents the  $k$ 'th best prediction (in our case, it is a predicted transition) given  $s_{1j}$  (e.g.,  $p_{21}$  is the 2nd-best prediction given  $s_{11}$ ).

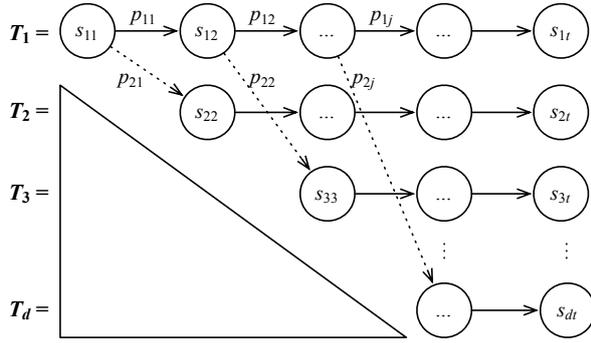

Figure 2: An overview of our branching strategy. Each sequence  $T_{i>1}$  branches from  $T_1$ .

Initially, the one-best sequence  $T_1 = [s_{11}, \dots, s_{1t}]$  is generated by a greedy parser. While generating  $T_1$ , the parser adds tuples  $(s_{1j}, p_{2j}), \dots, (s_{1j}, p_{kj})$  to a list  $\lambda$  for each low confidence prediction  $p_{1j}$  given  $s_{1j}$ .<sup>4</sup> Then, new transition sequences are generated by using the  $b$  highest scoring predictions in  $\lambda$ , where  $b$  is the beam size. If  $|\lambda| < b$ , all predictions in  $\lambda$  are used. The same greedy parser is used to generate these new sequences although it now starts with  $s_{1j}$  instead of an initial parsing state, applies  $p_{kj}$  to  $s_{1j}$ , and performs further transitions. Once all transition sequences are generated, a parse tree is built from a sequence with the highest score.

For our experiments, we set  $k = 2$ , which gave noticeably more accurate results than  $k = 1$ . We also experimented with  $k > 2$ , which did not show significant improvement over  $k = 2$ . Note that assigning a greater  $k$  may increase  $|\lambda|$  but not the total number of transition sequences generated, which is restricted by the beam size,  $b$ . Since each sequence  $T_{i>1}$  branches from  $T_1$ , selectional branching performs fewer transitions than beam search: at least  $\frac{d(d-1)}{2}$  transitions are inherited from  $T_1$ ,

<sup>4</sup> $\lambda$  is initially empty, which is hidden in Figure 2.

where  $d = \min(b, |\lambda| + 1)$ ; thus, it performs that many transitions less than beam search (see the left lower triangle in Figure 2). Furthermore, selectional branching generates a  $d$  number of sequences, where  $d$  is proportional to the number of low confidence predictions made by  $T_1$ . To sum up, selectional branching generates the same or fewer transition sequences than beam search and each sequence  $T_{i>1}$  performs fewer transitions than  $T_1$ ; thus, it performs faster than beam search in general given the same beam size.

### 3.3 Finding low confidence predictions

For each parsing state  $s_{ij}$ , a prediction is made by generating a feature vector  $x_{ij} \in \mathcal{X}$ , feeding it into a classifier  $C^1$  that uses a feature map  $\Phi(x, y)$  and a weight vector  $\mathbf{w}$  to measure a score for each label  $y \in \mathcal{Y}$ , and choosing a label with the highest score. When there is a tie between labels with the highest score, the first one is chosen. This can be expressed as a logistic regression:

$$C^1(x) = \arg \max_{y \in \mathcal{Y}} \{f(x, y)\}$$

$$f(x, y) = \frac{\exp(\mathbf{w} \cdot \Phi(x, y))}{\sum_{y' \in \mathcal{Y}} \exp(\mathbf{w} \cdot \Phi(x, y'))}$$

To find low confidence predictions, we use the margins (score differences) between the best prediction and the other predictions. If all margins are greater than a threshold, the best prediction is considered highly confident; otherwise, it is not. Given this analogy, the  $k$ -best predictions can be found as follows ( $m \geq 0$  is a margin threshold):

$$C^k(x, m) = \mathcal{K} \arg \max_{y \in \mathcal{Y}} \{f(x, y)\}$$

$$\text{s.t. } f(x, C^1(x)) - f(x, y) \leq m$$

' $\mathcal{K} \arg \max$ ' returns a set of  $k'$  labels whose margins to  $C^1(x)$  are smaller than any other label's margin to  $C^1(x)$  and also  $\leq m$ , where  $k' \leq k$ . When  $m = 0$ , it returns a set of the highest scoring labels only, including  $C^1(x)$ . When  $m = 1$ , it returns a set of all labels. Given this, a prediction is considered not confident if  $|C^k(x, m)| > 1$ .

### 3.4 Finding the best transition sequence

Let  $P_i$  be a list of all predictions that lead to generate a transition sequence  $T_i$ . The predictions in  $P_i$  are either inherited from  $T_1$  or made specifically for  $T_i$ . In Figure 2,  $P_3$  consists of  $p_{11}$  as its first prediction,  $p_{22}$  as its second prediction, and

further predictions made specifically for  $T_3$ . The score of each prediction is measured by  $f(x, y)$  in Section 3.3. Then, the score of  $T_i$  is measured by averaging scores of all predictions in  $P_i$ .

$$\text{score}(T_i) = \frac{\sum_{p \in P_i} \text{score}(p)}{|P_i|}$$

Unlike Zhang and Clark (2008), we take the average instead of the sum of all prediction scores. This is because our algorithm does not guarantee the same number of transitions for every sequence, so the sum of all scores would weigh more on sequences with more transitions. We experimented with both the sum and the average, and taking the average led to slightly higher parsing accuracy.

### 3.5 Bootstrapping transition sequences

During training, a training instance is generated for each parsing state  $s_{ij}$  by taking a feature vector  $x_{ij}$  and its true label  $y_{ij}$ . To generate multiple transition sequences during training, the bootstrapping technique of Choi and Palmer (2011) is used, which is described in Algorithm 1.<sup>5</sup>

---

#### Algorithm 1 Bootstrapping

---

**Input:**  $D_t$ : training set,  $D_d$ : development set.  
**Output:** A model  $M$ .

- 1:  $r \leftarrow 0$
- 2:  $I \leftarrow \text{getTrainingInstances}(D_t)$
- 3:  $M_0 \leftarrow \text{buildModel}(I)$
- 4:  $S_0 \leftarrow \text{getScore}(D_d, M_0)$
- 5: **while** ( $r = 0$ ) or ( $S_{r-1} < S_r$ ) **do**
- 6:    $r \leftarrow r + 1$
- 7:    $I \leftarrow \text{getTrainingInstances}(D_t, M_{r-1})$
- 8:    $M_r \leftarrow \text{buildModel}(I)$
- 9:    $S_r \leftarrow \text{getScore}(D_d, M_r)$
- 10: **return**  $M_{r-1}$

---

First, an initial model  $M_0$  is trained on all data by taking the one-best sequences, and its score is measured by testing on a development set (lines 2-4). Then, the next model  $M_r$  is trained on all data but this time,  $M_{r-1}$  is used to generate multiple transition sequences (line 7-8). Among all transition sequences generated by  $M_{r-1}$ , training instances from only  $T_1$  and  $T_g$  are used to train  $M_r$ , where  $T_1$  is the one-best sequence and  $T_g$  is a sequence giving the most accurate parse output compared to the gold-standard tree. The score of  $M_r$  is measured (line 9), and repeat the procedure if  $S_{r-1} < S_r$ ; otherwise, return the previous model  $M_{r-1}$ .

<sup>5</sup>Alternatively, the dynamic oracle approach of Goldberg and Nivre (2012) can be used to generate multiple transition sequences, which is expected to show similar results.

### 3.6 Adaptive subgradient algorithm

To build each model during bootstrapping, we use a stochastic adaptive subgradient algorithm called ADAGRAD that uses per-coordinate learning rates to exploit rarely seen features while remaining scalable (Duchi et al., 2011). This is suitable for NLP tasks where rarely seen features often play an important role and training data consists of a large number of instances with high dimensional features. Algorithm 2 shows our adaptation of ADAGRAD with logistic regression for multi-class classification. Note that when used with logistic regression, ADAGRAD takes a regular gradient instead of a subgradient method for updating weights. For our experiments, ADAGRAD slightly outperformed learning algorithms such as average perceptron (Collins, 2002) or Liblinear SVM (Hsieh et al., 2008).

---

#### Algorithm 2 ADAGRAD + logistic regression

---

**Input:**  $D = \{(x_i, y_i)\}_{i=1}^n$  s.t.  $x_i \in \mathcal{X}, y_i \in \mathcal{Y}$   
 $\Phi(x, y) \in \mathbb{R}^d$  s.t.  $d = \text{dimension}(\mathcal{X}) \times |\mathcal{Y}|$   
 $T$ : iterations,  $\alpha$ : learning rate,  $\rho$ : ridge  
**Output:** A weight vector  $\mathbf{w} \in \mathbb{R}^d$ .

- 1:  $\mathbf{w} \leftarrow 0$ , where  $\mathbf{w} \in \mathbb{R}^d$
- 2:  $\mathbf{G} \leftarrow 0$ , where  $\mathbf{G} \in \mathbb{R}^d$
- 3: **for**  $t \leftarrow 1 \dots T$  **do**
- 4:   **for**  $i \leftarrow 1 \dots n$  **do**
- 5:      $\mathbf{Q}_{y \in \mathcal{Y}} \leftarrow I(y_i, y) - f(x_i, y)$ , s.t.  $\mathbf{Q} \in \mathbb{R}^{|\mathcal{Y}|}$
- 6:      $\partial \leftarrow \sum_{y \in \mathcal{Y}} (\Phi(x_i, y) \cdot \mathbf{Q}_y)$
- 7:      $\mathbf{G} \leftarrow \mathbf{G} + \partial \circ \partial$
- 8:     **for**  $j \leftarrow 1 \dots d$  **do**
- 9:        $\mathbf{w}_j \leftarrow \mathbf{w}_j + \alpha \cdot \frac{1}{\rho + \sqrt{\mathbf{G}_j}} \cdot \partial_j$

---

$$I(y, y') = \begin{cases} 1 & y = y' \\ 0 & \text{otherwise} \end{cases}$$

The algorithm takes three hyper-parameters;  $T$  is the number of iterations,  $\alpha$  is the learning rate, and  $\rho$  is the ridge ( $T > 0, \alpha > 0, \rho \geq 0$ ).  $\mathbf{G}$  is our running estimate of a diagonal covariance matrix for the gradients (per-coordinate learning rates). For each instance, scores for all labels are measured by the logistic regression function  $f(x, y)$  in Section 3.3. These scores are subtracted from an output of the indicator function  $I(y, y')$ , which forces our model to keep learning this instance until the prediction is 100% confident (in other words, until the score of  $y_i$  becomes 1). Then, a subgradient is measured by taking all feature vectors together weighted by  $\mathbf{Q}$  (line 6). This subgradient is used to update  $\mathbf{G}$  and  $\mathbf{w}$ , where  $\circ$  is the Hadamard product (lines 7-9).  $\rho$  is a ridge term to keep the inverse covariance well-conditioned.

## 4 Experiments

### 4.1 Corpora

For projective parsing experiments, the Penn English Treebank (Marcus et al., 1993) is used with the standard split: sections 2-21 for training, 22 for development, and 23 for evaluation. All constituent trees are converted with the head-finding rules of Yamada and Matsumoto (2003) and the labeling rules of Nivre (2006). For non-projective parsing experiments, four languages from the CoNLL-X shared task are used: Danish, Dutch, Slovene, and Swedish (Buchholz and Marsi, 2006). These languages are selected because they contain non-projective trees and are publicly available from the CoNLL-X webpage.<sup>6</sup> Since the CoNLL-X data we have does not come with development sets, the last 10% of each training set is used for development.

### 4.2 Feature engineering

For English, we mostly adapt features from Zhang and Nivre (2011) who have shown state-of-the-art parsing accuracy for transition-based dependency parsing. Their distance features are not included in our approach because they do not seem to show meaningful improvement. Feature selection is done on the English development set.

For the other languages, the same features are used with the addition of morphological features provided by CoNLL-X; specifically, morphological features from the top of  $\sigma$  and the front of  $\beta$  are added as unigram features. Moreover, all POS tag features from English are duplicated with coarse-grained POS tags provided by CoNLL-X. No more feature engineering is done for these languages; it is possible to achieve higher performance by using different features, especially when these languages contain non-projective dependencies whereas English does not, which we will explore in the future.

### 4.3 Development

Several parameters need to be optimized during development. For ADAGRAD,  $T$ ,  $\alpha$ , and  $\rho$  need to be tuned (Section 3.6). For bootstrapping, the number of iterations, say  $r$ , needs to be tuned (Section 3.5). For selectional branching, the margin threshold  $m$  and the beam size  $b$  need to be tuned (Section 3.3). First, all parameters are tuned on the English development set by using grid search on  $T = [1, \dots, 10]$ ,  $\alpha = [0, 01, 0, 02]$ ,  $\rho = [0.1, 0.2]$ ,  $r = [1, 2, 3]$ ,

$m = [0.83, \dots, 0.92]$ , and  $b = [16, 32, 64, 80]$ . As a result, the following parameters are found:  $\alpha = 0.02$ ,  $\rho = 0.1$ ,  $m = 0.88$ , and  $b = 64|80$ . For this development set, the beam size of 64 and 80 gave the exact same result, so we kept the one with a larger beam size ( $b = 80$ ).

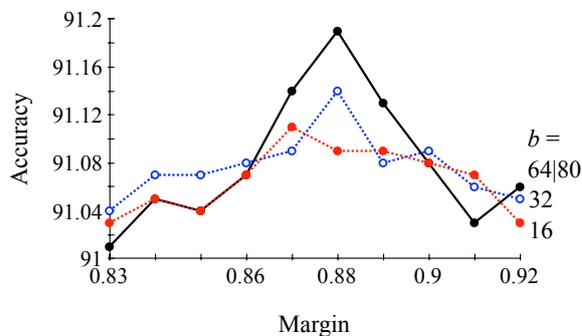

Figure 3: Parsing accuracies with respect to margins and beam sizes on the English development set.  $b = 64|80$ : the black solid line with solid circles,  $b = 32$ : the blue dotted line with hollow circles,  $b = 16$ : the red dotted line with solid circles.

Figure 3 shows parsing accuracies with respect to different margins and beam sizes on the English development set. These parameters need to be tuned jointly because different margins prefer different beam sizes. For instance,  $m = 0.85$  gives the highest accuracy with  $b = 32$ , but  $m = 0.88$  gives the highest accuracy with  $b = 64|80$ .

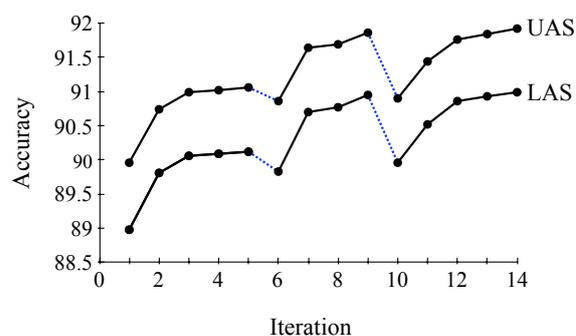

Figure 4: Parsing accuracies with respect to ADAGRAD and bootstrap iterations on the English development set when  $\alpha = 0.02$ ,  $\rho = 0.1$ ,  $m = 0.88$ , and  $b = 64|80$ . UAS: unlabeled attachment score, LAS: labeled attachment score.

Figure 4 shows parsing accuracies with respect to ADAGRAD and bootstrap iterations on the English development set. The range 1-5 shows results of 5 ADAGRAD iterations before bootstrapping, the range 6-9 shows results of 4 iterations during the

<sup>6</sup><http://ilk.uvt.nl/conll/>

first bootstrapping, and the range 10-14 shows results of 5 iterations during the second bootstrapping. Thus, the number of bootstrap iteration is 2 where each bootstrapping takes a different number of ADAGRAD iterations. Using an Intel Xeon 2.57GHz machine, it takes less than 40 minutes to train the entire Penn Treebank, which includes times for IO, feature extraction and bootstrapping.

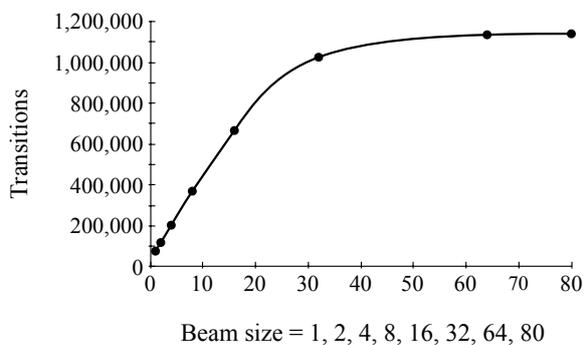

Figure 5: The total number of transitions performed during decoding with respect to beam sizes on the English development set.

Figure 5 shows the total number of transitions performed during decoding with respect to beam sizes on the English development set (1,700 sentences, 40,117 tokens). With selectional branching, the number of transitions grows logarithmically as the beam size increases whereas it would have grown linearly if beam search were used. We also checked how often the one best sequence is chosen as the final sequence during decoding. Out of 1,700 sentences, the one best sequences are chosen for 1,095 sentences. This implies that about 64% of time, our greedy parser performs as accurately as our non-greedy parser using selectional branching.

For the other languages, we use the same values as English for  $\alpha$ ,  $\rho$ ,  $m$ , and  $b$ ; only the ADAGRAD and bootstrap iterations are tuned on the development sets of the other languages.

#### 4.4 Projective parsing experiments

Before parsing, POS tags were assigned to the training set by using 20-way jackknifing. For the automatic generation of POS tags, we used the domain-specific model of Choi and Palmer (2012a)’s tagger, which gave 97.5% accuracy on the English evaluation set (0.2% higher than Collins (2002)’s tagger).

Table 4 shows comparison between past and current state-of-the-art parsers and our approach. The first block shows results from transition-based de-

pendency parsers using beam search. The second block shows results from other kinds of parsing approaches (e.g., graph-based parsing, ensemble parsing, linear programming, dual decomposition). The third block shows results from parsers using external data. The last block shows results from our approach. The Time column show how many seconds per sentence each parser takes.<sup>7</sup>

Table 4: Parsing accuracies and speeds on the English evaluation set, excluding tokens containing only punctuation.  $b_t$  and  $b_d$  indicate the beam sizes used during training and decoding, respectively. UAS: unlabeled attachment score, LAS: labeled attachment score, Time: seconds per sentence.

For evaluation, we use the model trained with  $b = 80$  and  $m = 0.88$ , which is the best setting found during development. Our parser shows higher accuracy than Zhang and Nivre (2011), which is the current state-of-the-art transition-based parser that uses beam search. Bohnet and Nivre (2012)’s transition-based system jointly performs POS tagging and dependency parsing, which shows higher accuracy than ours. Our parser gives a comparative accuracy to Koo and Collins (2010) that is a 3rd-order graph-based parsing approach. In terms of speed, our parser outperforms all other transition-based parsers; it takes about 9 milliseconds per

<sup>7</sup>Dhillon et al. (2012) and Rush and Petrov (2012) also have shown good results on this data but they are excluded from our comparison because they use different kinds of constituent-to-dependency conversion methods.

Table 5: Parsing accuracies on four languages with non-projective dependencies, excluding punctuation.

sentence using the beam size of 80. Our parser is implemented in Java and tested on an Intel Xeon 2.57GHz. Note that we do not include input/output time for our speed comparison.

For a proof of concept, we run the same model, trained with  $b_t = 80$ , but decode with different beam sizes using the same margin. Surprisingly, our parser gives the same accuracy (0.01% higher for labeled attachment score) on this data even with  $b_d = 16$ . More importantly,  $b_d = 16$  shows about the same parsing speed as  $b_d = 80$ , which indicates that selectional branching automatically reduced down the beam size by estimating low confidence predictions, so even if we assigned a larger beam size for decoding, it would have performed as efficiently. This implies that we no longer need to be so conscious about the beam size during decoding.

Another interesting part is that ( $b_t = 80, b_d = 1$ ) shows higher accuracy than ( $b_t = 1, b_d = 1$ ); this implies that our training method of bootstrapping transition sequences can improve even a greedy parser. Notice that our greedy parser shows higher accuracy than many other greedy parsers (Hall et al., 2006; Goldberg and Elhadad, 2010) because it uses the non-local features of Zhang and Nivre (2011) and the bootstrapping technique of Choi and Palmer (2011) that had not been used for most other greedy parsing approaches.

#### 4.5 Non-projective parsing experiments

Table 5 shows comparison between state-of-the-art parsers and our approach for four languages with non-projective dependencies. Nivre et al. (2006) uses a pseudo-projective transition-based parsing approach. McDonald et al. (2006) uses a 2nd-order maximum spanning tree approach. Nivre (2009) and Fernández-González and Gómez-Rodríguez (2012) use different non-projective transition-based parsing approaches. Nivre and McDonald (2008) uses an ensemble model between transition-based and graph-based parsing approaches. Martins et

al. (2010) uses integer linear programming for the optimization of their parsing model.

Some of these approaches use greedy parsers, so we include our results from models using ( $b_t = 80, b_d = 1, m = 0.88$ ), which finds only the one-best sequences during decoding although it is trained on multiple transition sequences (see Section 4.4). Our parser shows higher accuracies for most languages except for unlabeled attachment scores in Danish and Slovene. Our greedy approach outperforms both Nivre (2009) and Fernández-González and Gómez-Rodríguez (2012) who use different non-projective parsing algorithms.

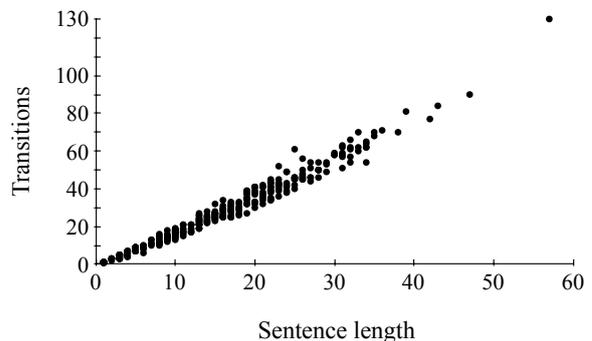

Figure 6: The # of transitions performed during decoding with respect to sentence lengths for Dutch.

Figure 6 shows the number of transitions performed during decoding with respect to sentence lengths for Dutch using  $b_d = 1$ . Our parser still shows a linear growth in transition during decoding.

## 5 Related work

Our parsing algorithm is most similar to Choi and Palmer (2011) who integrated our LEFT-REDUCE transition into Nivre’s list-based algorithm. Our algorithm is distinguished from theirs because ours gives different parsing complexities of  $O(n)$  and  $O(n^2)$  for projective and non-projective parsing, respectively, whereas their algorithm gives  $O(n^2)$

for both cases; this is possible because of the new integration of the RIGHT-SHIFT and NO-REDUCE transitions. There are other transition-based dependency parsing algorithms that take a similar approach; Nivre (2009) integrated a SWAP transition into Nivre’s arc-standard algorithm (Nivre, 2004) and Fernández-González and Gómez-Rodríguez (2012) integrated a buffer transition into Nivre’s arc-eager algorithm to handle non-projectivity.

Our selectional branching method is most relevant to Zhang and Clark (2008) who introduced a transition-based dependency parsing model that uses beam search. Huang and Sagae (2010) later applied dynamic programming to this approach and showed improved efficiency. Zhang and Nivre (2011) added non-local features to this approach and showed improved parsing accuracy. Bohnet and Nivre (2012) introduced a transition-based system that jointly performed POS tagging and dependency parsing. Our work is distinguished from theirs because we use selectional branching instead.

## 6 Conclusion

We present selectional branching that uses confidence estimates to decide when to employ a beam. Coupled with our new hybrid parsing algorithm, ADAGRAD, rich non-local features, and bootstrapping, our parser gives higher parsing accuracy than most other transition-based dependency parsers in multiple languages and shows faster parsing speed. It is interesting to see that our greedy parser outperformed most other greedy dependency parsers. This is because our parser used both bootstrapping and Zhang and Nivre (2011)’s non-local features, which had not been used by other greedy parsers.

In the future, we will experiment with more advanced dependency representations (de Marneffe and Manning, 2008; Choi and Palmer, 2012b) to show robustness of our approach. Furthermore, we will evaluate individual methods of our approach separately to show impact of each method on parsing performance. We also plan to implement the typical beam search approach to make a direct comparison to our selectional branching.<sup>8</sup>

## Abstract

This paper describes a novel strategy for automatic induction of a monolingual dependency grammar under the guidance of bilingually-projected dependency. By moderately leveraging the dependency information projected from the parsed counterpart language, and simultaneously mining the underlying syntactic structure of the language considered, it effectively integrates the advantages of bilingual projection and unsupervised induction, so as to induce a monolingual grammar much better than previous models only using bilingual projection or unsupervised induction. We induced dependency grammar for five different languages under the guidance of dependency information projected from the parsed English translation, experiments show that the bilingually-guided method achieves a significant improvement of 28.5% over the unsupervised baseline and 3.0% over the best projection baseline on average.

## 1 Introduction

In past decades supervised methods achieved the state-of-the-art in constituency parsing (Collins, 2003; Charniak and Johnson, 2005; Petrov et al., 2006) and dependency parsing (McDonald et al., 2005a; McDonald et al., 2006; Nivre et al., 2006; Nivre et al., 2007; Koo and Collins, 2010). For supervised models, the human-annotated corpora on which models are trained, however, are expensive and difficult to build. As alternative strategies, methods which utilize raw texts have been investigated recently, including unsupervised meth-

ods which use only raw texts (Klein and Manning, 2004; Smith and Eisner, 2005; William et al., 2009), and semi-supervised methods (Koo et al., 2008) which use both raw texts and annotated corpus. And there are a lot of efforts have also been devoted to bilingual projection (Chen et al., 2010), which resorts to bilingual text with one language parsed, and projects the syntactic information from the parsed language to the unparsed one (Hwa et al., 2005; Ganchev et al., 2009).

In dependency grammar induction, unsupervised methods achieve continuous improvements in recent years (Klein and Manning, 2004; Smith and Eisner, 2005; Bod, 2006; William et al., 2009; Spitkovsky et al., 2010). Relying on a predefined distributional assumption and iteratively maximizing an approximate indicator (entropy, likelihood, etc.), an unsupervised model usually suffers from two drawbacks, i.e., lower performance and higher computational cost. On the contrary, bilingual projection (Hwa et al., 2005; Smith and Eisner, 2009; Jiang and Liu, 2010) seems a promising substitute for languages with a large amount of bilingual sentences and an existing parser of the counterpart language. By projecting syntactic structures directly (Hwa et al., 2005; Smith and Eisner, 2009; Jiang and Liu, 2010) across bilingual texts or indirectly across multilingual texts (Snyder et al., 2009; McDonald et al., 2011; Naseem et al., 2012), a better dependency grammar can be easily induced, if syntactic isomorphism is largely maintained between target and source languages.

Unsupervised induction and bilingual projection run according to totally different principles, the former mines the underlying structure of the monolingual language, while the latter leverages the syntactic knowledge of the parsed counter-

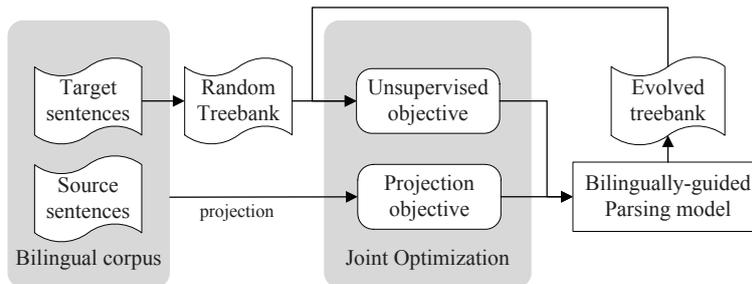

Figure 1: Training the bilingually-guided parsing model by iteration.

part language. Considering this, we propose a novel strategy for automatically inducing a monolingual dependency grammar under the guidance of bilingually-projected dependency information, which integrates the advantage of bilingual projection into the unsupervised framework. A randomly-initialized monolingual treebank evolves in a self-training iterative procedure, and the grammar parameters are tuned to simultaneously maximize both the monolingual likelihood and bilingually-projected likelihood of the evolving treebank. The monolingual likelihood is similar to the optimization objectives of conventional unsupervised models, while the bilingually-projected likelihood is the product of the projected probabilities of dependency trees. By moderately leveraging the dependency information projected from the parsed counterpart language, and simultaneously mining the underlying syntactic structure of the language considered, we can automatically induce a monolingual dependency grammar which is much better than previous models only using bilingual projection or unsupervised induction. In addition, since both likelihoods are fundamentally factorized into dependency edges (of the hypothesis tree), the computational complexity approaches to unsupervised models, while with much faster convergence. We evaluate the final automatically-induced dependency parsing model on 5 languages. Experimental results show that our method significantly outperforms previous work based on unsupervised method or indirect/direct dependency projection, where we see an average improvement of 28.5% over unsupervised baseline on all languages, and the improvements are 3.9%/3.0% over indirect/direct baselines. And our model achieves the most significant gains on Chinese, where the improvements are 12.0%, 4.5% over indirect and direct projection baselines respectively.

In the rest of the paper, we first describe the unsupervised dependency grammar induction framework in section 2 (where the unsupervised optimization objective is given), and introduce the bilingual projection method for dependency parsing in section 3 (where the projected optimization objective is given); Then in section 4 we present the bilingually-guided induction strategy for dependency grammar (where the two objectives above are jointly optimized, as shown in Figure 1). After giving a brief introduction of previous work in section 5, we finally give the experimental results in section 6 and conclude our work in section 7.

## 2 Unsupervised Dependency Grammar Induction

In this section, we introduce the unsupervised objective and the unsupervised training algorithm which is used as the framework of our bilingually-guided method. Unlike previous unsupervised work (Klein and Manning, 2004; Smith and Eisner, 2005; Bod, 2006), we select a self-training approach (similar to hard EM method) to train the unsupervised model. And the framework of our unsupervised model builds a random treebank on the monolingual corpus firstly for initialization and trains a discriminative parsing model on it. Then we use the parser to build an evolved treebank with the 1-best result for the next iteration run. In this way, the parser and treebank evolve in an iterative way until convergence. Let's introduce the parsing objective firstly:

Define  $e_i$  as the  $i^{th}$  word in monolingual sentence  $E$ ;  $d_{e_{ij}}$  denotes the word pair dependency relationship ( $e_i \rightarrow e_j$ ). Based on the features around  $d_{e_{ij}}$ , we can calculate the probability  $Pr(y|d_{e_{ij}})$  that the word pair  $d_{e_{ij}}$  can form a dependency arc

as:

$$Pr(y|d_{e_{ij}}) = \frac{1}{Z(d_{e_{ij}})} \exp\left(\sum_n \lambda_n \cdot f_n(d_{e_{ij}}, y)\right) \quad (1)$$

where  $y$  is the category of the relationship of  $d_{e_{ij}}$ :  $y = +$  means it is the probability that the word pair  $d_{e_{ij}}$  can form a dependency arc and  $y = -$  means the contrary.  $\lambda_n$  denotes the weight for feature function  $f_n(d_{e_{ij}}, y)$ , and the features we used are presented in Table 1 (Section 6).  $Z(d_{e_{ij}})$  is a normalizing constant:

$$Z(d_{e_{ij}}) = \sum_y \exp\left(\sum_n \lambda_n \cdot f_n(d_{e_{ij}}, y)\right) \quad (2)$$

Given a sentence  $E$ , parsing a dependency tree is to find a dependency tree  $D_E$  with maximum probability  $P_E$ :

$$P_E = \arg \max_{D_E} \prod_{d_{e_{ij}} \in D_E} Pr(+|d_{e_{ij}}) \quad (3)$$

## 2.1 Unsupervised Objective

We select a simple classifier objective function as the unsupervised objective function which is instinctively in accordance with the parsing objective:

$$\theta(\lambda) = \prod_{d_e \in D_{\bar{E}}} Pr(+|d_e) \prod_{d_e \in \tilde{D}_{\bar{E}}} Pr(-|d_e) \quad (4)$$

where  $\bar{E}$  is the monolingual corpus and  $E \in \bar{E}$ ,  $D_{\bar{E}}$  is the treebank that contains all  $D_E$  in the corpus, and  $\tilde{D}_{\bar{E}}$  denotes all other possible dependency arcs which do not exist in the treebank.

Maximizing the Formula (4) is equivalent to maximizing the following formula:

$$\begin{aligned} \theta_1(\lambda) = & \sum_{d_e \in D_{\bar{E}}} \log Pr(+|d_e) \\ & + \sum_{d_e \in \tilde{D}_{\bar{E}}} \log Pr(-|d_e) \end{aligned} \quad (5)$$

Since the size of edges between  $D_{\bar{E}}$  and  $\tilde{D}_{\bar{E}}$  is disproportionate, we use an empirical value to reduce the impact of the huge number of negative instances:

$$\begin{aligned} \theta_2(\lambda) = & \sum_{d_e \in D_{\bar{E}}} \log Pr(+|d_e) \\ & + \frac{|D_{\bar{E}}|}{|\tilde{D}_{\bar{E}}|} \sum_{d_e \in \tilde{D}_{\bar{E}}} \log Pr(-|d_e) \end{aligned} \quad (6)$$

where  $|x|$  is the size of  $x$ .

## Algorithm 1 Training unsupervised model

---

```

1: build random  $D_{\bar{E}}$ 
2:  $\lambda \leftarrow \text{train}(D_{\bar{E}}, \tilde{D}_{\bar{E}})$ 
3: repeat
4:   for each  $E \in \bar{E}$  do ▷ E step
5:      $D_E \leftarrow \text{parse}(E, \lambda)$ 
6:      $\lambda \leftarrow \text{train}(D_{\bar{E}}, \tilde{D}_{\bar{E}})$  ▷ M step
7: until convergence

```

---

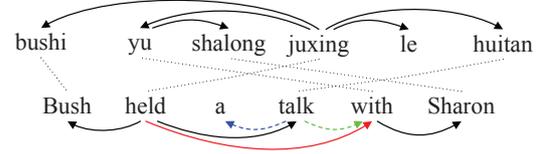

Figure 2: Projecting a Chinese dependency tree to English side according to DPA. Solid arrows are projected dependency arcs; dashed arrows are missing dependency arcs.

## 2.2 Unsupervised Training Algorithm

Algorithm 1 outlines the unsupervised training in its entirety, where the treebank  $D_{\bar{E}}$  and unsupervised parsing model with  $\lambda$  are updated iteratively.

In line 1 we build a random treebank  $D_{\bar{E}}$  on the monolingual corpus, and then train the parsing model with it (line 2) through a training procedure  $\text{train}(\cdot, \cdot)$  which needs  $D_{\bar{E}}$  and  $\tilde{D}_{\bar{E}}$  as classification instances. From line 3-7, we train the unsupervised model in self training iterative procedure, where line 4-5 are similar to the E-step in EM algorithm where calculates objective instead of expectation of 1-best tree (line 5) which is parsed according to the parsing objective (Formula 3) by parsing process  $\text{parse}(\cdot, \cdot)$ , and update the tree bank with the tree. Similar to M-step in EM, the algorithm maximizes the whole treebank's unsupervised objective (Formula 6) through the training procedure (line 6).

## 3 Bilingual Projection of Dependency Grammar

In this section, we introduce our projection objective and training algorithm which trains the model with arc instances.

Because of the heterogeneity between different languages and word alignment errors, projection methods may contain a lot of noises. Take Figure 2 as an example, following the Direct Projection Algorithm (DPA) (Hwa et al., 2005) (Section 5), the dependency relationships between words can be directly projected from the source

---

**Algorithm 2** Training projection model

---

```
1:  $D_P, D_N \leftarrow \text{proj}(\overline{F}, D_{\overline{F}}, A, \overline{E})$ 
2: repeat  $\triangleright \text{train}(D_P, D_N)$ 
3:    $\nabla\phi \leftarrow \text{grad}(D_P, D_N, \phi(\lambda))$ 
4:    $\lambda \leftarrow \text{climb}(\phi, \nabla\phi, \lambda)$ 
5: until maximization
```

---

language to the target language. Therefore, we can hardly obtain a treebank with complete trees through direct projection. So we extract projected discrete dependency arc instances instead of treebank as training set for the projected grammar induction model.

### 3.1 Projection Objective

Correspondingly, we select an objective which has the same form with the unsupervised one:

$$\begin{aligned} \phi(\lambda) = & \sum_{d_e \in D_P} \log Pr(+|d_e) \\ & + \sum_{d_e \in D_N} \log Pr(-|d_e) \end{aligned} \quad (7)$$

where  $D_P$  is the positive dependency arc instance set, which is obtained by direct projection methods (Hwa et al., 2005; Jiang and Liu, 2010) and  $D_N$  is the negative one.

### 3.2 Projection Algorithm

Basically, the training procedure in line 2,7 of Algorithm 1 can be divided into smaller iterative steps, and Algorithm 2 outlines the training step of projection model with instances.  $\overline{F}$  in Algorithm 2 is source sentences in bilingual corpus, and  $A$  is the alignments. Function  $\text{grad}(\cdot, \cdot, \cdot)$  gives the gradient ( $\nabla\phi$ ) and the objective is optimized with a generic optimization step (such as an LBFGS iteration (Zhu et al., 1997)) in the subroutine  $\text{climb}(\cdot, \cdot, \cdot)$ .

## 4 Bilingually-Guided Dependency Grammar Induction

This section presents our bilingually-guided grammar induction model, which incorporates unsupervised framework and bilingual projection model through a joint approach.

According to following observation: unsupervised induction model mines underlying syntactic structure of the monolingual language, however, it is hard to find good grammar induction in the exponential parsing space; bilingual projection obtains relatively reliable syntactic knowledge of the

parsed counterpart, but it possibly contains a lot of noises (e.g. Figure 2). We believe that unsupervised model and projection model can complement each other and a joint model which takes better use of both unsupervised parse trees and projected dependency arcs can give us a better parser.

Based on the idea, we propose a novel strategy for training monolingual grammar induction model with the guidance of unsupervised and bilingually-projected dependency information. Figure 1 outlines our bilingual-guided grammar induction process in its entirety. In our method, we select compatible objectives for unsupervised and projection models, in order to they can share the same grammar parameters. Then we incorporate projection model into our iterative unsupervised framework, and jointly optimize unsupervised and projection objectives with evolving treebank and constant projection information respectively. In this way, our bilingually-guided model’s parameters are tuned to simultaneously maximizing both monolingual likelihood and bilingually-projected likelihood by 4 steps:

1. Randomly build treebank on target sentences for initialization, and get the projected arc instances through projection from bitext.
2. Train the bilingually-guided grammar induction model by multi-objective optimization method with unsupervised objective and projection objective on treebank and projected arc instances respectively.
3. Use the parsing model to build new treebank on target language for next iteration.
4. Repeat steps 1, 2 and 3 until convergence.

The unsupervised objective is optimized by the loop—”tree bank→optimized model→new tree bank”. The treebank is evolved for runs. The unsupervised model gets projection constraint implicitly from those parse trees which contain information from projection part. The projection objective is optimized by the circulation—”projected instances→optimized model”, these projected instances will not change once we get them.

The iterative procedure proposed here is not a co-training algorithm (Sarkar, 2001; Hwa et al., 2003), because the input of the projection objective is static.

## 4.1 Joint Objective

For multi-objective optimization method, we employ the classical weighted-sum approach which just calculates the weighted linear sum of the objectives:

$$OBJ = \sum_m weight_m obj_m \quad (8)$$

We combine the unsupervised objective (Formula (6)) and projection objective (Formula (7)) together through the weighted-sum approach in Formula (8):

$$\ell(\lambda) = \alpha\theta_2(\lambda) + (1 - \alpha)\phi(\lambda) \quad (9)$$

where  $\ell(\lambda)$  is our weight-sum objective. And  $\alpha$  is a mixing coefficient which reflects the relative confidence between the unsupervised and projection objectives. Equally,  $\alpha$  and  $(1 - \alpha)$  can be seen as the weights in Formula (8). In that case, we can use a single parameter  $\alpha$  to control both weights for different objective functions. When  $\alpha = 1$  it is the unsupervised objective function in Formula (6). Contrary, if  $\alpha = 0$ , it is the projection objective function (Formula (7)) for projected instances.

With this approach, we can optimize the mixed parsing model by maximizing the objective in Formula (9). Though the function (Formula (9)) is an interpolation function, we use it for training instead of parsing. In the parsing procedure, our method calculates the probability of a dependency arc according to the Formula (2), while the interpolating method calculates it by:

$$Pr(y|d_{e_{ij}}) = \alpha Pr_1(y|d_{e_{ij}}) + (1 - \alpha) Pr_2(y|d_{e_{ij}}) \quad (10)$$

where  $Pr_1(y|d_{e_{ij}})$  and  $Pr_2(y|d_{e_{ij}})$  are the probabilities provided by different models.

## 4.2 Training Algorithm

We optimize the objective (Formula (9)) via a gradient-based search algorithm. And the gradient with respect to  $\lambda_k$  takes the form:

$$\nabla\ell(\lambda_k) = \alpha \frac{\partial\theta_2(\lambda)}{\partial\lambda_k} + (1 - \alpha) \frac{\partial\phi(\lambda)}{\partial\lambda_k} \quad (11)$$

Algorithm 3 outlines our joint training procedure, which tunes the grammar parameter  $\lambda$  simultaneously maximize both unsupervised objective

---

### Algorithm 3 Training joint model

---

```

1:  $D_P, D_N \leftarrow proj(\overline{F}, D_{\overline{F}}, A, \overline{E})$ 
2: build random  $D_{\overline{E}}$ 
3:  $\lambda \leftarrow train(D_P, D_N)$ 
4: repeat
5:   for each  $E \in \overline{E}$  do ▷ E step
6:      $D_{\overline{E}} \leftarrow parse(E, \lambda)$ 
7:      $\nabla\ell(\lambda) \leftarrow grad(D_{\overline{E}}, \tilde{D}_{\overline{E}}, D_P, D_N, \ell(\lambda))$ 
8:      $\lambda \leftarrow climb(\ell(\lambda), \nabla\ell(\lambda), \lambda)$  ▷ M step
9: until convergence

```

---

and projection objective. And it incorporates unsupervised framework and projection model algorithm together. It is grounded on the work which uses features in the unsupervised model (Berg-Kirkpatrick et al., 2010).

In line 1, 2 we get projected dependency instances from source side according to projection methods and build a random treebank (step 1). Then we train an initial model with projection instances in line 3. From line 4-9, the objective is optimized with a generic optimization step in the subroutine *climb*( $\cdot, \cdot, \cdot, \cdot, \cdot$ ). For each sentence we parse its dependency tree, and update the tree into the treebank (step 3). Then we calculate the gradient and optimize the joint objective according to the evolved treebank and projected instances (step 2). Lines 5-6 are equivalent to the E-step of the EM algorithm, and lines 7-8 are equivalent to the M-step.

## 5 Related work

The DMV (Klein and Manning, 2004) is a single-state head automata model (Alshawi, 1996) which is based on POS tags. And DMV learns the grammar via inside-outside re-estimation (Baker, 1979) without any smoothing, while Spitzkovsky et al. (2010) utilizes smoothing and learning strategy during grammar learning and William et al. (2009) improves DMV with richer context.

The dependency projection method DPA (Hwa et al., 2005) based on Direct Correspondence Assumption (Hwa et al., 2002) can be described as: if there is a pair of source words with a dependency relationship, the corresponding aligned words in target sentence can be considered as having the same dependency relationship equivalently (e.g. Figure 2). The Word Pair Classification (WPC) method (Jiang and Liu, 2010) modifies the DPA method and makes it more robust. Smith and Eisner (2009) propose an adaptation method founded on quasi-synchronous grammar features

Type	Feature Template		
Unigram	$word_i$	$pos_i$	$word_i \circ pos_i$
	$word_j$	$pos_j$	$word_j \circ pos_j$
Bigram	$word_i \circ pos_j$	$word_j \circ pos_i$	$pos_i \circ pos_j$
	$word_i \circ word_j$	$word_i \circ pos_i \circ word_j$	$word_i \circ word_j \circ pos_j$
	$word_i \circ pos_i \circ pos_j$	$pos_i \circ word_j \circ pos_j$	
	$word_i \circ pos_i \circ word_j \circ pos_j$		
Surrounding	$pos_{i-1} \circ pos_i \circ pos_j$	$pos_i \circ pos_{i+1} \circ pos_j$	$pos_i \circ pos_{j-1} \circ pos_j$
	$pos_i \circ pos_j \circ pos_{j+1}$	$pos_{i-1} \circ pos_i \circ pos_{j-1}$	$pos_i \circ pos_{i+1} \circ pos_{j+1}$
	$pos_{i-1} \circ pos_{j-1} \circ pos_j$	$pos_{i+1} \circ pos_j \circ pos_{j+1}$	$pos_{i-1} \circ pos_i \circ pos_{j+1}$
	$pos_i \circ pos_{i+1} \circ pos_{j-1}$	$pos_{i-1} \circ pos_j \circ pos_{j+1}$	$pos_{i+1} \circ pos_{j-1} \circ pos_j$
	$pos_{i-1} \circ pos_i \circ pos_{j-1} \circ pos_j$	$pos_i \circ pos_{i+1} \circ pos_j \circ pos_{j+1}$	
	$pos_i \circ pos_{i+1} \circ pos_{j-1} \circ pos_j$	$pos_{i-1} \circ pos_i \circ pos_j \circ pos_{j+1}$	

Table 1: Feature templates for dependency parsing. For edge  $d_{e_{ij}}$ :  $word_i$  is the parent word and  $word_j$  is the child word, similar to "pos". "+1" denotes the preceding token of the sentence, similar to "-1".

for dependency projection and annotation, which requires a small set of dependency annotated corpus of target language.

Similarly, using indirect information from multilingual (Cohen et al., 2011; Täckström et al., 2012) is an effective way to improve unsupervised parsing. (Zeman and Resnik, 2008; McDonald et al., 2011; Sjøgaard, 2011) employ non-lexicalized parser trained on other languages to process a target language. McDonald et al. (2011) adapts their multi-source parser according to DCA, while Naseem et al. (2012) selects a selective sharing model to make better use of grammar information in multi-sources.

Due to similar reasons, many works are devoted to POS projection (Yarowsky et al., 2001; Shen et al., 2007; Naseem et al., 2009), and they also suffer from similar problems. Some seek for unsupervised methods, e.g. Naseem et al. (2009), and some further improve the projection by a graph-based projection (Das and Petrov, 2011).

Our model differs from the approaches above in its emphasis on utilizing information from both sides of bilingual corpus in an unsupervised training framework, while most of the work above only utilize the information from a single side.

## 6 Experiments

In this section, we evaluate the performance of the MST dependency parser (McDonald et al., 2005b) which is trained by our bilingually-guided model on 5 languages. And the features used in our experiments are summarized in Table 1.

### 6.1 Experiment Setup

**Datasets and Evaluation** Our experiments are run on five different languages: Chinese(ch), Danish(da), Dutch(nl), Portuguese(pt) and

Swedish(sv) (da, nl, pt and sv are free data sets distributed for the 2006 CoNLL Shared Tasks (Buchholz and Marsi, 2006)). For all languages, we only use English-target parallel data: we take the FBIS English-Chinese bitext as bilingual corpus for English-Chinese dependency projection which contains 239K sentence pairs with about 8.9M/6.9M words in English/Chinese, and for other languages we use the readily available data in the Europarl corpus. Then we run tests on the Penn Chinese Treebank (CTB) and CoNLL-X test sets.

English sentences are tagged by the implementations of the POS tagger of Collins (2002), which is trained on WSJ. The source sentences are then parsed by an implementation of 2nd-ordered MST model of McDonald and Pereira (2006), which is trained on dependency trees extracted from Penn Treebank.

As the evaluation metric, we use parsing accuracy which is the percentage of the words which have found their correct parents. We evaluate on sentences with all length for our method.

**Training Regime** In experiments, we use the projection method proposed by Jiang and Liu (2010) to provide the projection instances. And we train the projection part  $\alpha = 0$  first for initialization, on which the whole model will be trained. Availing of the initialization method, the model can converge very fast (about 3 iterations is sufficient) and the results are more stable than the ones trained on random initialization.

**Baselines** We compare our method against three kinds of different approaches: unsupervised method (Klein and Manning, 2004); single-source direct projection methods (Hwa et al., 2005; Jiang and Liu, 2010); multi-source indirect projection methods with multi-sources (M-

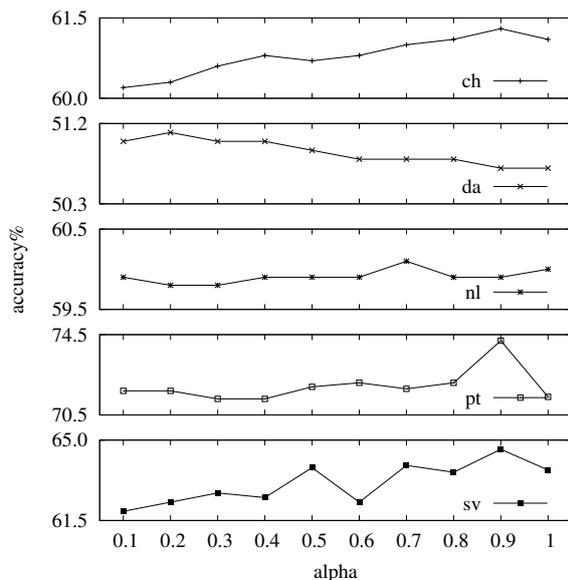

Figure 3: The performance of our model with respect to a series of ratio  $\alpha$

cDonald et al., 2011; Naseem et al., 2012).

## 6.2 Results

We test our method on CTB and CoNLL-X free test data sets respectively, and the performance is summarized in Table 2. Figure 3 presents the performance with different  $\alpha$  on different languages.

**Compare against Unsupervised Baseline** Experimental results show that our unsupervised framework’s performance approaches to the DMV method. And the bilingually-guided model can promote the unsupervised method consistency over all languages. On the best results’ average of four comparable languages (da, nl, pt, sv), the promotion gained by our model is 28.5% over the baseline method (DMV) (Klein and Manning, 2004).

**Compare against Projection Baselines** For all languages, the model consistently outperforms on direct projection baseline. On the average of each language’s best result, our model outperforms all kinds of baselines, yielding 3.0% gain over the single-source direct-projection method (Jiang and Liu, 2010) and 3.9% gain over the multi-source indirect-projection method (McDonald et al., 2011). On the average of all results with different parameters, our method also gains more than 2.0% improvements on all baselines. Particularly, our model achieves the most significant gains on Chinese, where the improvements are 4.5%/12.0% on direct/indirect projection base-

Model	Accuracy%					
	ch	da	nl	pt	sv	avg
DMV	42.5*	33.4	38.5	20.1	44.0	—.—
DPA	53.9	—.—	—.—	—.—	—.—	—.—
WPC	56.8	50.1	58.4	70.5	60.8	59.3
Transfer	49.3	49.5	53.9	75.8	63.6	58.4
Selective	51.2	—.—	55.9	73.5	61.5	—.—
<i>unsuper</i>	22.6	41.6	15.2	45.7	42.4	33.5
avg	61.0	50.7	59.9	72.0	63.1	61.3
max	61.3	51.1	60.1	74.2	64.6	62.3

Table 2: The directed dependency accuracy with different parameter of our model and the baselines. The first section of the table (row 3-7) shows the results of the baselines: a unsupervised method baseline (Klein and Manning, 2004)(DMV); a single-source projection method baseline (Hwa et al., 2005) (DPA) and its improvement (Jiang and Liu, 2010)(WPC); two multi-source baselines (McDonald et al., 2011)(Transfer) and (Naseem et al., 2012)(Selective). The second section of the table (row 8) presents the result of our unsupervised framework (unsuper). The third section gives the mean value (avg) and maximum value (max) of our model with different  $\alpha$  in Figure 3.

\*: The result is based on sentences with 10 words or less after the removal of punctuation, it is an incomparable result.

lines.

The results in Figure 3 prove that our unsupervised framework  $\alpha = 1$  can promote the grammar induction if it has a good start (well initialization), and it will be better once we incorporate the information from the projection side ( $\alpha = 0.9$ ). And the maximum points are not in  $\alpha = 1$ , which implies that projection information is still available for the unsupervised framework even if we employ the projection model as the initialization. So we suggest that a greater parameter is a better choice for our model. And there are some random factors in our model which make performance curves with more fluctuation. And there is just a little improvement shown in *da*, in which the same situation is observed by (McDonald et al., 2011).

## 6.3 Effects of the Size of Training Corpus

To investigate how the size of the training corpus influences the result, we train the model on extracted bilingual corpus with varying sizes: 10K, 50K, 100K, 150K and 200K sentences pairs.

As shown in Figure 4, our approach continu-

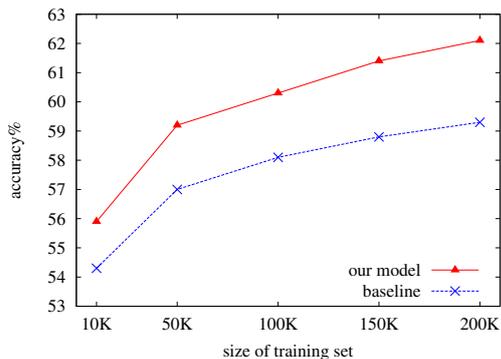

Figure 4: Performance on varying sizes (average of 5 languages,  $\alpha = 0.9$ )

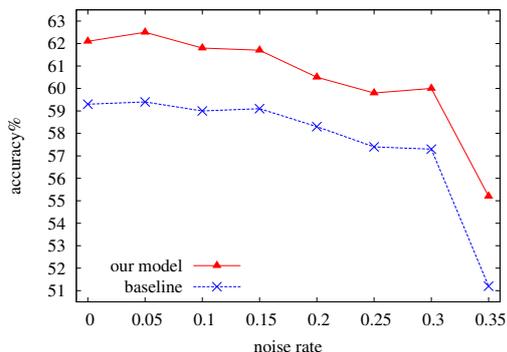

Figure 5: Performance on different projection quality (average of 5 languages,  $\alpha = 0.9$ ). The noise rate is the percentage of the projected instances being messed up.

ously outperforms the baseline with the increasing size of training corpus. It is especially noteworthy that the more training data is utilized the more superiority our model enjoys. That is, because our method not only utilizes the projection information but also avails itself of the monolingual corpus.

#### 6.4 Effect of Projection Quality

The projection quality can be influenced by the quality of the source parsing, alignments, projection methods, corpus quality and many other factors. In order to detect the effects of varying projection qualities on our approach, we simulate the complex projection procedure by messing up the projected instances randomly with different noise rates. The curves in Figure 5 show the performance of WPC baseline and our bilingual-guided method. For different noise rates, our model's results consistently outperform the baselines. When the noise rate is greater than 0.2, our improvement

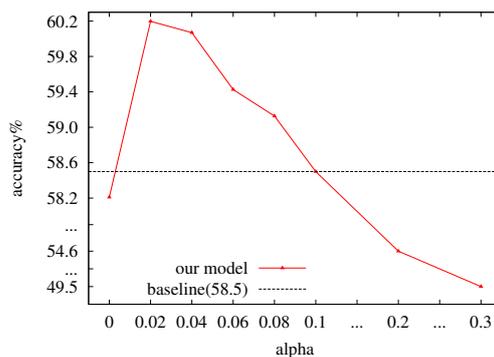

Figure 6: The performance curve of our model (random initialization) on Chinese, with respect to a series of ratio  $\alpha$ . The baseline is the result of WPC model.

increases with the growth of the noise rate. The result suggests that our method can solve some problems which are caused by projection noise.

#### 6.5 Performance on Random Initialization

We test our model with random initialization on different  $\alpha$ . The curve in Figure 6 shows the performance of our model on Chinese.

The results seem supporting our unsupervised optimization method when  $\alpha$  is in the range of  $(0, 0.1)$ . It implies that the unsupervised structure information is useful, but it seems creating a negative effect on the model when  $\alpha$  is greater than 0.1. Because the unsupervised part can gain constraints from the projection part. But with the increase of  $\alpha$ , the strength of constraint dwindles, and the unsupervised part will gradually lose control. And bad unsupervised part pulls the full model down.

### 7 Conclusion and Future Work

This paper presents a bilingually-guided strategy for automatic dependency grammar induction, which adopts an unsupervised skeleton and leverages the bilingually-projected dependency information during optimization. By simultaneously maximizing the monolingual likelihood and bilingually-projected likelihood in the EM procedure, it effectively integrates the advantages of bilingual projection and unsupervised induction. Experiments on 5 languages show that the novel strategy significantly outperforms previous unsupervised or bilingually-projected models. Since its computational complexity approaches to the skeleton unsupervised model (with much fewer iterations), and the bilingual text aligned to

resource-rich languages is easy to obtain, such a hybrid method seems to be a better choice for automatic grammar induction. It also indicates that the combination of bilingual constraint and unsupervised methodology has a promising prospect for grammar induction. In the future work we will investigate such kind of strategies, such as bilinearly unsupervised induction.

## Abstract

Translated bi-texts contain complementary language cues, and previous work on Named Entity Recognition (NER) has demonstrated improvements in performance over monolingual taggers by promoting agreement of tagging decisions between the two languages. However, most previous approaches to bilingual tagging assume word alignments are given as fixed input, which can cause cascading errors. We observe that NER label information can be used to correct alignment mistakes, and present a graphical model that performs bilingual NER tagging jointly with word alignment, by combining two monolingual tagging models with two unidirectional alignment models. We introduce additional cross-lingual edge factors that encourage agreements between tagging and alignment decisions. We design a dual decomposition inference algorithm to perform joint decoding over the combined alignment and NER output space. Experiments on the OntoNotes dataset demonstrate that our method yields significant improvements in both NER and word alignment over state-of-the-art monolingual baselines.

## 1 Introduction

We study the problem of Named Entity Recognition (NER) in a bilingual context, where the goal is to annotate parallel bi-texts with named entity tags. This is a particularly important problem for machine translation (MT) since entities such as person names, locations, organizations, etc. carry much of the information expressed in the source

sentence. Recognizing them provides useful information for phrase detection and word sense disambiguation (e.g., “melody” as in a female name has a different translation from the word “melody” in a musical sense), and can be directly leveraged to improve translation quality (Babych and Hartley, 2003). We can also automatically construct a named entity translation lexicon by annotating and extracting entities from bi-texts, and use it to improve MT performance (Huang and Vogel, 2002; Al-Onaizan and Knight, 2002). Previous work such as Burkett et al. (2010b), Li et al. (2012) and Kim et al. (2012) have also demonstrated that bi-texts annotated with NER tags can provide useful additional training sources for improving the performance of standalone monolingual taggers.

Because human translation in general preserves semantic equivalence, bi-texts represent two perspectives on the same semantic content (Burkett et al., 2010b). As a result, we can find complementary cues in the two languages that help to disambiguate named entity mentions (Brown et al., 1991). For example, the English word “Jordan” can be either a last name or a country. Without sufficient context it can be difficult to distinguish the two; however, in Chinese, these two senses are disambiguated: “乔丹” as a last name, and “约旦” as a country name.

In this work, we first develop a bilingual NER model (denoted as BI-NER) by embedding two monolingual CRF-based NER models into a larger undirected graphical model, and introduce additional edge factors based on word alignment (WA). Because the new bilingual model contains many cyclic cliques, exact inference is intractable. We employ a dual decomposition (DD) inference algorithm (Bertsekas, 1999; Rush et al., 2010) for performing approximate inference. Unlike most

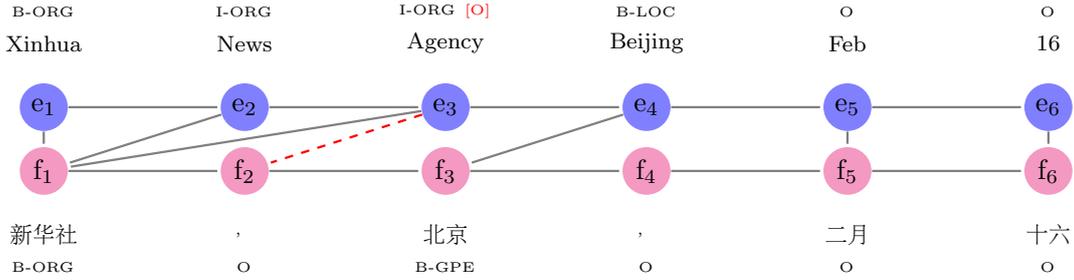

Figure 1: Example of NER labels between two word-aligned bilingual parallel sentences. The [O] tag is an example of a wrong tag assignment. The dashed alignment link between  $e_3$  and  $f_2$  is an example of alignment error.

previous applications of the DD method in NLP, where the model typically factors over two components and agreement is to be sought between the two (Rush et al., 2010; Koo et al., 2010; DeNero and Macherey, 2011; Chieu and Teow, 2012), our method decomposes the larger graphical model into many overlapping components where each alignment edge forms a separate factor. We design clique potentials over the alignment-based edges to encourage entity tag agreements. Our method does not require any manual annotation of word alignments or named entities over the bilingual training data.

The aforementioned BI-NER model assumes fixed alignment input given by an underlying word aligner. But the entity span and type predictions given by the NER models contain complementary information for correcting alignment errors. To capture this source of information, we present a novel extension that combines the BI-NER model with two uni-directional HMM-based alignment models, and perform joint decoding of NER and word alignments. The new model (denoted as BI-NER-WA) factors over five components: one NER model and one word alignment model for each language, plus a joint NER-alignment model which not only enforces NER label agreements but also facilitates message passing among the other four components. An extended DD decoding algorithm is again employed to perform approximate inference.

We give a formal definition of the Bi-NER model in Section 2, and then move to present the Bi-NER-WA model in Section 3.

## 2 Bilingual NER by Agreement

The inputs to our models are parallel sentence pairs (see Figure 1 for an example in English and

Chinese). We denote the sentences as  $e$  (for English) and  $f$  (for Chinese). We assume access to two monolingual linear-chain CRF-based NER models that are already trained. The English-side CRF model assigns the following probability for a tag sequence  $\mathbf{y}^e$ :

$$P_{CRF_e}(\mathbf{y}^e | \mathbf{e}) = \frac{\prod_{v_i \in \mathcal{V}^e} \psi(v_i) \prod_{(v_i, v_j) \in \mathcal{D}^e} \omega(v_i, v_j)}{\mathcal{Z}^e(\mathbf{e})}$$

where  $\mathcal{V}^e$  is the set of vertices in the CRF and  $\mathcal{D}^e$  is the set of edges.  $\psi(v_i)$  and  $\omega(v_i, v_j)$  are the node and edge clique potentials, and  $\mathcal{Z}^e(\mathbf{e})$  is the partition function for input sequence  $\mathbf{e}$  under the English CRF model. We let  $k(\mathbf{y}^e)$  be the un-normalized log-probability of tag sequence  $\mathbf{y}^e$ , defined as:

$$k(\mathbf{y}^e) = \log \left( \prod_{v_i \in \mathcal{V}^e} \psi(v_i) \prod_{(v_i, v_j) \in \mathcal{D}^e} \omega(v_i, v_j) \right)$$

Similarly, we define model  $P_{CRF_f}$  and un-normalized log-probability  $l(\mathbf{y}^f)$  for Chinese.

We also assume that a set of word alignments ( $\mathcal{A} = \{(i, j) : e_i \leftrightarrow f_j\}$ ) is given by a word aligner and remain fixed in our model.

For clarity, we assume  $\mathbf{y}^e$  and  $\mathbf{y}^f$  are binary variables in the description of our algorithms. The extension to the multi-class case is straight-forward and does not affect the core algorithms.

### 2.1 Hard Agreement

We define a BI-NER model which imposes hard agreement of entity labels over aligned word pairs. At inference time, we solve the following opti-

mization problem:

$$\begin{aligned}
& \max_{\mathbf{y}^e, \mathbf{y}^f} \log(P_{CRF_e}(\mathbf{y}^e)) + \log(P_{CRF_f}(\mathbf{y}^f)) \\
&= \max_{\mathbf{y}^e, \mathbf{y}^f} k(\mathbf{y}^e) + l(\mathbf{y}^f) - \log \mathcal{Z}_e(\mathbf{e}) - \log \mathcal{Z}_f(\mathbf{f}) \\
&\simeq \max_{\mathbf{y}^e, \mathbf{y}^f} k(\mathbf{y}^e) + l(\mathbf{y}^f) \\
&\quad \ni y_i^e = y_j^f \quad \forall (i, j) \in \mathcal{A}
\end{aligned}$$

We dropped the  $\mathcal{Z}_e(\mathbf{e})$  and  $\mathcal{Z}_f(\mathbf{f})$  terms because they remain constant at inference time.

The Lagrangian relaxation of this term is:

$$\begin{aligned}
L(\mathbf{y}^e, \mathbf{y}^f, \mathbf{U}) &= \\
& k(\mathbf{y}^e) + l(\mathbf{y}^f) + \sum_{(i,j) \in \mathcal{A}} u(i, j) (y_i^e - y_j^f)
\end{aligned}$$

where  $u(i, j)$  are the Lagrangian multipliers.

Instead of solving the Lagrangian directly, we can form the dual of this problem and solve it using dual decomposition (Rush et al., 2010):

$$\begin{aligned}
\min_{\mathbf{U}} \left( \max_{\mathbf{y}^e} \left[ k(\mathbf{y}^e) + \sum_{(i,j) \in \mathcal{A}} u(i, j) y_i^e \right] \right. \\
\left. + \max_{\mathbf{y}^f} \left[ l(\mathbf{y}^f) - \sum_{(i,j) \in \mathcal{A}} u(i, j) y_j^f \right] \right)
\end{aligned}$$

Similar to previous work, we solve this DD problem by iteratively updating the sub-gradient as depicted in Algorithm 1.  $T$  is the maximum number of iterations before early stopping, and  $\alpha_t$  is the learning rate at time  $t$ . We adopt a learning rate update rule from Koo et al. (2010) where  $\alpha_t$  is defined as  $\frac{1}{N}$ , where  $N$  is the number of times we observed a consecutive dual value increase from iteration 1 to  $t$ .

A thorough introduction to the theoretical foundations of dual decomposition algorithms is beyond the scope of this paper; we encourage unfamiliar readers to read Rush and Collins (2012) for a full tutorial.

## 2.2 Soft Agreement

The previously discussed hard agreement model rests on the core assumption that aligned words must have identical entity tags. In reality, however, this assumption does not always hold. Firstly, assuming words are correctly aligned, their entity tags may not agree due to inconsistency in annotation standards. In Figure 1, for example, the

```

 $\forall (i, j) \in \mathcal{A} : u(i, j) = 0$ 
for  $t \leftarrow 1$  to  $T$  do
   $\mathbf{y}^{e*} \leftarrow \operatorname{argmax}_{\mathbf{y}^e} k(\mathbf{y}^e) + \sum_{(i,j) \in \mathcal{A}} u(i, j) y_i^e$ 
   $\mathbf{y}^{f*} \leftarrow \operatorname{argmax}_{\mathbf{y}^f} l(\mathbf{y}^f) - \sum_{(i,j) \in \mathcal{A}} u(i, j) y_j^f$ 
  if  $\forall (i, j) \in \mathcal{A} : y_i^{e*} = y_j^{f*}$  then
    return  $(\mathbf{y}^{e*}, \mathbf{y}^{f*})$ 
  end if
  for all  $(i, j) \in \mathcal{A}$  do
     $u(i, j) \leftarrow u(i, j) + \alpha_t (y_j^{f*} - y_i^{e*})$ 
  end for
end for
return  $(\mathbf{y}_{(\mathbf{T})}^{e*}, \mathbf{y}_{(\mathbf{T})}^{f*})$ 

```

---

word ‘‘Beijing’’ can be either a Geo-Political Entity (GPE) or a location. The Chinese annotation standard may enforce that ‘‘Beijing’’ should always be tagged as GPE when it is mentioned in isolation, while the English standard may require the annotator to judge based on word usage context. The assumption in the hard agreement model can also be violated if there are word alignment errors.

In order to model this uncertainty, we extend the two previously independent CRF models into a larger undirected graphical model, by introducing a cross-lingual edge factor  $\phi(i, j)$  for every pair of word positions  $(i, j) \in \mathcal{A}$ . We associate a clique potential function  $h_{(i,j)}(y_i^e, y_j^f)$  for  $\phi(i, j)$ :

$$h_{(i,j)}(y_i^e, y_j^f) = \operatorname{pmi}(y_i^e, y_j^f)^{\hat{P}(e_i, f_j)}$$

where  $\operatorname{pmi}(y_i^e, y_j^f)$  is the point-wise mutual information (PMI) of the tag pair, and we raise it to the power of a posterior alignment probability  $\hat{P}(e_i, f_j)$ . For a pair of NEs that are aligned with low probability, we cannot be too sure about the association of the two NEs, therefore the model should not impose too much influence from the bilingual agreement model; instead, we will let the monolingual NE models make their decisions, and trust that those are the best estimates we can come up with when we do not have much confidence in their bilingual association. The use of the posterior alignment probability facilitates this purpose.

Initially, each of the cross-lingual edge factors will attempt to assign a pair of tags that has the highest PMI score, but if the monolingual taggers do not agree, a penalty will start accumulating over this pair, until some other pair that agrees better with the monolingual models takes the top spot.

Simultaneously, the monolingual models will also be encouraged to agree with the cross-lingual edge factors. This way, the various components effectively trade penalties indirectly through the cross-lingual edges, until a tag sequence that maximizes the joint probability is achieved.

Since we assume no bilingually annotated NER corpus is available, in order to get an estimate of the PMI scores, we first tag a collection of unannotated bilingual sentence pairs using the monolingual CRF taggers, and collect counts of aligned entity pairs from this auto-generated tagged data.

Each of the  $\phi(i, j)$  edge factors (e.g., the edge between node  $f_3$  and  $e_4$  in Figure 1) overlaps with each of the two CRF models over one vertex (e.g.,  $f_3$  on Chinese side and  $e_4$  on English side), and we seek agreement with the Chinese CRF model over tag assignment of  $f_j$ , and similarly for  $e_i$  on English side. In other words, no direct agreement between the two CRF models is enforced, but they both need to agree with the bilingual edge factors.

The updated optimization problem becomes:

$$\begin{aligned} & \max_{\mathbf{y}^{e(k)}, \mathbf{y}^{f(l)}, \mathbf{y}^{e(h)}, \mathbf{y}^{f(h)}} k \left( \mathbf{y}^{e(k)} \right) + l \left( \mathbf{y}^{f(l)} \right) + \\ & \sum_{(i,j) \in \mathcal{A}} h_{(i,j)} \left( y_i^{e(h)}, y_j^{f(h)} \right) \\ & \ni \forall (i, j) \in \mathcal{A}: \left( y_i^{e(k)} = y_i^{e(h)} \right) \wedge \left( y_j^{f(l)} = y_j^{f(h)} \right) \end{aligned}$$

where the notation  $y_i^{e(k)}$  denotes tag assignment to word  $e_i$  by the English CRF and  $y_i^{e(h)}$  denotes assignment to word  $e_i$  by the bilingual factor;  $y_j^{f(l)}$  denotes the tag assignment to word  $f_j$  by the Chinese CRF and  $y_j^{f(h)}$  denotes assignment to word  $f_j$  by the bilingual factor.

The updated DD algorithm is illustrated in Algorithm 2 (case 2). We introduce two separate sets of dual constraints  $\mathbf{w}^e$  and  $\mathbf{w}^f$ , which range over the set of vertices on their respective half of the graph. Decoding the edge factor model  $h_{(i,j)}(y_i^e, y_j^f)$  simply involves finding the pair of tag assignments that gives the highest PMI score, subject to the dual constraints.

The way DD algorithms work in decomposing undirected graphical models is analogous to other message passing algorithms such as loopy belief propagation, but DD gives a stronger optimality guarantee upon convergence (Rush et al., 2010).

### 3 Joint Alignment and NER Decoding

In this section we develop an extended model in which NER information can in turn be used to improve alignment accuracy. Although we have seen more than a handful of recent papers that apply the dual decomposition method for joint inference problems, all of the past work deals with cases where the various model components have the same inference output space (e.g., dependency parsing (Koo et al., 2010), POS tagging (Rush et al., 2012), etc.). In our case the output space is the much more complex joint alignment and NER tagging space. We propose a novel dual decomposition variant for performing inference over this joint space.

Most commonly used alignment models, such as the IBM models and HMM-based aligner are unsupervised learners, and can only capture simple distortion features and lexical translational features due to the high complexity of the structure prediction space. On the other hand, the CRF-based NER models are trained on manually annotated data, and admit richer sequence and lexical features. The entity label predictions made by the NER model can potentially be leveraged to correct alignment mistakes. For example, in Figure 1, if the tagger knows that the word ‘‘Agency’’ is tagged I-ORG, and if it also knows that the first comma in the Chinese sentence is not part of any entity, then we can infer it is very unlikely that there exists an alignment link between ‘‘Agency’’ and the comma.

To capture this intuition, we extend the BI-NER model to jointly perform word alignment and NER decoding, and call the resulting model BI-NER-WA. As a first step, instead of taking the output from an aligner as fixed input, we incorporate two uni-directional aligners into our model. We name the Chinese-to-English aligner model as  $m(\mathbf{B}^e)$  and the reverse directional model  $n(\mathbf{B}^f)$ .  $\mathbf{B}^e$  is a matrix that holds the output of the Chinese-to-English aligner. Each  $b^e(i, j)$  binary variable in  $\mathbf{B}^e$  indicates whether  $f_j$  is aligned to  $e_i$ ; similarly we define output matrix  $\mathbf{B}^f$  and  $b^f(i, j)$  for Chinese. In our experiments, we used two HMM-based alignment models. But in principle we can adopt any alignment model as long as we can perform efficient inference over it.

We introduce a cross-lingual edge factor  $\zeta(i, j)$  in the undirected graphical model for every pair of word indices  $(i, j)$ , which predicts a binary vari-

**Algorithm 2** DD inference algorithm for joint alignment and NER model. A line marked with (2) means it applies to the BI-NER model; a line marked with (3) means it applies to the BI-NER-WA model.

```

---

able  $a(i, j)$  for an alignment link between  $e_i$  and  $f_j$ . The edge factor also predicts the entity tags for  $e_i$  and  $f_j$ .

The new edge potential  $q$  is defined as:

$$q_{(i,j)}(y_i^e, y_j^f, a(i, j)) = \log(P(a(i, j) = 1)) + S(y_i^e, y_j^f | a(i, j))^{P(a(i, j) = 1)}$$

$$S(y_i^e, y_j^f | a(i, j)) = \begin{cases} \text{pmi}(y_i^e, y_j^f), & \text{if } a(i, j) = 1 \\ 0, & \text{else} \end{cases}$$

$P(a(i, j) = 1)$  is the alignment probability assigned by the bilingual edge factor between node  $e_i$  and  $f_j$ . We initialize this value to  $\hat{P}(e_i, f_j) = \frac{1}{2}(P_m(e_i, f_j) + P_n(e_i, f_j))$ , where  $P_m(e_i, f_j)$  and  $P_n(e_i, f_j)$  are the posterior probabilities assigned by the HMM-aligners.

The joint optimization problem is defined as:

$$\max_{\mathbf{y}^{e^{(k)}} \mathbf{y}^{f^{(l)}} \mathbf{y}^{e^{(h)}} \mathbf{y}^{f^{(h)}} \mathbf{B}^e \mathbf{B}^f \mathbf{A}} k(\mathbf{y}^{e^{(k)}}) + l(\mathbf{y}^{f^{(l)}}) + m(\mathbf{B}^e) + n(\mathbf{B}^f) + \sum_{(i \in |\mathbf{e}|, j \in |\mathbf{f}|)} q_{(i,j)}(y_i^{e^h}, y_j^{f^h}, a(i, j))$$

$$\ni \forall (i, j) : (b^e(i, j) = a(i, j)) \wedge (b^f(i, j) = a(i, j))$$

$$\wedge \text{if } a(i, j) = 1 \text{ then } (y_i^{e^{(k)}} = y_i^{e^{(h)}}) \wedge (y_j^{f^{(l)}} = y_j^{f^{(h)}})$$

We include two dual constraints  $d^e(i, j)$  and  $d^f(i, j)$  over alignments for every bilingual edge factor  $\zeta(i, j)$ , which are applied to the English and Chinese sides of the alignment space, respectively.

The DD algorithm used for this model is given in Algorithm 2 (case 3). One special note is that after each iteration when we consider updates to the dual constraint for entity tags, we only check tag agreements for cross-lingual edge factors that have an alignment assignment value of 1. In other words, cross-lingual edges that are not aligned do not affect bilingual NER tagging.

Similar to  $\phi(i, j)$ ,  $\zeta(i, j)$  factors do not provide that much additional information other than some selectional preferences via PMI score. But the real power of these cross-language edge cliques is that they act as a liaison between the NER and alignment models on each language side, and encourage these models to indirectly agree with each other by having them all agree with the edge cliques.

It is also worth noting that since we decode the alignment models with Viterbi inference, additional constraints such as the neighborhood constraint proposed by DeNero and Macherey (2011) can be easily integrated into our model. The neighborhood constraint enforces that if  $f_j$  is aligned to  $e_i$ , then  $f_j$  can only be aligned to  $e_{i+1}$  or  $e_{i-1}$  (with a small penalty), but not any other word position. We report results of adding neighborhood constraints to our model in Section 6.

## 4 Experimental Setup

We evaluate on the large OntoNotes (v4.0) corpus (Hovy et al., 2006) which contains manually

annotated NER tags for both Chinese and English. Document pairs are sentence aligned using the Champollion Tool Kit (Ma, 2006). After discarding sentences with no aligned counterpart, a total of 402 documents and 8,249 parallel sentence pairs were used for evaluation. We will refer to this evaluation set as *full-set*. We use odd-numbered documents as the dev set and even-numbered documents as the blind test set. We did not perform parameter tuning on the dev set to optimize performance, instead we fix the initial learning rate to 0.5 and maximum iterations to 1,000 in all DD experiments. We only use the dev set for model development.

The Stanford CRF-based NER tagger was used as the monolingual component in our models (Finkel et al., 2005). It also serves as a state-of-the-art monolingual baseline for both English and Chinese. For English, we use the default tagger setting from Finkel et al. (2005). For Chinese, we use an improved set of features over the default tagger, which includes distributional similarity features trained on large amounts of non-overlapping data.<sup>1</sup>

We train the two CRF models on all portions of the OntoNotes corpus that are annotated with named entity tags, except the parallel-aligned portion which we reserve for development and test purposes. In total, there are about 660 training documents ( $\sim 16k$  sentences) for Chinese and 1,400 documents ( $\sim 39k$  sentences) for English.

Out of the 18 named entity types that are annotated in OntoNotes, which include person, location, date, money, and so on, we select the four most commonly seen named entity types for evaluation. They are *person*, *location*, *organization* and *GPE*. All entities of these four types are converted to the standard BIO format, and background tokens and all other entity types are marked with tag *O*. When we consider label agreements over aligned word pairs in all bilingual agreement models, we ignore the distinction between *B-* and *I-* tags.

We report standard NER measures (entity precision (P), recall (R) and  $F_1$  score) on the test set. Statistical significance tests are done using the paired bootstrap resampling method (Efron and Tibshirani, 1993).

For alignment experiments, we train two uni-

<sup>1</sup>The exact feature set and the CRF implementation can be found here: <http://nlp.stanford.edu/software/CRF-NER.shtml>

directional HMM models as our baseline and monolingual alignment models. The parameters of the HMM were initialized by IBM Model 1 using the agreement-based EM training algorithms from Liang et al. (2006). Each model is trained for 2 iterations over a parallel corpus of 12 million English words and Chinese words, almost twice as much data as used in previous work that yields state-of-the-art unsupervised alignment results (DeNero and Klein, 2008; Haghighi et al., 2009; DeNero and Macherey, 2011).

Word alignment evaluation is done over the sections of OntoNotes that have matching gold-standard word alignment annotations from GALE Y1Q4 dataset.<sup>2</sup> This subset contains 288 documents and 3,391 sentence pairs. We will refer to this subset as *wa-subset*. This evaluation set is over 20 times larger than the 150 sentences set used in most past evaluations (DeNero and Klein, 2008; Haghighi et al., 2009; DeNero and Macherey, 2011).

Alignments input to the B1-NER model are produced by thresholding the averaged posterior probability at 0.5. In joint NER and alignment experiments, instead of posterior thresholding, we take the direct intersection of the Viterbi-best alignment of the two directional models. We report the standard P, R,  $F_1$  and Alignment Error Rate (AER) measures for alignment experiments.

An important past work to make comparisons with is Burkett et al. (2010b). Their method is similar to ours in that they also model bilingual agreement in conjunction with two CRF-based monolingual models. But instead of using just the PMI scores of bilingual NE pairs, as in our work, they employed a feature-rich log-linear model to capture bilingual correlations. Parameters in their log-linear model require training with bilingually annotated data, which is not readily available. To counter this problem, they proposed an “up-training” method which simulates a supervised learning environment by pairing a weak classifier with strong classifiers, and train the bilingual model to rank the output of the strong classifier highly among the N-best outputs of the weak classifier. In order to compare directly with their method, we obtained the code behind Burkett et al. (2010b) and reproduced their experimental setting for the OntoNotes data. An extra set of 5,000 unannotated parallel sentence pairs are used for

<sup>2</sup>LDC Catalog No. LDC2006E86.

training the reranker, and the reranker model selection was performed on the development dataset.

## 5 Bilingual NER Results

The main results on bilingual NER over the test portion of *full-set* are shown in Table 1. We initially experimented with the hard agreement model, but it performs quite poorly for reasons we discussed in Section 2.2. The BI-NER model with soft agreement constraints, however, significantly outperforms all baselines. In particular, it achieves an absolute F<sub>1</sub> improvement of 6.7% in Chinese and 2.1% in English over the CRF monolingual baselines.

A well-known issue with the DD method is that when the model does not necessarily converge, then the procedure could be very sensitive to hyper-parameters such as initial step size and early termination criteria. If a model only gives good performance with well-tuned hyper-parameters, then we must have manually annotated data for tuning, which would significantly reduce the applicability and portability of this method to other language pairs and tasks. To evaluate the parameter sensitivity of our model, we run the model from 50 to 3000 iterations before early stopping, and with 6 different initial step sizes from 0.01 to 1. The results are shown in Figure 2. The soft agreement model does not seem to be sensitive to initial step size and almost always converges to a superior solution than the baseline.

## 6 Joint NER and Alignment Results

We present results for the BI-NER-WA model in Table 2. By jointly decoding NER with word alignment, our model not only maintains significant improvements in NER performance, but also yields significant improvements to alignment performance. Overall, joint decoding with NER alone yields a 10.8% error reduction in AER over the baseline HMM-aligners, and also gives improve-

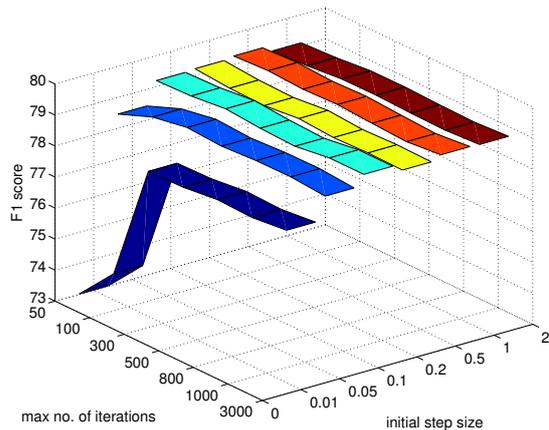

Figure 2: Performance variance of the soft agreement models on the Chinese dev dataset, as a function of step size (*x-axis*) and maximum number of iterations before early stopping (*y-axis*).

ment over BI-NER in NER. Adding additional neighborhood constraints gives a further 6% error reduction in AER, at the cost of a small loss in Chinese NER. In terms of word alignment results, we see great increases in F<sub>1</sub> and recall, but precision goes down significantly. This is because the joint decoding algorithm promotes an effect of “soft-union”, by encouraging the two unidirectional aligners to agree more often. Adding the neighborhood constraints further enhances this union effect.

## 7 Error Analysis and Discussion

We can examine the example in Figure 3 to gain an understanding of the model’s performance. In this example, a snippet of a longer sentence pair is shown with NER and word alignment results. The monolingual Chinese tagger provides a strong cue that word  $f_6$  is a person name because the unique 4-character word pattern is commonly associated with foreign names in Chinese, and also the word is immediately preceded by the word “president”. The English monolingual tagger, however, confuses the aligned word  $e_0$  with a GPE.

Our bilingual NER model is able to correct this error as expected. Similarly, the bilingual model corrects the error over  $e_{11}$ . However, the model also propagates labeling errors from the English side over the entity “Tibet Autonomous Region” to the Chinese side. Nevertheless, the resulting Chinese tags are arguably more useful than the original tags assigned by the baseline model.

In terms of word alignment, the HMM models failed badly on this example because of the long

	NER-Chinese			NER-English			word alignment			
	P	R	F <sub>1</sub>	P	R	F <sub>1</sub>	P	R	F <sub>1</sub>	AER

Table 2: Joint alignment and NER test results. +NC means incorporating additional neighbor constraints from DeNero and Macherey (2011) to the model. Best number in each column is highlighted in bold.

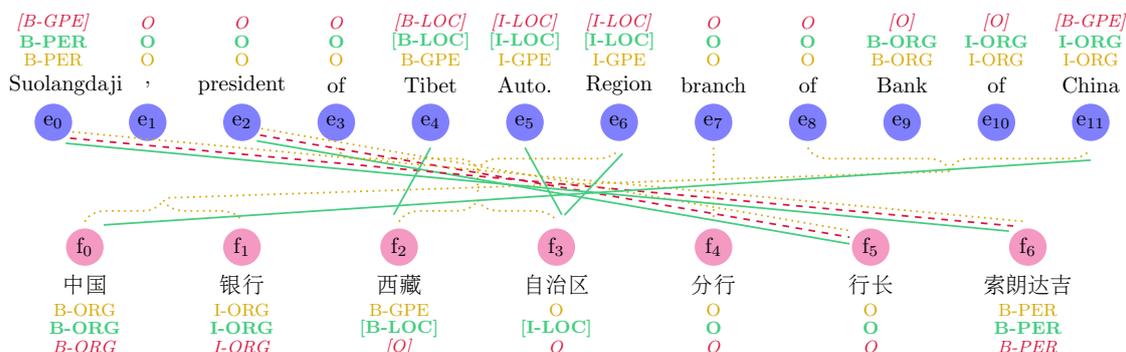

Figure 3: An example output of our BI-NER-WA model. Dotted alignment links are the oracle, dashed links are alignments from HMM baseline, and solid links are outputs of our model. Entity tags in the gold line (closest to nodes  $e_i$  and  $f_j$ ) are the gold-standard tags; in the green line (second closest to nodes) are output from our model; and in the crimson line (furthest from nodes) are baseline output.

distance swapping phenomena. The two unidirectional HMMs also have strong disagreements over the alignments, and the resulting baseline aligner output only recovers two links. If we were to take this alignment as fixed input, most likely we would not be able to recover the error over  $e_{11}$ , but the joint decoding method successfully recovered 4 more links, and indirectly resulted in the NER tagging improvement discussed above.

## 8 Related Work

The idea of employing bilingual resources to improve over monolingual systems has been explored by much previous work. For example, Huang et al. (2009) improved parsing performance using a bilingual parallel corpus. In the NER domain, Li et al. (2012) presented a cyclic CRF model very similar to our BI-NER model, and performed approximate inference using loopy belief propagation. The feature-rich CRF formulation of bilingual edge potentials in their model is much more powerful than our simple PMI-based bilingual edge model. Adding a richer bilingual edge model might well further improve our results, and this is a possible direction for further experimentation. However, a big drawback of this ap-

proach is that training such a feature-rich model requires manually annotated bilingual NER data, which can be prohibitively expensive to generate. How and where to obtain training signals without manual supervision is an interesting and open question. One of the most interesting papers in this regard is Burkett et al. (2010b), which explored an “up-training” mechanism by using the outputs from a strong monolingual model as ground-truth, and simulated a learning environment where a bilingual model is trained to help a “weakened” monolingual model to recover the results of the strong model. It is worth mentioning that since our method does not require additional training and can take pretty much any existing model as “black-box” during decoding, the richer and more accurate bilingual model learned from Burkett et al. (2010b) can be directly plugged into our model.

A similar dual decomposition algorithm to ours was proposed by Riedel and McCallum (2011) for biomedical event detection. In their Model 3, the trigger and argument extraction models are reminiscent of the two monolingual CRFs in our model; additional binding agreements are enforced over every protein pair, similar to how we enforce agreement between every aligned word

pair. Martins et al. (2011b) presented a new DD method that combines the power of DD with the augmented Lagrangian method. They showed that their method can achieve faster convergence than traditional sub-gradient methods in models with many overlapping components (Martins et al., 2011a). This method is directly applicable to our work.

Another promising direction for improving NER performance is in enforcing global label consistency across documents, which is an idea that has been greatly explored in the past (Sutton and McCallum, 2004; Bunescu and Mooney, 2004; Finkel et al., 2005). More recently, Rush et al. (2012) and Chieu and Teow (2012) have shown that combining local prediction models with global consistency models, and enforcing agreement via DD is very effective. It is straightforward to incorporate an additional global consistency model into our model for further improvements.

Our joint alignment and NER decoding approach is inspired by prior work on improving alignment quality through encouraging agreement between bi-directional models (Liang et al., 2006; DeNero and Macherey, 2011). Instead of enforcing agreement in the alignment space based on best sequences found by Viterbi, we could opt to encourage agreement between posterior probability distributions, which is related to the posterior regularization work by Graça et al. (2008). Cromières and Kurohashi (2009) proposed an approach that takes phrasal bracketing constraints from parsing outputs, and uses them to enforce phrasal alignments. This idea is similar to our joint alignment and NER approach, but in our case the phrasal constraints are indirectly imposed by entity spans. We also differ in the implementation details, where in their case belief propagation is used in both training and Viterbi inference.

Burkett et al. (2010a) presented a supervised learning method for performing joint parsing and word alignment using log-linear models over parse trees and an ITG model over alignment. The model demonstrates performance improvements in both parsing and alignment, but shares the common limitations of other supervised work in that it requires manually annotated bilingual joint parsing and word alignment data.

Chen et al. (2010) also tackled the problem of joint alignment and NER. Their method employs a

set of heuristic rules to expand a candidate named entity set generated by monolingual taggers, and then rank those candidates using a bilingual named entity dictionary. Our approach differs in that we provide a probabilistic formulation of the problem and do not require pre-existing NE dictionaries.

## 9 Conclusion

We introduced a graphical model that combines two HMM word aligners and two CRF NER taggers into a joint model, and presented a dual decomposition inference method for performing efficient decoding over this model. Results from NER and word alignment experiments suggest that our method gives significant improvements in both NER and word alignment. Our techniques make minimal assumptions about the underlying monolingual components, and can be adapted for many other tasks such as parsing.

## Abstract

In some societies, internet users have to create information morphs (e.g. “Peace West King” to refer to “Bo Xilai”) to avoid active censorship or achieve other communication goals. In this paper we aim to solve a new problem of resolving entity morphs to their real targets. We exploit temporal constraints to collect cross-source comparable corpora relevant to any given morph query and identify target candidates. Then we propose various novel similarity measurements including surface features, meta-path based semantic features and social correlation features and combine them in a learning-to-rank framework. Experimental results on Chinese Sina Weibo data demonstrate that our approach is promising and significantly outperforms baseline methods<sup>1</sup>.

## 1 Introduction

Language constantly evolves to maximize communicative success and expressive power in daily social interactions. The proliferation of online social media significantly expedites this evolution, as new phrases triggered by social events may be disseminated rapidly in social media. To automatically analyze such fast evolving language in social media, new computational models are demanded.

In this paper, we focus on one particular language evolution that creates new ways to communicate sensitive subjects because of the existence of internet information censorship. We call this

<sup>1</sup>Some of the resources and open source programs developed in this work are made freely available for research purpose at <http://nlp.cs.qc.cuny.edu/Morphing.tar.gz>

phenomenon *information morph*. For example, when Chinese online users talk about the former politician “Bo Xilai”, they use a morph “Peace West King” instead, a historical figure four hundreds years ago who governed the same region as Bo. Morph can be considered as a special case of alias used for hiding true entities in malicious environment (Hsiung et al., 2005; Pantel, 2006). However, social network plays an important role in generating morphs. Usually morphs are generated by harvesting the collective wisdom of the crowd to achieve certain communication goals. Aside from the purpose of avoiding censorship, other motivations for using morph include expressing sarcasm/irony, positive/negative sentiment or making descriptions more vivid toward some entities or events. Table 1 presents the wide range of cases that are used to create the morphs. We can see that a morph can be either a regular term with new meaning or a newly created term.

Morph	Target	Motivation
Peace West King	Bo Xilai	Sensitive
Blind Man	Chen Guangcheng	Sensitive
Miracle Brother	Wang Yongping	Irony
Kim Fat	Kim Joing-il	Negative
Kimchi Country	South Korea	Vivid

Table 1: Morph Examples and Motivations.

We believe that successful resolution of morphs is a crucial step for automated understanding of the fast evolving social media language, which is important for social media marketing (Barwise and Meehan, 2010). Another application is to help common users without enough background/cultural knowledge to understand internet language for their daily use. Furthermore, our approaches can also be applied for satire or other implicit meaning recognition, as well as information extraction (Bollegala et al., 2011).

However, morph resolution in social media is challenging due to the following reasons. First, the sensitive real targets that exist in the same data source under active censorship are often automatically filtered. Table 2 presents the distributions of some examples of morphs and their targets in English Twitter and Chinese Sina Weibo. For example, the target “*Chen Guangcheng*” only appears once in Weibo. Thus, the co-occurrence of a morph and its target is quite low in the vast amount of information in social media. Second, most morphs were not created based on pronunciations, spellings or other encryptions of their original targets. Instead, they were created according to semantically related entities in historical and cultural narratives (e.g. “*Peace West King*” as morph of “*Bo Xilai*”) and thus very difficult to capture based on typical lexical features. Third, tweets from Twitter/Chinese Weibo are short (only up to 140 characters) and noisy, resulting in difficult extraction of rich and accurate evidences due to the lack of enough contexts.

Morph	Target	Frequency in Twitter		Frequency in Weibo	
		Morph	Target	Morph	Target
Hu Ji	Hu Jintao	1	3,864	2,611	71
Blind Man	Chen Guangcheng	18	2,743	20,941	1
Baby	Wen Jiabao	2238	2021	26,279	8

Table 2: Distributions of Morph Examples

To the best of our knowledge, this is the first work to use NLP and social network analysis techniques to automatically resolve morphed information. To address the above challenges, our paper offers the following novel contributions.

- We detect target candidates by exploiting the dynamics of the social media to extract temporal distribution of entities, based on the assumption that the popularity of an individual is correlated between censored and uncensored text within a certain time window.
- Our approach builds and analyzes heterogeneous information networks from multiple sources, such as Twitter, Sina Weibo and web documents in formal genre (e.g. news) because a morph and its target tend to appear in similar contexts.
- We propose two new similarity measures, as well as integrating temporal information into

the similarity measures to generate global semantic features.

- We model social user behaviors and use social correlation to assist in measuring semantic similarities because the users who posted a morph and its corresponding target tend to share similar interests and opinions.

Our experiments demonstrate that the proposed approach significantly outperforms traditional alias detection methods (Hsiung et al., 2005).

## 2 Approach Overview

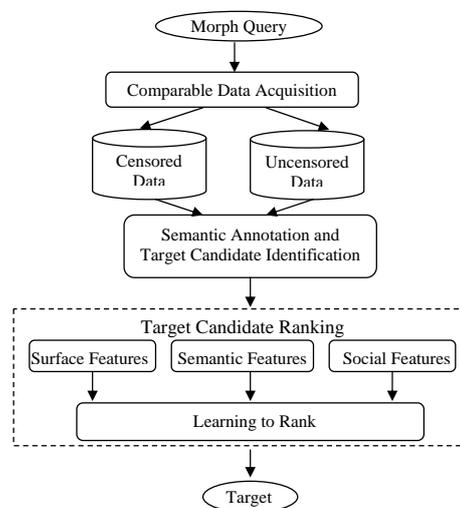

Figure 1: Overview of Morph Resolution

Given a morph query  $m$ , the goal of morph resolution is to find its real target. Figure 1 depicts the general procedure of our approach. It consists of two main sub-tasks:

- **Target Candidate Identification:** For each  $m$ , discover a list of target candidates  $E = \{e_1, e_2, \dots, e_N\}$ . First, relevant comparable data sets that include  $m$  are retrieved. In this paper we collect comparable censored data from Weibo and uncensored data from Twitter and Web documents such as news articles. We then apply various annotations such as word segmentation, part-of-speech tagging, noun phrase chunking, name tagging and event extraction to these data sets.
- **Target Candidate Ranking:** Rank the target candidates in  $E$ . We explore various features including surface, semantic and social features, and incorporate them into a learning to

rank framework. Finally, the top ranked candidate is produced as the resolved target.

### 3 Target Candidate Identification

The general goal of the first step is to identify a list of target candidates for each morph query from the comparable corpora including Sina Weibo, Chinese News websites and English Twitter. However, obviously we cannot consider all of the named entities in these sources as target candidates due to the sheer volume of information. In addition, morphs are not limited to named entity forms. In order to narrow down the scope of target candidates, we propose a *Temporal Distribution Assumption* as follows. The intuition is that a morph  $m$  and its real target  $e$  should have similar temporal distributions in terms of their occurrences. Suppose the data sets are separated into  $Z$  temporal slots (e.g. by day), the assumption can be stated as:

Let  $T_m = \{t_{m1}, t_{m2}, \dots, t_{mZ_m}\}$  be the set of temporal slots each morph  $m$  occurs, and  $T_e = \{t_{e1}, t_{e2}, \dots, t_{eZ_e}\}$  be the set of slots a target candidate  $e$  occurs. Then  $e$  is considered as a target candidate of  $m$  if and only if, for each  $t_{mi} \in T_m$  ( $i = 1, 2, \dots, Z_m$ ), there exist a  $j \in \{1, 2, \dots, Z_e\}$  such that  $t_{mi} - t_{ej} \leq \delta$ , where  $\delta$  is a threshold value (in this paper we set the threshold to 7 days, which is optimized from a development set). For comparison we also attempted topic modeling approach to detect target candidates, as shown in section 5.3.

### 4 Target Candidate Ranking

Next, we propose a learning-to-rank framework to rank target candidates based on various levels of novel features based on surface, semantic and social analysis.

#### 4.1 Surface Features

We first extract surface features between the morph and the candidate based on measuring orthographic similarity measures which were commonly used in entity coreference resolution (e.g. (Ng, 2010; Hsiung et al., 2005)). The measures we use include “string edit distance”, “normalized string edit distance” (Wagner and Fischer, 1974) and “longest common subsequence” (Hirschberg, 1977).

## 4.2 Semantic Features

### 4.2.1 Motivations

Fortunately, although a morph and its target may have very different orthographic forms, they tend to be embedded in *similar semantic contexts* which involve similar topics and events. Figure 2 presents some example messages under censorship (Weibo) and not under censorship (Twitter and Chinese Daily). We can see that they include similar topics, events (e.g., “fell from power”, “gang crackdown”, “sing red songs”), and semantic relations (e.g., family relations with “Bo Guagua”). Therefore if we can automatically extract and exploit these indicative semantic contexts, we can narrow down the real targets effectively.

Figure 2: Cross-source Comparable Data Example (each morph and target pair is shown in the same color)

### 4.2.2 Information Network Construction

We define an information network as a directed graph  $G = (\mathcal{V}, \mathcal{E})$  with an object type mapping function  $\tau : \mathcal{V} \rightarrow \mathcal{A}$  and a link type mapping function  $\phi : \mathcal{E} \rightarrow \mathcal{R}$ , where each object  $v \in \mathcal{V}$  belongs to one particular object type  $\tau(v) \in \mathcal{A}$ , each link  $e \in \mathcal{E}$  belongs to a particular relation  $\phi(e) \in \mathcal{R}$ . If two links belong to the same relation type, then they share the same starting object type as well as the same ending object type. An information network is *homogeneous* if and only if there is only one type for both objects and links, and an information network is *heterogeneous* when the objects are from multiple distinct types or there exist more than one type of links.

In order to construct the information networks for morphs, we apply the Stanford Chinese word

segmenter with Chinese Penn Treebank segmentation standard (Chang et al., 2008) and Stanford part-of-speech tagger (Toutanova et al., 2003) to process each sentence in the comparable data sets. Then we apply a hierarchical Hidden Markov Model (HMM) based Chinese lexical analyzer ICTCLAS (Zhang et al., 2003) to extract named entities, noun phrases and events.

We have also attempted using the results from Dependency Parsing, Relation Extraction and Event Extraction tools (Ji and Grishman, 2008) to enrich the link types. Unfortunately the state-of-the-art techniques for these tasks still perform poorly on social media in terms of both accuracy and coverage of important information, these sophisticated semantic links all produced negative impact on the target ranking performance. Therefore we limited the types of vertices into: *Morph* (M), *Entity*(E), which includes target candidates, *Event* (EV), and *Non-Entity Noun Phrases* (NP); and used *co-occurrence* as the edge type. We extract entities, events, and non-entity noun phrases that occur in more than one tweet as neighbors. And for two vertices  $x_i$  and  $x_j$ , the weight  $w_{ij}$  of their edge is the frequency they co-occur together within the tweets. A network schema of such networks is shown in Figure 3. Figure 4

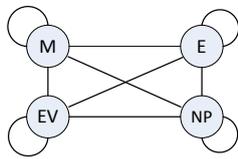

Figure 3: Network Schema of Morph-Related Heterogeneous Information Network

presents an example of a heterogeneous information network from the motivation examples following the above network schema, which connects the morphs “*Peace West King*”, “*Buhou*” and their corresponding target “*Bo Xilai*”.

#### 4.2.3 Meta-Path-Based Semantic Similarity Measurements

Given the constructed network, a straightforward solution for finding the target for a morph is to use link-based similarity search. However, now objects are linked to different types of neighbors, if all neighbors are treated as the same, it may cause information loss problems. For example, the entity “*重庆 (Chongqing)*” is a very important aspect characterizing the politician “*薄熙来 (Bo Xilai)*”

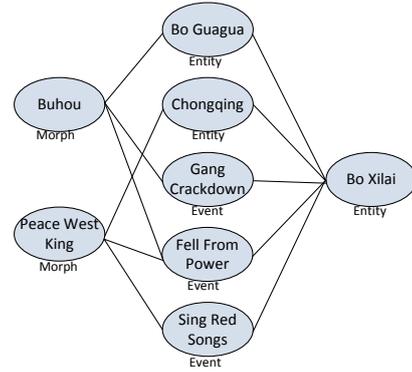

Figure 4: Example of Morph-Related Heterogeneous Information Network

since he governed it, and if a morph  $m$  which is also highly correlated with “*重庆 (Chongqing)*”, it is very likely that “*Bo Xilai*” is the real target of  $m$ . Therefore, the semantic features generated from neighbors such as the entity “*重庆 (Chongqing)*” should be treated differently from other types of neighbors such as “*人才 (talented people)*”.

In this work, we propose to measure the similarity of two nodes over heterogeneous networks as shown in Figure 3, by distinguishing neighbors into three types according to the network schema (i.e. entities, events, non-entity noun phrases). We then adopt meta-path-based similarity measures (Sun et al., 2011a; Sun et al., 2011b), which are defined over heterogeneous networks to extract semantic features. A meta-path is a path defined over a network, and composed of a sequence of relations between different object types. For example, as shown in Figure 3, a morph and its target candidate can be connected by three meta-paths, including “*M - E - E*”, “*M - EV - E*”, and “*M - NP - E*”. Intuitively, each meta-path provides a unique angle to measure how similar two objects are.

For the determined meta-paths, we extract semantic features using the similarity measures proposed in (Sun et al., 2011a; Hsiung et al., 2005). We denote the neighbor sets of certain type for a morph  $m$  and a target candidate  $e$  as  $\Gamma(m)$  and  $\Gamma(e)$ , and a meta-path as  $\mathcal{P}$ . We now list several meta-path-based similarity measures below.

*Common neighbors (CN)*. It measures the number of common neighbors that  $m$  and  $e$  share as  $|\Gamma(m) \cap \Gamma(e)|$ .

*Path count (PC)*. It measures the number of path instances between  $m$  and  $e$  following meta-path  $\mathcal{P}$ .

*Pairwise random walk (PRW)*. For a meta-path  $\mathcal{P}$  that can be decomposed into two shorter

meta-paths with the same length  $\mathcal{P} = (\mathcal{P}_1\mathcal{P}_2)$ , pairwise random walk measures the probability of the pairwise random walk starting from both  $m$  and  $e$  and reaching the same middle object. More formally, it is computed as  $\sum_{(p_1 p_2) \in (\mathcal{P}_1 \mathcal{P}_2)} prob(p_1)prob(p_2^{-1})$ , where  $p_2^{-1}$  is the inverse of  $p_2$ .

**Kullback-Leibler distance (KLD).** For  $m$  and  $e$ , the pairwise random walk probability of their neighbors can be represented as two probability vectors, then Kullback-Leibler distance (Hsiung et al., 2005) can be used to compute  $sim(m, e)$ .

Beyond the above similarity measures, we also propose to use cosine-similarity-style normalization method to modify common neighbor and pairwise random walk measures so that we can ensure the morph node and the target candidate node are strongly connected and also have similar popularity. The modified algorithms penalize features involved with the highly popular objects, since they are more likely to have accidental interactions with each other.

**Normalized common neighbors (NCN).** Normalized common neighbors can be measured as  $sim(m, e) = \frac{|\Gamma(m) \cap \Gamma(e)|}{\sqrt{|\Gamma(m)|} \sqrt{|\Gamma(e)|}}$ . It refines the simple counting of common neighbors by avoiding bias to highly visible or concentrated objects.

**Pairwise random walk/cosine (PRW/cosine).** Pairwise random walk measures linkage weights disproportionately with their visibility to their neighbors, which may be too strong. Instead, we propose to use a tamer normalization method as  $\sum_{(p_1 p_2) \in (\mathcal{P}_1 \mathcal{P}_2)} f(p_1)f(p_2^{-1})$ , where.

$$f(p_1) = \frac{count(m, x)}{\sqrt{\sum_{x \in \Omega} count(m, x)}},$$

$$f(p_2) = \frac{count(e, x)}{\sqrt{\sum_{x \in \Omega} count(e, x)}},$$

and  $\Omega$  is the set of middle objects connecting the decomposed meta-paths  $p_1$  and  $p_2^{-1}$ ,  $count(y, x)$  is the total number of paths between  $y$  and the middle object  $x$ ,  $y$  could be  $m$  or  $e$ .

The above similarity measures can also be applied to homogeneous networks that do not differentiate the neighbor types.

#### 4.2.4 Global Semantic Feature Generation

A morph tends to have higher temporal correlation with its real target, and share more similar topics compared to other irrelevant targets. Therefore, we propose to incorporate temporal information

into similarity measures to generate global semantic features.

Let  $T = t_1 \cup t_2 \cup \dots \cup t_N$  be a set of temporal slots (i.e. by day),  $E$  be the set of target candidates for each morph  $m$ . Then for each  $t_i \in T$ , and each  $e \in E$ , the local semantic features  $sim_{t_i}(m, e)$  is extracted based only on the information posted within  $t_i$  using one of the similarity measures introduced in Section 4.2.3. Then we propose two approaches to generate global semantic features. The first approach is adding the similarity score between  $m$  and  $e$  in each temporal slot to attain the first set of global features:

$$sim_{global\_sum}(m, e) = \sum_{t_i \in T} sim_{t_i}(m, e).$$

The second method first normalizes the similarity score in each temporal slot  $t_i$ , then sum the normalized scores to generate the second set of global features, which can be calculated as

$$sim_{global\_norm}(m, e) = \sum_{t_i \in T} norm_{t_i}(m, e).$$

where  $norm_{t_i}(m, e) = \frac{sim_{t_i}(m, e)}{\sum_{e \in E} sim_{t_i}(m, e)}$ .

#### 4.2.5 Integrate Cross Source/Cross Genre Information

Due to internet information censorship or surveillance, users may need to use morphs to post sensitive information. For example, the Chinese Weibo message “都进去了,还要贡着不厚吗 (*Already put in prison, still need to serve Buhou?*)” include a morph 不厚 (*Buhou*). In contrast, users are less restricted in some other uncensored social media such as Twitter. For example, the tweet from Twitter “...把薄熙来称作“平西王”或者“不厚”... (...call Bo Xilai “peace west king” or “buhou”...)” contains both the morph and the real target 薄熙来 (*Bo Xilai*). Therefore, we propose to integrate information from another source (e.g. Twitter) to help resolution of sensitive morphs in Weibo.

Another difficulty from morph resolution in micro-blogging is that tweets are only allowed to contain maximum 140 characters with a lot of noise and diverse topics. The shortness and diversity of tweets may limit the power of content analysis for semantic feature extraction. However, formal genres such as web documents are cleaner and contain richer contexts, thus can provide more topically related information. In this work, we also exploit the background web documents from the

embedded URLs in tweets to enrich information network construction. After applying the same annotation techniques as tweets for uncensored data sets, sentence-level co-occurrence relations are extracted and integrated into the network as shown in Figure 3.

### 4.3 Social Features

It has been shown that there exist correlation between neighbors in social networks (Anagnostopoulos et al., 2008; Wen and Lin, 2010). Because of such social correlation, close social neighbors in social media such as Twitter and Weibo may post similar information, or share similar opinion. Therefore, we can utilize social correlation to assist in resolving morphs.

As social correlation can be defined as a function of social distance between a pair of users, we use social distance as a proxy to social correlation in our approach. The social distance between user  $i$  and  $j$  is defined by considering the degree of separation in their interaction (e.g. retweeting and mentioning) and the amount of the interaction. Similar definition has been shown effective in characterizing social distance in social networks extracted from communication data (Lin et al., 2012; Wen and Lin, 2010). Specifically, it is  $dist(i, j) = \sum_{k=1}^{K-1} \frac{1}{strength(v_k, v_{k+1})}$ , where  $v_1, \dots, v_k$  are the nodes on the shortest path from user  $i$  to user  $j$ , and  $strength(v_k, v_{k+1})$  measures the strength of interactions between  $v_k$  and  $v_{k+1}$  as:  $strength(i, j) = \frac{\log(X_{ij})}{\max_j \log(X_{ij})}$ , where  $X_{ij}$  is the total interactions between user  $i$  and  $j$ , including both retweeting and mentioning (If  $X_{ij} < 10$ , we set  $strength(i, j) = 0$ ).

We integrate social correlation and temporal information to define our social features. The intuition is that when a morph is used by an user, the real target may also in the posts by the user or his/her close friends within a certain time period. Let  $T$  be the set of temporal slots a morph  $m$  occurs,  $U_t$  be the set of users whose posts include  $m$  in slot  $t$  where  $t \in T$ , and  $U_c$  be the set of close friends (i.e., social distance  $< 0.5$ ) for  $U_t$ . The social features are defined as

$$s(m, e) = \frac{\sum_{t \in T} f(e, t, U_t, U_c)}{|T|}.$$

where  $f(e, t, U_t, U_c)$  is a indicator function which return 1 if one of the users in  $U_t$  or  $U_c$  posts tweets include the target candidate  $e$  within 7 days before  $t$ .

### 4.4 Learning-to-Rank

Similar to (Hsiung et al., 2005; Sun et al., 2011a), we then model the probability of linkage prediction between a morph  $m$  and its target candidate  $e$  as a function incorporating the surface, semantic and social features. Given a training pair  $\langle m, e \rangle$ , we choose the standard logistic regression model to learn weights for the features defined above. The learnt model is used to predict the probability of linking an unseen morph and its target candidate. Based on the descending ranking order of the probability, we select top  $k$  candidates as the final answers based on the answer size  $k$ .

## 5 Experiments

Next, we present the experiment under various settings shown in Table 3, and the impacts of cross source and cross genre information.

### 5.1 Data and Evaluation Metric

We collected 1,553,347 tweets from Chinese Sina Weibo from May 1 to June 30 to construct the censored data set, and retrieved 66,559 web documents from the embedded URLs in tweets as the initial uncensored data set. Retweets and redundant web documents are filtered to ensure more reliable frequency counting of co-occurrence relations. We asked two native Chinese annotators to analyze the data, and construct a test set consisted of 107 morph entities (81 persons and 26 locations) and their real targets as our references. We verified the references by Web resources including the summary of popular morphs in Wikipedia<sup>2</sup>. In addition, we used 23 sensitive morphs and the entities that appear in the tweets as queries and retrieved 25,128 Chinese tweets from 10% Twitter feeds within the same time period, as well as 7,473 web documents from the embedded URLs and added them into the uncensored data set.

To evaluate the system performance, we use leave-one-out cross validation by computing accuracy as  $Acc@k = \frac{C_k}{Q}$ , where  $C_k$  is the total number of correctly resolved morphs at top  $k$  ranked answers, and  $Q$  is the total number of morph queries. We consider a morph as correctly resolved at the top  $k$  answers if the top  $k$  answer set contains the real target of the morph.

<b>Social</b>	Social network features

Table 3: Description of feature sets. \* Glob only uses the same set of similarity measures when combined with other semantic features.

## 5.2 Resolution Performance

### 5.2.1 Single Genre Information

We first study the contributions of each set of surface and semantic features, as shown in the first five rows in Table 4. The poor performance based on surface features shows that morph resolution task is very challenging since 70% of morphs are not orthographically similar to their real targets. Thus, capturing a morph’s semantic meaning is crucial. Overall, the results demonstrate the effectiveness of our proposed methods. Specifically, comparing “HomB” and “HetB”, “HomE” and “HetE”, we can see that the semantic features based on heterogeneous networks have advantages over those based on homogeneous networks. This corroborates that different neighbor sets contribute differently, and such discrepancies should be captured. And comparisons of “HomB” and “HomE”, “HetB” and “HetE” demonstrate the effectiveness of our two new proposed measures. To evaluate the importance of each similarity measures, we delete the semantic features obtained from each measure in “HetE” and re-evaluate the system. We find that NCN is the most effective measure, while KLD is the least important one. Further adding the global semantic features significantly improves the performance. This indicates that capturing both temporal correlations and semantics of morphing simultaneously are important for morph resolution.

Table 5 shows that combination of surface and semantic features further improves the performance, showing that they are complementary. For example, using only surface features, the real target “乔布斯 (Steve Jobs)” of the morph “乔帮主 (Qiao Boss)” is not top ranked since some other candidates such as “乔治 (George)” are more orthographically similar. However, “Steve Jobs” is ranked top when combined with semantic features.

### 5.2.2 Cross Source and Cross Genre Information

We integrate the cross source information from Twitter, and the cross genre information from web documents into Weibo tweets for information network construction, and extract a new set of semantic features. Table 6 shows that further gains can be achieved. Notice that integrating tweets from Twitter mainly improves the ranking for top  $k$  where  $k > 1$ . This is because Weibo dominates our dataset, and in Weibo many of these sensitive morphs are mostly used with their traditional meanings instead of the morph senses. Further performance improvement is achieved by integrating information from background formal web documents which can provide richer context and relations.

Table 6: The System Performance of Integrating Cross Source and Cross Genre Information.

### 5.2.3 Effects of Social Features

Table 7 shows that adding social features can improve the best performance achieved so far. This is because a group of people with close relationships may share similar opinion. As an example, two tweets “...of course the reputation of Buhou is a little too high! //@User1: //@User2: Chongqing event tells us...” and “...do not follow Bo Xilai...@User1...” are from two users in the same social group. One includes a morph “Buhou” and the other includes its target “Bo Xilai”.

Acc@20	0.645	0.664	<b>0.701</b>	<b>0.701</b>

Table 7: The Effects of Social Features.

### 5.3 Effects of Candidate Detection

The performance with and without candidate detection step (using all features) is shown in Table 8. The gain is small since the combination of all features in the learning to rank framework can already well capture the relationship between a morph and a target candidate. Nevertheless, the temporal distribution assumption is effective. It helps to filter out 80% of unrelated targets and

speed up the system 5 times, while retain 98.5% of the morph candidates that can be detected.

System	Acc@1	Acc@5	Acc@10	Acc@20
Without	0.365	0.579	0.645	0.696
With	<b>0.379</b>	<b>0.594</b>	<b>0.659</b>	<b>0.701</b>

Table 8: The Effects of Temporal Constraint

We also attempted using topic modeling approach to detect target candidates. Due to the large amount of data, we first split the data set on a daily basis, then applied Probabilistic Latent Semantic Analysis (PLSA) (Hofmann, 1999). Named entities which co-occur at least  $\delta$  times with a morph query in the same topic are selected as its target candidates. As shown in Table9 ( $K$  is the number of predefined topics), PLSA is not quite effective mainly because traditional topic modeling approaches do not perform well on short texts from social media. Therefore, in this paper we choose a simple method based on temporal distribution to detect target candidates.

Method	All	Temporal	PLSA( $K = 5$ $\delta = 1$ )	PLSA( $K = 5$ $\delta = 2$ )
Acc	0.935	0.921	0.935	0.925
No.	8,111	1,964	6,380	4,776
Method	PLSA( $K = 10$ $\delta = 1$ )	PLSA( $K = 10$ $\delta = 2$ )	PLSA( $K = 20$ $\delta = 1$ )	PLSA( $K = 20$ $\delta = 2$ )
Acc	0.935	0.907	0.888	0.757
No.	5,117	3,138	3,702	1,664

Table 9: Accuracy of Target Candidate Detection

### 5.4 Discussions

Compared with the standard alias detection (“Surf+HomB”) approach (Hsiung et al., 2005), our proposed approach achieves significantly better performance (99.9% confidence level by the Wilcoxon Matched-Pairs Signed-Ranks Test for Acc@1). We further explore two types of factors which may affect the system performance as follows.

One important aspect affecting the resolution performance is the morph & non-morph ambiguity. We categorize a morph query as “Unique” if the string is mainly used as a morph when it occurs, such as “薄督 (Bodu)” which is used to refer to “Bo Xilai”; otherwise as “Common” (e.g. “宝宝 (Baby)”, “校长 (President)”). Table 10 presents the separate scores for these two categories. We can see that the morphs in “Unique”

category have much better resolution performance than those in “Common” category.

Category	Number	Acc@1	Acc@5	Acc@10	Acc@20
Unique	72	0.479	0.715	0.771	0.819
Common	35	0.171	0.343	0.40	0.429

Table 10: Performance of Two Categories

We also investigate the effects of popularity of morphs on the resolution performance. We split the queries into 5 bins with equal size based on the non-descending frequency, and evaluate Acc@1 separately. As shown in Table 11, we can see that the popularity is not highly correlated with the performance.

Rank	0 ~ 20%	20% ~ 40%	40% ~ 60%	60% ~ 80%	80% ~ 100%
All	0.333	0.476	0.341	0.429	0.318
Unique	0.321	0.679	0.379	0.571	0.483
Common	0.214	0.214	0.071	0.071	0.286

Table 11: Effects of Popularity of Morphs

## 6 Related Work

To analyze social media behavior under active censorship, (Bamman et al., 2012) automatically discovered politically sensitive terms from Chinese tweets based on message deletion analysis. In contrast, our work goes beyond target identification by resolving implicit morphs to their real targets.

Our work is closely related to alias detection (Hsiung et al., 2005; Pantel, 2006; Bollegala et al., 2011; Holzer et al., 2005). We demonstrated that state-of-the-art alias detection methods did not perform well on morph resolution. In this paper we exploit cross-genre information and social correlation to measure semantic similarity. (Yang et al., 2011; Huang et al., 2012) also showed the effectiveness of exploiting information from formal web documents to enhance tweet summarization and tweet ranking.

Other similar research lines are the TAC-KBP Entity Linking (EL) (Ji et al., 2010; Ji et al., 2011), which links a named entity in news and web documents to an appropriate knowledge base (KB) entry, the task of mining name translation pairs from comparable corpora (Udupa et al., 2009; Ji, 2009; Fung and Yee, 1998; Rapp, 1999; Shao and Ng, 2004; Hassan et al., 2007) and the link prediction problem (Adamic and Adar, 2001; Liben-Nowell and Kleinberg, 2003; Sun et al., 2011b;

Hasan et al., 2006; Wang et al., 2007; Sun et al., 2011a). Most of the work focused on unstructured or structured data with clean and rich relations (e.g. DBLP). In contrast, our work constructs heterogeneous information networks from unstructured, noisy multi-genre text without explicit entity attributes.

## 7 Conclusion and Future Work

To the best of our knowledge, this is the first work of resolving implicit information morphs from the data under active censorship. Our promising results can well serve as a benchmark for this new problem. Both of the Meta-path based and social correlation based semantic similarity measurements are proven powerful and complementary.

In this paper we have focused on entity morphs. In the future we will extend our method to discover other types of information morphs, such as events and nominal mentions. In addition, automatic identification of candidate morphs is another challenging task, especially when the mentions are ambiguous and can also refer to other real entities. Our ongoing work includes identifying candidate morphs from scratch, as well as discovering morphs for a given target based on anomaly analysis and textual coherence modeling.

## Abstract

We describe a new probabilistic model for extracting events between major political actors from news corpora. Our unsupervised model brings together familiar components in natural language processing (like parsers and topic models) with contextual political information—temporal and dyad dependence—to infer latent event classes. We quantitatively evaluate the model’s performance on political science benchmarks: recovering expert-assigned event class valences, and detecting real-world conflict. We also conduct a small case study based on our model’s inferences.

A supplementary appendix, and replication software/data are available online, at: <http://brenocon.com/irevents>

## 1 Introduction

The digitization of large news corpora has provided an unparalleled opportunity for the systematic study of international relations. Since the mid-1960s political scientists have used political *events data*, records of public micro-level interactions between major political actors of the form “someone does something to someone else” as reported in the open press (Schrodt, 2012), to study the patterns of interactions between political actors and how they evolve over time. Scaling this data effort to modern corpora presents an information extraction challenge: can a structured collection of accurate, politically relevant events between major political actors be extracted automatically and efficiently? And can they be grouped into meaningful event types with a low-dimensional structure useful for further analysis?

We present an unsupervised approach to event extraction, in which political structure and linguistic evidence are combined. A political context

model of the relationship between a pair of political actors imposes a prior distribution over types of linguistic events. Our probabilistic model infers latent frames, each a distribution over textual expressions of a kind of event, as well as a representation of the relationship between each political actor pair at each point in time. We use syntactic preprocessing and a logistic normal topic model, including latent temporal smoothing on the political context prior.

We apply the model in a series of comparisons to benchmark datasets in political science. First, we compare the automatically learned verb classes to a pre-existing ontology and hand-crafted verb patterns from TABARI,<sup>1</sup> an open-source and widely used rule-based event extraction system for this domain. Second, we demonstrate correlation to a database of real-world international conflict events, the Militarized Interstate Dispute (MID) dataset (Jones *et al.*, 1996). Third, we qualitatively examine a prominent case not included in the MID dataset, Israeli-Palestinian relations, and compare the recovered trends to the historical record.

We outline the data used for event discovery (§2), describe our model (§3), inference (§4), evaluation (§5), and comment on related work (§6).

## 2 Data

The model we describe in §3 is learned from a corpus of 6.5 million newswire articles from the English Gigaword 4th edition (1994–2008, Parker *et al.*, 2009). We also supplement it with a sample of data from the *New York Times* Annotated Corpus (1987–2007, Sandhaus, 2008).<sup>2</sup> The Stan-

<sup>1</sup>Available from the Penn State Event Data Project: <http://eventdata.psu.edu/>

<sup>2</sup>For arbitrary reasons this portion of the data is much smaller (we only parse the first five sentences of each article, while Gigaword has all sentences parsed), resulting in less than 2% as many tuples as from the Gigaword data.

ford CoreNLP system,<sup>3</sup> under default settings, was used to POS-tag and parse the articles, to eventually produce event tuples of the form

$$\langle s, r, t, w_{\text{predpath}} \rangle$$

where  $s$  and  $r$  denote “source” and “receiver” arguments, which are political actor entities in a pre-defined set  $\mathcal{E}$ ,  $t$  is a timestep (i.e., a 7-day period) derived from the article’s published date, and  $w_{\text{predpath}}$  is a textual predicate expressed as a dependency path that typically includes a verb (we use the terms “predicate-path” and “verb-path” interchangeably). For example, on January 1, 2000, the AP reported “Pakistan promptly accused India,” from which our preprocessing extracts the tuple  $\langle \text{PAK}, \text{IND}, 678, \text{accuse} \xrightarrow{\text{dobj}} \rangle$ . (The path excludes the first source-side arc.) Entities and verb paths are identified through the following sets of rules.

Named entity recognition and resolution is done deterministically by finding instances of country names from the *CountryInfo.txt* dictionary from TABARI,<sup>4</sup> which contains proper noun and adjectival forms for countries and administrative units. We supplement these with a few entries for international organizations from another dictionary provided by the same project, and clean up a few ambiguous names, resulting in a final actor dictionary of 235 entities and 2,500 names.

Whenever a name is found, we identify its entity’s mention as the minimal noun phrase that contains it; if the name is an adjectival or noun-noun compound modifier, we traverse any such *amod* and *nn* dependencies to the noun phrase head. Thus *NATO bombing*, *British view*, and *Palestinian militant* resolve to the entity codes IG-ONAT, GBR, and PSE respectively.

We are interested in identifying actions initiated by agents of one country targeted towards another, and hence concentrate on verbs, analyzing the “CCprocessed” version of the Stanford Dependencies (de Marneffe and Manning, 2008). Verb paths are identified by looking at the shortest dependency path between two mentions in a sentence. If one of the mentions is immediately dominated by a *nsubj* or *agent* relation, we consider that the Source actor, and the other mention is the Receiver. The most common cases are simple direct objects and prepositional arguments like *talk*

<sup>3</sup><http://nlp.stanford.edu/software/corenlp.shtml>

<sup>4</sup><http://eventdata.psu.edu/software/dir/dictionaries.html>.

$\xleftarrow{\text{prep.with}}$  and *fight*  $\xleftarrow{\text{prep.alongside}}$  (“talk with  $R$ ,” “fight alongside  $R$ ”) but many interesting multiword constructions also result, such as *reject*  $\xleftarrow{\text{dobj}}$  *allegation*  $\xleftarrow{\text{poss}}$  (“rejected  $R$ ’s allegation”) or verb chains as in *offer*  $\xleftarrow{\text{xcomp}}$  *help*  $\xleftarrow{\text{dobj}}$  (“offer to help  $R$ ”).

We wish to focus on instances of directly reported events, so attempt to remove factively complicated cases such as indirect reporting and hypotheticals by discarding all predicate paths for which any verb on the path has an off-path governing verb with a non-*conj* relation. (For example, the verb at the root of a sentence always survives this filter.) Without this filter, the  $\langle s, r, w \rangle$  tuple  $\langle \text{USA}, \text{CUB}, \text{want} \xleftarrow{\text{xcomp}} \text{seize} \xleftarrow{\text{dobj}} \rangle$  is extracted from the sentence “Parliament Speaker Ricardo Alarcon said the United States wants to seize Cuba and take over its lands”; the filter removes it since *wants* is dominated by an off-path verb through *say*  $\xleftarrow{\text{ccomp}}$  *wants*. The filter was iteratively developed by inspecting dozens of output examples and their labelings under successive changes to the rules.

Finally, only paths length 4 or less are allowed, the final dependency relation for the receiver may not be *nsubj* or *agent*, and the path may not contain any of the dependency relations *conj*, *parataxis*, *det*, or *dep*. We use lemmatized word forms in defining the paths.

Several document filters are applied before tuple extraction. Deduplication removes 8.5% of articles.<sup>5</sup> For topic filtering, we apply a series of keyword filters to remove sports and finance news, and also apply a text classifier for diplomatic and military news, trained on several hundred manually labeled news articles (using  $\ell_1$ -regularized logistic regression with unigram and bigram features). Other filters remove non-textual junk and non-standard punctuation likely to cause parse errors.

For experiments we remove tuples where the source and receiver entities are the same, and restrict to tuples with dyads that occur at least 500 times, and predicate paths that occur at least 10 times. This yields 365,623 event tuples from 235,830 documents, for 421 dyads and 10,457 unique predicate paths. We define timesteps to be 7-day periods, resulting in 1,149 discrete

<sup>5</sup>We use a simple form of shingling (ch. 3, Rajaraman and Ullman, 2011): represent a document signature as its  $J = 5$  lowercased bigrams with the lowest hash values, and reject a document with a signature that has been seen before within the same month.  $J$  was manually tuned, as it affects the precision/recall tradeoff.

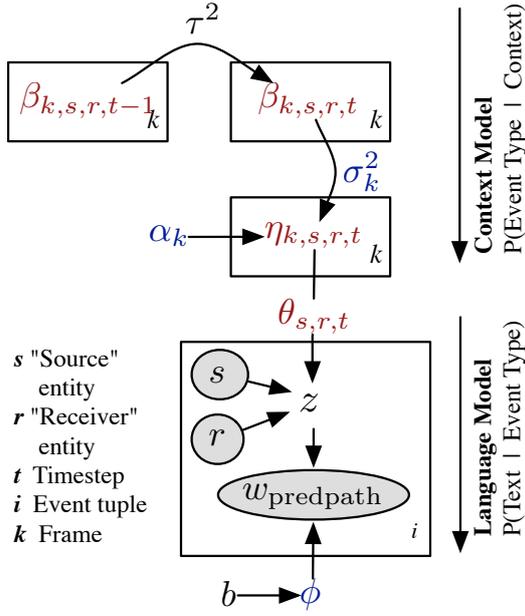

Figure 1: Directed probabilistic diagram of the model for one  $(s, r, t)$  dyad-time context, for the smoothed model.

timesteps (1987 through 2008, though the vast majority of data starts in 1994).

### 3 Model

We design two models to learn linguistic event classes over predicate paths by conditioning on real-world contextual information about international politics,  $p(w_{\text{predpath}} | s, r, t)$ , leveraging the fact there tends to be dyadic and temporal coherence in international relations: the types of actions that are likely to occur between nations tend to be similar within the same dyad, and usually their distribution changes smoothly over time.

Our model decomposes into two submodels: a Context submodel, which encodes how political context affects the probability distribution over event types, and a Language submodel, for how those events are manifested as textual predicate paths (Figure 1). The overall generative process is as follows. We color global parameters for a frame **blue**, and local context parameters **red**, and use the term “frame” as a synonym for “event type.” The fixed hyperparameter  $K$  denotes the number of frames.

- The **context model** generates a frame prior  $\theta_{s,r,t}$  for every context  $(s, r, t)$ .
- **Language model:**
  - Draw lexical sparsity parameter  $b$  from a diffuse prior (see §4).

- For each frame  $k$ , draw a multinomial distribution of dependency paths,  $\phi_k \sim \text{Dir}(b/V)$  (where  $V$  is the number of dependency path types).
- For each  $(s, r, t)$ , for every event tuple  $i$  in that context,
  - Sample its frame  $z^{(i)} \sim \text{Mult}(\theta_{s,r,t})$ .
  - Sample its predicate realization  $w_{\text{predpath}}^{(i)} \sim \text{Mult}(\phi_{z^{(i)}})$ .

Thus the language model is very similar to a topic model’s generation of token topics and wordtypes.

We use structured logistic normal distributions to represent contextual effects. The simplest is the **vanilla (v)** context model,

- For each frame  $k$ , draw global parameters from diffuse priors: prevalence  $\alpha_k$  and variability  $\sigma_k^2$ .
- For each  $(s, r, t)$ ,
  - Draw  $\eta_{k,s,r,t} \sim N(\alpha_k, \sigma_k^2)$  for each frame  $k$ .
  - Apply a softmax transform,

$$\theta_{k,s,r,t} = \frac{\exp \eta_{k,s,r,t}}{\sum_{k'=1}^K \exp \eta_{k',s,r,t}}$$

Thus the vector  $\eta_{*,s,r,t}$  encodes the relative log-odds of the different frames for events appearing in the context  $(s, r, t)$ . This simple logistic normal prior is, in terms of topic models, analogous to the asymmetric Dirichlet prior version of LDA in Wallach *et al.* (2009), since the  $\alpha_k$  parameter can learn that some frames tend to be more likely than others. The variance parameters  $\sigma_k^2$  control admixture sparsity, and are analogous to a Dirichlet’s concentration parameter.

#### Smoothing Frames Across Time

The vanilla model is capable of inducing frames through dependency path co-occurrences, when multiple events occur in a given context. However, many dyad-time slices are very sparse; for example, most dyads (all but 18) have events in fewer than half the time slices in the dataset. One solution is to increase the bucket size (e.g., to months); however, previous work in political science has demonstrated that answering questions of interest about reciprocity dynamics requires recovering the events at weekly or even daily granularity (Shellman, 2004), and in any case wide buckets help only so much for dyads with fewer events or less media attention. Therefore we propose a **smoothed frames (SF)** model, in which the

frame distribution for a given dyad comes from a latent parameter  $\beta_{*,s,r,t}$  that smoothly varies over time. For each  $(s, r)$ , draw the first timestep’s values as  $\beta_{k,s,r,1} \sim N(0, 100)$ , and for each context  $(s, r, t > 1)$ ,

- Draw  $\beta_{k,s,r,t} \sim N(\beta_{k,s,r,t-1}, \tau^2)$
- Draw  $\eta_{k,s,r,t} \sim N(\alpha_k + \beta_{k,s,r,t}, \sigma_k^2)$

Other parameters  $(\alpha_k, \sigma_k^2)$  are same as the vanilla model. This model assumes a random walk process on  $\beta$ , a variable which exists even for contexts that contain no events. Thus inferences about  $\eta$  will be smoothed according to event data at nearby timesteps. This is an instance of a linear Gaussian state-space model (also known as a linear dynamical system or dynamic linear model), and is a convenient formulation because it has well-known exact inference algorithms. Dynamic linear models have been used elsewhere in machine learning and political science to allow latent topic frequencies (Blei and Lafferty, 2006; Quinn *et al.*, 2010) and ideological positions (Martin and Quinn, 2002) to smoothly change over time, and thus share statistical strength between timesteps.

## 4 Inference

After randomly initializing all  $\eta_{k,s,r,t}$ , inference is performed by a blocked Gibbs sampler, alternating resamplings for three major groups of variables: the language model  $(z, \phi)$ , context model  $(\alpha, \gamma, \beta, p)$ , and the  $\eta, \theta$  variables, which bottleneck between the submodels.

The **language model** sampler sequentially updates every  $z^{(i)}$  (and implicitly  $\phi$  via collapsing) in the manner of Griffiths and Steyvers (2004):  $p(z^{(i)} | \theta, w^{(i)}, b) \propto \theta_{s,r,t,z} (n_{w,z} + b/V) / (n_z + b)$ , where counts  $n$  are for all event tuples besides  $i$ .

For the **context model**,  $\alpha$  is conjugate resampled as a normal mean. The random walk variables  $\beta$  are sampled with the forward-filtering-backward-sampling algorithm (FFBS; Harrison and West, 1997; Carter and Kohn, 1994); there is one slight modification of the standard dynamic linear model that the zero-count weeks have no  $\eta$  observation; the Kalman filter implementation is appropriately modified to handle this.

The  $\eta$  update step is challenging since it is a nonconjugate prior to the  $z$  counts. Logistic normal distributions were introduced to text modeling by Blei and Lafferty (2007), who developed a variational approximation; however, we

find that experimenting with different models is easier in the Gibbs sampling framework. While Gibbs sampling for logistic normal priors is possible using auxiliary variable methods (Mimno *et al.*, 2008; Holmes and Held, 2006; Polson *et al.*, 2012), it can be slow to converge. We opt for the more computationally efficient approach of Zeger and Karim (1991) and Hoff (2003), using a Laplace approximation to  $p(\eta | \bar{\eta}, \Sigma, z)$ , which is a mode-centered Gaussian having inverse covariance equal to the unnormalized log-posterior’s negative Hessian (§8.4 in Murphy, 2012). We find the mode with the linear-time Newton algorithm from Eisenstein *et al.* (2011), and sample in linear time by only using the Hessian’s diagonal as the inverse covariance (i.e., an axis-aligned normal), since a full multivariate normal sample requires a cubic-time-to-compute Cholesky root of the covariance matrix. This  $\eta^*$  sample is a proposal for a Metropolis-within-Gibbs step, which is moved to according to the standard Metropolis-Hastings acceptance rule. Acceptance rates differ by  $K$ , ranging approximately from 30% ( $K = 100$ ) to nearly 100% (small  $K$ ).

Finally, we use diffuse priors on all global parameters, conjugate resampling variances  $\tau^2, \sigma_k$  once per iteration, and slice sampling (Neal, 2003) the Dirichlet concentration  $b$  every 100 iterations. Automatically learning these was extremely convenient for model-fitting; the only hyperparameter we set manually was  $K$ . It also allowed us to monitor the convergence of dispersion parameters to help debug and assess MCMC mixing. For other modeling and implementation details, see the online appendix and software.

## 5 Experiments

We fit the two models on the dataset described in §2, varying the number of frames  $K$ , with 8 or more separate runs for each setting. Posteriors are saved and averaged from 11 Gibbs samples (every 100 iterations from 9,000 to 10,000) for analysis.

We present intrinsic (§5.1) and extrinsic (§5.2) quantitative evaluations, and a qualitative case study (§5.4).

### 5.1 Lexical Scale Impurity

In the international relations literature, much of the analysis of text-based events data makes use of a unidimensional conflict to cooperation scale. A popular event ontology in this domain, CAMEO, consists of around 300 different event types, each

given an expert-assigned scale in the range from  $-10$  to  $+10$  (Gerner *et al.*, 2002), derived from a judgement collection experiment in Goldstein (1992). The TABARI pattern-based event extraction program comes with a list of almost 16,000 manually engineered verb patterns, each assigned to one CAMEO event type.

It is interesting to consider the extent to which our unsupervised model is able to recover the expert-designed ontology. Given that many of the categories are very fine-grained (e.g. “Express intent to de-escalate military engagement”), we elect to measure model quality as *lexical scale purity*: whether all the predicate paths within one automatically learned frame tend to have similar gold-standard scale scores. (This measures cluster cohesiveness against a one-dimensional continuous scale, instead of measuring cluster cohesiveness against a gold-standard clustering as in VI, Rand index, or purity.) To calculate this, we construct a mapping between our corpus-derived verb path vocabulary and the TABARI verb patterns, many of which contain one to several word stems that are intended to be matched in surface order. Many of our dependency paths, when traversed from the source to receiver direction, also follow surface order, due to English’s SVO word order.<sup>6</sup> Therefore we convert each path to a word sequence and match against the TABARI lexicon—plus a few modifications for differences in infinitives and stemming—and find 528 dependency path matches. We assign each path  $w$  a gold-standard scale  $g(w)$  by resolving through its matching pattern’s CAMEO code.

We formalize *lexical scale impurity* as the average absolute difference of scale values between two predicate paths under the same frame. Specifically, we want a token-level posterior expectation

$$\mathbb{E}(|g(w_i) - g(w_j)| \mid z_i = z_j, w_i \neq w_j) \quad (1)$$

which is taken over pairs of path instances  $(i, j)$  where both paths  $w_i, w_j$  are in  $M$ , the set of verb paths that were matched between the lexicons. This can be reformulated at the type level as:<sup>7</sup>

$$\frac{1}{N} \sum_k \sum_{\substack{w, v \in M \\ w \neq v}} n_{w,k} n_{v,k} |g(w) - g(v)| \quad (2)$$

<sup>6</sup>There are plenty of exceptions where a Source-to-Receiver path traversal can have a right-to-left move, such as dependency edges for possessives. This approach can not match them.

<sup>7</sup>Derivation in supplementary appendix.

where  $n$  refers to the averaged Gibbs samples’ counts of event tuples having frame  $k$  and a particular verb path,<sup>8</sup> and  $N$  is the number of token comparisons (i.e. the same sum, but with a 1 replacing the distance). The worst possible impurity is upper bounded at 20 ( $= \max(g(w)) - \min(g(w))$ ) and the best possible is 0. We also compute a randomized null hypothesis to see how low impurity can be by chance: each of  $\sim 1000$  simulations randomly assigns each path in  $M$  to one of  $K$  frames (all its instances are exclusively assigned to that frame), and computes the impurity. On average the impurity is same at all  $K$ , but variance increases with  $K$  (since small clusters might by chance get a highly similar paths in them), necessitating this null hypothesis analysis. We report the 5th percentile over simulations.

## 5.2 Conflict Detection

Political events data has shown considerable promise as a tool for crisis early warning systems (O’Brien, 2010; Brandt *et al.*, 2011). While conflict forecasting is a potential application of our model, we conduct a simpler prediction task to validate whether the model is learning something useful: based on news text, tell whether or not an armed conflict is *currently* happening. For a gold standard, we use the Militarized Interstate Dispute (MID) dataset (Jones *et al.*, 1996; Ghosn *et al.*, 2004), which documents historical international disputes. While not without critics, the MID data is the most prominent dataset in the field of international relations. We use the Dyadic MIDs, each of which ranks hostility levels between pairs of actors on a five point scale over a date interval; we define conflict to be the top two categories “Use of Force” (4) and “War” (5). We convert the data into a variable  $y_{s,r,t}$ , the highest hostility level reached by actor  $s$  directed towards receiver  $r$  in the dispute that overlaps with our 7-day interval  $t$ , and want to predict the binary indicator  $\mathbf{1}\{y_{s,r,t} \geq 4\}$ . For the illustrative examples (USA to Iraq, and the Israel-Palestine example below) we use results from a smaller but more internally comparable dataset consisting of the 2 million Associated Press articles within the Gigaword corpus.

For an example of the MID data, see Figure 2, which depicts three disputes between the US and

<sup>8</sup>Results are nearly identical whether we use counts averaged across samples (thus giving posterior marginals), or simply use counts from a single sample (i.e., iteration 10,000).

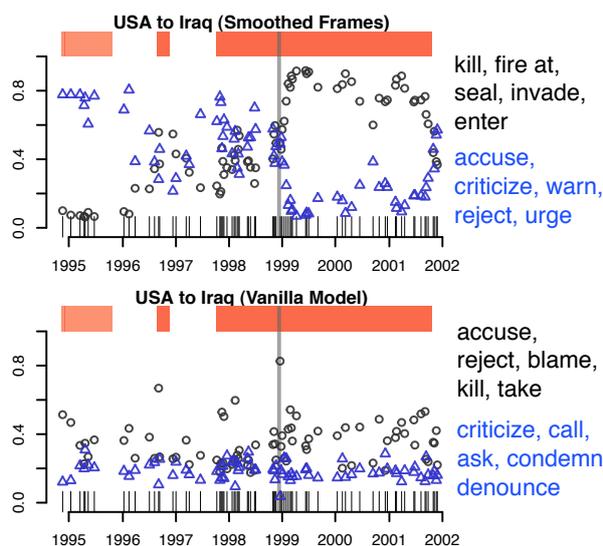

Figure 2: The USA→Iraq directed dyad, analyzed by smoothed (above) and vanilla (below) models, showing (1) gold-standard MID values (red intervals along top), (2) weeks with non-zero event counts (vertical lines along x-axis), (3) posterior  $E[\theta_{k, \text{USA}, \text{IRQ}, t}]$  inferences for two frames chosen from two different  $K = 5$  models, and (4) most common verb paths for each frame (right). Frames corresponding to material and verbal conflict were chosen for display. Vertical line indicates Operation Desert Fox (see §5.2).

Iraq in this time period. The MID labels are marked in red.

The first dispute is a “display of force” (level 3), cataloguing the U.S. response to a series of troop movements along the border with Kuwait. The third dispute (10/7/1997 to 10/10/2001) begins with increasing Iraqi violations of the no-fly zone, resulting in U.S. and U.K. retaliation, reaching a high intensity with Operation Desert Fox, a four-day bombing campaign from December 16 to 19, 1998—which is not shown in MID. These cases highlight MID’s limitations—while it is well regarded in the political science literature, its coarse level of aggregation can fail to capture variation in conflict intensity.

Figure 2 also shows model inferences. Our smoothed model captures some of these phenomena here, showing clear trends for two relevant frames, including a dramatic change in December 1998. The vanilla model has a harder time, since it cannot combine evidence between different timesteps.

The MID dataset overlaps with our data for 470 weeks, from 1993 through 2001. After excluding dyads with actors that the MID data does not intend to include—Kosovo, Tibet, Palestine, and international organizations—we have 267 directed dyads for evaluation, 117 of which have at least

one dispute in the MID data. (Dyads with no dispute in the MID data, such as Germany-France, are assumed to have  $y = 0$  throughout the time period.) About 7% of the dyad-time contexts have a dispute under these definitions.

We split the dataset by time, training on the first half of the data and testing on the second half, and measure area under the receiver operating characteristic curve (AUC).<sup>9</sup> For each model, we train an  $\ell_1$ -regularized logistic regression<sup>10</sup> with the  $K$  elements of  $\theta_{*,s,r,t}$  as input features, tuning the regularization parameter within the training set (by splitting it in half again) to optimize held-out likelihood. We weight instances to balance positive and negative examples. Training is on all individual  $\theta$  samples at once (thus accounting for posterior uncertainty in learning), and final predicted probabilities are averaged from individual probabilities from each  $\theta$  test set sample, thus propagating posterior uncertainty into the predictions. We also create a baseline  $\ell_1$ -regularized logistic regression that uses normalized dependency path counts as the features (10,457 features). For both the baseline and vanilla model, contexts with no events are given a feature vector of all zeros.<sup>11</sup> (We also explored an alternative evaluation setup, to hold out by dyad; however, the performance variance is quite high between different random dyad splits.)

### 5.3 Results

Results are shown in Figure 3.<sup>12</sup>

The verb-path logistic regression performs strongly at AUC 0.62; it outperforms all of the vanilla frame models. This is an example of individual lexical features outperforming a topic model for predictive task, because the topic model’s dimension reduction obscures important indicators from individual words. Similarly, [Gerish and Blei \(2011\)](#) found that word-based regression outperformed a customized topic model when predicting Congressional bill passage, and [Eisen-](#)

<sup>9</sup>AUC can be interpreted as follows: given a positive and negative example, what is the probability that the classifier’s confidences order them correctly? Random noise or predicting all the same class both give AUC 0.5.

<sup>10</sup>Using the R *glmnet* package (Friedman *et al.*, 2010).

<sup>11</sup>For the vanilla model, this performed better than linear interpolation (about 0.03 AUC), and with less variance between runs.

<sup>12</sup>Due to an implementation bug, the model put the vast majority of the probability mass only on  $K - 1$  frames, so these settings might be better thought of as  $K = 1, 2, 3, 4, 9, \dots$ ; see the appendix for details.

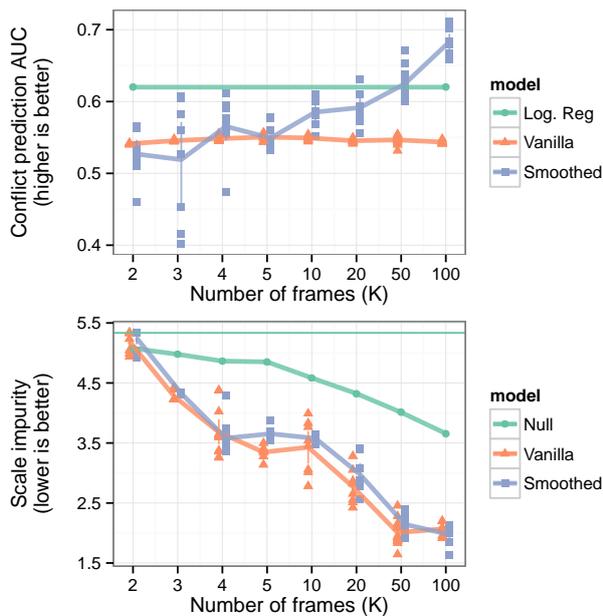

Figure 3: Evaluation results. Each point indicates one model run. Lines show the average per  $K$ , with vertical lines indicating the 95% bootstrapped interval. **Top:** Conflict detection AUC for different models (§5.2). Green line is the verb-path logistic regression baseline. **Bottom:** Lexical scale impurity (§5.1). Top green line indicates the simple random baseline  $E(|g(w_i) - g(w_j)|) = 5.33$ ; the second green line is from the random assignment baseline.

stein *et al.* (2010) found word-based regression outperformed Supervised LDA for geolocation,<sup>13</sup> and we have noticed this phenomenon for other text-based prediction problems.

However, adding smoothing to the model substantially increases performance, and in fact outperforms the verb-path regression at  $K = 100$ . It is unclear why the vanilla model fails to increase performance in  $K$ . Note also, the vanilla model exhibits very little variability in prediction performance between model runs, in comparison to the smoothed model which is much more variable (presumably due to the higher number of parameters in the model); at small values of  $K$ , the smoothed model can perform poorly. It would also be interesting to analyze the smoothed model with higher values of  $K$  and find where it peaks.

We view the conflict detection task only as one of several validations, and thus turn to lexical evaluation of the induced frames. For lexical scale purity (bottom of Figure 3), the models perform about the same, with the smoothed model a little bit worse at some values of  $K$  (though sometimes with better stability of the fits—opposite of the conflict detection task). This suggests that semantic coherence does not benefit from the longer-

<sup>13</sup>In the latter, a problem-specific topic model did best.

range temporal dependencies.

In general, performance improves with higher  $K$ , but not beyond  $K = 50$ . This suggests the model reaches a limit for how fine-grained of semantics it can learn.

## 5.4 Case study

Here we qualitatively examine the narrative story between the dyad with the highest frequency of events in our dataset, the Israeli-Palestinian relationship, finding qualitative agreement with other case studies of this conflict (Brandt *et al.*, 2012; Goldstein *et al.*, 2001; Schrodt and Gerner, 2004). (The MID dataset does not include this conflict because the Palestinians are not considered a state actor.) Using the Associated Press subset, we plot the highest incidence frames from one run of the  $K = 20$  smoothed frame models, for the two directed dyads, and highlight some of the interesting relationships.

Figure 4(a) shows that tradeoffs in the use of military vs. police action by Israel towards the Palestinians tracks with major historical events. The first period in the data where police actions (‘impose, seal, capture, seize, arrest’) exceed military actions (‘kill, fire, enter, attack, raid’) is with the signing of the “Interim Agreement on the West Bank and the Gaza Strip,” also known as the Oslo II agreement. This balance persists until the abrupt breakdown in relations that followed the unsuccessful Camp David Summit in July of 2000, which generally marks the starting point of the wave of violence known as the Second Intifada.

In Figure 4(b) we show that our model produces a frame which captures the legal aftermath of particular events (‘accuse, criticize,’ but also ‘detain, release, extradite, charge’). Each of the major spikes in the data coincides with a particular event which either involves the investigation of a particular attack or series of attacks (as in A,B,E) or a discussion about prisoner swaps or mass arrests (as in events D, F, J).

Our model also picks up positive diplomatic events, as seen in Figure 4(c), a frame describing Israeli diplomatic actions towards Palestine (‘meet with, sign with, praise, say with, arrive in’). Not only do the spikes coincide with major peace treaties and negotiations, but the model correctly characterizes the relative lack of positively valenced action from the beginning of the Second Intifada until its end around 2005–2006.

In Figure 4(d) we show the relevant frames de-

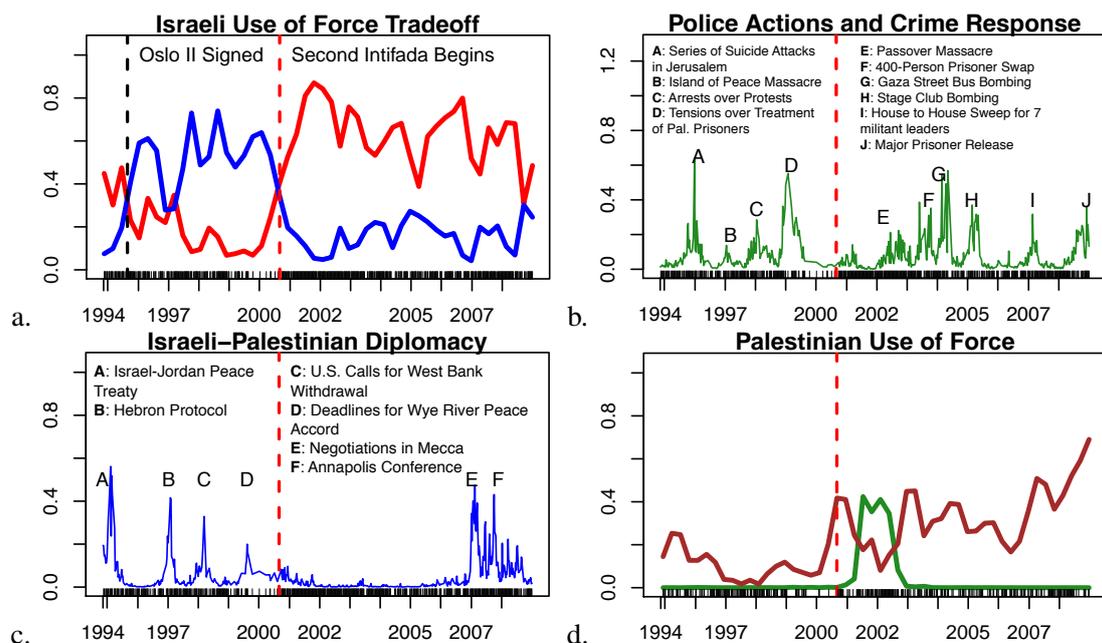

Figure 4: For Israel-Palestinian directed dyads, plots of  $E[\theta]$  (proportion of weekly events in a frame) over time, annotated with historical events. (a): Words are ‘kill, fire at, enter, kill, attack, raid, strike, move, pound, bomb’ and ‘impose, seal, capture, seize, arrest, ease, close, deport, close, release’ (b): ‘accuse, criticize, reject, tell, hand to, warn, ask, detain, release, order’ (c): ‘meet with, sign with, praise, say with, arrive in, host, tell, welcome, join, thank’ (d): again the same ‘kill, fire at’ frame in (a), plus the erroneous frame (see text) ‘include, join, fly to, have relation with, protest to, call, include bomber <sup>←appos</sup> informer for’. Figures (b) and (c) use linear interpolation for zero-count weeks (thus relying exclusively on the model for smoothing); (a) and (d) apply a loess smoother. (a-c) are for the ISR→PSE direction; (d) is PSE→ISR.

picting use of force from the Palestinians towards the Israelis (brown trend line). At first, the drop in the use of force frame immediately following the start of the Second Intifada seems inconsistent with the historical record. However, there is a concurrent rise in a different frame driven by the word ‘include’, which actually appears here due to an NLP error compounded with an artifact of the data source. A casualties report article, containing variants of the text “The Palestinian figure includes... 13 Israeli Arabs...”, is repeated 27 times over two years. “Palestinian figure” is erroneously identified as the PSE entity, and several noun phrases in a list are identified as separate receivers. This issue causes 39 of all 86 PSE→ISR events during this period to use the word ‘include’, accounting for the rise in that frame. (This highlights how better natural language processing could help the model, and the dangers of false positives for this type of data analysis, especially in small-sample drilldowns.) Discounting this erroneous inference, the results are consistent with heightened violence during this period.

We conclude the frame extractions for the Israeli-Palestinian case are consistent with the historical record over the period of study.

## 6 Related Work

### 6.1 Events Data in Political Science

Projects using hand-collected events data represent some of the earliest efforts in the statistical study of international relations, dating back to the 1960s (Rummel, 1968; Azar and Sloan, 1975; McClelland, 1970). Beginning in the mid-1980s, political scientists began experimenting with automated rule-based extraction systems (Schrodt and Gerner, 1994). These efforts culminated in the open-source program, TABARI, which uses pattern matching from extensive hand-developed phrase dictionaries, combined with basic part of speech tagging (Schrodt, 2001); a rough analogue in the information extraction literature might be the rule-based, finite-state FASTUS system for MUC IE (Hobbs *et al.*, 1997), though TABARI is restricted to single sentence analysis. Later proprietary work has apparently incorporated more extensive NLP (e.g., sentence parsing) though few details are available (King and Lowe, 2003). The most recent published work we know of, by Boschee *et al.* (2013), uses a proprietary parsing and coreference system (BBN SERIF, Ramshaw *et al.*, 2011), and directly compares to TABARI, finding significantly higher accuracy. The origi-

nal TABARI system is still actively being developed, including just-released work on a new 200 million event dataset, GDELT (Schrodtt and Leertaru, 2013).<sup>14</sup> All these systems crucially rely on hand-built pattern dictionaries.

It is extremely labor intensive to develop these dictionaries. Schrodtt (2006) estimates 4,000 trained person-hours were required to create dictionaries of political actors in the Middle East, and the phrase dictionary took dramatically longer; the comments in TABARI's phrase dictionary indicate some of its 15,789 entries were created as early as 1991. Ideally, any new events data solution would incorporate the extensive work already completed by political scientists in this area while minimizing the need for further dictionary development. In this work we use the actor dictionaries, and hope to incorporate the verb patterns in future work.

## 6.2 Events in Natural Language Processing

Political event extraction from news has also received considerable attention within natural language processing in part due to government-funded challenges such as MUC-3 and MUC-4 (Lehnert, 1994), which focused on the extraction of terrorist events, as well as the more recent ACE program. The work in this paper is inspired by unsupervised approaches that seek to discover types of relations and events, instead of assuming them to be pre-specified; this includes research under various headings such as template/frame/event learning (Cheung *et al.*, 2013; Modi *et al.*, 2012; Chambers and Jurafsky, 2011; Li *et al.*, 2010; Bejan, 2008), script learning (Regneri *et al.*, 2010; Chambers and Jurafsky, 2009), relation learning (Yao *et al.*, 2011), open information extraction (Banko *et al.*, 2007; Carlson *et al.*, 2010), verb caseframe learning (Rooth *et al.*, 1999; Gildea, 2002; Grenager and Manning, 2006; Lang and Lapata, 2010; Ó Séaghdha, 2010; Titov and Klementiev, 2012), and a version of frame learning called "unsupervised semantic parsing" (Titov and Klementiev, 2011; Poon and Domingos, 2009). Unlike much of the previous literature, we do not learn latent roles/slots. Event extraction is also a large literature, including supervised systems targeting problems similar to MUC and political events (Piskorski and Atkinson, 2011; Piskorski *et al.*, 2011; Sanfilippo *et al.*, 2008).

One can also see this work as a relational ex-

<sup>14</sup><http://eventdata.psu.edu/data.dir/GDELT.html>

ension of co-occurrence-based methods such as Gerrish (2013; ch. 4), Diesner and Carley (2005), Chang *et al.* (2009), or Newman *et al.* (2006), which perform bag-of-words-style analysis of text fragments containing co-occurring entities. (Gerrish also analyzed the international relations domain, using supervised bag-of-words regression to assess the expressed valence between a pair of actors in a news paragraph, using the predictions as observations in a latent temporal model, and compared to MID.) We instead use parsing to get a much more focused and interpretable representation of the relationship between textually co-occurring entities; namely, that they are the source and target of an action event. This is more in line with work in relation extraction on biomedical scientific articles (Friedman *et al.*, 2001; Rzhetsky *et al.*, 2004) which uses parsing to extracting a network of how different entities, like drugs or proteins, interact.

## 7 Conclusion

Large-scale information extraction can dramatically enhance the study of political behavior. Here we present a novel unsupervised approach to an important data collection effort in the social sciences. We see international relations as a rich and practically useful domain for the development of text analysis methods that jointly infer events, relations, and sociopolitical context. There are numerous areas for future work, such as: using verb dictionaries as semi-supervised seeds or priors; interactive learning between political science researchers and unsupervised algorithms; building low-dimensional scaling, or hierarchical structure, into the model; and learning the actor lists to handle changing real-world situations and new domains. In particular, adding more supervision to the model will be crucial to improve semantic quality and make it useful for researchers.

## Acknowledgments

Thanks to Justin Betteridge for providing the parsed Gigaword corpus, Erin Baggott for help in developing the document filter, and the anonymous reviewers for helpful comments. This research was supported in part by NSF grant IIS-1211277, and was made possible through the use of computing resources made available by the Pittsburgh Supercomputing Center. Brandon Stewart gratefully acknowledges funding from an NSF Graduate Research Fellowship.

## Abstract

Out-of-vocabulary (oov) words or phrases still remain a challenge in statistical machine translation especially when a limited amount of parallel text is available for training or when there is a domain shift from training data to test data. In this paper, we propose a novel approach to finding translations for oov words. We induce a lexicon by constructing a graph on source language monolingual text and employ a graph propagation technique in order to find translations for all the source language phrases. Our method differs from previous approaches by adopting a graph propagation approach that takes into account not only one-step (from oov directly to a source language phrase that has a translation) but multi-step paraphrases from oov source language words to other source language phrases and eventually to target language translations. Experimental results show that our graph propagation method significantly improves performance over two strong baselines under intrinsic and extrinsic evaluation metrics.

## 1 Introduction

Out-of-vocabulary (oov) words or phrases still remain a challenge in statistical machine translation. SMT systems usually copy unknown words verbatim to the target language output. Although this is helpful in translating a small fraction of oovs such as named entities for languages with same writing systems, it harms the translation in other types of oovs and distant language pairs. In general, copied-over oovs are a hindrance to fluent, high quality translation, and we can see evidence of this in automatic measures such as BLEU (Papineni et al., 2002) and also in human evaluation scores such as HTER. The problem becomes more severe when only a limited amount of parallel text is available for training or when the training and test data are from different domains. Even noisy translation of oovs can aid the language model to better

re-order the words in the target language (Zhang et al., 2012).

Increasing the size of the parallel data can reduce the number of oovs. However, there will always be some words or phrases that are new to the system and finding ways to translate such words or phrases will be beneficial to the system. Researchers have applied a number of approaches to tackle this problem. Some approaches use pivot languages (Callison-Burch et al., 2006) while others use lexicon-induction-based approaches from source language monolingual corpora (Koehn and Knight, 2002; Garera et al., 2009; Marton et al., 2009).

Pivot language techniques tackle this problem by taking advantage of available parallel data between the source language and a third language. Using a pivot language, oovs are translated into a third language and back into the source language and thereby paraphrases to those oov words are extracted (Callison-Burch et al., 2006). For each oov, the system can be augmented by aggregating the translations of all its paraphrases and assign them to the oov. However, these methods require parallel corpora between the source language and one or multiple pivot languages.

Another line of work exploits spelling and morphological variants of oov words. Habash (2008) presents techniques for online handling of oov words for Arabic to English such as spelling expansion and morphological expansion. Huang et al. (2011) proposes a method to combine sublexical/constituent translations of an oov word or phrase to generate its translations.

Several researchers have applied lexicon-induction methods to create a bilingual lexicon for those oovs. Marton et al. (2009) use a monolingual text on the source side to find paraphrases to oov words for which the translations are available. The translations for these paraphrases are

\*This research was partially supported by an NSERC, Canada (RGPIN: 264905) grant. The third author was supported by an early career research award from Monash University to visit Simon Fraser University.

then used as the translations of the oov word. These methods are based on the *distributional hypothesis* which states that words appearing in the same contexts tend to have similar meaning (Harris, 1954). Marton et al. (2009) showed that this method improves over the baseline system where oovs are untranslated.

We propose a graph propagation-based extension to the approach of Marton et al. (2009) in which a graph is constructed from source language monolingual text<sup>1</sup> and the source-side of the available parallel data. Nodes that have related meanings are connected together and nodes for which we have translations in the phrase-table are annotated with target-side translations and their feature values. A graph propagation algorithm is then used to propagate translations from labeled nodes to unlabeled nodes (phrases appearing only in the monolingual text and oovs). This provides a general purpose approach to handle several types of oovs, including morphological variants, spelling variants and synonyms<sup>2</sup>.

Constructing such a huge graph and propagating messages through it pose severe computational challenges. Throughout the paper, we will see how these challenges are dealt with using scalable algorithms.

## 2 Collocational Lexicon Induction

Rapp (1995) introduced the notion of a distributional profile in bilingual lexicon induction from monolingual data. A *distributional profile* (DP) of a word or phrase type is a co-occurrence vector created by combining all co-occurrence vectors of the tokens of that phrase type. Each distributional profile can be seen as a point in a  $|V|$ -dimensional space where  $V$  is the vocabulary where each word type represents a unique axis. Points (i.e. phrase types) that are close to one another in this high-dimensional space can represent paraphrases. This approach has also been used in machine translation to find in-vocabulary paraphrases for oov words on the source side and find a way to translate them.

### 2.1 Baseline System

Marton et al. (2009) was the first to successfully integrate a collocational approach to finding trans-

<sup>1</sup>Here on by monolingual data we always mean monolingual data on the source language

<sup>2</sup>Named entity oovs may be handled properly by copying or transliteration.

lations for oov words into an end-to-end SMT system. We explain their method in detail as we will compare against this approach. The method relies on monolingual distributional profiles (DPs) which are numerical vectors representing the context around each word. The goal is to find words or phrases that appear in similar contexts as the oovs. For each oov a distributional profile is created by collecting all words appearing in a fixed distance from all occurrences of the oov word in the monolingual text. These co-occurrence counts are converted to an association measure (Section 2.2) that encodes the relatedness of each pair of words or phrases.

Then, the most similar phrases to each oov are found by measuring the similarity of their DPs to that of the oov word. Marton et al. (2009) uses a heuristic to prune the search space for finding candidate paraphrases by keeping the surrounding context (e.g.  $L\_R$ ) of each occurrences of the oov word. All phrases that appear in any of such contexts are collected as candidate paraphrases. For each of these paraphrases, a DP is constructed and compared to that of the oov word using a similarity measure (Section 2.2).

The top-k paraphrases that have translations in the phrase-table are used to assign translations and scores to each oov word by marginalizing translations over paraphrases:

$$p(t|o) = \sum_s p(t|s)p(s|o)$$

where  $t$  is a phrase on the target side,  $o$  is the oov word or phrase, and  $s$  is a paraphrase of  $o$ .  $p(s|o)$  is estimated using a similarity measure over DPs and  $p(t|s)$  is coming from the phrase-table.

We reimplemented this collocational approach for finding translations for oovs and used it as a baseline system.

Alternative ways of modeling and comparing distributional profiles have been proposed (Rapp, 1999; Fung and Yee, 1998; Terra and Clarke, 2003; Garera et al., 2009; Marton et al., 2009). We review some of them here and compare their performance in Section 4.3.

### 2.2 Association Measures

Given a word  $u$ , its distributional profile  $DP(u)$  is constructed by counting surrounding words (in a fixed window size) in a monolingual corpus.

$$DP(u) = \{\langle A(u, w_i) \rangle \mid w_i \in V\}$$

The counts can be collected in positional<sup>3</sup> (Rapp, 1999) or non-positional way (count all the word occurrences within the sliding window).  $A(\cdot, \cdot)$  is an association measure and can simply be defined as co-occurrence counts within sliding windows. Stronger association measures can also be used such as:

**Conditional probability:** the probability for the occurrence of each word in DP given the occurrence of  $u$ :  $CP(u, w_i) = P(w_i|u)$  (Schütze and Pedersen, 1997)

**Pointwise Mutual Information:** this measure is a transformation of the independence assumption into a ratio. Positive values indicate that words co-occur more than what we expect under the independence assumption (Lin, 1998):

$$PMI(u, w_i) = \log_2 \frac{P(u, w_i)}{P(u)P(w_i)}$$

**Likelihood ratio:** (Dunning, 1993) uses the likelihood ratio for word similarity:

$$\lambda(u, w_i) = \frac{L(P(w_i|u); p) * L(P(w_i|\neg u); p)}{L(P(w_i|u); p_1) * L(P(w_i|\neg u); p_2)}$$

where  $L$  is likelihood function under the assumption that word counts in text have binomial distributions. The numerator represents the likelihood of the hypothesis that  $u$  and  $w_i$  are independent ( $P(w_i|u) = P(w_i|\neg u) = p$ ) and the denominator represents the likelihood of the hypothesis that  $u$  and  $w_i$  are dependent ( $P(w_i|u) \neq P(w_i|\neg u)$ ,  $P(w_i|u) = p_1$ ,  $P(w_i|\neg u) = p_2$ )<sup>4</sup>.

**Chi-square test:** is a statistical hypothesis testing method to evaluate independence of two categorical random variables, e.g. whether the *occurrence* of  $u$  and  $w_i$  (denoted by  $x$  and  $y$  respectively) are independent. The test statistics  $\chi^2(u, w_i)$  is the deviation of the observed counts  $f_{x,y}$  from their expected values  $E_{x,y}$ :

$$\chi^2(u, w_i) := \sum_{x \in \{w_i, \neg w_i\}} \sum_{y \in \{u, \neg u\}} \frac{(f_{x,y} - E_{x,y})^2}{E_{x,y}}$$

### 2.3 Similarity Measures

Various functions have been used to estimate the similarity between distributional profiles.

<sup>3</sup>e.g., position 1 is the word immediately after, position -1 is the word immediately before etc.

<sup>4</sup>Binomial distribution  $B(k; n, \theta)$  gives the probability of observing  $k$  heads in  $n$  tosses of a coin where the coin parameter is  $\theta$ . In our context,  $p$ ,  $p_1$  and  $p_2$  are parameters of Binomial distributions estimated using maximum likelihood.

Given two distributional profiles  $DP(u)$  and  $DP(v)$ , some similarity functions can be defined as follows. Note that  $A(\cdot, \cdot)$  stands for the various association measures defined in Sec. 2.2.

**Cosine coefficient** is the cosine the angle between two vectors  $DP(u)$  and  $DP(v)$ :

$$\cos(DP(u), DP(v)) = \frac{\sum_{w_i \in V} A(u, w_i)A(v, w_i)}{\sqrt{\sum_{w_i \in V} A(u, w_i)^2} \sqrt{\sum_{w_i \in V} A(v, w_i)^2}}$$

**$L_1$ -Norm** computes the accumulated distance between entries of two distributional profiles ( $L_1(\cdot, \cdot)$ ). It has been used as word similarity measure in language modeling (Dagan et al., 1999).

$$L_1(DP(u), DP(v)) = \sum_{w_i \in V} |A(u, w_i) - A(v, w_i)|$$

**Jensen-Shannon Divergence** is a symmetric version of *contextual average mutual information* ( $KL$ ) which is used by (Dagan et al., 1999) as word similarity measure.

$$JSD(DP(u), DP(v)) = KL(DP(u), AVG_{DP}(u, v)) + KL(DP(v), AVG_{DP}(u, v))$$

$$AVG_{DP}(u, v) = \left\{ \frac{A(u, w_i) + A(v, w_i)}{2} \mid w_i \in V \right\}$$

$$KL(DP(u), DP(v)) = \sum_{w_i \in V} A(u, w_i) \log \frac{A(u, w_i)}{A(v, w_i)}$$

## 3 Graph-based Lexicon Induction

We propose a novel approach to alleviate the oov problem. Given a (possibly small amount of) parallel data between the source and target languages, and a large monolingual data in the source language, we construct a graph over all phrase types in the monolingual text and the source side of the parallel corpus and connect phrases that have similar meanings (i.e. appear in similar context) to one another. To do so, the distributional profiles of all source phrase types are created. Each phrase type represents a vertex in the graph and is connected to other vertices with a weight defined by a similarity measure between the two profiles (Section 2.3). There are three types of vertices in the graph: i) labeled nodes which appear in the parallel corpus and for which we have the target-side

translations<sup>5</sup>; ii) oov nodes from the *dev/test set* for which we seek labels (translations); and iii) unlabeled nodes (words or phrases) from the *monolingual data* which appear usually between oov nodes and labeled nodes. When a relatively small parallel data is used, unlabeled nodes outnumber labeled ones and many of them lie on the paths between an oov node to labeled ones.

Marton et al. (2009)’s approach ignores these bridging nodes and connects each oov node to the  $k$ -nearest *labeled* nodes. One may argue that these unlabeled nodes do not play a major role in the graph and the labels will eventually get to the oov nodes from the labeled nodes by directly connecting them. However based on the definition of the similarity measures using context, it is quite possible that an oov node and a labeled node which are connected to the same unlabeled node do not share any context words and hence are not directly connected. For instance, consider three nodes,  $u$  (unlabeled),  $o$  (oov) and  $l$  (labeled) where  $u$  has the same left context words with  $o$  but share the right context with  $l$ .  $o$  and  $l$  are not connected since they do not share any context word.

Once a graph is constructed based on similarities of phrases, graph propagation is used to propagate the labels from labeled nodes to unlabeled and oov nodes. The approach is based on the *smoothness assumption* (Chapelle et al., 2006) which states if two nodes are similar according to the graph, then their output labels should also be similar.

The baseline approach (Marton et al., 2009) can be formulated as a *bipartite graph* with two types of nodes: labeled nodes ( $L$ ) and oov nodes ( $O$ ). Each oov node is connected to a number of labeled nodes, and vice versa and there is no edge between nodes of the same type. In such a graph, the similarity of each pair of nodes is computed using one of the similarity measures discussed above. The labels are translations and their probabilities (more specifically  $p(e|f)$ ) from the phrase-table extracted from the parallel corpus. Translations get propagated to oov nodes using a label propagation technique. However beside the difference in the oov label assignment, there is a major difference between our bipartite graph and the baseline (Marton et al., 2009): we do not use a heuristic to

<sup>5</sup>It is possible that a phrase appears in the parallel corpus, but not in the phrase-table. This happens when the word-alignment module is not able to align the phrase to a target side word or words.

reduce the number of neighbor candidates and we consider all possible candidates that share at least one context word. This makes a significant difference in practice as shown in Section 4.3.1.

We also take advantage of unlabeled nodes to help connect oov nodes to labeled ones. The discussed bipartite graph can easily be expanded to a *tripartite graph* by adding unlabeled nodes. Figure 1 illustrate a tripartite graph in which unlabeled nodes are connected to both labeled and oov nodes. Again, there is no edge between nodes of the same type. We also created the *full graph* where all nodes can be freely connected to nodes of any type including the same type. However, constructing such graph and doing graph propagation on it is computationally very expensive for large  $n$ -grams.

### 3.1 Label Propagation

Let  $G = (V, E, W)$  be a graph where  $V$  is the set of vertices,  $E$  is the set of edges, and  $W$  is the edge weight matrix. The vertex set  $V$  consists of labeled  $V_L$  and unlabeled  $V_U$  nodes, and the goal of the labeling propagation algorithm is to compute soft labels for unlabeled vertices from the labeled vertices. Intuitively, the edge weight  $W(u, v)$  encodes the degree of our belief about the similarity of the soft labeling for nodes  $u$  and  $v$ . A soft label  $\hat{Y}_v \in \Delta^{m+1}$  is a probability vector in  $(m + 1)$ -dimensional simplex, where  $m$  is the number of possible labels and the additional dimension accounts for the *undefined*  $\perp$  label<sup>6</sup>.

In this paper, we make use of the *modified Adsorption* (MAD) algorithm (Talukdar and Crammer, 2009) which finds soft label vectors  $\hat{Y}_v$  to solve the following unconstrained optimization problem:

$$\min_{\hat{Y}} \mu_1 \sum_{v \in V_L} p_{1,v} \|Y_v - \hat{Y}_v\|_2^2 + \quad (1)$$

$$\mu_2 \sum_{v,u} p_{2,v} W_{v,u} \|\hat{Y}_v - \hat{Y}_u\|_2^2 + \quad (2)$$

$$\mu_3 \sum_v p_{3,v} \|\hat{Y}_v - R_v\|_2^2 \quad (3)$$

where  $\mu_i$  and  $p_{i,v}$  are hyper-parameters ( $\forall v : \sum_i p_{i,v} = 1$ )<sup>7</sup>, and  $R_v \in \Delta^{m+1}$  encodes our prior belief about the labeling of a node  $v$ . The first

<sup>6</sup>Capturing those cases where the given data is not enough to reliably compute a soft labeling using the initial  $m$  real labels.

<sup>7</sup>The values of these hyper-parameters are set to their defaults in the *Junto* toolkit (Talukdar and Crammer, 2009).

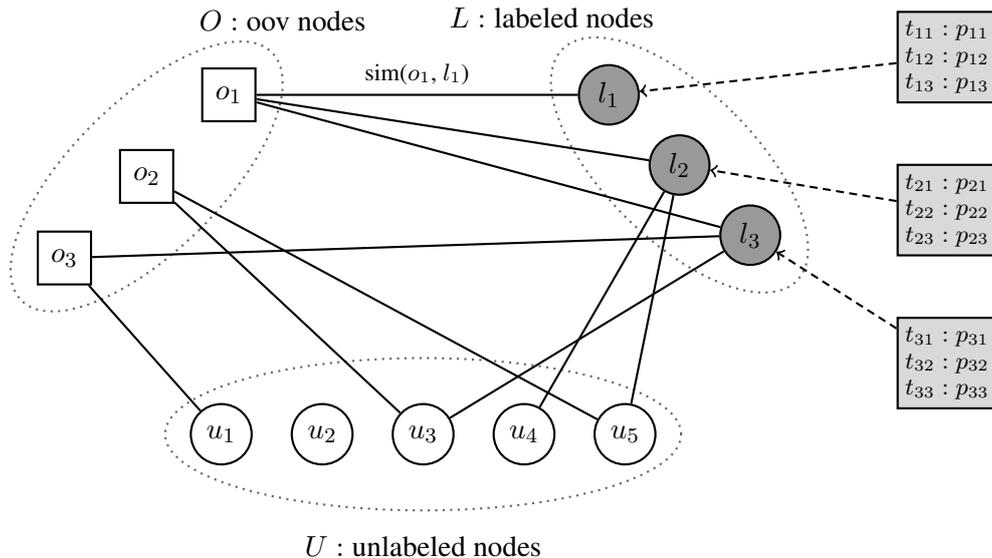

Figure 1: A tripartite graph between oov, labeled and unlabeled nodes. Translations propagate either directly from labeled nodes to oov nodes or indirectly via unlabeled nodes.

term (1) enforces the labeling of the algorithm to match the seed labeling  $Y_v$  with different extent for different labeled nodes. The second term (2) enforces the *smoothness* of the labeling according to the graph structure and edge weights. The last term (3) regularizes the soft labeling for a vertex  $v$  to match a priori label  $R_v$ , e.g. for high-degree unlabeled nodes (hubs in the graph) we may believe that the neighbors are not going to produce reliable label and hence the probability of undefined label  $\perp$  should be higher. The optimization problem can be solved with an efficient iterative algorithm which is parallelized in a MapReduce framework (Talukdar et al., 2008; Rao and Yarowsky, 2009). We used the *Junto label propagation* toolkit (Talukdar and Crammer, 2009) for label propagation.

### 3.2 Efficient Graph Construction

Graph-based approaches can easily become computationally very expensive as the number of nodes grow. In our case, we use phrases in the monolingual text as graph vertices. These phrases are n-grams up to a certain value, which can result in millions of nodes. For each node a distributional profile (DP) needs to be created. The number of possible edges can easily explode in size as there can be as many as  $O(n^2)$  edges where  $n$  is the number of nodes. A common practice to control the number of edges is to connect each node to at most  $k$  other nodes (k-nearest neigh-

bor). However, finding the top-k nearest nodes to each node requires considering its similarity to all the other nodes which requires  $O(n^2)$  computations and since  $n$  is usually very large, doing such is practically intractable. Therefore, researchers usually resort to an approximate k-NN algorithms such as *locality-sensitive hashing* (?; Goyal et al., 2012).

Fortunately, since we use context words as cues for relating their meaning and since the similarity measures are defined based on these cues, the number of neighbors we need to consider for each node is reduced by several orders of magnitude. We incorporate an inverted-index-style data structure which indicates what nodes are neighbors based on each context word. Therefore, the set of neighbors of a node consists of union of all the neighbors bridged by each context word in the DP of the node. However, the number of neighbors to be considered for each node even after this drastic reduction is still large (in order of a few thousands).

In order to deal with the computational challenges of such a large graph, we take advantage of the Hadoop’s MapReduce functionality to do both graph construction and label propagation steps.

## 4 Experiments & Results

### 4.1 Experimental Setup

We experimented with two different domains for the bilingual data: *Europarl* corpus (v7) (Koehn,

Dataset	Domain	Sents	Tokens	
			Fr	En
Bitext	Europarl	10K	298K	268K
	EMEA	1M	16M	14M
Monotext	Europarl	2M	60M	–
Dev-set	WMT05	2K	67K	58K
Test-set	WMT05	2K	66K	58K

Table 1: Statistics of training sets in different domains.

2005), and *European Medicines Agency* documents (EMEA) (Tiedemann, 2009) from French to English. For the monolingual data, we used French side of the Europarl corpus and we used ACL/WMT 2005<sup>8</sup> data for dev/test sets. Table 1 summarizes statistics of the datasets used.

From the dev and test sets, we extract all source words that do not appear in the phrase-table constructed from the parallel data. From the oovs, we exclude numbers as well as named entities. We apply a simple heuristic to detect named entities: basically words that are capitalized in the original dev/test set that do not appear at the beginning of a sentence are named entities. Table 2 shows the number of oov types and tokens for Europarl and EMEA systems in both dev and test sets.

Dataset	Dev		Test	
	types	tokens	types	tokens
Europarl	1893	2229	1830	2163
EMEA	2325	4317	2294	4190

Table 2: number of oovs in dev and test sets for Europarl and EMEA systems.

For the end-to-end MT pipeline, we used Moses (Koehn et al., 2007) with these standard features: relative-frequency and lexical translation model (TM) probabilities in both directions; distortion model; language model (LM) and word count. Word alignment is done using GIZA++ (Och and Ney, 2003). We used distortion limit of 6 and max-phrase-length of 10 in all the experiments. For the language model, we used the KenLM toolkit (Heafield, 2011) to create a 5-gram language model on the target side of the Europarl corpus (v7) with approximately 54M tokens with Kneser-Ney smoothing.

#### 4.1.1 Phrase-table Integration

Once the translations and their probabilities for each oov are extracted, they are added to the

<sup>8</sup><http://www.statmt.org/wpt05/mt-shared-task/>

phrase-table that is induced from the parallel text. The probability for new entries are added as a new feature in the log-linear framework to be tuned along with other features. The value of this newly introduced feature for original entries in the phrase-table is set to 1. Similarly, the value of original four probability features in the phrase-table for the new entries are set to 1. The entire training pipeline is as follows: (i) a phrase table is constructed using parallel data as usual, (ii) oovs for dev and test sets are extracted, (iii) oovs are translated using graph propagation, (iv) oovs and translations are added to the phrase table, introducing a new feature type, (v) the new phrase table is tuned (with a LM) using MERT (Och, 2003) on the dev set.

## 4.2 Evaluation

If we have a list of possible translations for oovs with their probabilities, we become able to evaluate different methods we discussed. We word-aligned the dev/test sets by concatenating them to a large parallel corpus and running GIZA++ on the whole set. The resulting word alignments are used to extract the translations for each oov. The correctness of this gold standard is limited to the size of the parallel data used as well as the quality of the word alignment software toolkit, and is not 100% precise. However, it gives a good estimate of how each oov should be translated without the need for human judgments.

For evaluating our baseline as well as graph-based approaches, we use both intrinsic and extrinsic evaluations. Two intrinsic evaluation metrics that we use to evaluate the possible translations for oovs are *Mean Reciprocal Rank* (MRR) (Voorhees, 1999) and *Recall*. Intrinsic evaluation metrics are faster to apply and are used to optimize different hyper-parameters of the approach (e.g. window size, phrase length, etc.). Once we come up with the optimized values for the hyper-parameters, we extrinsically evaluate different approaches by adding the new translations to the phrase-table and run it through the MT pipeline.

### 4.2.1 MRR

MRR is an Information Retrieval metric used to evaluate any process that produces a ranked list of possible candidates. The reciprocal rank of a list is the inverse of the rank of the correct answer in the list. Such score is averaged over a set, oov set

in our case, to get the mean-reciprocal-rank score.

$$\text{MRR} = \frac{1}{|O|} \sum_{i=1}^{|O|} \frac{1}{\text{rank}_i} \quad O = \{oov\}$$

In a few cases, there are multiple translations for an oov word (i.e. appearing more than once in the parallel corpus and being assigned to multiple different phrases), we take the average of reciprocal ranks for each of them.

#### 4.2.2 Recall

MRR takes the probabilities of oov translations into account in sorting the list of candidate translations. However, in an MT pipeline, the language model is supposed to rerank the hypotheses and move more appropriate translations (in terms of fluency) to the top of the list. Hence, we also evaluate our candidate translation regardless of the ranks. Since Moses uses a certain number of translations per source phrase (called the translation table limit or *ttl* which we set to 20 in our experiments), we use the *recall* measure to evaluate the top *ttl* translations in the list. Recall is another Information Retrieval measure that is the fraction of correct answers that are retrieved. For example, it assigns score of 1 if the correct translation of the oov word is in the top-k list and 0 otherwise. The scores are averaged over all oovs to compute recall.

$$\text{Recall} = \frac{|\{\text{gold standard}\} \cap \{\text{candidate list}\}|}{|\{\text{gold standard}\}|}$$

#### 4.3 Intrinsic Results

In Section 2.2 and 2.3, different types of association measures and similarity measures have been explained to build and compare distributional profiles. Table 3 shows the results on Europarl when using different similarity combinations. The measures are evaluated by fixing the window size to 4 and maximum candidate paraphrase length to 2 (e.g. bigram). First column shows the association measures used to build DPs. As the results show, the combination of PMI as association measure and cosine as DP similarity measure outperforms the other possible combinations. We use these two measures throughout the rest of the experiments.

Figure 2 illustrates the effects of different window sizes and paraphrase lengths on MRR. As the figure shows, the best MRR is reached when using window size of 4 and trigram nodes. Going from trigram to 4-gram results in a drop in MRR. One

Assoc	cosine(%)		$L_1$ norm(%)		JSD(%)	
	MRR	RCL	MRR	RCL	MRR	RCL
CP	1.66	4.16	2.18	5.55	2.33	6.32
LLR	1.79	4.26	0.13	0.37	0.5	1.00
PMI	<b>3.91</b>	<b>7.75</b>	0.50	1.17	0.59	1.21

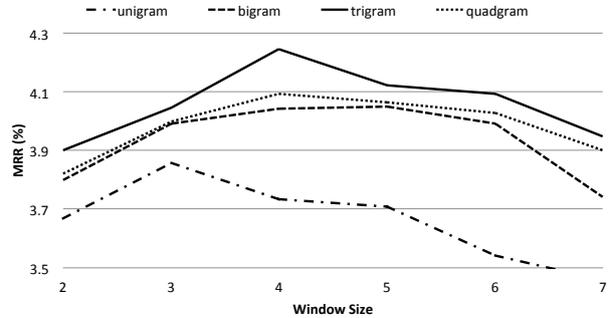

Figure 2: Effects of different window sizes and paraphrase length on the MRR of the dev set.

reason would be that distributional profiles for 4-grams are very sparse and that negatively affects the stability of similarity measures.

Figure 3 illustrates the effect of increasing the size of monolingual text on both MRR and recall.  $1\times$  refers to the case of using  $125k$  sentences for the monolingual text and the  $16\times$  indicates using the whole Europarl text on the source side ( $\approx 2M$  sentences). As shown, there is a linear correlation between the logarithm of the data size and the MRR and recall ratios. Interestingly, MRR is growing faster than recall by increasing the monolingual text size, which means that the scoring function gets better when more data is available. The figure also indicates that a much bigger monolingual text data can be used to further improve the quality of the translations, however, at the expense of more computational resources.

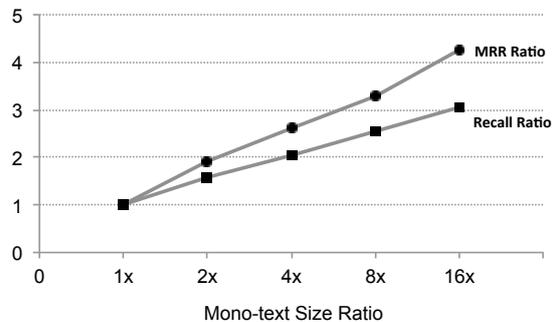

Figure 3: Effect of increasing the monolingual text size on MRR and Recall.

Graph	Neighbor	MRR %	RCL %
Bipartite	20	5.2	12.5
Tripartite	15+5	5.9	12.6
Full	20	5.1	10.9
Baseline	20	3.7	7.2

Tripartite	unigram	5.9	12.6
	bigram	6.9	15.9
Baseline	bigram	3.9	7.7

Table 5: Results on using unigram or bigram nodes.

### 4.3.1 Graph-based Results

Table 4 shows the intrinsic results on the Europarl corpus when using unigram nodes in each of the graphs. The results are evaluated on the dev-set based on the gold alignment created using GIZA++. Each node is connected to at most 20 other nodes (same as the max-paraphrase-limit in the baseline). For the tripartite graph, each node is connected to 15 labeled nodes and 5 unlabeled ones. The tripartite graph gets a slight improvement over the bipartite one, however, the full graph failed to have the same increase. One reason is that allowing paths longer than 2 between oov and labeled nodes causes more noise to propagate into the graph. In other words, a paraphrase of a paraphrase of a paraphrase is not necessarily a useful paraphrase for an oov as the translation may no longer be a valid one.

Table 5 also shows the effect of using bigrams instead of unigrams as graph nodes. There is an improvement by going from unigrams to bigrams in both bipartite and tripartite graphs. We did not use trigrams or larger n-grams in our experiments.

### 4.4 Extrinsic Results

The generated candidate translations for the oovs can be added to the phrase-table created using the parallel corpus to increase the coverage of the phrase-table. This aggregated phrase-table is to be tuned along with the language model on the dev set, and run on the test set. BLEU (Papineni et al., 2002) is still the de facto evaluation metric for machine translation and we use that to measure the quality of our proposed approaches for MT.

In these experiments, we do not use alignment information on dev or test sets unlike the previous section.

Table 6 reports the Bleu scores for different domains when the oov translations from the graph propagation is added to the phrase-table and compares them with the baseline system (i.e. Moses). Results for our approach is based on unigram tripartite graphs and show that we improve over the baseline in both the same-domain (Europarl) and domain adaptation (EMEA) settings.

Table 7 shows some translations found by our system for oov words.

## 5 Related work

There has been a long line of research on learning translation pairs from non-parallel corpora (Rapp, 1995; Koehn and Knight, 2002; Haghghi et al., 2008; Garera et al., 2009; Marton et al., 2009; Laws et al., 2010). Most have focused on extracting a translation lexicon by mining monolingual resources of data to find clues, using probabilistic methods to map words, or by exploiting the cross-language evidence of closely related languages. Most of them evaluated only high-frequency words of specific types (nouns or content words) (Rapp, 1995; Koehn and Knight, 2002; Haghghi et al., 2008; Garera et al., 2009; Laws et al., 2010) In contrast, we do not consider any constraint on our test data and our data includes many low frequency words. It has been shown that translation of high-frequency words is easier than low frequency words (Tamura et al., 2012).

Some methods have used a third language(s) as pivot or bridge to find translation pairs (Mann and Yarowsky, 2001; Schafer and Yarowsky, 2002; Callison-Burch et al., 2006).

\* Statistically significant with  $p < 0.02$  using the bootstrap resampling significance test (in Moses).

Table 6: Bleu scores for different domains with or without using oov translations.

Context similarity has been used effectively in bilingual lexicon induction (Rapp, 1995; Koehn and Knight, 2002; Haghighi et al., 2008; Garera et al., 2009; Marton et al., 2009; Laws et al., 2010). It has been modeled in different ways: in terms of adjacent words (Rapp, 1999; Fung and Yee, 1998), or dependency relations (Garera et al., 2009). Laws et al. (2010) used linguistic analysis in the form of graph-based models instead of a vector space. But all of these researches used an available seed lexicon as the basic source of similarity between source and target languages unlike our method which just needs a monolingual corpus of source language which is freely available for many languages and a small bilingual corpora.

Some methods tried to alleviate the lack of seed lexicon by using orthographic similarity to extract a seed lexicon (Koehn and Knight, 2002; Fiser and Ljubesic, 2011). But it is not a practical solution in case of unrelated languages.

Haghighi et al. (2008) and Daumé and Jagarlamudi (2011) proposed generative models based on canonical correlation analysis to extract translation lexicons for non-parallel corpora by learning a matching between source and target lexicons. Using monolingual features to represent words, feature vectors are projected from source and target words into a canonical space to find the appropriate matching between them. Their method relies on context features which need a seed lexicon and orthographic features which only works for phylogenetically related languages.

Graph-based semi-supervised methods have been shown to be useful for domain adaptation in MT as well. Alexandrescu and Kirchhoff (2009) applied a graph-based method to determine similarities between sentences and use these similarities to promote similar translations for similar sentences. They used a graph-based semi-supervised model to re-rank the n-best translation hypothesis. Liu et al. (2012) extended Alexandrescu’s model to use translation consensus among simi-

lar sentences in bilingual training data by developing a new structured label propagation method. They derived some features to use during decoding process that has been shown useful in improving translation quality. Our graph propagation method connects monolingual source phrases with oovs to obtain translation and so is a very different use of graph propagation from these previous works.

Recently label propagation has been used for lexicon induction (Tamura et al., 2012). They used a graph based on context similarity as well as co-occurrence graph in propagation process. Similar to our approach they used unlabeled nodes in label propagation process. However, they use a seed lexicon to define labels and comparable corpora to construct graphs unlike our approach.

## 6 Conclusion

We presented a novel approach for inducing oov translations from a monolingual corpus on the source side and a parallel data using graph propagation. Our results showed improvement over the baselines both in intrinsic evaluations and on BLEU. Future work includes studying the effect of size of parallel corpus on the induced oov translations. Increasing the size of parallel corpus on one hand reduces the number of oovs. But, on the other hand, there will be more labeled paraphrases that increases the chance of finding the correct translation for oovs in the test set.

Currently, we find paraphrases for oov words. However, oovs can be considered as n-grams (phrases) instead of unigrams. In this scenario, we also can look for paraphrases and translations for phrases containing oovs and add them to the phrase-table as new translations along with the translations for unigram oovs.

We also plan to explore different graph propagation objective functions. Regularizing these objective functions appropriately might let us scale to much larger data sets with an order of magnitude more nodes in the graph.

## Abstract

Recent advances in large-margin learning have shown that better generalization can be achieved by incorporating higher order information into the optimization, such as the spread of the data. However, these solutions are impractical in complex structured prediction problems such as statistical machine translation. We present an online gradient-based algorithm for relative margin maximization, which bounds the spread of the projected data while maximizing the margin. We evaluate our optimizer on Chinese-English and Arabic-English translation tasks, each with small and large feature sets, and show that our learner is able to achieve significant improvements of 1.2-2 BLEU and 1.7-4.3 TER on average over state-of-the-art optimizers with the large feature set.

## 1 Introduction

The desire to incorporate high-dimensional sparse feature representations into statistical machine translation (SMT) models has driven recent research away from Minimum Error Rate Training (MERT) (Och, 2003), and toward other discriminative methods that can optimize more features. Examples include minimum risk (Smith and Eisner, 2006), pairwise ranking (PRO) (Hopkins and May, 2011), RAMPION (Gimpel and Smith, 2012), and variations of the margin-infused relaxation algorithm (MIRA) (Watanabe et al., 2007; Chiang et al., 2008; Cherry and Foster, 2012). While the objective function and optimization method vary for each optimizer, they can all be broadly described as learning a linear model, or parameter vector  $\mathbf{w}$ , which is used to score alternative translation hypotheses.

In every SMT system, and in machine learning in general, the goal of learning is to find a

model that generalizes well, i.e. one that will yield good translations for previously unseen sentences. However, as the dimension of the feature space increases, generalization becomes increasingly difficult. Since only a small portion of all (sparse) features may be observed in a relatively small fixed set of instances during tuning, we are prone to overfit the training data. An alternative approach for solving this problem is estimating discriminative feature weights directly on the training bi-text (Tillmann and Zhang, 2006; Blunsom et al., 2008; Simianer et al., 2012), which is usually substantially larger than the tuning set, but this is complementary to our goal here of better generalization given a fixed size tuning set.

In order to achieve that goal, we need to carefully choose what objective to optimize, and how to perform parameter estimation of  $\mathbf{w}$  for this objective. We focus on large-margin methods such as SVM (Joachims, 1998) and passive-aggressive algorithms such as MIRA. Intuitively these seek a  $\mathbf{w}$  such that the *separating distance* in geometric space of two hypotheses is at least as large as the *cost* incurred by selecting the incorrect one. This criterion performs well in practice at finding a linear separator in high-dimensional feature spaces (Tsochantaridis et al., 2004; Crammer et al., 2006).

Now, recent advances in machine learning have shown that the generalization ability of these learners can be improved by utilizing second order information, as in the Second Order Perceptron (Cesa-Bianchi et al., 2005), Gaussian Margin Machines (Crammer et al., 2009b), confidence-weighted learning (Dredze and Crammer, 2008), AROW (Crammer et al., 2009a; Chiang, 2012) and Relative Margin Machines (RMM) (Shivaswamy and Jebara, 2009b). The latter, RMM, was introduced as an effective and less computationally expensive way to incorporate the *spread* of the data – second order information about the

distance between hypotheses when projected onto the line defined by the weight vector  $\mathbf{w}$ .

Unfortunately, not all advances in machine learning are easy to apply to structured prediction problems such as SMT; the latter often involve latent variables and surrogate references, resulting in loss functions that have not been well explored in machine learning (Mcalister and Keshet, 2011; Gimpel and Smith, 2012). Although Shivaswamy and Jebara extended RMM to handle sequential structured prediction (Shivaswamy and Jebara, 2009a), their batch approach to quadratic optimization, using existing off-the-shelf QP solvers, does not provide a practical solution: as Taskar et al. (2006) observe, “off-the-shelf QP solvers tend to scale poorly with problem and training sample size” for structured prediction problems. This motivates an online gradient-based optimization approach—an approach that is particularly attractive because its simple update is well suited for efficiently processing structured objects with sparse features (Crammer et al., 2012).

The contributions of this paper include (1) introduction of a loss function for structured RMM in the SMT setting, with surrogate reference translations and latent variables; (2) an online gradient-based solver, RM, with a closed-form parameter update to optimize the relative margin loss; and (3) an efficient implementation that integrates well with the open source cdec SMT system (Dyer et al., 2010).<sup>1</sup> In addition, (4) as our solution is not dependent on any specific QP solver, it can be easily incorporated into practically any gradient-based learning algorithm.

After background discussion on learning in SMT (§2), we introduce a novel online learning algorithm for relative margin maximization suitable for SMT (§3). First, we introduce RMM (§3.1) and propose a latent structured relative margin objective which incorporates cost-augmented hypothesis selection and latent variables. Then, we derive a simple closed-form online update necessary to create a large margin solution while simultaneously bounding the spread of the projection of the data (§3.2). Chinese-English translation experiments show that our algorithm, RM, significantly outperforms strong state-of-the-art optimizers, in both a basic feature setting and high-dimensional (sparse) feature space (§4). Additional Arabic-English experiments further validate these results,

<sup>1</sup><https://github.com/veidel/cdec>

even where previously MERT was shown to be advantageous (§5). Finally, we discuss the spread and other key issues of RM (§6), and conclude with discussion of future work (§7).

## 2 Learning in SMT

Given an input sentence in the source language  $x \in \mathcal{X}$ , we want to produce a translation  $y \in \mathcal{Y}(x)$  using a linear model parameterized by a weight vector  $\mathbf{w}$ :

$$(y^*, d^*) = \arg \max_{(y,d) \in \mathcal{Y}(x), \mathcal{D}(x)} \mathbf{w}^\top \mathbf{f}(x, y, d)$$

where  $\mathbf{w}^\top \mathbf{f}(x, y, d)$  is the weighted feature scoring function, hereafter  $s(x, y, d)$ , and  $\mathcal{Y}(x)$  is the space of possible translations of  $x$ . While many derivations  $d \in \mathcal{D}(x)$  can produce a given translation, we are only able to observe  $y$ ; thus we model  $d$  as a latent variable. Although our models are actually defined over derivations, they are always paired with translations, so our feature function  $\mathbf{f}(x, y, d)$  is defined over derivation–translation pairs.<sup>2</sup> The learning goal is then to estimate  $\mathbf{w}$ .

The instability of MERT in larger feature sets (Foster and Kuhn, 2009; Hopkins and May, 2011), has motivated many alternative tuning methods for SMT. These include strategies based on batch log-linear models (Tillmann and Zhang, 2006; Blunsom et al., 2008), as well as the introduction of online linear models (Liang et al., 2006a; Arun and Koehn, 2007).

Recent batch optimizers, PRO and RAMPION, and Batch-MIRA (Cherry and Foster, 2012), have been partly motivated by existing MT infrastructures, as they iterate between decoding the entire tuning set and optimizing the parameters. PRO considers tuning a classification problem and employs a binary classifier to rank pairs of outputs. RAMPION aims to address the disconnect between MT and machine learning by optimizing a structured ramp loss with a concave-convex procedure.

### 2.1 Large-Margin Learning

Online large-margin algorithms, such as MIRA, have also gained prominence in SMT, thanks to their ability to learn models in high-dimensional feature spaces (Watanabe et al., 2007; Chiang et al., 2009). The usual presentation of MIRA’s optimization problem is given as a quadratic program:

<sup>2</sup>We may omit  $d$  in some equations for clarity.

$$\mathbf{w}_{t+1} = \arg \min_{\mathbf{w}} \frac{1}{2} \|\mathbf{w} - \mathbf{w}_t\|^2 + C\xi_i \quad (1)$$

$$\text{s.t. } s(x_i, y_i, d) - s(x_i, y', d) \geq \Delta_i(y') - \xi_i$$

where  $y'$  is the single most violated constraint, the cost  $\Delta_i(y)$  is computed using an external measure of quality, such as 1-BLEU( $y_i, y$ ), and a slack variable  $\xi_i$  is introduced to allow for non-separable instances.  $C$  acts as a regularization parameter, trading off between margin maximization and constraint violations.

While solving the optimization problem relies on computing the margin between the correct output  $y_i$ , and  $y'$ , in SMT our decoder is often incapable of producing the reference translation, i.e.  $y_i \notin \mathcal{Y}(x_i)$ . We must instead resort to selecting a surrogate reference,  $y^+ \in \mathcal{Y}(x_i)$ . This issue has recently received considerable attention (Liang et al., 2006a; Eidelman, 2012; Chiang, 2012), with preference given to surrogate references obtained through cost-diminished hypothesis selection. Thus,  $y^+$  is selected based on a combination of model score and error metric from the  $k$ -best list produced by our current model. A similar selection is made for the cost-augmented hypothesis  $y^- \in \mathcal{Y}(x_i)$ :

$$(y^+, d^+) \leftarrow \arg \max_{(y,d) \in \mathcal{Y}(x_i), \mathcal{D}(x_i)} s(x_i, y, d) - \Delta_i(y)$$

$$(y^-, d^-) \leftarrow \arg \max_{(y,d) \in \mathcal{Y}(x_i), \mathcal{D}(x_i)} s(x_i, y, d) + \Delta_i(y)$$

In this setting, the optimization problem becomes:

$$\mathbf{w}_{t+1} = \arg \min_{\mathbf{w}} \frac{1}{2} \|\mathbf{w} - \mathbf{w}_t\|^2 + C\xi_i \quad (2)$$

$$\text{s.t. } \delta s(x_i, y^+, y^-) \geq \Delta_i(y^-) - \Delta_i(y^+) - \xi_i$$

where  $\delta s(x_i, y^+, y^-) = s(x_i, y^+, d^+) - s(x_i, y^-, d^-)$

This leads to a variant of the structured ramp loss to be optimized:

$$\begin{aligned} \ell = & \\ & - \max_{(y^+, d^+) \in \mathcal{Y}(x_i), \mathcal{D}(x_i)} (s(x_i, y^+, d^+) - \Delta_i(y^+)) \\ & + \max_{(y^-, d^-) \in \mathcal{Y}(x_i), \mathcal{D}(x_i)} (s(x_i, y^-, d^-) + \Delta_i(y^-)) \end{aligned} \quad (3)$$

The passive-aggressive update (Crammer et al., 2006), which is used to solve this problem, updates  $\mathbf{w}$  on each round such that the score of the correct hypothesis  $y^+$  is greater than the score of the incorrect  $y^-$  by a margin at least as large as the cost incurred by predicting the incorrect hypothesis, while keeping the change to  $\mathbf{w}$  small.

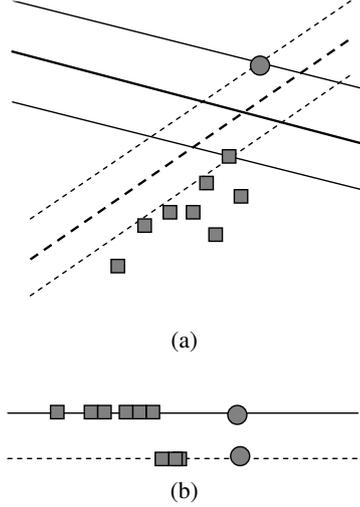

Figure 1: (a) RM and large margin solution comparison and (b) the spread of the projections given by each. RM and large margin solutions are shown with a darker dotted line and a darker solid line, respectively.

### 3 The Relative Margin Machine in SMT

#### 3.1 Relative Margin Machine

The margin, the distance between the correct hypothesis and incorrect one, is defined by  $s(x_i, y^+, d^+)$  and  $s(x_i, y^-, d^-)$ . It is maximized by minimizing the norm in SVM, or analogously, the proximity constraint in MIRA:  $\arg \min_{\mathbf{w}} \frac{1}{2} \|\mathbf{w} - \mathbf{w}_t\|^2$ . However, theoretical results supporting large-margin learning, such as the VC-dimension (Vapnik, 1995) or the Rademacher bound (Bartlett and Mendelson, 2003) consider measures of complexity, in addition to the empirical performance, when describing future predictive ability. The measures of complexity usually take the form of some value on the radius of the data, such as the ratio of the radius of the data to the margin (Shivaswamy and Jebara, 2009a). As radius is a way of measuring spread in any projection direction, here we will specifically be interested in the spread of the data as measured after the projection defined by the learned model  $\mathbf{w}$ .

More formally, the *spread* is the distance between  $y^+$ , and the worst candidate  $(y^w, d^w) \leftarrow \arg \min_{(y,d) \in \mathcal{Y}(x_i), \mathcal{D}(x_i)} s(x_i, y, d)$ , after projecting both onto the line defined by the weight vector  $\mathbf{w}$ . For each  $y'$ , this projection is conveniently given by  $s(x_i, y', d)$ , thus the spread is calculated as  $\delta s(x_i, y^+, y^w)$ .

RMM was introduced as a generalization over SVM that incorporates both the margin constraint

and information regarding the spread of the data. The relative margin is the ratio of the absolute, or maximum margin, to the spread of the projected data. Thus, the RMM learns a large margin solution relative to the spread of the data, or in other words, creates a max margin while simultaneously bounding the spread of the projected data. As a concrete example, consider the plot shown in Figure 1(a), with hypotheses represented by two-dimensional feature vectors. The point marked with a circle in the upper right represents  $\mathbf{f}(x_i, y^+)$ , while all other squares represent alternative incorrect hypotheses  $\mathbf{f}(x_i, y')$ . The large margin decision boundary is shown with a darker solid line, while the relative margin solution is shown with a darker dotted line. The lighter lines parallel to each define the margins, with the square at the intersection being  $\mathbf{f}(x_i, y^-)$ . The bottom portion of Figure 1(b) presents an alternative view of each solution, showing the projections of the hypotheses given the learned model of each. Notice that with a large margin solution, although the distance between  $y^+$  and  $y^-$  is greater, the points are highly spread, extending far to the left of the decision boundary.

In contrast, with a relative margin, although we have a smaller absolute margin, the spread is smaller, all points being within a smaller distance  $\epsilon$  of the decision boundary. The higher the spread of the projection, the higher the variance of the projected points, and the greater the likelihood that we will mislabel a new instance, since the high variance projections may cross the learned decision boundary. In higher dimensions, accounting for the spread becomes even more crucial, as will be discussed in Section 6.<sup>3</sup>

Although RMM is theoretically well-founded and improves practical performance over large-margin learning in the settings where it was introduced, it is unsuitable for most complex structured prediction in NLP. Nonetheless, since structured RMM is a generalization of Structured SVM, which shares its underlying objective with MIRA, our intuition is that SMT should be able to benefit as well. But to take advantage of the second-order information RMM utilizes for increased generalizability in SMT, we need a computationally effi-

<sup>3</sup>The motivation of confidence-weighted estimation (Dredze and Crammer, 2008) and AROW (Crammer et al., 2009a) is related in spirit. They use second-order information in the form of a distribution over weights to change the maximum margin solution.

cient optimization procedure that does not require batch training or an off-the-shelf QP solver.

### 3.2 RM Algorithm

We address the above-mentioned limitations by introducing a novel online learning algorithm for relative margin maximization, RM. The relative margin solution is obtained by maximizing the same margin as Equation (2), but now with respect to the distance between  $y^+$ , and the worst candidate  $y^w$ . Thus, the relative margin dictates trading-off between a large margin as before, and a small spread of the projection, in other words, bounding the distance between  $y^+$  and  $y^w$ . The additional computation required, namely, obtaining  $y^w$ , is efficient to perform, and has likely already happened while obtaining the  $k$ -best derivations necessary for the margin update. The online latent structured soft relative margin optimization problem is then:

$$\begin{aligned} \mathbf{w}_{t+1} &= \arg \min_{\mathbf{w}} \frac{1}{2} \|\mathbf{w} - \mathbf{w}_t\|^2 + C\xi_i + D\tau_i \\ \text{s.t.} \quad & \delta s(x_i, y^+, y^-) \geq \Delta_i(y^-) - \Delta_i(y^+) - \xi_i \\ & -B - \tau_i \leq \delta s(x_i, y^+, y^w) \leq B + \tau_i \end{aligned} \quad (4)$$

where additional bounding constraints are added to the usual margin constraints in order to contain the spread by bounding the difference in projections.  $B$  is an additional parameter; it controls the spread, trading off between margin maximization and spread minimization. Notice that when  $B \rightarrow \infty$ , the bounding constraints disappear, and we are left with the original problem in Equation (2).  $D$ , which plays an analogous role to  $C$ , allows penalized violations of the bounding constraints.

The dual of Equation (4) can be derived as:

$$\begin{aligned} \max_{\alpha, \beta, \beta^*} \mathcal{L} &= \sum_{y \in \mathcal{Y}(x_i)} \alpha_y - B \sum_{y \in \mathcal{Y}(x_i)} \beta_y - B \sum_{y \in \mathcal{Y}(x_i)} \beta_y^* \\ &- \frac{1}{2} \left\langle \sum_{y \in \mathcal{Y}(x_i)} \alpha_y \omega_i(y^+, y) - \sum_{y \in \mathcal{Y}(x_i)} \beta_y \omega_i(y^+, y) \right. \\ &\quad \left. + \sum_{y \in \mathcal{Y}(x_i)} \beta_y^* \omega_i(y^+, y), \right. \\ &\quad \left. \sum_{y' \in \mathcal{Y}(x_j)} \alpha_{y'} \omega_j(y^+, y') - \sum_{y' \in \mathcal{Y}(x_j)} \beta_{y'} \omega_j(y^+, y') \right. \\ &\quad \left. + \sum_{y' \in \mathcal{Y}(x_j)} \beta_{y'}^* \omega_j(y^+, y') \right\rangle \end{aligned} \quad (5)$$

where the  $\alpha$  Lagrange multiplier corresponds to the standard margin constraint, while  $\beta$  and

$\beta^*$  each correspond to a bounding constraint, and  $\omega_i(y^+, y')$  corresponds to the difference of  $f(x_i, y^+, d^+)$  and  $f(x_i, y', d')$ . The weight update can then be obtained from the dual variables:

$$\sum \alpha_y \omega_i(y^+, y) - \sum \beta_y \omega_i(y^+, y) + \sum \beta_y^* \omega_i(y^+, y) \quad (6)$$

The dual in Equation (5) can be optimized using a cutting plane algorithm, an effective method for solving a relaxed optimization problem in the dual, used in Structured SVM, MIRA, and RMM (Tsochantaridis et al., 2004; Chiang, 2012; Shivaswamy and Jebara, 2009a). The cutting plane presented in Alg. 1 decomposes the overall problem into subproblems which are solved independently by creating working sets  $S_i^j$ , which correspond to the largest violations of either the margin constraint, or bounding constraints, and iteratively satisfying the constraints in each set.

The cutting plane in Alg. 1 makes use of the the closed-form gradient-based updates we derived for RM presented in Alg. 2. The updates amount to performing a subgradient descent step to update  $\mathbf{w}$  in accordance with the constraints. Since the constraint matrix of the dual program is not strictly decomposable across constraint types, we are in effect solving an approximation of the original problem.

each set, if there is one, and perform the corresponding parameter updates in Alg. 2. We refer to the resulting passive-aggressive algorithm as RM-PA, and the cutting plane version as RM-CP. Preliminary experiments showed that RM-PA performs on par with RM-CP, thus RM-PA is the one used in the empirical evaluation below.

A graphical depiction of the passive-aggressive RM update is presented in Figure 2. The upper right circle represents  $y^+$ , while all other squares represent alternative hypotheses  $y'$ . As in the standard MIRA solution, we select the maximum margin constraint violator,  $y^-$ , shown as the triangle, and update such that the margin is greater than the cost. Additionally, we select the maximum bound-

ing constraint violator,  $y^w$ , shown as the upside-down triangle, and update so the distance from  $y^+$  is no greater than  $B$ .

## 4 Experiments

### 4.1 Setup

To evaluate the advantage of explicitly accounting for the spread of the data, we conducted several experiments on two Chinese-English translation test sets, using two different feature sets in each. For training we used the non-UN and non-HK Hansards portions of the NIST training corpora, which was segmented using the Stanford segmenter (Tseng et al., 2005). The data statistics are summarized in the top half of Table 1. The English data was lowercased, tokenized and aligned using GIZA++ (Och and Ney, 2003) to obtain bidirectional alignments, which were symmetrized using the grow-diag-final-and method (Koehn et al., 2003). We trained a 4-gram LM on the

English side of the corpus with additional words from non-NYT and non-LAT, randomly selected portions of the Gigaword v4 corpus, using modified Kneser-Ney smoothing (Chen and Goodman, 1996). We used cdec (Dyer et al., 2010) as our hierarchical phrase-based decoder, and tuned the parameters of the system to optimize BLEU (Papineni et al., 2002) on the NIST MT06 corpus.

We applied several competitive optimizers as baselines: hypergraph-based MERT (Kumar et al., 2009),  $k$ -best variants of MIRA (Crammer et al., 2006; Chiang et al., 2009), PRO (Hopkins and May, 2011), and RAMPION (Gimpel and Smith, 2012). The size of the  $k$ -best list was set to 500 for RAMPION, MIRA and RM, and 1500 for PRO, with both PRO and RAMPION utilizing  $k$ -best aggregation across iterations. RAMPION settings were as described in (Gimpel and Smith, 2012), and PRO settings as described in (Hopkins and May, 2011), with PRO requiring regularization tuning in order to be competitive with the other optimizers. MIRA and RM were run with 15 parallel learners using iterative parameter mixing (McDonald et al., 2010). All optimizers were implemented in cdec and use the same system configuration, thus the only independent variable is the optimizer itself. We set  $C$  to 0.01, and  $MaxIter$  to 100. We selected the bound step size  $D$ , based on performance on a held-out dev set, to be 0.01 for the basic feature set and 0.1 for the sparse feature set. The bound constraint  $B$  was set to 1.<sup>4</sup> The approximate sentence-level BLEU cost  $\Delta_i$  is computed in a manner similar to (Chiang et al., 2009), namely, in the context of previous 1-best translations of the tuning set. All results are averaged over 3 runs.

### 4.2 Feature Sets

We experimented with a small (basic) feature set, and a large (sparse) feature set. For the small feature set, we use 14 features, including a language model, 5 translation model features, penalties for unknown words, the glue rule, and rule arity. For experiments with a larger feature set, we introduced additional lexical and non-lexical sparse Boolean features of the form commonly found in the literature (Chiang et al., 2009; Watan-

<sup>4</sup>We also conducted an investigation into the setting of the  $B$  parameter. We explored alternative values for  $B$ , as well as scaling it by the current candidate’s cost, and found that the optimizer is fairly insensitive to these changes, resulting in only minor differences in BLEU.

Optimizer	Zh	Ar
MIRA	35k	37k
PRO	95k	115k
RAMPION	22k	24k
RM	30k	32k
Active+Inactive	3.4M	4.9M

Table 2: Active sparse feature templates

abe et al., 2007; Simianer et al., 2012).

Non-lexical features include structural distortion, which captures the dependence between re-ordering and the size of a filler, and rule shape, which bins grammar rules by their sequence of terminals and nonterminals (Chiang et al., 2008). Lexical features on rules include rule ID, which fires on a specific grammar rule. We also introduce context-dependent lexical features for the 300 most frequent aligned word pairs  $(f, e)$  in the training corpus, which fire on triples  $(f, e, f_{+1})$  and  $(f, e, f_{-1})$ , capturing when we see  $f$  aligned to  $e$ , with  $f_{+1}$  and  $f_{-1}$  occurring to the right or left of  $f$ , respectively. All other words fall into the default  $\langle unk \rangle$  feature bin. In addition, we have insertion and deletion features for the 150 most frequently unaligned target and source words. These feature templates resulted in a total of 3.4 million possible features, of which only a fraction were active for the respective tuning set and optimizer, as shown in Table 2.

### 4.3 Results

As can be seen from the results in Table 3, our RM method was the best performer in all Chinese-English tests according to all measures – up to 1.9 BLEU and 6.6 TER over MIRA – even though we only optimized for BLEU.<sup>5</sup> Surprisingly, it seems that MIRA did not benefit as much from the sparse features as RM. The results are especially notable for the basic feature setting – up to 1.2 BLEU and 4.6 TER improvement over MERT – since MERT has been shown to be competitive with small numbers of features compared to high-dimensional optimizers such as MIRA (Chiang et al., 2008).

For the tuning set, the decoder performance was consistently the *lowest* with RM, compared to the

<sup>5</sup>In the small feature set RAMPION yielded similar best BLEU scores, but worse TER. In preliminary experiments with a smaller trigram LM, our RM method consistently yielded the highest scores in all Chinese-English tests – up to 1.6 BLEU and 6.4 TER from MIRA, the second best performer.

other optimizers. We believe this is due to the RM bounding constraint being more resistant to overfitting the training data, and thus allowing for improved generalization. Conversely, while PRO had the second lowest tuning scores, it seemed to display signs of underfitting in the basic and large feature settings.

## 5 Additional Experiments

In order to explore the applicability of our approach to a wider range of languages, we also evaluated its performance on Arabic-English translation. All experimental details were the same as above, except those noted below.

For training, we used the non-UN portion of the NIST training corpora, which was segmented using an HMM segmenter (Lee et al., 2003). Dataset statistics are given in the bottom part of Table 1. The sparse feature templates resulted here in a total of 4.9 million possible features, of which again only a fraction were active, as shown in Table 2.

As can be seen in Table 4, in the smaller feature set, RM and MERT were the best performers, with the exception that on MT08, MIRA yielded somewhat better (+0.7) BLEU but a somewhat worse (-0.9) TER score than RM.

On the large feature set, RM is again the best performer, except, perhaps, a tied BLEU score with MIRA on MT08, but with a clear 1.8 TER gain. In both Arabic-English feature sets, MIRA seems to take the second place, while RAMPION lags behind, unlike in Chinese-English (§4).<sup>6</sup>

Interestingly, RM achieved substantially higher BLEU precision scores in all tests for both language pairs. However, this was also usually coupled had a higher brevity penalty (BP) than MIRA, with the BP increasing slightly when moving to the sparse setting.

## 6 Discussion

The trend of the results, summarized as RM gain over other optimizers averaged over all test sets, is presented in Table 5. RM shows clear advantage in both basic and sparse feature sets, over all other state-of-the-art optimizers. The RM gains are notably higher in the large feature set, which we take

<sup>6</sup>In our preliminary experiments with the smaller trigram LM, MERT did better on MT05 in the smaller feature set, and MIRA had a small advantage in two cases. RAMPION performed similarly to RM on the smaller feature set. RM’s loss was only up to 0.8 BLEU (0.7 TER) from MERT or MIRA, while its gains were up to 1.7 BLEU and 2.1 TER over MIRA.

RAMPION	0.6	1.6	1.2	2.8

Table 5: RM gain over other optimizers averaged over all test sets.

as an indication for the importance of bounding the spread.

**Spread analysis:** For RM, the average spread of the projected data in the Chinese-English small feature set was  $0.9 \pm 3.6$  for all tuning iterations, and  $0.7 \pm 2.9$  for the iteration with the highest decoder performance. In comparison, the spread of the data for MIRA was  $5.9 \pm 20.5$  for the best iteration. In the sparse setting, RM had an average spread of  $0.9 \pm 2.4$  for the best iteration, while MIRA had a spread of  $14.0 \pm 31.1$ . Similarly, on Arabic-English, RM had a spread of  $0.7 \pm 2.4$  in the small setting, and  $0.82 \pm 1.4$  in the sparse setting, while MIRA’s spread was  $9.4 \pm 26.8$  and  $11.4 \pm 22.1$ , for the small and sparse settings, respectively. Notice that the average spread for RM stays about the same when moving to higher dimensions, with the variance decreasing in both cases. For MIRA, however, the average spread

increases in both cases, with the variance being much higher than RM. For instance, observe that the spread of MIRA on Chinese grows from 5.9 to 14.0 in the sparse feature setting. While bounding the spread is useful in the low-dimensional setting (0.7-1.5 BLEU gain with RM over MIRA as shown in Table 3), accounting for the spread is even more crucial with sparse features, where MIRA gains only up to 0.1 BLEU, while RM gains 1 BLEU. These results support the claim that our imposed bound  $B$  indeed helps decrease the spread, and that, in turn, lower spread yields better generalization performance.

**Error Analysis:** The inconclusive advantage of RM over MIRA (in BLEU vs. TER scores) on Arabic-English MT08 calls for a closer look. Therefore we conducted a coarse error analysis on 15 randomly selected sentences from MERT, RMM and MIRA, with basic and sparse feature settings for the latter two. This sample yielded 450 data points for analysis: output of the 5 conditions on 15 sentences scored in 6 violation categories. The categories were: function word drop, content word drop, syntactic error (with a reasonable meaning), semantic error (regardless of syntax), word order issues, and function word mis-translation and “hallucination”. The purpose of this analysis was to get a *qualitative* feel for the output of each model, and a better idea as to why we obtained performance improvements. RM no-

ticeably had more word order and excess/wrong function word issues in the basic feature setting than any optimizer. However, RM seemed to benefit the most from the sparse features, as its bad word order rate dropped close to MIRA, and its excess/wrong function word rate dropped below that of MIRA with sparse features (MIRA’s rate actually doubled from its basic feature set). We conjecture both these issues will be ameliorated with syntactic features such as those in Chiang et al. (2008). This correlates with our observation that RM’s overall BLEU score is negatively impacted by the BP, as the BLEU precision scores are noticeably higher.

**K-best:** RM is potentially more sensitive to the size and order of the  $k$ -best list. While MIRA is only concerned with the margin between  $y^+$  and  $y^-$ , RM also accounts for the distance between  $y^+$  and  $y^w$ . It might be the case that a larger  $k$ -best, or revisiting previous strategies for  $y^+$  and  $y^-$  selection, such as bold updating, local updating (Liang et al., 2006b), or max-BLEU updating (Tillmann and Zhang, 2006) might have a greater impact. Also, we only explored several settings of  $B$ , and there remains a continuum of RM solutions that trade off between margin and spread in different ways.

**Active features:** Perhaps contrary to expectation, we did not see evidence of a correlation between the number of active features and optimizer performance. RAMPION, with the fewest features, is the closest performer to RM in Chinese, while MIRA, with a greater number, is the closest on Arabic. We also notice that while PRO had the lowest BLEU scores in Chinese, it was competitive in Arabic with the highest number of features.

## 7 Conclusions and Future Work

We have introduced RM, a novel online margin-based algorithm designed for optimizing high-dimensional feature spaces, which introduces constraints into a large-margin optimizer that bound the spread of the projection of the data while maximizing the margin. The closed-form online update for our relative margin solution accounts for surrogate references and latent variables.

Experimentation in statistical MT yielded significant improvements over several other state-of-the-art optimizers, especially in a high-dimensional feature space (up to 2 BLEU and 4.3 TER on average). Overall, RM achieves the best or

comparable performance according to two scoring methods in two language pairs, with two test sets each, in small and large feature settings. Moreover, across conditions, RM always yielded the best combined TER-BLEU score.<sup>7</sup>

These improvements are achieved using standard, relatively small tuning sets, contrasted with improvements involving sparse features obtained using much larger tuning sets, on the order of hundreds of thousands of sentences (Liang et al., 2006a; Tillmann and Zhang, 2006; Blunsom et al., 2008; Simianer et al., 2012). Since our approach is complementary to scaling up the tuning data, in future work we intend to combine these two methods. In future work we also intend to explore using additional sparse features that are known to be useful in translation, e.g. syntactic features explored by Chiang et al. (2008).

Finally, although motivated by statistical machine translation, RM is a gradient-based method that can easily be applied to other problems. We plan to investigate its utility elsewhere in NLP (e.g. for parsing) as well as in other domains involving high-dimensional structured prediction.

## Abstract

Predicate-argument structure (PAS) has been demonstrated to be very effective in improving SMT performance. However, since a source-side PAS might correspond to multiple different target-side PASs, there usually exist many PAS ambiguities during translation. In this paper, we group PAS ambiguities into two types: role ambiguity and gap ambiguity. Then we propose two novel methods to handle the two PAS ambiguities for SMT accordingly: 1) inside context integration; 2) a novel maximum entropy PAS disambiguation (MEPD) model. In this way, we incorporate rich context information of PAS for disambiguation. Then we integrate the two methods into a PAS-based translation framework. Experiments show that our approach helps to achieve significant improvements on translation quality.

## 1 Introduction

Predicate-argument structure (PAS) depicts the relationship between a predicate and its associated arguments, which indicates the skeleton structure of a sentence on semantic level. Basically, PAS agrees much better between two languages than syntax structure (Fung et al., 2006; Wu and Fung, 2009b). Considering that current syntax-based translation models are always impaired by cross-lingual structure divergence (Eisner, 2003; Zhang et al., 2010), PAS is really a better representation of a sentence pair to model the bilingual structure mapping.

However, since a source-side PAS might correspond to multiple different target-side PASs, there usually exist many PAS ambiguities during translation. For example, in Figure 1, (a) and (b) carry the same source-side PAS  $\langle [A0]_1 [Pred(\text{是})]_2 [A1]_3 \rangle$  for Chinese predicate “是”. However, in Figure 1(a), the corresponding target-side-like PAS is  $\langle [X_1] [X_2] [X_3] \rangle$ , while in

Figure 1(b), the counterpart target-side-like PAS<sup>1</sup> is  $\langle [X_2] [X_3] [X_1] \rangle$ . This is because the two PASs play different roles in their corresponding sentences. Actually, Figure 1(a) is an independent PAS, while Figure 1(b) is a modifier of the noun phrase “中国和俄罗斯”. We call this kind of PAS ambiguity *role ambiguity*.

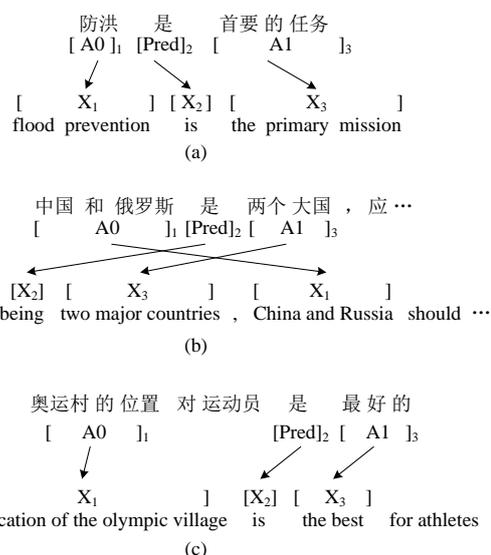

Figure 1. An example of ambiguous PASs.

Meanwhile, Figure 1 also depicts another kind of PAS ambiguity. From Figure 1, we can see that (a) and (c) get the same source-side PAS and target-side-like PAS. However, they are different because in Figure 1(c), there is a gap string “对运动员” between [A0] and [Pred]. Generally, the gap strings are due to the low recall of automatic semantic role labeling (SRL) or complex sentence structures. For example, in Figure 1(c), the gap string “对运动员” is actually an argument “AM-PRP” of the PAS, but the SRL system has

<sup>1</sup>We use *target-side-like PAS* to refer to a list of general non-terminals in target language order, where a non-terminal aligns to a source argument.

ignored it. We call this kind of PAS ambiguity *gap ambiguity*.

During translation, these PAS ambiguities will greatly affect the PAS-based translation models. Therefore, in order to incorporate the bilingual PAS into machine translation effectively, we need to decide which target-side-like PAS should be chosen for a specific source-side PAS. We call this task *PAS disambiguation*.

In this paper, we propose two novel methods to incorporate rich context information to handle PAS ambiguities. Towards the gap ambiguity, we adopt a method called *inside context integration* to extend PAS to IC-PAS. In terms of IC-PAS, the gap strings are combined effectively to deal with the gap ambiguities. As to the role ambiguity, we design a novel *maximum entropy PAS disambiguation (MEPD)* model to combine various context features, such as context words of PAS. For each ambiguous source-side PAS, we build a specific MEPD model to select appropriate target-side-like PAS for translation. We will detail the two methods in Section 3 and 4 respectively.

Finally, we integrate the above two methods into a PAS-based translation framework (Zhai et al. 2012). Experiments show that the two PAS disambiguation methods significantly improve the baseline translation system. The main contribution of this work can be concluded as follows:

- 1) We define two kinds of PAS ambiguities: role ambiguity and gap ambiguity. To our best knowledge, we are the first to handle these PAS ambiguities for SMT.
- 2) Towards the two different ambiguities, we design two specific methods for PAS disambiguation: inside context integration and the novel MEPD model.

## 2 PAS-based Translation Framework

PAS-based translation framework is to perform translation based on PAS transformation (Zhai et al., 2012). In the framework, a source-side PAS is first converted into target-side-like PASs by PAS transformation rules, and then perform translation based on the obtained target-side-like PASs.

### 2.1 PAS Transformation Rules

PAS transformation rules (PASTR) are used to convert a source-side PAS into a target one. Formally, a PASTR is a triple  $\langle Pred, SP, TP \rangle$ :

- *Pred* means the predicate where the rule is extracted.
- *SP* denotes the list of source elements in source language order.
- *TP* refers to the target-side-like PAS, i.e., a list of general non-terminals in target language order.

For example, Figure 2 shows the PASTR extracted from Figure 1(a). In this PASTR, *Pred* is Chinese verb “是”, *SP* is the source element list  $\langle [A0]_1 [Pred]_2 [A1]_3 \rangle$ , and *TP* is the list of non-terminals  $\langle X_1 X_2 X_3 \rangle$ . The same subscript in *SP* and *TP* means a one-to-one mapping between a source element and a target non-terminal. Here, we utilize the source element to refer to the predicate or argument of the source-side PAS.

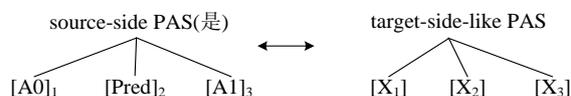

Figure 2. An example PASTR.

### 2.2 PAS Decoding

The PAS decoding process is divided into 3 steps:

(1) **PAS acquisition**: perform semantic role labeling (SRL) on the input sentences to achieve their PASs, i.e., source-side PASs;

(2) **Transformation**: use the PASTR to match the source-side PAS i.e., the predicate *Pred* and the source element list *SP*. Then by the matching PASTRs, transform source-side PASs to target-side-like PASs.

(3) **Translation**: in this step, the decoder first translates each source element respectively, and then a CKY-style decoding algorithm is adopted to combine the translation of each element and get the final translation of the PAS.

### 2.3 Sentence Decoding with the PAS-based translation framework

Sometimes, the source sentence cannot be fully covered by the PAS, especially when there are several predicates. Thus to translate the whole sentence, Zhai et al. (2012) further designed an algorithm to decode the entire sentence.

In the algorithm, they organized the space of translation candidates into a hypergraph. For the span covered by PAS (PAS span), a multiple-branch hyperedge is employed to connect it to the PAS's elements. For the span not covered by PAS (non-PAS span), the decoder considers all the possible binary segmentations of it and utilizes binary hyperedges to link them.

During translation, the decoder fills the spans with translation candidates in a bottom-up manner. For the PAS span, the PAS-based translation framework is adopted. Otherwise, the BTG system (Xiong et al., 2006) is used. When the span covers the whole sentence, we get the final translation result.

Obviously, PAS ambiguities are not considered in this framework at all. The target-side-like PAS is selected only according to the language model and translation probabilities, without considering any context information of PAS. Consequently, it would be difficult for the decoder to distinguish the source-side PAS from different context. This harms the translation quality. Thus to overcome this problem, we design two novel methods to cope with the PAS ambiguities: inside-context integration and a maximum entropy PAS disambiguation (MEPD) model. They will be detailed in the next two sections.

### 3 Inside Context Integration

In this section, we integrate the inside context of the PAS into PASTRs to do PAS disambiguation. Basically, a PAS consists of several elements (a predicate and several arguments), which are actually a series of continuous spans. For a specific PAS  $\langle E_1, \dots, E_n \rangle$ , such as the source-side PAS  $\langle [A0][Pred][A1] \rangle$  in Figure 2, its *controlled range* is defined as:

$$range(PAS) = \{s(E_i), \forall i \in [1, n]\}$$

where  $s(E_i)$  denotes the span of element  $E_i$ . Further, we define the *closure range* of a PAS. It refers to the shortest continuous span covered by the entire PAS:

$$closure\_range = \left[ \min_{j \in s(E_0)} j, \max_{j \in s(E_n)} j \right]$$

Here,  $E_0$  and  $E_n$  are the leftmost and rightmost element of the PAS respectively. The closure range is introduced here because adjacent source elements in a PAS are usually separated by gap strings in the sentence. We call these gap strings the *inside context* (IC) of the PAS, which satisfy:

$$closure\_range(PAS) = \oplus (IC(PAS) \cup range(PAS))$$

The operator  $\oplus$  takes a list of neighboring spans as input<sup>2</sup>, and returns their combined continuous span. As an example, towards the PAS “ $\langle [A0][Pred][A1] \rangle$ ” (the one for Chinese predicate “是(shi)”) in Figure 3, its controlled range is  $\{[3,5],[8,8],[9,11]\}$  and its closure range is  $[3,11]$ . The IC of the PAS is thus  $\{[6,7]\}$ .

To consider the PAS’s IC during PAS transformation process, we incorporate its IC into the extracted PASTR. For each gap string in IC, we abstract it by the sequence of highest node categories (named as s-tag sequence). The s-tag sequence dominates the corresponding syntactic tree fragments in the parse tree. For example, in Figure 3, the s-tag sequence for span  $[6,8]$  is “PP VC”. Thus, the sequence for the IC (span  $[6,7]$ ) in Figure 3 is “PP”. We combine the s-tag sequences with elements of the PAS in order. The resulting PAS is called IC-PAS, just like the left side of Figure 4(b) shows.

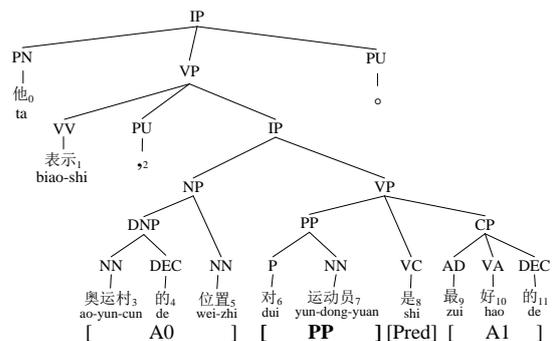

Figure 3. The illustration of inside context (IC). The subscript in each word refers to its position in sentence.

Differently, Zhai et al. (2012) attached the IC to its neighboring elements based on parse trees. For example, in Figure 3, they would attach the gap string “对(dui) 运动员(yun-dong-yuan)” to the PAS’s element “Pred”, and then the span of “Pred” would become  $[6,8]$ . Consequently, the span  $[6,8]$  will be translated as a whole source element in the decoder. This results in a bad translation because the gap string “对(dui) 运动员(yun-dong-yuan)” and predicate “是(shi)” should be translated separately, just as Figure 4(a) shows. Therefore, we can see that the attachment decision in (Zhai et al., 2012) is sometimes unreasonable and the IC also cannot be used for PAS disambiguation at all. In contrast, our meth-

<sup>2</sup> Here, two spans are neighboring means that the beginning of the latter span is the former span’s subsequent word in the sentence. For example, span  $[3,6]$  and  $[7,10]$  are neighboring spans.

od of inside context integration is much flexible and beneficial for PAS disambiguation.

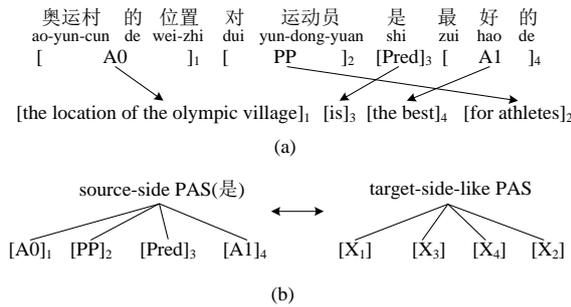

Figure 4. Example of IC-PASTR. (a) The aligned span of each element of the PAS in Figure 3; (b) The extracted IC-PASTR from (a).

Using the IC-PASs, we look for the aligned target span for each element of the IC-PAS. We demand that every element and its corresponding target span must be consistent with word alignment. Otherwise, we discard the IC-PAS. Afterwards, we can easily extract a rule for PAS transformation, which we call IC-PASTR. As an example, Figure 4(b) is the extracted IC-PASTR from Figure 4(a).

Note that we only apply the source-side PAS and word alignment for IC-PASTR extraction. By contrast, Zhai et al. (2012) utilized the result of bilingual SRL (Zhuang and Zong, 2010b). Generally, bilingual SRL could give a better alignment between bilingual elements. However, bilingual SRL usually achieves a really low recall on PASs, about 226,968 entries in our training set while it is 882,702 by using monolingual SRL system. Thus to get a high recall for PASs, we only utilize word alignment instead of capturing the relation between bilingual elements. In addition, to guarantee the accuracy of IC-PASTRs, we only retain rules with more than 5 occurrences.

#### 4 Maximum Entropy PAS Disambiguation (MEPD) Model

In order to handle the role ambiguities, in this section, we concentrate on utilizing a maximum entropy model to incorporate the context information for PAS disambiguation. Actually, the disambiguation problem can be considered as a multi-class classification task. That is to say, for a source-side PAS, every corresponding target-side-like PAS can be considered as a label. For example, in Figure 1, for the source-side PAS “[A0]1[Pred]2[A1]3”, the target-side-like PAS “[X1] [X2] [X3]” in Figure 1(a) is thus a label and

“[X2] [X3] [X1]” in Figure 1(b) is another label of this classification problem.

The maximum entropy model is the classical way to handle this problem:

$$P_{\theta}(tp | sp, c(sp), c(tp)) = \frac{\exp(\sum_i \theta_i h_i(sp, tp, c(sp), c(tp)))}{\sum_{sp'} \exp(\sum_i \theta_i h_i(sp, tp, c(sp), c(tp)))}$$

where  $sp$  and  $tp$  refer to the source-side PAS (not including the predicate) and the target-side-like PAS respectively.  $c(sp)$  and  $c(tp)$  denote the surrounding context of  $sp$  and  $tp$ .  $h_i$  is a binary feature function and  $\theta_i$  is the weight of  $h_i$ .

We train a maximum entropy classifier for each  $sp$  via the off-the-shelf MaxEnt toolkit<sup>3</sup>. Note that to avoid sparseness,  $sp$  does not include predicate of the PAS. Practically, the predicate serves as a feature of the MEPD model. As an example, for the rule illustrated in Figure 4(b), we build a MEPD model for its source element list  $sp <[A0] [PP] [Pred] [A1]>$ , and integrate the predicate “是(shi)” into the MEPD model as a feature.

In detail, we design a list of features for each pair  $<sp, tp>$  as follows:

- **Lexical Features.** These features include the words immediately to the left and right of  $sp$ , represented as  $w_{-1}$  and  $w_{+1}$ . Moreover, the head word of each argument also serves as a lexical feature, named as  $hw(E_i)$ . For example, Figure 3 shows the context of the IC-PASTR in Figure 4(b), and the extracted lexical features of the instance are:  $w_{-1} =$ ,  $w_{+1} =$ ,  $hw([A0]_1) =$ 位置(wei-zhi),  $hw([A1]_4) =$ 好(hao).

- **POS Features.** These features are defined as the POS tags of the lexical features,  $p_{-1}$ ,  $p_{+1}$  and  $phw(E_i)$  respectively. Thus, the corresponding POS features of Figure 4 (b) are:  $p_{-1} =$ PU,  $p_{+1} =$ PU,  $phw([A0]_1) =$ NN,  $phw([A1]_4) =$ VA.

- **Predicate Feature.** It is the pair of source predicate and its corresponding target predicate. For example, in Figure 4(b), the source and target predicate are “是(shi)” and “is” respectively. The predicate feature is thus “PredF=是(shi)+is”. The target predicate is determined by:

$$t-pred = \arg \max_{j \in \text{range}(PAS)} p(t_j | s-pred)$$

where  $s-pred$  is the source predicate and  $t-pred$  is the corresponding target predicate.

<sup>3</sup>[http://homepages.inf.ed.ac.uk/lzhang10/maxent\\_toolkit.htm](http://homepages.inf.ed.ac.uk/lzhang10/maxent_toolkit.htm)

$t\_range(PAS)$  refers to the target range covering all the words that are reachable from the PAS via word alignment.  $t_j$  refers to the  $j$ th word in  $t\_range(PAS)$ . The utilized lexical translation probabilities are from the toolkit in Moses (Koehn et al., 2007).

● **Syntax Features.** These features include  $st(Ei)$ , i.e., the highest syntax tag for each argument, and  $fst(PAS)$  which is the lowest father node of  $sp$  in the parse tree. For example, for the rule shown in Figure 4(b), syntax features are  $st([A0]_1)=NP$ ,  $st([A1]_4)=CP$ , and  $fst(PAS)=IP$  respectively.

Using these features, we can train the MEPD model. We set the Gaussian prior to 1.0 and perform 100 iterations of the L-BFGS algorithm for each MEPD model. At last, we build 160 and 215 different MEPD classifiers, respectively, for the PASTRs and IC-PASTRs. Note that since the training procedure of maximum entropy classifier is really fast, it does not take much time to train these classifiers.

## 5 Integrating into the PAS-based Translation Framework

In this section, we integrate our method of PAS disambiguation into the PAS-based translation framework when translating each test sentence.

For inside context integration, since the format of IC-PASTR is the same to PASTR<sup>4</sup>, we can use the IC-PASTR to substitute PASTR for building a PAS-based translation system directly. We use “IC-PASTR” to denote this system. In addition, since our method of rule extraction is different from (Zhai et al., 2012), we also use PASTR to construct a translation system as the baseline system, which we call “PASTR”.

On the basis of PASTR and IC-PASTR, we further integrate our MEPD model into translation. Specifically, we take the score of the MEPD model as another informative feature for the decoder to distinguish good target-side-like PASs from bad ones. The weights of the MEPD feature can be tuned by MERT (Och, 2003) together with other translation features, such as language model.

## 6 Related Work

The method of PAS disambiguation for SMT is relevant to the previous work on context depend-

ent translation.

Carpuat and Wu (2007a, 2007b) and Chan et al. (2007) have integrated word sense disambiguation (WSD) and phrase sense disambiguation (PSD) into SMT systems. They combine rich context information to do disambiguation for words or phrases, and achieve improved translation performance.

Differently, He et al. (2008), Liu et al. (2008) and Cui et al. (2010) designed maximum entropy (ME) classifiers to do better rule section for hierarchical phrase-based model and tree-to-string model respectively. By incorporating the rich context information as features, they chose better rules for translation and yielded stable improvements on translation quality.

Our work differs from the above work in the following two aspects: 1) in our work, we focus on the problem of disambiguates on PAS; 2) we define two kinds of PAS ambiguities: role ambiguity and gap ambiguity. 3) towards the two different ambiguities, we design two specific methods for PAS disambiguation: inside context integration and the novel MEPD model.

In addition, Xiong et al. (2012) proposed an argument reordering model to predict the relative position between predicates and arguments. They also combine the context information in the model. But they only focus on the relation between the predicate and a specific argument, rather than the entire PAS. Different from their work, we incorporate the context information to do PAS disambiguation based on the entire PAS. This is very beneficial for global reordering during translation (Zhai et al., 2012).

## 7 Experiment

### 7.1 Experimental Setup

We perform Chinese-to-English translation to demonstrate the effectiveness of our PAS disambiguation method. The training data contains about 260K sentence pairs<sup>5</sup>. To get accurate SRL results, we ensure that the length of each sentence in the training data is among 10 and 30 words. We run GIZA++ and then employ the *grow-diag-final-and* (*gdfa*) strategy to produce symmetric word alignments. The development set and test set come from the NIST evaluation test data (from 2003 to 2005). Similar to the training set, we also only retain the sentences

<sup>4</sup> The only difference between IC-PASTR and PASTR is that there are many syntactic labels in IC-PASTRs.

<sup>5</sup> It is extracted from the LDC corpus. The LDC category number: LDC2000T50, LDC2002E18, LDC2003E07, LDC2004T07, LDC2005T06, LDC2002L27, LDC2005T10 and LDC2005T34.

whose lengths are among 10 and 30 words. Finally, the development set includes 595 sentences from NIST MT03 and the test set contains 1,786 sentences from NIST MT04 and MT05.

We train a 5-gram language model with the Xinhua portion of English Gigaword corpus and target part of the training data. The translation quality is evaluated by case-insensitive BLEU-4 with shortest length penalty. The statistical significance test is performed by the re-sampling approach (Koehn, 2004).

We perform SRL on the source part of the training set, development set and test set by the Chinese SRL system used in (Zhuang and Zong, 2010b). To relieve the negative effect of SRL errors, we get the multiple SRL results by providing the SRL system with 3-best parse trees of Berkeley parser (Petrov and Klein, 2007), 1-best parse tree of Bikel parser (Bikel, 2004) and Stanford parser (Klein and Manning, 2003). Therefore, at last, we can get 5 SRL result for each sentence. For the training set, we use these SRL results to do rule extraction respectively. We combine the obtained rules together to get a combined rule set. We discard the rules with fewer than 5 appearances. Using this set, we can train our MEPD model directly.

As to translation, we match the 5 SRL results with transformation rules respectively, and then apply the resulting target-side-like PASs for decoding. As we mentioned in section 2.3, we use the state-of-the-art BTG system to translate the non-PAS spans.

source-side PAS	counts	number of classes
[A0] [Pred(是)] [A1]	245	6
[A0] [Pred(说)] [A1]	148	6
[A0] [AM-ADV] [Pred(是)] [A1]	68	20
[A0] [Pred(表示)] [A1]	66	6
[A0] [Pred(有)] [A1]	42	6
[A0] [Pred(认为)] [A1]	32	4
[A0] [AM-ADV] [Pred(有)] [A1]	32	19
[A0] [Pred(指出)] [A1]	29	4
[AM-ADV] [Pred(有)] [A1]	26	6
[A2] [Pred(为)] [A1]	16	5

Table 1. The top 10 frequent source-side PASs in the dev and test set.

## 7.2 Ambiguities in Source-side PASs

We first give Table 1 to show some examples of role ambiguity. In the table, for instance, the second line denotes that the source-side PAS “[A0] [Pred(说)] [A1]” appears 148 times in the devel-

opment and test set all together, and it corresponds to 6 different target-side-like PASs in the training set.

As we can see from Table 1, all the top 10 PASs correspond to several different target-side-like PASs. Moreover, according to our statistics, among all PASs appearing in the development set and test set, 56.7% of them carry gap strings. These statistics demonstrate the importance of handling the role ambiguity and gap ambiguity in the PAS-based translation framework. Therefore, we believe that our PAS disambiguation method would be helpful for translation.

## 7.3 Translation Result

We compare the translation result using PASTR, IC-PASTR and our MEPD model in this section. The final translation results are shown in Table 2. As we can see, after employing PAS for translation, all systems outperform the baseline BTG system significantly. This comparison verifies the conclusion of (Zhai et al., 2012) and thus also demonstrates the effectiveness of PAS.

MT system	Test set	n-gram precision			
		1	2	3	4
BTG	32.75	74.39	41.91	24.75	14.91
PASTR	33.24*	75.28	42.62	25.18	15.10
PASTR+MEPD	33.78*	75.32	43.08	25.75	15.58
IC-PASTR	33.95*#	75.62	43.36	25.92	15.58
IC-PASTR+MEPD	<b>34.19*#</b>	75.66	43.40	26.15	15.92

Table 2. Result of baseline system and the MT systems using our PAS-based disambiguation method. The “\*” and “#” denote that the result is significantly better than BTG and PASTR respectively ( $p < 0.01$ ).

Specifically, after integrating the inside context information of PAS into transformation, we can see that system IC-PASTR significantly outperforms system PASTR by 0.71 BLEU points. Moreover, after we import the MEPD model into system PASTR, we get a significant improvement over PASTR (by 0.54 BLEU points). These comparisons indicate that both the inside context integration and our MEPD model are beneficial for the decoder to choose better target-side-like PAS for translation.

On the basis of IC-PASTR, we further add our MEPD model into translation and get system IC-PASTR+MEPD. We can see that this system further achieves a remarkable improvement over system PASTR (0.95 BLEU points).

However, from Table 2, we find that system IC-PASTR+MEPD only outperforms system IC-PASTR slightly (0.24 BLEU points). The result seems to show that our MEPD model is not such

useful after using IC-PASTR. We will explore the reason in section 7.5.

### 7.4 Effectiveness of Inside Context Integration

The method of inside context integration is used to combine the inside context (gap strings) into PAS for translation, i.e., extend the PASTR to IC-PASTR. In order to demonstrate the effectiveness of inside context integration, we first give Table 3, which illustrates statistics on the matching PASs. The statistics are conducted on the combination of development set and test set.

Transformation Rules	Matching PAS		
	None Gap PAS	Gap PAS	Total
PASTR	1702	1539	3241
IC-PASTR	1546	832	2378

Table 3. Statistics on the matching PAS.

In Table 3, for example, the line for PASTR means that if we use PASTR for the combined set, 3241 PASs (column “Total”) can match PASTRs in total. Among these matching PASs, 1539 ones (column “Gap PAS”) carry gap strings, while 1702 ones do not (column “None Gap PAS”). Consequently, since PASTR does not consider the inside context during translation, the Gap PASs, which account for 47% (1539/3241) of all matching PASs, might be handled inappropriately in the PAS-based translation framework. Therefore, integrating the inside context into PASTRs, i.e., using the proposed IC-PASTRs, would be helpful for translation. The translation result shown in Table 2 also demonstrates this conclusion.

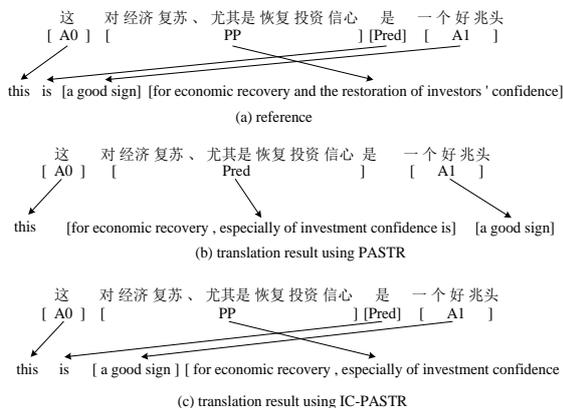

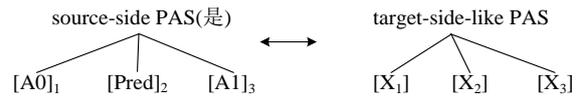

Figure 5. Translation examples to verify the effectiveness of inside context.

From Table 3, we can also find that the number of matching PASs decreases after using IC-PASTR. This is because IC-PASTR is more spe-

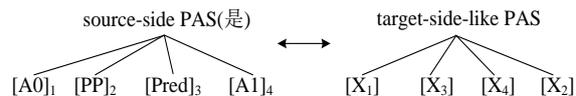

cific than PASTR. Therefore, for a PAS with specific inside context (gap strings), even if the matched PASTR is available, the matched IC-PASTR might not. This indicates that comparing with PASTR, IC-PASTR is more capable of distinguishing different PASs. Therefore, based on this advantage, although the number of matching PASs decreases, IC-PASTR still improves the translation system using PASTR significantly. Of course, we believe that it is also possible to integrate the inside context without decreasing the number of matching PASs and we plan this as our future work.

We further give a translation example in Figure 5 to illustrate the effectiveness of our inside context integration method. In the example, the automatic SRL system ignores the long preposition phrase “对经济复苏、尤其是恢复投资信心” for the PAS. Thus, the system using PASTRs can only attach the long phrase to the predicate “是” according to the parse tree, and meanwhile, make use of a transformation rule as follows:

In this way, the translation result is very bad, just as Figure 5(b) shows. The long preposition phrases are wrongly positioned in the translation.

In contrast, after inside context integration, we match the inside context during PAS transformation. As Figure 5(c) shows, the inside context helps to select a right transformation rule as follows and gets a good translation result finally.

### 7.5 Effectiveness of the MEPD Model

The MEPD model incorporates various context features to select better target-side-like PAS for translation. On the basis of PASTR and IC-PASTR, we build 160 and 215 different MEPD classifiers, respectively, for the frequent source-side PASs.

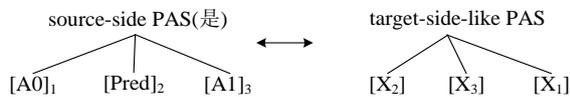

In Table 2, we have found that our MEPD model improves system IC-PASTR slightly. We conjecture that this phenomenon is due to two possible reasons. On one hand, sometimes, many PAS ambiguities might be resolved by both inside context and the MEPD model. Therefore, the improvement would not be such significant

when we combine these two methods together. On the other hand, as Table 3 shows, the number of matching PASs decreases after using IC-PASTR. Since the MEPD model works on PASs, its effectiveness would also weaken to some extent. Future work will explore this phenomenon more thoroughly.

Ref	<p>... , [海牙] [是] [其 最后 一站] 。</p> <p>... [the hague] [is] [his last stop] .</p>
PASTR	<p>... , [海牙]<sub>A0</sub> [是]<sub>Pred</sub> [其 最后 一站]<sub>A1</sub> 。</p> <p>... [is] [his last leg of] [the hague] .</p>
PASTR + MEPD	<p>... , [海牙]<sub>A0</sub> [是]<sub>Pred</sub> [其 最后 一站]<sub>A1</sub> 。</p> <p>... [the hague] [is] [the last leg] .</p>

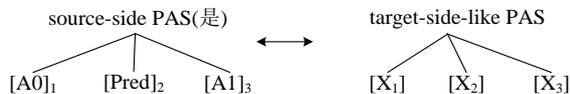

Figure 6. Translation examples to demonstrate the effectiveness of our MEPD model.

Now, we give Figure 6 to demonstrate the effectiveness of our MEPD model. From the Figure, we can see that the system using PASTRs selects an inappropriate transformation rule for translation:

This rule wrongly moves the subject “海牙 (Hague)” to the end of the translation. We do not give the translation result of the BTG system here because it makes the same mistake.

Conversely, by considering the context information, the PASTR+MEPD system chooses a correct rule for translation:

As we can see, the used rule helps to keep the SVO structure unchanged, and gets the correct translation.

## 8 Conclusion and Future Work

In this paper, we focus on the problem of ambiguities for PASs. We first propose two ambiguities: gap ambiguity and role ambiguity. Accordingly, we design two novel methods to do efficient PAS disambiguation: inside-context integration and a novel MEPD model. For inside context integration, we abstract the inside con-

text and combine them into the PASTRs for PAS transformation. Towards the MEPD model, we design a maximum entropy model for each ambitious source-side PASs. The two methods successfully incorporate the rich context information into the translation process. Experiments show that our PAS disambiguation methods help to improve the translation performance significantly.

In the next step, we will conduct experiments on other language pairs to demonstrate the effectiveness of our PAS disambiguation method. In addition, we also will try to explore more useful and representative features for our MEPD model.

## Abstract

Mother tongue interference is the phenomenon where linguistic systems of a mother tongue are transferred to another language. Although there has been plenty of work on mother tongue interference, very little is known about how strongly it is transferred to another language and about what relation there is across mother tongues. To address these questions, this paper explores and visualizes mother tongue interference preserved in English texts written by Indo-European language speakers. This paper further explores linguistic features that explain why certain relations are preserved in English writing, and which contribute to related tasks such as native language identification.

## 1 Introduction

Transfer of linguistic systems of a mother tongue to another language, namely *mother tongue interference*, is often observable in the writing of non-native speakers. The reader may be able to determine the mother tongue of the writer of the following sentence from the underlined article error:

*The alien wouldn't use my spaceship but the hers.*

The answer would probably be French or Spanish; the definite article is allowed to modify possessive pronouns in these languages, and the usage is sometimes negatively transferred to English writing. Researchers such as Swan and Smith (2001), Aarts and Granger (1998), Davidsen-Nielsen and Harder (2001), and Altenberg and Tapper (1998) work on mother tongue interference to reveal overused/underused words, part of speech (POS), or grammatical items.

In contrast, very little is known about how strongly mother tongue interference is transferred to another language and about what relation there is across mother tongues. At one extreme, one could argue that it is so strongly transferred to texts in another language that the linguistic relations between mother tongues are perfectly preserved in the texts. At the other extreme, one can counter it, arguing that other features such as non-nativeness are more influential than mother tongue interference. One possible reason for this is that a large part of the distinctive language systems of a mother tongue may be eliminated when transferred to another language from a speaker's mother tongue. For example, Slavic languages have a rich inflectional case system (e.g., Czech has seven inflectional cases) whereas French does not. However, the difference in the richness cannot be transferred into English because English has almost no inflectional case system. Thus, one cannot determine the mother tongue of a given non-native text from the inflectional case. A similar argument can be made about some parts of gender, tense, and aspect systems. Besides, Wong and Dras (2009) show that there are no significant differences, between mother tongues, in the misuse of certain syntactic features such as subject-verb agreement that have different tendencies depending on their mother tongues. Considering these, one could not be so sure which argument is correct. In any case, to the best of our knowledge, no one has yet answered this question.

In view of this background, we take the first step in addressing this question. We hypothesize that:

**Hypothesis:** Mother tongue interference is so strong that the relations in a language family are preserved in texts written in another language.

In other words, mother tongue interference is so strong that one can reconstruct a language fam-

ily tree from non-native texts. One of the major contributions of this work is to reveal and visualize a language family tree preserved in non-native texts, by examining the hypothesis. This becomes important in native language identification<sup>1</sup> which is useful for improving grammatical error correction systems (Chodorow et al., 2010) or for providing more targeted feedback to language learners. As we will see in Sect. 6, this paper reveals several crucial findings that contribute to improving native language identification. In addition, this paper shows that the findings could contribute to reconstruction of language family trees (Enright and Kondrak, 2011; Gray and Atkinson, 2003; Barbañon et al., 2007; Batagelj et al., 1992; Nakhleh et al., 2005), which is one of the central tasks in historical linguistics.

The rest of this paper is structured as follows. Sect. 2 introduces the basic approach of this work. Sect. 3 discusses the methods in detail. Sect. 4 describes experiments conducted to investigate the hypothesis. Sect. 5 discusses the experimental results. Sect. 6 discusses implications for work in related domains.

## 2 Approach

To examine the hypothesis, we reconstruct a language family tree from English texts written by non-native speakers of English whose mother tongue is one of the Indo-European languages (Beekes, 2011; Ramat and Ramat, 2006). If the reconstructed tree is sufficiently similar to the original Indo-European family tree, it will support the hypothesis. If not, it suggests that some features other than mother tongue interference are more influential.

The approach we use for reconstructing a language family tree is to apply agglomerative hierarchical clustering (Han and Kamber, 2006) to English texts written by non-native speakers. Researchers have already performed related work on reconstructing language family trees. For instance, Kroeber and Chriétien (1937) and Ellegård (1959) proposed statistical methods for measuring the similarity metric between languages. More recently, Batagelj et al. (1992) and Kita (1999) proposed methods for reconstructing language family trees using clustering. Among them, the

<sup>1</sup>Recently, native language identification has drawn the attention of NLP researchers. For instance, a shared task on native language identification took place at an NAACL-HLT 2013 workshop.

most related method is that of Kita (1999). In his method, a variety of languages are modeled by their spelling systems (i.e., character-based  $n$ -gram language models). Then, agglomerative hierarchical clustering is applied to the language models to reconstruct a language family tree. The similarity used for clustering is based on a divergence-like distance between two language models that was originally proposed by Juang and Rabiner (1985). This method is purely data-driven and does not require human expert knowledge for the selection of linguistic features.

Our work closely follows Kita’s work. However, it should be emphasized that there is a significant difference between the two. Kita’s work (and other previous work) targets clustering of a variety of languages whereas our work tries to reconstruct a language family tree preserved in non-native English. This significant difference prevents us from directly applying techniques in the literature to our task. For instance, Batagelj et al. (1992) use basic vocabularies such as *belly* in English and *ventre* in French to measure similarity between languages. Obviously, this does not work on our task; *belly* is *belly* in English writing whoever writes it. Kita’s method is also likely not to work well because all texts in our task share the same spelling system (i.e., English spelling). Although spelling is sometimes influenced by mother tongues, it involves a lot more including overuse, underuse, and misuse of lexical, grammatical, and syntactic systems.

To solve the problem, this work adopts a word-based language model in the expectation that word sequences reflect mother tongue interference. At the same time, its simple application would cause a serious side effect. It would reflect the topics of given texts rather than mother tongue interference. Unfortunately, there exists no such English corpus that covers a variety of language speakers with uniform topics; moreover the availability of non-native corpora is still somewhat limited. This also means that available non-native corpora may be too small to train reliable word-based language models. The next section describes two methods (language model-based and vector-based), which address these problems.

## 3 Methods

### 3.1 Language Model-based Method

To begin with, let us define the following symbols used in the methods. Let  $D_i$  be a set of English

texts where  $i$  denotes a mother tongue  $i$ . Similarly, let  $M_i$  be a language model trained using  $D_i$ .

To solve the problems pointed out in Sect. 2, we use an  $n$ -gram language model based on a mixture of word and POS tokens instead of a simple word-based language model. In this language model, content words in  $n$ -grams are replaced with their corresponding POS tags. This greatly decreases the influence of the topics of texts, as desired. It also decreases the number of parameters in the language model.

To build the language model, the following three preprocessing steps are applied to  $D_i$ . First, texts in  $D_i$  are split into sentences. Second, each sentence is tokenized, POS-tagged, and mapped entirely to lowercase. For instance, the first example sentence in Sect. 1 would give:

the/DT alien/NN would/MD not/RB  
use/VB my/PRP\$ spaceship/NN but/CC  
the/DT hers/PRP ./.

Finally, words are replaced with their corresponding POS tags; for the following words, word tokens are used as their corresponding POS tags: coordinating conjunctions, determiners, prepositions, modals, predeterminers, possessives, pronouns, question adverbs. Also, proper nouns are treated as common nouns. At this point, the special POS tags *BOS* and *EOS* are added at the beginning and end of each sentence, respectively. For instance, the above example would result in the following word/POS sequence:

BOS the NN would RB VB my NN but  
the hers . EOS

Note that the content of the original sentence is far from clear while reflecting mother tongue interference, especially in *the hers*.

Now, the language model  $M_i$  can be built from  $D_i$ . We set  $n = 3$  (i.e., trigram language model) following Kita's work and use Kneser-Ney (KN) smoothing (Kneser and Ney, 1995) to estimate its conditional probabilities.

With  $M_i$  and  $D_i$ , we can naturally apply Kita's method to our task. The clustering algorithm used is agglomerative hierarchical clustering with the average linkage method. The distance<sup>2</sup> between two language models is measured as follows. The

<sup>2</sup>It is not a distance in a mathematical sense. However, we will use the term *distance* following the convention in the literature.

probability that  $M_i$  generates  $D_i$  is calculated by  $\Pr(D_i|M_i)$ . Note that

$$\Pr(D_i|M_i) \approx \Pr(w_{1,i}) \Pr(w_{2,i}|w_{1,i}) \times \prod_{t=3}^{|D_i|} \Pr(w_{t,i}|w_{t-2,i}, w_{t-1,i}) \quad (1)$$

where  $w_{t,i}$  and  $|D_i|$  denote the  $t$ th token in  $D_i$  and the number of tokens in  $D_i$ , respectively, since we use the trigram language model. Then, the distance from  $M_i$  to  $M_j$  is defined by

$$d(M_i \rightarrow M_j) = \frac{1}{|D_j|} \log \frac{\Pr(D_j|M_j)}{\Pr(D_j|M_i)}. \quad (2)$$

In other words, the distance is determined based on the ratio of the probabilities that each language model generates the language data. Because  $d(M_i \rightarrow M_j)$  and  $d(M_j \rightarrow M_i)$  are not symmetrical, we define the distance between  $M_i$  and  $M_j$  to be their average:

$$d(M_i, M_j) = \frac{d(M_i \rightarrow M_j) + d(M_j \rightarrow M_i)}{2}. \quad (3)$$

Equation (3) is used to calculate the distance between two language models for clustering.

To sum up, the procedure of the language family tree construction method is as follows: (i) Pre-process each  $D_i$ ; (ii) Build  $M_i$  from  $D_i$ ; (iii) Calculate the distances between the language models; (iv) Cluster the language data using the distances; (v) Output the result as a language family tree.

### 3.2 Vector-based Method

We also examine a vector-based method for language family tree reconstruction. As we will see in Sect. 5, this method allows us to interpret clustering results more easily than with the language model-based method while both result in similar language family trees.

In this method,  $D_i$  is modeled by a vector. The vector is constructed based on the relative frequencies of trigrams. As a consequence, the distance is naturally defined by the Euclidean distance between two vectors. The clustering procedure is the same as for the language model-based method except that  $M_i$  is vector-based and that the distance metric is Euclidean.

## 4 Experiments

We selected the ICLE corpus v.2 (Granger et al., 2009) as the target language data. It consists of English essays written by a wide variety of non-native speakers of English. Among them, the 11 shown in Table 1 are of Indo-European languages. Accordingly, we selected the subcorpora of the 11 languages in the experiments. Before the experiments, we preprocessed the corpus data to control the experimental conditions. Because some of the writers had more than one native language, we excluded essays that did not meet the following three conditions: (i) the writer has only one native language; (ii) the writer has only one language at home; (iii) the two languages in (i) and (ii) are the same as the native language of the subcorpus to which the essay belongs<sup>3</sup>. After the selection, markup tags such as essay IDs were removed from the corpus data. Also, the symbols ‘ and ’ were unified into ’<sup>4</sup>. For reference, we also used native English (British and American university students’ essays in the LOCNESS corpus<sup>5</sup>) and two sets of Japanese English (ICLE and the NICE corpus (Sugiura et al., 2007)). Table 1 shows the statistics on the corpus data.

Performance of POS tagging is an important factor in our methods because they are based on word/POS sequences. Existing POS taggers might not perform well on non-native English texts because they are normally developed to analyze native English texts. Considering this, we tested CRFTagger<sup>6</sup> on non-native English texts containing various grammatical errors before the experiments (Nagata et al., 2011). It turned out that CRFTagger achieved an accuracy of 0.932 (compared to 0.970 on native texts). Although it did not perform as well as on native texts, it still achieved a fair accuracy. Accordingly, we decided to use it in our experiments.

Then, we generated cluster trees from the corpus data using the methods described in Sect. 3.

<sup>3</sup>For example, because of (iii), essays written by native speakers of Swedish in the Finnish subcorpus were excluded from the experiments. This is because they were collected in Finland and might be influenced by Finnish.

<sup>4</sup>The symbol ‘ is sometimes used for ’ (e.g., *I’m*).

<sup>5</sup>The LOCNESS corpus is a corpus of native English essays made up of British pupils’ essays, British university students’ essays, and American university students’ essays: <https://www.uclouvain.be/en-cecl-locness.html>

Japanese2 (NICE)	340	130,156
Total	4,018	3,159,166

Table 1: Statistics on target corpora.

We used the Kyoto Language Modeling toolkit<sup>7</sup> to build language models from the corpus data. We removed  $n$ -grams that appeared less than five times<sup>8</sup> in each subcorpus in the language models. Similarly, we implemented the vector-based method with trigrams using the same frequency cutoff (but without smoothing).

Fig. 1 shows the experimental results. The tree at the top is the Indo-European family tree drawn based on the figure shown in Crystal (1997). It shows that the 11 languages are divided into three groups: Italic, Germanic, and Slavic branches. The second and third trees are the cluster trees generated by the language model-based and vector-based methods, respectively. The number at each branching node denotes in which step the two clusters were merged.

The experimental results strongly support the hypothesis we made in Sect. 1. Fig. 1 reveals that the language model-based method correctly groups the 11 Englishes into the Italic, Germanic, and Slavic branches. It first merges Norwegian-English and Swedish-English into a cluster. The two languages belong to the North Germanic branch of the Germanic branch and thus are closely related. Subsequently, the language model-based method correctly merges the other languages into the three branches. A dif-

<sup>7</sup>The Kyoto Language Modeling toolkit: <http://www.phontron.com/kylm/>

<sup>8</sup>We found that the results were not sensitive to the value of frequency cutoff so long as we set it to a small number.

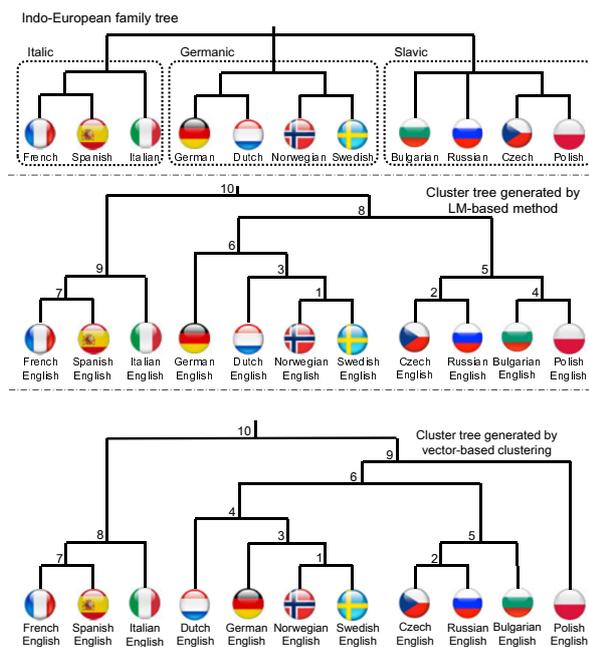

Figure 1: Experimental results.

ference between its cluster tree and the Indo-European family tree is that there are some mismatches within the Germanic and Slavic branches. While the difference exists, the method strongly distinguishes the three branches from one another. The third tree shows that the vector-based method behaves similarly while it mistakenly attaches Polish-English into an independent branch. From these results, we can say that mother tongue interference is transferred into the 11 Englishes, strongly enough for reconstructing its language family tree, which we propose calling *the interlanguage Indo-European family tree* in English.

Fig. 2 shows the experimental results with native and Japanese Englishes. It shows that the same interlanguage Indo-European family tree was reconstructed as before. More interestingly, native English was detached from the interlanguage Indo-European family tree contrary to the expectation that it would be attached to the Germanic branch because English is of course a member of the Germanic branch. This implies that non-nativeness common to the 11 Englishes is more influential than the intrafamily distance is<sup>9</sup>;

<sup>9</sup>Admittedly, we need further investigation to confirm this argument especially because we applied CRFTagger, which is developed to analyze native English, to both non-native and native Englishes, which might affect the results.

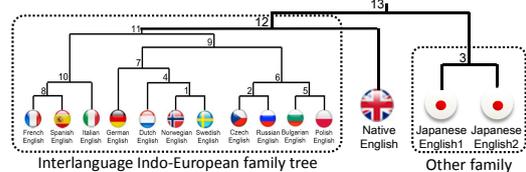

Figure 2: Experimental results with native and Japanese Englishes.

otherwise, native English would be included in the German branch. Fig. 2 also shows that the two sets of Japanese English were merged into a cluster and that it was the most distant in the whole tree. This shows that the interfamily distance is the most influential factor. Based on these results, we can further hypothesize as follows: interfamily distance > non-nativeness > intrafamily distance.

## 5 Discussion

To get a better understanding of the interlanguage Indo-European family tree, we further explore linguistic features that explain well the above phenomena. When we analyze the experimental results, however, some problems arise. It is almost impossible to find someone who has a good knowledge of the 11 languages and their mother language interference in English writing. Besides, there are a large number of language pairs to compare. Thus, we need an efficient and effective way to analyze the experimental results.

To address these problems, we did the following. First, we focused on only a few Englishes out of the 11. Because one of the authors had some knowledge of French, we selected French-English as the main target. This naturally made us select the other Italic Englishes as its counterparts. Also, because we had access to a native speaker of Russian who had a good knowledge of English, we included Russian-English in our focus. We analyzed these Englishes and then examined whether the findings obtained apply to the other Englishes or not. Second, we used a method for extracting interesting trigrams from the corpus data. The method compares three out of the 11 corpora (for example, French-, Spanish-, and Russian-Englishes). If we remove instances of a trigram from each set, the clustering tree involving

the three may change. For example, the removal of *but the hers* may result in a cluster tree merging French- and Russian-Englishes before French- and Spanish-Englishes. Even if it does not change, the distances may change in that direction. We analyzed what trigrams had contributed to the clustering results with this approach.

To formalize this approach, we will denote a trigram by  $t$ . We will also denote its relative frequency in the language data  $D_i$  by  $r_{ti}$ . Then, the change in the distances caused by the removal of  $t$  from  $D_i$ ,  $D_j$ , and  $D_k$  is quantified by

$$s = (r_{tk} - r_{ti})^2 - (r_{tj} - r_{ti})^2 \quad (4)$$

in the vector-based method. The quantity  $(r_{tk} - r_{ti})^2$  is directly related to the decrease in the distance between  $D_i$  and  $D_k$  and similarly,  $(r_{tj} - r_{ti})^2$  to that between  $D_i$  and  $D_j$  in the vector-based method. Thus, the greater  $s$  is, the higher the chance that the cluster tree changes. Therefore, we can obtain a list of interesting trigrams by sorting them according to  $s$ . We could do a similar calculation in the language model-based method using the conditional probabilities. However, it requires a more complicated calculation. Accordingly, we limit ourselves to the vector-based method in this analysis, noting that both methods generated similar cluster trees.

Table 2 shows the top 15 interesting trigrams where  $D_i$ ,  $D_j$ , and  $D_k$  are French-, Spanish-, and Russian-Englishes, respectively. Note that  $s$  is multiplied by  $10^6$  and  $r$  is in % for readability. The list reveals that many of the trigrams contain the article *a* or *the*. Interestingly, their frequencies are similar in French-English and Spanish-English, and both are higher than in Russian-English. This corresponds to the fact that French and Spanish have articles whereas Russian does not. Actually, the same argument can be made about the other Italic and Slavic Englishes (e.g., *the JJ NN*: Italian-English 0.82; Polish-English 0.72)<sup>10</sup>. An exception is that of trigrams containing the definite article in Bulgarian-English; it tends to be higher in Bulgarian-English than in the other Slavic Englishes. Surprisingly and interestingly, however, it reflects the fact that Bulgarian does have the definite article but not the indefinite article (e.g., *the JJ NN*: 0.82; *a JJ NN*: 0.60 in Bulgarian-English).

<sup>10</sup>Due to the space limitation, other lists were not included in this paper but are available at <http://web.hyogo-u.ac.jp/nagata/acl/>.

Table 3 shows that the differences in article use exist even between the Italic and Germanic branches despite the fact that both have the indefinite and definite articles. The list still contains a number of trigrams containing articles. For a better understanding of this, we looked further into the distribution of articles in the corpus data. It turns out that the distribution almost perfectly groups the 11 Englishes into the corresponding branches as shown in Fig. 3. The overall use of articles is less frequent in the Slavic-Englishes. The definite article is used more frequently in the Italic-Englishes than in the Germanic Englishes (except for Dutch-English). We speculate that this is perhaps because the Italic languages have a wider usage of the definite article such as its modification of possessive pronouns and proper nouns. The Japanese Englishes form another group (this is also true for the following findings). This corresponds to the fact that the Japanese language does not have an article system similar to that of English.

$s$	Trigram $t$	$r_{ti}$	$r_{tj}$	$r_{tk}$
5.14	the NN of	1.01	0.98	0.78
4.38	a JJ NN	0.85	0.77	0.62

Table 2: Interesting trigrams (French- ( $D_i$ ), Spanish- ( $D_j$ ), and Russian- ( $D_k$ ) Englishes).

Another interesting trigram, though not as obvious as article use, is *NN of NN*, which ranks 12th and 2nd in Table 2 and 3, respectively. In the Italic Englishes, the trigram is more frequent than the other non-native Englishes as shown in Fig. 4. This corresponds to the fact that noun-noun compounds are less common in the Italic languages than in English and that instead, the *of*-phrase (*NN of NN*) is preferred (Swan and Smith, 2001). For

instance, *orange juice* is expressed as *juice of orange* in the Italic languages (e.g., *jus d'orange* in French). In contrast, noun-noun compounds or similar constructions are more common in Russian and Swedish. As a result, *NN of NN* becomes relatively frequent in the Italic Englishes. Fig. 4 also shows that its distribution roughly groups the 11 Englishes into the three branches. Therefore, the way noun phrases (NPs) are constructed is a clue to how the three branches were clustered.

This finding in turn reveals that the consecutive repetitions of nouns occur less in the Italic Englishes. In other words, the length tends to be shorter than in the others where we define the length as the number of consecutive repetitions of common nouns (for example, the length of *orange juice* is one because a noun is consecutively repeated once). To see if this is true, we calculated the average length for each English. Fig. 5 shows that the average length roughly distinguishes the Italic Englishes from the other non-native Englishes; French-English is the shortest, which is explained by the discussion above, while Dutch- and German-Englishes are longest, which may correspond to the fact that they have a preference for noun-noun compounds as Snyder (1996) argues. For instance, German allows the concatenated form as in *Orangensaft* (equivalently *orangejuice*). This tendency in the length of noun-noun compounds provides us with a crucial insight for native language identification, which we will

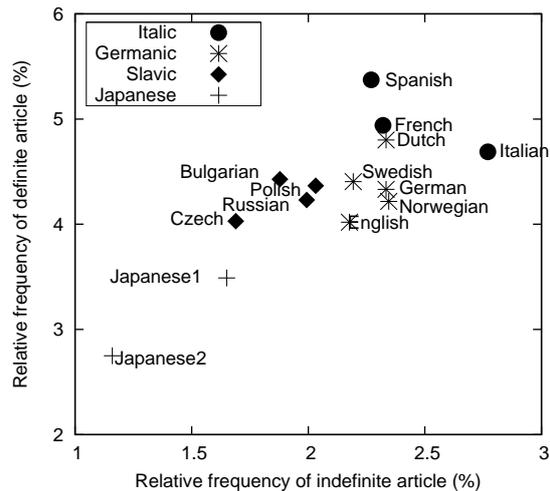

Figure 3: Distribution of articles.

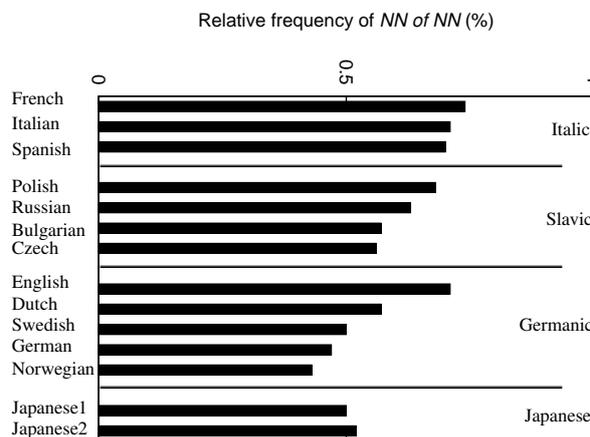

Figure 4: Relative frequency of *NN of NN* in each corpus (%).

come back to in Sect. 6.

The trigrams *BOS RB*, in Table 2 and *RB . EOS* in Table 3 imply that there might also be a certain pattern in adverb position in the 11 Englishes (they roughly correspond to adverbs at the beginning and end of sentences). Fig. 6 shows an insight into this. The horizontal and vertical axes correspond to the ratio of adverbs at the beginning and the end of sentences, respectively. It turns out that the German Englishes form a group. So do the Italic Englishes although it is less dense. In contrast, the Slavic Englishes are scattered. However, the ratios give a clue to how to distinguish Slavic Englishes from the others when combined with other

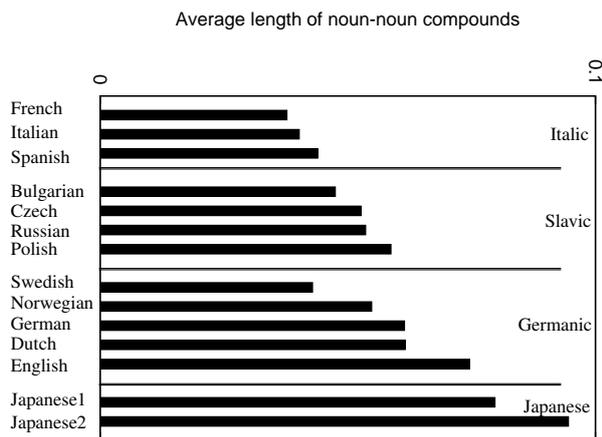

Figure 5: Average length of noun-noun compounds in each corpus.

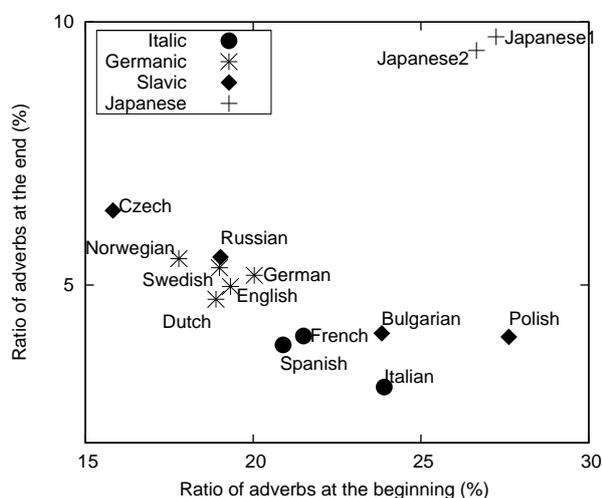

Figure 6: Distribution of adverb position.

trigrams. For instance, although Polish-English is located in the middle of Swedish-English and Bulgarian-English in the distribution of articles (in Fig. 3), the ratios tell us that Polish-English is much nearer to Bulgarian-English.

## 6 Implications for Work in Related Domains

Researchers including Wong and Dras (2009), Wong et al. (2011; 2012), and Koppel et al. (2005) work on native language identification and show that machine learning-based methods are effective. Wong and Dras (2009) propose using information about grammatical errors such as errors in determiners to achieve better performance while

they show that its use does not improve the performance, contrary to the expectation. Related to this, other researchers (Koppel and Ordan, 2011; van Halteren, 2008) show that machine learning-based methods can also predict the source language of a given translated text although it should be emphasized that it is a different task from native language identification because translation is not typically performed by non-native speakers but rather native speakers of the target language<sup>11</sup>.

The experimental results show that  $n$ -grams containing articles are predictive for identifying native languages. This indicates that they should be used in the native language identification task. Importantly, all  $n$ -grams containing articles should be used in the classifier unlike the previous methods that are based only on  $n$ -grams containing article errors. Besides, no articles should be explicitly coded in  $n$ -grams for taking the overuse/underuse of articles into consideration. We can achieve this by adding a special symbol such as  $\phi$  to the beginning of each NP whose head noun is a common noun and that has no determiner in it as in “I like  $\phi$  orange juice.”

In addition, the length of noun-noun compounds and the position of adverbs should also be considered in native language identification. In particular, the former can be modeled by the Poisson distribution as follows. The Poisson distribution gives the probability of the number of events occurring in a fixed time. In our case, the number of events in a fixed time corresponds to the number of consecutive repetitions of common nouns in NPs, which in turn corresponds to the length. To be precise, the probability of a noun-noun compound with length  $l$  is given by

$$\Pr(l) = \frac{\lambda^l}{l!} e^{-\lambda}, \quad (5)$$

where  $\lambda$  corresponds to the average length. Fig. 7 shows that the observed values in the French-English data very closely fit the theoretical proba-

<sup>11</sup>For comparison, we conducted a pilot study where we reconstructed a language family tree from English texts in European Parliament Proceedings Parallel Corpus (Europarl) (Koehn, 2011). It turned out that the reconstructed tree was different from the canonical tree (available at <http://web.hyogo-u.ac.jp/nagata/acl/>). However, we need further investigation to confirm it because each sub-corpus in Europarl is variable in many dimensions including its size and style (e.g., overuse of certain phrases such as *ladies and gentlemen*).

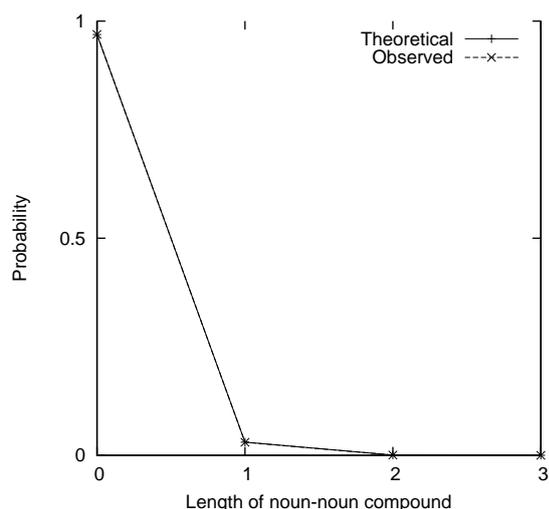

Figure 7: Distribution of noun-noun compound length for French-English.

bilities given by Equation (5)<sup>12</sup>. This holds for the other Englishes although we cannot show them because of the space limitation. Consequently, Equation (5) should be useful in native language identification. Fortunately, it can be naturally integrated into existing classifiers.

In the domain of historical linguistics, researchers have used computational and corpus-based methods for reconstructing language family trees. Some (Enright and Kondrak, 2011; Gray and Atkinson, 2003; Barbançon et al., 2007; Batagelj et al., 1992; Nakhleh et al., 2005) apply clustering techniques to the task of language family tree reconstruction. Others (Kita, 1999; Rama and Singh, 2009) use corpus statistics for the same purpose. These methods reconstruct language family trees based on linguistic features that exist within words including lexical, phonological, and morphological features.

The experimental results in this paper suggest the possibility of the use of non-native texts for reconstructing language family trees. It allows us to use linguistic features that exist between words, as seen in our methods, which has been difficult with previous methods. Language involves the features between words such as phrase construction and syntax as well as the features within words and thus they should both be considered in reconstructing

<sup>12</sup>The theoretical and observed values are so close that it is difficult to distinguish between the two lines in Fig. 7. For example,  $\Pr(l = 1) = 0.0303$  while the corresponding observed value is 0.0299.

tion of language family trees.

## 7 Conclusions

In this paper, we have shown that mother tongue interference is so strong that the relations between members of the Indo-European language family are preserved in English texts written by Indo-European language speakers. To show this, we have used clustering to reconstruct a language family tree from 11 sets of non-native English texts. It turned out that the reconstructed tree correctly groups them into the Italic, Germanic, and Slavic branches of the Indo-European family tree. Based on the resulting trees, we have then hypothesized that the following relation holds in mother tongue interference: interfamily distance  $>$  non-nativeness  $>$  intrafamily distance. We have further explored several intriguing linguistic features that play an important role in mother tongue interference: (i) article use, (ii) NP construction, and (iii) adverb position, which provide several insights for improving the tasks of native language identification and language family tree reconstruction.

## Acknowledgments

This work was partly supported by the Digiteo foreign guest project. # Word Association Profiles and their Use for Automated Scoring of Essays

Beata Beigman Klebanov and Michael Flor

{bbeigmanklebanov,mflor}@ets.org

## Abstract

We describe a new representation of the content vocabulary of a text we call *word association profile* that captures the proportions of highly associated, mildly associated, unassociated, and dis-associated pairs of words that co-exist in the given text. We illustrate the shape of the distribution and observe variation with genre and target audience. We present a study of the relationship between quality of writing and word association profiles. For a set of essays written by college graduates on a number of general topics, we show that the higher scoring essays tend to have higher percentages of both highly associated and dis-associated pairs, and lower percentages of mildly associated pairs of words. Finally, we use word association profiles to improve a system for automated scoring of essays.

## 1 Introduction

The vast majority of contemporary research that investigates statistical properties of language deals with characterizing *words* by extracting information about their behavior from large corpora. Thus, co-occurrence of words in  $n$ -word windows, syntactic structures, sentences, paragraphs, and even whole documents is captured in vector-space models built from text corpora (Turney and Pantel, 2010; Basili and Pennacchiotti, 2010; Erk and Padó, 2008; Mitchell and Lapata, 2008; Bullinaria and Levy, 2007; Jones and Mewhort, 2007; Pado and Lapata, 2007; Lin, 1998; Landauer and Dumais, 1997; Lund and Burgess, 1996; Salton et al., 1975). However, little is known about typical profiles of *texts* in terms of co-occurrence behavior of their words. Some information can be inferred from the success of statistical techniques in predicting certain structures in text. For example, the

fact that a text segmentation algorithm that uses information about patterns of word co-occurrences can detect sub-topic shifts in a text (Riedl and Bie-mann, 2012; Misra et al., 2009; Eisenstein and Barzilay, 2008) tells us that texts contain some proportion of more highly associated word pairs (those in subsequent sentences within the same topical unit) and of less highly associated pairs (those in sentences from different topical units).<sup>1</sup> Yet, does each text have a different distribution of highly associated, mildly associated, unassociated, and dis-associated pairs of words, or do texts tend to strike a similar balance of these? What are the proportions of the different levels of association, how much variation there exists, and are there systematic differences between various kinds of texts? We present research that makes a first step in addressing these questions.

From the applied perspective, our interest is in quantifying differences between well-written and poorly written essays, for the purposes of automated scoring of essays. We therefore concentrate on essay data for the main experiments reported in this paper, although some additional corpora will be used for illustration purposes.

The paper is organized as follows. Section 2 presents our methodology for building word association profiles for texts. Section 3 illustrates the profiles for three corpora from different genres. Section 4.2 presents our study of the relationship between writing quality and patterns of word associations, with section 4.5 showing the results of adding a feature based on word association profile to a state-of-art essay scoring system. Related work is reviewed in section 5.

---

<sup>1</sup>Note that the classical approach to topical segmentation of texts, TextTiling (Hearst, 1997), uses only word repetitions. The cited approaches use topic models that are in turn estimated using word co-occurrence.

## 2 Methodology

In order to describe the word association profile of a text, three decisions need to be made. The first decision is how to quantify the extent of co-occurrence between two words; we will use point-wise mutual information (**PMI**) estimated from a large and diverse corpus of texts. The second is which pairs of words in a text to consider when building a profile for the text; we opted for all pairs of content word types occurring in a text, irrespective of the distance between them. We consider word types, not tokens; no lemmatization is performed. The third decision is how to represent the co-occurrence profiles; we use a histogram where each bin represents the proportion of word pairs in the given interval of PMI values. The rest of the section gives more detail about these decisions.

To obtain comprehensive information about typical co-occurrence behavior of words of English, we build a first-order co-occurrence word-space model (Turney and Pantel, 2010; Baroni and Lenci, 2010). The model was generated from a corpus of texts of about 2.5 billion words, counting co-occurrence in a paragraph,<sup>2</sup> using no distance coefficients (Bullinaria and Levy, 2007). About 2 billion words come from the Gigaword 2003 corpus (Graff and Cieri, 2003). Additional 500 million words come from an in-house corpus containing popular science and fiction texts. Occurrence counts of 2.1 million word types and of 1,279 million word type pairs are efficiently compressed using the TrendStream technology (Flor, 2013), resulting in a database file of 4.7GB. TrendStream is a trie-based architecture for storage, retrieval, and updating of very large word n-gram datasets. We store pairwise word associations as bigrams; since associations are unordered, only one of the orders is actually stored in the database.

There is an extensive literature on the use of word-association measures for NLP, especially for detection of collocations (Pecina, 2010; Evert, 2008; Futagi et al., 2008). The use of point-wise mutual information with word-space models is noted in (Zhang et al., 2012; Baroni and Lenci, 2010; Mitchell and Lapata, 2008; Turney, 2001). Point-wise mutual information is defined as follows (Church and Hanks, 1990):

<sup>2</sup>In all texts, we use human-marked paragraphs, indicated either by a new line or by an xml markup.

$$PMI(x, y) = \log_2 \frac{P(x, y)}{P(x)P(y)} \quad (1)$$

Differently from Church and Hanks (1990), we disregard word order when computing  $P(x, y)$ . All probabilities are estimated using frequencies.

We define **WAP<sub>T</sub>** – a **word association profile** of a text  $T$  – as the distribution of  $PMI(x, y)$  for all pairs of content<sup>3</sup> word types  $(x, y) \in T$ . All pairs of word types for which the associations database returned a null value (the pair has never been observed in the same paragraph) are excluded from the calculation. For our main dataset (described later as setA, section 4.1), the average percentage of non-null values per text is 92%.

To represent the WAP of a text, we use a 60-bin histogram spanning all PMI values. The lowest bin (shown in Figures 1 and 2 as  $PMI = -5$ ) contains pairs with  $PMI \leq -5$ ; the topmost bin (shown in Figures 1 and 2 as  $PMI = 4.83$ ) contains pairs with  $PMI > 4.67$ , while the rest of the bins contain word pairs  $(x, y)$  with  $-5 < PMI(x, y) \leq 4.67$ . Each bin in the histogram (apart from the top and the bottom ones) corresponds to a PMI interval of 0.167. We chose a relatively fine-grained binning and performed no optimization for grid selection; for more sophisticated gridding approaches to study non-linear relationships in the data, see Reshef et al. (2011).

We will say that a text A is **tighter** than text B if the WAP of A is shifted towards the higher end of PMI values relative to text B. The intuition behind the terminology is that texts with higher proportions of highly associated pairs are likelier to be more focused, dealing with a small number of topics at greater length, as opposed to texts that bring various different themes into the text to various extents. Thus, the text “The dog barked and wagged its tail” is much tighter than the text “Green ideas sleep furiously”, with all the six content word pairs scoring above  $PMI=5.5$  in the first and below  $PMI=2.2$  in the second.<sup>4</sup>

## 3 Illustration: The shape of the distribution

For a first illustration, we use a corpus of 5,904 essays written as part of a standardized graduate

<sup>3</sup>We part-of-speech tag a text using OpenNLP tagger (<http://opennlp.apache.org>) and only take into account common and proper nouns, verbs, adjectives, and adverbs.

<sup>4</sup>We omitted *colorless* from the second example, as *colorless* is actually highly associated with *green* ( $PMI=4.36$ ).

school admission test (a full description of these data is given in section 4.1, under setA p1-p6). For each essay, we compute the WAP and represent it using the 60-bin histogram. For each bin in the histogram, we compute its average value over the 5,904 essays; additionally, we compute the 15<sup>th</sup> and 85<sup>th</sup> percentiles for each bin, so that the band between them contains values observed for 70% of the texts. The series with the solid thick (blue) line in Figure 1 shows the distribution of the average percentage of word type pairs per bin (essays-av); the dotted lines above and below show the band capturing the middle 70% of the distribution (essays-15 and essays-85).

We observe that the shape of the WAP is very stable across essays, and the variation around the average is quite limited.

Next, consider the thin solid (green) line with asterisk-shaped markers in Figure 1 that plots a similarly-binned histogram for the normal distribution with  $\mu=0.90$  and  $\sigma=0.66$ . We note that for values below  $\text{PMI}=2.17$ , the normal curve is within or almost within the 70% band for the essay data. The divergence occurs at the right tail with  $\text{PMI}>2.17$ , that covers, on average, about 8% of the pairs (5.6% and 10.4% for the 15<sup>th</sup> and 85<sup>th</sup> percentiles, respectively).

To get an idea about possible variation in the distribution, we consider two additional corpora from different genres. We use a corpus of Wall Street Journal 1987 articles from the TIPSTER collection.<sup>5</sup> We picked articles of 250 to 700 words in length, in order to keep the length of texts comparable to the essay data, while varying the genre; 770 such articles were found. The dashed (orange) line in Figure 1 shows the distribution of average values for the WSJ collection (wsj-av). We observe that the shape of the distribution is similar to that of essay data, although WSJ articles tend to be less tight, on average, since the distribution in  $\text{PMI}<2.17$  area in the WSJ data is shifted to the left relative to essays. Yet, the picture at the right tail is remarkably similar to that of the essays, with 9% of word pairs, on average, having  $\text{PMI}>2.17$ .

The second additional corpus contains 140 literary texts written or adapted for readers in grades 3 and 4 in US schools (Sheehan et al., 2008). In terms of length, these texts fall into the same range as the other corpora, averaging 507 words.

<sup>5</sup>LDC93T3A in LDC catalogue

The average WAP for these texts is shown with a thin solid (purple) line with circular markers in Figure 1 (Grades 3-4). These texts are much tighter than texts in the other two collections, as the distribution is shifted to the right. The right tail, with  $\text{PMI}>2.17$ , holds 19% of all word pairs in these texts – more than twice the proportion in essays written by college graduates or in texts from the WSJ.

It is instructive to check whether the over-use of highly associated pairs is *felt* during reading. These texts strike an adult reader as overly explicit, taking the space to state things that an adult reader would readily infer or assume. For example, consider the following opening paragraph:

“Grandma Rose gave Daniel a recorder. A recorder is a musical instrument. Daniel learned to play by blowing on the recorder. It didn’t take lots of air. It didn’t take big hands to hold since it was pocket-sized. His fingers covered the toneholes just fine. Soon Daniel played entire songs. His mother loved to listen. Sometimes she hummed along with Daniel’s recorder.”

The second and the third sentences state things that for an adult reader would be too obvious to need mention. In fact, these sentences almost seem like *training* sentences – the kind of sentences from which the associations between *recorder* and *musical instrument*, *play*, *blowing* can be learned. According to Hoey’s theory of lexical priming (Hoey, 2005), one of the main functions of schooling is to imbue children with the societally sanctioned word associations.

To conclude the illustration, we observe that there are some broad similarities between the different corpora in terms of the distribution of pairs of word types. Thus, texts seem to be mainly made of pairs of weakly associated words – about half the pairs of word types lie between PMI of 0.5 and 1.5, in all the examined collections (52% for essays, 44% for each of WSJ and young reader corpora). The percentages of pairs at the low and the high ends of PMI differ with genre – writing for children favors the higher end, while typical Wall Street Journal writing favors the low end, relatively to a corpus of essays on general topics written by college graduates.

These observations are necessarily very tentative, as only a few corpora were examined. Still,

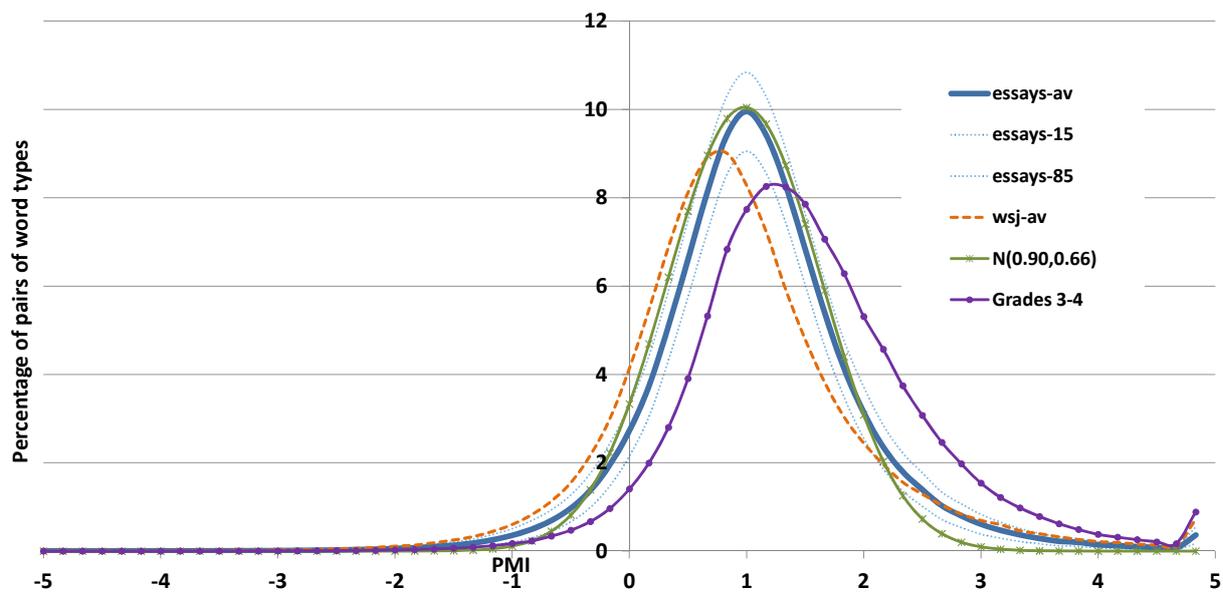

Figure 1: WAP histograms for three corpora, shown with smooth lines instead of bars for readability. Average for essays (a thick solid blue line), average for WSJ articles (a dashed orange line); average for Grades 3-4 corpus (a thin solid purple line with round markers). Normal distribution is shown with a thin solid green line with asterisk markers. Middle 70% of essays fall between the dotted lines.

we believe the illustration is suggestive, in that there is both constancy in writing for a similar purpose (observe the limited variation around the average that captures 70% of the essays) and variation with genre and target audience. In what follows, we will explore more thoroughly the information provided by word association profiles regarding the quality of writing.

#### 4 Application to Essay Scoring

Texts written for a test and scored by relevant professionals is a setting where variation in text quality is expected. In this section, we report our experiments with using WAPs to explore the variation in quality as quantified by essay scores. We first describe the data (section 4.1), then show the patterns of relationships between essay scores and word association profiles (section 4.2). Finally, we report on an experiment where we significantly improve the performance of a very competitive, state-of-art system for automated scoring of essays, using a feature derived from WAP.

##### 4.1 Data

We consider two collections of essays written as responses in an analytical writing section of a high-stakes standardized test for graduate school admission; the time limit for essay composition was 45 minutes. Essays were written in response

to a prompt (essay question). A prompt is usually a general statement, and the test-taker is asked to develop an argument supporting or refuting the statement. Example prompts are: “High-speed electronic communications media, such as electronic mail and television, tend to prevent meaningful and thoughtful communication” and “In the age of television, reading books is not as important as it once was. People can learn as much by watching television as they can by reading books.”

The first collection (henceforth, **setA**) contains 8,899 essays written in response to nine different prompts, about 1,000 per prompt;<sup>6</sup> the per-prompt subsets will be termed **setA-p1** through **setA-p9**. Each essay in setA was scored by 1 to 4 human raters on a scale of 1 to 6; the majority of essays received 2 human scores. We use the average of the available human scores as the gold-standard score for the essay. Most essays thereby receive an integer score,<sup>7</sup> so the ranking of the essays is coarse. From this set, p1-p6 were used for feature selection, data visualization, and estimation of the regression models (training), while sets p7-p9 were reserved for a blind test.

The second collection (henceforth, **setB**) con-

<sup>6</sup>While we sampled exactly 1,000 essays per prompt, we removed empty responses, resulting in 975 to 1,000 essays per sample.

<sup>7</sup>as the two raters agree most of the time

tains 400 essays, with 200 essays written on each of two prompts given as examples above (**setB-p1** and **setB-p2**). In an experimental study by Attali et al. (2013), each essay was scored by 16 professional raters on a scale of 1 to 6, allowing plus and minus scores as well, quantified as 0.33 – thus, a score of 4- is rendered as 3.67. This fine-grained scale resulted in higher mean pairwise inter-rater correlations than the traditional integer-only scale ( $r=0.79$  vs around  $r=0.70$  for the operational scoring). We use the average of 16 raters as the final grade for each essay. This dataset provides a very fine-grained ranking of the essays, with almost no two essays getting exactly the same score.

Rounded Score	setA p1-p9			setB	
	av	min	max	p1	p2
1	.01	.00	.01	–	–
2	.05	.04	.06	.03	.03
3	.25	.20	.29	.30	.28
4	.44	.42	.47	.54	.55
5	.21	.16	.24	.13	.14
6	.04	.02	.07	.01	.02

Table 1: Score distribution in the essay data. For the sake of presentation in this table, all scores were rounded to integer scores, so a score of 3.33 was counted as 3, and a score of 3.5 was counted as 4. A cell with the value of .13 (row titled 5 and column titled SetB p1) means that 13% of the essays in setB-p1 received scores that round to 5. For setA, average, minimum, and maximum values across the nine prompts are shown.

Table 1 shows the distribution of rounded scores in both collections. Average essay scores are between 3.74 to 3.98 across the different prompts from both collections. The use of 16 raters seems to have moved the rounded scores towards the middle; however, the relative ranking of the essays is much more delicate in setB than in setA.

## 4.2 Essay Score vs WAP

We calculated correlations between essay score and the proportion of word pairs in each of the 60 bins of the WAP histogram, separately for each of the prompts p1-p6 in setA. For a sample of 1,000 instances, a correlation of  $r=0.065$  is significant at  $p = 0.05$ . Figure 2 plots the correlations.

First, we observe that, perhaps contrary to expectation, the proportion of the highest values of PMI (the area to the right of  $PMI=4$  in Figure 2)

does not yield a consistent correlation with essay scores. Thus, inasmuch as highest PMI values tend to capture multi-word expressions (*South* and *Africa*; *Merill* and *Lynch*), morphological variants (*bids* and *bidding*), or synonyms (*mergers* and *takeovers*), their proportion in word type pairs does not seem to give a clear signal regarding the quality of writing.<sup>8</sup>

In contrast, the area of moderately high PMI values (from  $PMI=2.5$  to  $PMI=3.67$  in Figure 2) produces a very consistent picture, with only two points out of 48 in that interval<sup>9</sup> lacking significant positive correlation with essay score (p2 at  $PMI=3.17$  and p5 at  $PMI=3$ ).

Next, observe the consistent negative correlations between essay score and the proportion of word pairs in bins  $PMI=0.833$  through  $PMI=1.5$ . Here again, out of the 30 data points corresponding to these values, only 3 failed to reach statistical significance, although the trend there is still negative.

Finally, there is a trend towards a positive correlation between essay scores and the proportion of mildly negative PMI values ( $-2 < PMI < 0$ ), that is, better essays tend to use *more* pairs of disassociated words, although this trend is not as clear-cut as the one on the right-hand side of the distribution.

Assuming that a higher proportion of high PMI pairs corresponds to more topic development and that a higher proportion of negative PMIs corresponds to more creative use of language (in that pairs are chosen that do not generally tend to appear together), it seems that the better essays are *both* more topical *and* more creative than the lower scoring ones. In what follows, we check whether the information about essay quality provided by WAP can be used to improve essay scoring.

<sup>8</sup>It is also possible that some of the instances with very high PMI are pairs that contain low frequency words for which the database predicts a spuriously high PMI based on a single (and a-typical) co-occurrence that happens to repeat in an essay – similar to the *Schwartz eschews* example in (Manning and Schütze, 1999, Table 5.16, p. 181). On the one hand, we do not expect such pairs to occur in any systematic pattern, so they could obscure an otherwise more systematic pattern in the high PMI bins. On the other hand, we do not expect to see many such pairs, simply because a repetition of an a-typical event is likely to be very rare. We thank an anonymous reviewer for suggesting this direction, and leave a more detailed examination of the pairs in the highest-PMI bins to future work.

<sup>9</sup>There are 8 bins of width of 0.167 in the given interval, with 6 datapoints per bin.

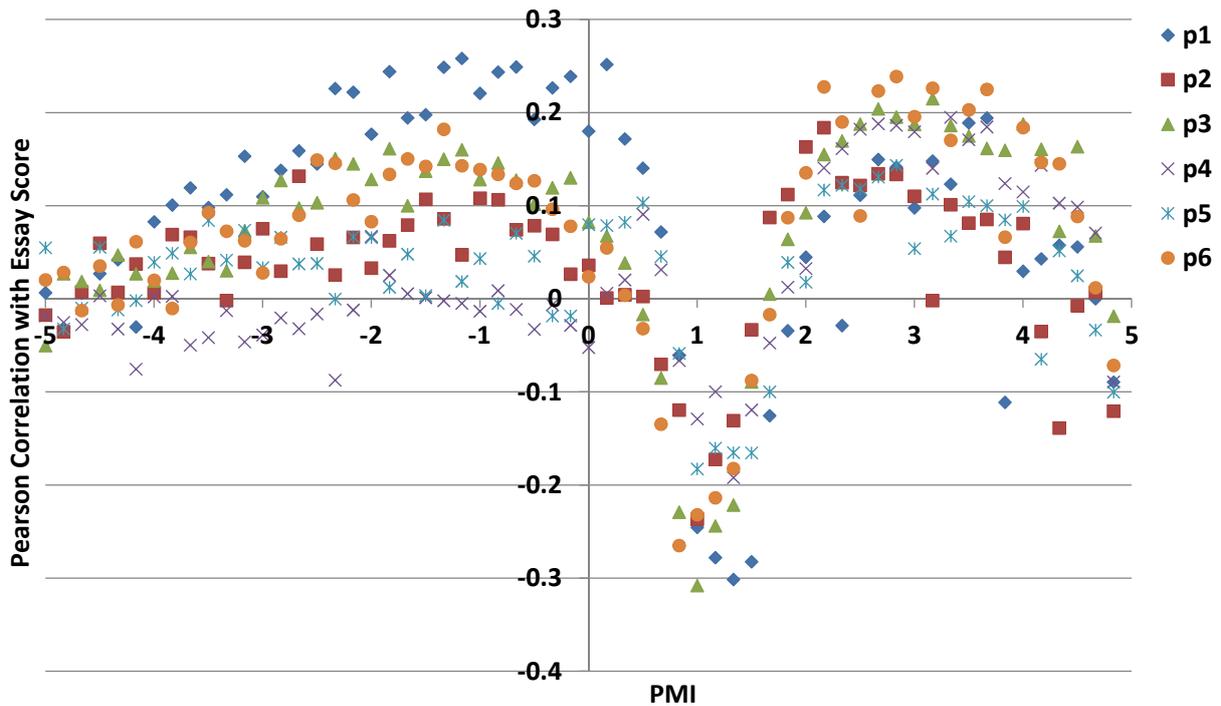

Figure 2: Correlations with essay score for various bins of the WAP histogram. P1 to P6 correspond to the first 6 prompts in SetA.

### 4.3 Baseline

As a baseline, we use e-rater (Attali and Burstein, 2006), a state-of-art essay scoring system developed at Educational Testing Service.<sup>10</sup> E-rater computes more than 100 micro-features, which are aggregated into macro-features aligned with specific aspects of the writing construct. The system incorporates macro-features measuring grammar, usage, mechanics, style, organization and development, lexical complexity, and vocabulary usage. Table 2 gives examples of micro-features covered by the different macro-features.

E-rater models are built using linear regression on large samples of test-taker essays. We use a generic e-rater model built at Educational Testing Service using essays across a variety of writing prompts, with no connection to the current project and its authors. This model obtains Pearson correlations of  $r=0.8324-0.8721$  with the human scores on setA, and the staggering  $r=0.9191$  and  $r=0.9146$  with the human scores on setB-p1 and setB-p2, respectively. This is a very competitive baseline, as e-rater features explain more than 70% of the variation in essay scores on a relatively coarse scale (setA) and more than 80% of the variation in scores on a fine-grained scale (setB).

<sup>10</sup><http://www.ets.org/erater/about/>

Macro-Feature	Example Micro-Features
Grammar, Usage, and Mechanics	agreement errors verb formation errors missing punctuation
Style	passive very long or short sentences excessive repetition
Organization and Development	use of discourse elements: thesis, support, conclusion
Lexical Complexity	average word frequency average word length
Vocabulary	similarity to vocabulary in high- vs low-scoring essays

Table 2: Features used in e-rater (Attali and Burstein, 2006).

### 4.4 Adding WAP

We define **HAT** – high associative tightness – as the percentage of word type pairs with  $2.33 < PMI \leq 3.67$  (bins  $PMI=2.5$  through  $PMI=3.67$ ). This range corresponds to the longest sequence of adjacent bins in the  $PMI > 0$  area that had a positive correlation with essay score in the setA-p1 set. The HAT feature attains significant

(at  $p = 0.05$ ) correlations with essay scores,  $r=0.11$  to  $r=0.27$  for the prompts in setA, and  $r=0.22$  and  $r=0.21$  for the two prompts in setB. We note that the HAT feature is not correlated with essay length. Essay length is not used as a feature in e-rater models, but it typically correlates strongly with the human essay score (at about  $r=0.70$  in our data), as well as with the score provided by e-rater (at about  $r=0.80$ ).

We also explored a feature that captured the area with the negative correlations identified in section 4.2. This feature did not succeed in improving the performance over the baseline on setA p1-p6; we tentatively conclude that information contained in that feature, i.e. the proportion of mildly associated vocabulary in an essay, is indirectly captured by another feature or group of features already present in e-rater. Likewise, a feature that calculates the average PMI for all pairs of content word types in the text failed to produce an improvement over the baseline for setA p1-p6. The reason for this can be observed in Figure 2: The higher-scoring essays having more of *both* the low and the high PMI pairs leads to about the same average PMI as for the lower-scoring essays that have a higher concentration of values closer to the average PMI.

#### 4.5 Evaluation

To evaluate the usefulness of WAP in improving automated scoring of essays, we estimate a linear regression model using the human score as a dependent variable (label) and e-rater score and the HAT as the two independent variables (features). The correlations between the two independent variables (e-rater and HAT) are between  $r=0.11$  and  $r=0.24$  on the prompts in setA and setB.

We estimate a regression model on each of setA- $p_i$ ,  $i \in \{1, \dots, 6\}$ , and evaluate them on each of setA- $p_j$ ,  $j \in \{7, \dots, 9\}$ , and compare the performance with that of e-rater alone on setA- $p_j$ . Note that e-rater itself is not trained on any of the data in setA and setB; we use the same e-rater model for all evaluations, a generic model that was pre-trained on a large number of essays across different prompts. For setB, we estimate the regression model on setB-p1 and test on setB-p2, and vice versa.

Table 3 shows the evaluation results. The HAT feature leads to a statistically significant improve-

Train	Test	E-rater on Test	E-rater+HAT on Test	$t$
<b>setA</b>				
p1	p7	0.84043	0.84021	-0.371

p5	p9	0.86370	0.86591	<u>4.390</u>
p6	p9	0.86370	0.86730	<u>3.448</u>
<b>setB</b>				
p1	p2	0.9146	0.9178	0.983
p2	p1	0.9191	0.9242	<u>2.690</u>

Table 3: Performance of baseline model (e-rater) and models where e-rater was augmented with HAT, a feature based on the word association profile. Performance is measured using Pearson correlation with essay score. We use Wilcoxon Signed-Ranked test for matched pairs, and report the sum of signed ranks (W), the number of ranks (n), and the  $p$  value. E-rater+HAT is significantly better than e-rater alone,  $W=138$ ,  $n=20$ ,  $p<0.05$ . We also measure significance of the improvement for each row individually, using McNemar’s test for significance of difference in same-sample correlations (McNemar, 1955, p.148); we report the  $t$  value for each test. For values of  $t > 1.645$ , we can reject the hypothesis that e-rater+HAT is not better than e-rater alone with 95% confidence. Significant improvements are underlined.

ment in the performance of automated scoring. An improvement is observed for 14 out of the 18 evaluations for setA, as well as for both evaluations for setB.<sup>11</sup> Moreover, the largest relative improvement of 0.55%, from 0.9191 to 0.9242, was observed for the setting with the highest baseline performance, suggesting that the HAT feature is still effective even after the delicate ranking of the essays revealed an exceptionally strong performance of e-rater.

## 5 Related Work

Most of the attention in the computational linguistics research that deals with analysis of the lexis of texts has so far been paid to what in our terms would be the very high end of the word association profile. Thus, following Halliday and Hasan (1976), Hoey (1991), and Morris and Hirst (1991), the notion of *lexical cohesion* has been used to capture repetitions of words and occurrence of words with related meanings in a text. Lexically cohesive words are traced through the text, forming lexical chains or graphs, and these representations are used in a variety of applications, such as segmentation, keyword extraction, summarization, sentiment analysis, temporal indexing, hypelink generation, error correction (Guinaudeau et al., 2012; Marathe and Hirst, 2010; Ercan and Cicekli, 2007; Devitt and Ahmad, 2007; Hirst and Budanitsky, 2005; Inkpen and Désilets, 2005; Gurevych and Strube, 2004; Stokes et al., 2004; Silber and McCoy, 2002; Green, 1998; Al-Halimi and Kazman, 1998; Barzilay and Elhadad, 1997). To our knowledge, lexical cohesion has not so far been used for automated scoring of essays. Our results suggest that this direction is promising, as merely the *proportion* of highly associated word pairs is already contributing a clear signal regarding essay quality; it is possible that additional information can be derived from richer representations common in the lexical cohesion literature.

Aspects related to the distribution of words in essays have been studied in relation to essay scoring. One line of work focuses on assessing coherence of essays. Foltz et al. (1998) use Latent

<sup>11</sup>We also performed a cross-validation test on setA p1-p6, where we estimated a regression model on setA-p*i* and evaluate it on setA-p*j*, for all  $i, j \in \{1, \dots, 6\}, i \neq j$ , and compared the performance with that of e-rater alone on setA-p*j*, yielding 30 different train-test combinations. The results were similar to those of the blind test presented here, with e-rater+HAT significantly improving upon e-rater alone, using Wilcoxon test,  $W=374, n=29, p<0.05$ .

Semantic Analysis to model the smoothness of transitions between adjacent segments of an essay. Higgins et al. (2004) compare sentences from certain discourse segments in an essay to determine their semantic similarity, such as comparing thesis statements to conclusions or thesis statements to essay prompts. Additional approaches include evaluation of coherence based on repeated reference to entities (Burstein et al., 2010; Barzilay and Lapata, 2008; Miltsakaki and Kukich, 2004). Our approach is different in that it does not measure the flow of the text, that is, the sequencing and repetition of the words, but rather assesses the choice of vocabulary as a whole.

Topic models have been proposed as a technique for capturing clusters of related words that tend to occur in the same documents in a given collection. A text is modeled as being composed of a small number of topics, and words in the text are generated conditioned on the selected topics (Gruber et al., 2007; Blei et al., 2003). Since (a) topics encapsulate clusters of highly associated words, and (b) topics for a given text are modeled as being chosen independently from each other, we expect a negative correlation between the number of topics in a document and the tightness of the word association profile of the text.

An alternative representation of word association profile would be a weighted graph, where the weights correspond to pairwise associations between words. Thus, for longer texts, graph analysis techniques would be applicable. Steyvers and Tenenbaum (2005) analyze the graphs induced from large repositories like WordNet or databases of free associations, and find them to be scale-free and small-world; it is an open question whether word association graphs induced from book-length texts would exhibit similar properties.

In the theoretical tradition, our work is closest in spirit to Michael Hoey's theory of lexical priming (Hoey, 2005), positing that users of language internalize patterns of occurrence and non-occurrence of words not only with other words, but also in certain positions in a text, in certain syntactic environments, and in certain evaluative contexts, and use these when creating their own texts. We believe that word association profiles reflect the artwork that goes into using those internalized associations between words when creating a text, achieving the right mix of strong and weak, positive and negative associations.

## 6 Conclusion

In this paper, we described a new representation of the content vocabulary of a text we call *word association profile* that captures the proportions of highly associated, mildly associated, unassociated, and dis-associated pairs of words selected to co-exist in the given text by its author. We observed that the shape of the distribution is quite stable across various texts, with about half the pairs having a mild association; the allocation of pairs to the higher and the lower levels of association does vary across genres and target audiences.

We further presented a study of the relationship between quality of writing and word association profiles. For a dataset of essays written by college graduates on a number of general topics in a standardized test for graduate school admission and scored by professional raters, we showed that the higher scoring essays tend to have higher percentages of both highly associated and dis-associated pairs, and lower percentages of mildly associated pairs of words. We hypothesize that this pattern is consistent with the better essays demonstrating both a better topic development (hence the higher percentage of highly related pairs) and a more creative use of language resources, as manifested in a higher percentage of word pairs that generally do not tend to appear together.

Finally, we demonstrated that the information provided by word association profiles leads to a significant improvement in a highly competitive, state-of-art essay scoring system that already measures various aspects of writing quality.

In future work, we intend to investigate in more detail the contribution of various kinds of words to word association profiles, as well as pursue application to evaluation of text complexity.

## Abstract

Text normalization is an important first step towards enabling many Natural Language Processing (NLP) tasks over informal text. While many of these tasks, such as parsing, perform the best over fully grammatically correct text, most existing text normalization approaches narrowly define the task in the *word-to-word* sense; that is, the task is seen as that of mapping all out-of-vocabulary non-standard words to their in-vocabulary standard forms. In this paper, we take a parser-centric view of normalization that aims to convert raw informal text into grammatically correct text. To understand the real effect of normalization on the parser, we tie normalization performance directly to parser performance. Additionally, we design a customizable framework to address the often overlooked concept of domain adaptability, and illustrate that the system allows for transfer to new domains with a minimal amount of data and effort. Our experimental study over datasets from three domains demonstrates that our approach outperforms not only the state-of-the-art word-to-word normalization techniques, but also manual word-to-word annotations.

## 1 Introduction

Text normalization is the task of transforming informal writing into its standard form in the language. It is an important processing step for a wide range of Natural Language Processing (NLP) tasks such as text-to-speech synthesis, speech recognition, information extraction, parsing, and machine translation (Sproat et al., 2001).

The use of normalization in these applications poses multiple challenges. First, as it is most often conceptualized, normalization is seen as the task of mapping all out-of-vocabulary non-standard word tokens to their in-vocabulary standard forms. However, the scope of the task can also be seen as much wider, encompassing whatever actions are required to convert the raw text into a fully grammatical sentence. This broader definition of the normalization task may include modifying punctuation and capitalization, and adding, removing, or reordering words. Second, as with other NLP techniques, normalization approaches are often focused on one primary domain of interest (e.g., Twitter data). Because the style of informal writing may be different in different data sources, tailoring an approach towards a particular data source can improve performance in the desired domain. However, this is often done at the cost of adaptability.

This work introduces a customizable normalization approach designed with domain transfer in mind. In short, customization is done by providing the normalizer with *replacement generators*, which we define in Section 3. We show that the introduction of a small set of domain-specific generators and training data allows our model to outperform a set of competitive baselines, including state-of-the-art word-to-word normalization. Additionally, the flexibility of the model also allows it to attempt to produce fully grammatical sentences, something not typically handled by word-to-word normalization approaches.

Another potential problem with state-of-the-art normalization is the lack of appropriate evaluation metrics. The normalization task is most frequently motivated by pointing to the need for clean text for downstream processing applications, such as syntactic parsing. However, most studies of normalization give little insight into whether and to what degree the normalization process improves

---

\*This work was conducted at IBM.

the performance of the downstream application. For instance, it is unclear how performance measured by the typical normalization evaluation metrics of word error rate and BLEU score (Papineni et al., 2002) translates into performance on a parsing task, where a well placed punctuation mark may provide more substantial improvements than changing a non-standard word form. To address this problem, this work introduces an evaluation metric that ties normalization performance directly to the performance of a downstream dependency parser.

The rest of this paper is organized as follows. In Section 2 we discuss previous approaches to the normalization problem. Section 3 presents our normalization framework, including the actual normalization and learning procedures. Our instantiation of this model is presented in Section 4. In Section 5 we introduce the parser driven evaluation metric, and present experimental results of our model with respect to several baselines in three different domains. Finally, we discuss our experimental study in Section 6 and conclude in Section 7.

## 2 Related Work

Sproat et al. (2001) took the first major look at the normalization problem, citing the need for normalized text for downstream applications. Unlike later works that would primarily focus on specific noisy data sets, their work is notable for attempting to develop normalization as a general process that could be applied to different domains. The recent rise of heavily informal writing styles such as Twitter and SMS messages set off a new round of interest in the normalization problem.

Research on SMS and Twitter normalization has been roughly categorized as drawing inspiration from three other areas of NLP (Kobus et al., 2008): machine translation, spell checking, and automatic speech recognition. The statistical machine translation (SMT) metaphor was the first proposed to handle the text normalization problem (Aw et al., 2006). In this mindset, normalizing SMS can be seen as a translation task from a source language (informal) to a target language (formal), which can be undertaken with typical noisy channel based models. Work by Choudhury et al. (2007) adopted the spell checking metaphor, casting the problem in terms of character-level, rather than word-level, edits. They proposed an HMM based model that

takes into account both grapheme and phoneme information. Kobus et al. (2008) undertook a hybrid approach that pulls inspiration from both the machine translation and speech recognition metaphors.

Many other approaches have been examined, most of which are at least partially reliant on the above three metaphors. Cook and Stevenson (2009) perform an unsupervised method, again based on the noisy channel model. Pennell and Liu (2011) developed a CRF tagger for deletion-based abbreviation on tweets. Xue et al. (2011) incorporated orthographic, phonetic, contextual, and acronym expansion factors to normalize words in both Twitter and SMS. Liu et al. (2011) modeled the generation process from dictionary words to non-standard tokens under an unsupervised sequence labeling framework. Han and Baldwin (2011) use a classifier to detect ill-formed words, and then generate correction candidates based on morphophonemic similarity. Recent work has looked at the construction of normalization dictionaries (Han et al., 2012) and on improving coverage by integrating different human perspectives (Liu et al., 2012).

Although it is almost universally used as a motivating factor, most normalization work does not directly focus on improving downstream applications. While a few notable exceptions highlight the need for normalization as part of text-to-speech systems (Beaufort et al., 2010; Pennell and Liu, 2010), these works do not give any direct insight into how much the normalization process actually improves the performance of these systems. To our knowledge, the work presented here is the first to clearly link the output of a normalization system to the output of the downstream application. Similarly, our work is the first to prioritize domain adaptation during the new wave of text message normalization.

## 3 Model

In this section we introduce our normalization framework, which draws inspiration from our previous work on spelling correction for search (Bao et al., 2011).

### 3.1 Replacement Generators

Our input the original, unnormalized text, represented as a sequence  $\mathbf{x} = x_1, x_2, \dots, x_n$  of *tokens*  $x_i$ . In this section we will use the following se-

quence as our running example:

$\mathbf{x} = \text{Ay}_1 \text{ wou}d\text{ent}_2 \text{ of}_3 \text{ see}_4 \text{ 'em}_5$

where space replaces comma for readability, and each token is subscripted by its position. Given the input  $\mathbf{x}$ , we apply a series of replacement generators, where a *replacement generator* is a function that takes  $\mathbf{x}$  as input and produces a collection of replacements. Here, a *replacement* is a statement of the form “replace tokens  $x_i, \dots, x_{j-1}$  with  $\mathbf{s}$ .” More precisely, a replacement is a triple  $\langle i, j, \mathbf{s} \rangle$ , where  $1 \leq i \leq j \leq n + 1$  and  $\mathbf{s}$  is a sequence of tokens. Note that in the case where  $i = j$ , the sequence  $\mathbf{s}$  should be *inserted* right before  $x_i$ ; and in the special case where  $\mathbf{s}$  is empty, we simply delete  $x_i, \dots, x_{j-1}$ . For instance, in our running example the replacement  $\langle 2, 3, \text{would not} \rangle$  replaces  $x_2 = \text{wou}d\text{ent}$  with  $\text{would not}$ ;  $\langle 1, 2, \text{Ay} \rangle$  replaces  $x_1$  with itself (hence, does not change  $\mathbf{x}$ );  $\langle 1, 2, \epsilon \rangle$  (where  $\epsilon$  is the empty sequence) deletes  $x_1$ ;  $\langle 6, 6, . \rangle$  inserts a period at the end of the sequence.

The provided replacement generators can be either generic (cross domain) or domain-specific, allowing for domain customization. In Section 4, we discuss the replacement generators used in our empirical study.

### 3.2 Normalization Graph

Given the input  $\mathbf{x}$  and the set of replacements produced by our generators, we associate a unique Boolean variable  $X_r$  with each replacement  $r$ . As expected,  $X_r$  being **true** means that the replacement  $r$  takes place in producing the output sequence.

Next, we introduce dependencies among variables. We first discuss the syntactic consistency of truth assignments. Let  $r_1 = \langle i_1, j_1, \mathbf{s}_1 \rangle$  and  $r_2 = \langle i_2, j_2, \mathbf{s}_2 \rangle$  be two replacements. We say that  $r_1$  and  $r_2$  are *locally consistent* if the intervals  $[i_1, j_1)$  and  $[i_2, j_2)$  are disjoint. Moreover, we do not allow two insertions to take place at the same position; therefore, we exclude  $[i_1, j_1)$  and  $[i_2, j_2)$  from the definition of local consistency when  $i_1 = j_1 = i_2 = j_2$ . If  $r_1$  and  $r_2$  are locally consistent and  $j_1 = i_2$ , then we say that  $r_2$  is a *consistent follower* of  $r_1$ .

A truth assignment  $\alpha$  to our variables  $X_r$  is *sound* if every two replacements  $r$  and  $r'$  with  $\alpha(X_r) = \alpha(X_{r'}) = \mathbf{true}$  are locally consistent. We say that  $\alpha$  is *complete* if every token

of  $\mathbf{x}$  is captured by at least one replacement  $r$  with  $\alpha(X_r) = \mathbf{true}$ . Finally, we say that  $\alpha$  is *legal* if it is sound and complete. The output (normalized sequence) defined by a legal assignment  $\alpha$  is, naturally, the concatenation (from left to right) of the strings  $\mathbf{s}$  in the replacements  $r = \langle i, j, \mathbf{s} \rangle$  with  $\alpha(X_r) = \mathbf{true}$ . In Figure 1, for example, if the nodes with a grey shade are the ones associated with **true** variables under  $\alpha$ , then the output defined by  $\alpha$  is I would not have seen them.

Our variables carry two types of interdependencies. The first is that of syntactic consistency: the entire assignment is required to be legal. The second captures correlation among replacements. For instance, if we replace `of` with `have` in our running example, then the next `see` token is more likely to be replaced with `seen`. In this work, dependencies of the second type are restricted to pairs of variables, where each pair corresponds to a replacement and a consistent follower thereof.

The above dependencies can be modeled over a standard undirected graph using Conditional Random Fields (Lafferty et al., 2001). However, the graph would be complex: in order to model local consistency, there should be edges between every two nodes that violate local consistency. Such a model renders inference and learning infeasible. Therefore, we propose a clearer model by a directed graph, as illustrated in Figure 1 (where nodes are represented by replacements  $r$  instead of the variables  $X_r$ , for readability). To incorporate correlation among replacements, we introduce an edge from  $X_r$  to  $X_{r'}$  whenever  $r'$  is a consistent follower of  $r$ . Moreover, we introduce two dummy nodes, `start` and `end`, with an edge from `start` to each variable that corresponds to a prefix of the input sequence  $\mathbf{x}$ , and an edge from each variable that corresponds to a suffix of  $\mathbf{x}$  to `end`.

The principal advantage of modeling the dependencies in such a directed graph is that now, the legal assignments are in one-to-one correspondence with the paths from `start` to `end`; this is a straightforward observation that we do not prove here.

We appeal to the log-linear model formulation to define the probability of an assignment. The conditional probability of an assignment  $\alpha$ , given an input sequence  $\mathbf{x}$  and the weight vector  $\Theta = \langle \theta_1, \dots, \theta_k \rangle$  for our features, is defined as  $p(\alpha |$

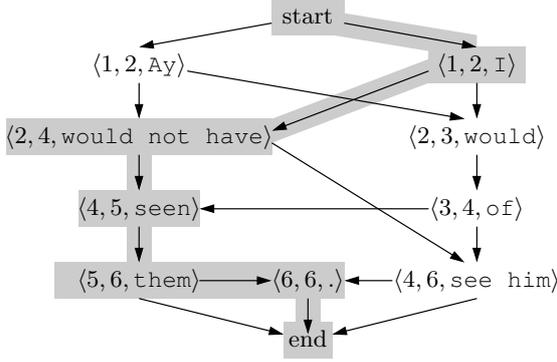

Figure 1: Example of a normalization graph; the nodes are replacements generated by the replacement generators, and every path from start to end implies a legal assignment

$\mathbf{x}, \Theta) = 0$  if  $\alpha$  is not legal, and otherwise,

$$p(\alpha \mid \mathbf{x}, \Theta) = \frac{1}{Z(\mathbf{x})} \prod_{X \rightarrow Y \in \alpha} \exp\left(\sum_j \theta_j \phi_j(X, Y, \mathbf{x})\right).$$

Here,  $Z(\mathbf{x})$  is the partition function,  $X \rightarrow Y \in \alpha$  refers to an edge  $X \rightarrow Y$  with  $\alpha(X) = \mathbf{true}$  and  $\alpha(Y) = \mathbf{true}$ , and  $\phi_1(X, Y, \mathbf{x}), \dots, \phi_k(X, Y, \mathbf{x})$  are real valued feature functions that are weighted by  $\theta_1, \dots, \theta_k$  (the model’s parameters), respectively.

### 3.3 Inference

When performing inference, we wish to select the output sequence with the highest probability, given the input sequence  $\mathbf{x}$  and the weight vector  $\Theta$  (i.e., MAP inference). Specifically, we want an assignment  $\alpha^* = \arg \max_{\alpha} p(\alpha \mid \mathbf{x}, \Theta)$ .

While exact inference is computationally hard on general graph models, in our model it boils down to finding the longest path in a weighted and acyclic directed graph. Indeed, our directed graph (illustrated in Figure 1) is acyclic. We assign the real value  $\sum_j \theta_j \phi_j(X, Y, \mathbf{x})$  to the edge  $X \rightarrow Y$ , as the weight. As stated in Section 3.2, a legal assignment  $\alpha$  corresponds to a path from start to end; moreover, the sum of the weights on that path is equal to  $\log p(\alpha \mid \mathbf{x}, \Theta) + \log Z(\mathbf{x})$ . In particular, a longer path corresponds to an assignment with greater probability. Therefore, we can solve the MAP inference within our model by finding the weighted longest path in the directed acyclic graph. The algorithm in Figure 2 summarizes the inference procedure to normalize the input sequence  $\mathbf{x}$ .

#### Input:

1. A sequence  $\mathbf{x}$  to normalize;
2. A weight vector  $\Theta = \langle \theta_1, \dots, \theta_k \rangle$ .

**Generate replacements:** Apply all replacement generators to get a set of replacements  $r$ , each  $r$  is a triple  $\langle i, j, s \rangle$ .

#### Build a normalization graph:

1. For each replacement  $r$ , create a node  $X_r$ .
2. For each  $r'$  and  $r$ , create an edge  $X_r$  to  $X_{r'}$  if  $r'$  is a consistent follower of  $r$ .
3. Create two dummy nodes start and end, and create edges from start to all prefix nodes and end to all suffix nodes.
4. For each edge  $X \rightarrow Y$ , compute the features  $\phi_j(X, Y, \mathbf{x})$ , and weight the edge by  $\sum_j \theta_j \phi_j(X, Y, \mathbf{x})$ .

**MAP Inference:** Find a weighted longest path  $P$  from start to end, and return  $\alpha^*$ , where  $\alpha^*(X_r) = \mathbf{true}$  iff  $X_r \in P$ .

Figure 2: Normalization algorithm

### 3.4 Learning

Our labeled data consists of pairs  $(\mathbf{x}_i, \mathbf{y}_i^{\text{gold}})$ , where  $\mathbf{x}_i$  is an input sequence (to normalize) and  $\mathbf{y}_i^{\text{gold}}$  is a (manually) normalized sequence. We obtain a truth assignment  $\alpha_i^{\text{gold}}$  from each  $\mathbf{y}_i^{\text{gold}}$  by selecting an assignment  $\alpha$  that minimizes the edit distance between  $\mathbf{y}_i^{\text{gold}}$  and the normalized text implied by  $\alpha$ :

$$\alpha_i^{\text{gold}} = \arg \min_{\alpha} \text{DIST}(y(\alpha), \mathbf{y}_i^{\text{gold}}) \quad (1)$$

Here,  $y(\alpha)$  denotes the normalized text implied by  $\alpha$ , and DIST is a token-level edit distance. We apply a simple dynamic-programming algorithm to compute  $\alpha_i^{\text{gold}}$ . Finally, the items in our training data are the pairs  $(\mathbf{x}_i, \alpha_i^{\text{gold}})$ .

Learning over similar models is commonly done via maximum likelihood estimation:

$$L(\Theta) = \log \prod_i p(\alpha_i = \alpha_i^{\text{gold}} \mid \mathbf{x}_i, \Theta)$$

Taking the partial derivative gives the following:

$$\sum_i \left( \Phi_j(\alpha_i^{\text{gold}}, \mathbf{x}_i) - E_{p(\alpha_i \mid \mathbf{x}_i, \Theta)} \Phi_j(\alpha_i, \mathbf{x}_i) \right)$$

where  $\Phi_j(\alpha, \mathbf{x}) = \sum_{X \rightarrow Y} \phi_j(X, Y, \mathbf{x})$ , that is, the sum of values for the  $j$ th feature along the

<p><b>Input:</b></p> <ol style="list-style-type: none"> <li>1. A set <math>\{(\mathbf{x}_i, \mathbf{y}_i^{\text{gold}})\}_{i=1}^n</math> of sequences and their gold normalization;</li> <li>2. Number <math>T</math> of iterations.</li> </ol> <p><b>Initialization:</b> Initialize each <math>\theta_j</math> as zero, and obtain each <math>\alpha_i^{\text{gold}}</math> according to (1).</p> <p><b>Repeat <math>T</math> times:</b></p> <ol style="list-style-type: none"> <li>1. Infer each <math>\alpha_i^*</math> from <math>\mathbf{x}_i</math> using the current <math>\Theta</math>;</li> <li>2. <math>\theta_j \leftarrow \theta_j + \sum_i (\Phi_j(\alpha_i^{\text{gold}}, \mathbf{x}_i) - \Phi_j(\alpha_i^*, \mathbf{x}_i))</math> for all <math>j = 1, \dots, k</math>.</li> </ol> <p><b>Output:</b> <math>\Theta = \langle \theta_1, \dots, \theta_k \rangle</math></p>
--

Figure 3: Learning algorithm

path defined by  $\alpha$ , and  $E_{p(\alpha_i|\mathbf{x}_i, \Theta)} \Phi_j(\alpha_i, \mathbf{x}_i)$  is the expected value of that sum (over all legal assignments  $\alpha_i$ ), assuming the current weight vector.

How to efficiently compute  $E_{p(\alpha_i|\mathbf{x}_i, \Theta)} \Phi_j(\alpha_i, \mathbf{x}_i)$  in our model is unclear; naively, it requires enumerating all legal assignments. We instead opt to use a more tractable perceptron-style algorithm (Collins, 2002). Instead of computing the expectation, we simply compute  $\Phi_j(\alpha_i^*, \mathbf{x}_i)$ , where  $\alpha_i^*$  is the assignment with the highest probability, generated using the current weight vector. The result is then:

$$\sum_i \left( \Phi_j(\alpha_i^{\text{gold}}, \mathbf{x}_i) - \Phi_j(\alpha_i^*, \mathbf{x}_i) \right)$$

Our learning applies the following two steps iteratively. (1) Generate the most probable sequence within the current weights. (2) Update the weights by comparing the path generated in the previous step to the gold standard path. The algorithm in Figure 3 summarizes the procedure.

## 4 Instantiation

In this section, we discuss our instantiation of the model presented in the previous section. In particular, we describe our replacement generators and features.

### 4.1 Replacement Generators

One advantage of our proposed model is that the reliance on replacement generators allows for strong flexibility. Each generator can be seen as a black box, allowing replacements that are created heuristically, statistically, or by external tools to be incorporated within the same framework.

Generator	From	To
leave intact	good	good
edit distance	bac	back
lowercase	NEED	need
capitalize	it	It
Google spell	disspaear	disappear
contraction	wouldn't	would not
slang language	ima	I am going to
insert punctuation	€	.
duplicated punctuation	!?	!
delete filler	lmao	€

Table 1: Example replacement generators

To build a set of generic replacement generators suitable for normalizing a variety of data types, we collected a set of about 400 Twitter posts as development data. Using that data, a series of generators were created; a sample of them are shown in Table 1. As shown in the table, these generators cover a variety of normalization behavior, from changing non-standard word forms to inserting and deleting tokens.

### 4.2 Features

Although the proposed framework supports real valued features, all features in our system are binary. In total, we used 70 features. Our feature set pulls information from several different sources:

**N-gram:** Our n-gram features indicate the frequency of the phrases induced by an edge. These features are turned into binary ones by bucketing their log values. For example, on the edge from  $\langle 1, 2, \text{I} \rangle$  to  $\langle 2, 3, \text{would} \rangle$  such a feature will indicate whether the frequency of `I would` is over a threshold. We use the Corpus of Contemporary English (Davies, 2008) to produce our n-gram information.

**Part-of-speech:** Part-of-speech information can be used to produce features that encourage certain behavior, such as avoiding the deletion of noun phrases. We generate part-of-speech information over the original raw text using a Twitter part-of-speech tagger (Ritter et al., 2011). Of course, the part-of-speech information obtained this way is likely to be noisy, and we expect our learning algorithm to take that into account.

**Positional:** Information from positions is used primarily to handle capitalization and punctuation insertion, for example, by incorporating features for capitalized words after stop punctuation or the insertion of stop punctuation at the end of the sentence.

**Lineage:** Finally, we include binary features

that indicate which generator spawned the replacement.

## 5 Evaluation

In this section, we present an empirical study of our framework. The study is done over datasets from three different domains. The goal is to evaluate the framework in two aspects: (1) usefulness for downstream applications (specifically dependency parsing), and (2) domain adaptability.

### 5.1 Evaluation Metrics

A few different metrics have been used to evaluate normalizer performance, including word error rate and BLEU score. While each metric has its pros and cons, they all rely on word-to-word matching and treat each word equally. In this work, we aim to evaluate the performance of a normalizer based on how it affects the performance of downstream applications. We find that the conventional metrics are not directly applicable, for several reasons. To begin with, the assumption that words have equal weights is unlikely to hold. Additionally, these metrics tend to ignore other important non-word information such as punctuation or capitalization. They also cannot take into account other aspects that may have an impact on downstream performance, such as the word reordering as seen in the example in Figure 4. Therefore, we propose a new evaluation metric that directly equates normalization performance with the performance of a common downstream application—dependency parsing.

To realize our desired metric, we apply the following procedure. First, we produce gold standard normalized data by manually normalizing sentences to their full grammatically correct form. In addition to the word-to-word mapping performed in typical normalization gold standard generation, this annotation procedure includes all actions necessary to make the sentence grammatical, such as word reordering, modifying capitalization, and removing emoticons. We then run an off-the-shelf dependency parser on the gold standard normalized data to produce our gold standard parses. Although the parser could still produce mistakes on the grammatical sentences, we feel that this provides a realistic benchmark for comparison, as it represents an upper bound on the possible performance of the parser, and avoids an expensive second round of manual annotation.

Test	Gold	SVO
<i>I kinda wanna get ipad NEW</i>	<i>I kind of want to get a new iPad.</i>	
<b>verb(get)</b>	verb(want) <b>verb(get)</b>	$\text{precision}_v = \frac{1}{1}$ $\text{recall}_v = \frac{1}{2}$
<b>subj(get,I)</b> subj(get,wanna) obj(get,NEW)	subj(want,I) <b>subj(get,I)</b> obj(get,iPad)	$\text{precision}_{so} = \frac{1}{3}$ $\text{recall}_{so} = \frac{1}{3}$

Figure 4: The subjects, verbs, and objects identified on example test/gold text, and corresponding metric scores

To compare the parses produced over automatically normalized data to the gold standard, we look at the subjects, verbs, and objects (SVO) identified in each parse. The metric shown in Equations (2) and (3) below is based on the identified subjects and objects in those parses. Note that  $SO$  denotes the set of identified subjects and objects whereas  $SO^{\text{gold}}$  denotes the set of subjects and objects identified when parsing the gold-standard normalization.

$$\text{precision}_{so} = \frac{|SO \cap SO^{\text{gold}}|}{|SO|} \quad (2)$$

$$\text{recall}_{so} = \frac{|SO \cap SO^{\text{gold}}|}{|SO^{\text{gold}}|} \quad (3)$$

We similarly define  $\text{precision}_v$  and  $\text{recall}_v$ , where we compare the set  $V$  of identified verbs to  $V^{\text{gold}}$  of those found in the gold-standard normalization. An example is shown in Figure 4.

### 5.2 Results

To establish the extensibility of our normalization system, we present results in three different domains: Twitter posts, Short Message Service (SMS) messages, and call-center logs. For Twitter and SMS messages, we used established datasets to compare with previous work. As no established call-center log dataset exists, we collected our own. In each case, we ran the proposed system with two different configurations: one using only the generic replacement generators presented in Section 4 (denoted as *generic*), and one that adds additional domain-specific generators for the corresponding domain (denoted as *domain-specific*). All runs use ten-fold cross validation for training and evaluation. The Stanford parser<sup>1</sup> (Marneffe et al., 2006) was used to produce all dependency

<sup>1</sup>Version 2.0.4, <http://nlp.stanford.edu/software/lex-parser.shtml>

parses. We compare our system to the following baseline solutions:

**w/oN:** No normalization is performed.

**Google:** Output of the Google spell checker.

**w2wN:** The output of the word-to-word normalization of Han and Baldwin (2011). Not available for call-center data.

**Gw2wN:** The manual gold standard word-to-word normalizations of previous work (Choudhury et al., 2007; Han and Baldwin, 2011). Not available for call-center data.

Our results use the metrics of Section 5.1.

### 5.2.1 Twitter

To evaluate the performance on Twitter data, we use the dataset of randomly sampled tweets produced by (Han and Baldwin, 2011). Because the gold standard used in this work only provided word mappings for out-of-vocabulary words and did not enforce grammaticality, we reannotated the gold standard data<sup>2</sup>. Their original gold standard annotations were kept as a baseline.

To produce Twitter-specific generators, we examined the Twitter development data collected for generic generator production (Section 4). These generators focused on the Twitter-specific notions of hashtags (#), ats (@), and retweets (RT). For each case, we implemented generators that allowed for either the initial symbol or the entire token to be deleted (e.g., @Hertz to Hertz, @Hertz to  $\epsilon$ ).

The results are given in Table 2. As shown, the domain-specific generators yielded performance significantly above the generic ones and all baselines. Even without domain-specific generators, our system outperformed the word-to-word normalization approaches. Most notably, both the generic and domain-specific systems outperformed the gold standard word-to-word normalizations. These results validate the hypothesis that simple word-to-word normalization is insufficient if the goal of normalization is to improve dependency parsing; even if a system could produce perfect word-to-word normalization, it would produce lower quality parses than those produced by our approach.

<sup>2</sup>Our results and the reannotations of the Twitter and SMS data are available at <https://www.cs.washington.edu/node/9091/>

domain specific	95.3	88.7	<b>91.9</b>	72.5	76.3	<b>74.4</b>

Table 2: Performance on Twitter dataset

### 5.2.2 SMS

To evaluate the performance on SMS data, we use the Treasure My Text data collected by Choudhury et al. (2007). As with the Twitter data, the word-to-word normalizations were reannotated to enforce grammaticality. As a replacement generator for SMS-specific substitutions, we used a mapping dictionary of SMS abbreviations.<sup>3</sup> No further SMS-specific development data was needed.

Table 3 gives the results on the SMS data. The SMS dataset proved to be more difficult than the Twitter dataset, with the overall performance of every system being lower. While this drop of performance may be a reflection of the difference in data styles between SMS and Twitter, it is also likely a product of the collection methodology. The collection methodology of the Treasure My Text dataset dictated that every message must have at least one mistake, which may have resulted in a dataset that was noisier than average.

Nonetheless, the trends on SMS data mirror those on Twitter data, with the domain-specific generators achieving the greatest overall performance. However, while the generic setting still manages to outperform most baselines, it did not outperform the gold word-to-word normalization. In fact, the gold word-to-word normalization was much more competitive on this data, outperforming even the domain-specific system on verbs alone. This should not be seen as surprising, as word-to-word normalization is most likely to be beneficial for cases like this where the proportion of non-standard tokens is high.

It should be noted that the SMS dataset as available has had all punctuation removed. While this may be appropriate for word-to-word normalization, this preprocessing may have an effect on the parse of the sentence. As our system has the ability to add punctuation but our baseline systems do not, this has the potential to artificially inflate our results. To ensure a fair comparison, we manually

Table 4: Performance on call-center dataset

added punctuation to a randomly selected small subset of the SMS data and reran each system. This experiment suggested that, in contrast to the hypothesis, adding punctuation actually improved the results of the proposed system more substantially than that of the baseline systems.

### 5.2.3 Call-Center

Although Twitter and SMS data are unmistakably different, there are many similarities between the two, such as the frequent use of shorthand word forms that omit letters. The examination of call-center logs allows us to examine the ability of our system to perform normalization in more disparate domains. Our call-center data consists of text-based responses to questions about a user’s experience with a call-center (e.g., their overall satisfaction with the service). We use call-center logs from a major company, and collect about 150 responses for use in our evaluation. We collected an additional small set of data to develop our call-center-specific generators.

Results on the call-center dataset are in Table 4. As shown, the raw call-center data was comparatively clean, resulting in higher baseline performance than in other domains. Unlike on previous datasets, the use of generic mappings only provided a small improvement over the baseline. However, the use of domain-specific generators once again led to significantly increased performance on subjects and objects.

## 6 Discussion

The results presented in the previous section suggest that domain transfer using the proposed nor-

malization framework is possible with only a small amount of effort. The relatively modest set of additional replacement generators included in each data set allowed the domain-specific approaches to significantly outperform the generic approach. In the call-center case, performance improvements could be seen by referencing a very small amount of development data. In the SMS case, the presence of a domain-specific dictionary allowed for performance improvements without the need for any development data at all. It is likely, though not established, that employing further development data would result in further performance improvements. We leave further investigation to future work.

The results in Section 5.2 establish a point that has often been assumed but, to the best of our knowledge, has never been explicitly shown: performing normalization is indeed beneficial to dependency parsing on informal text. The parse of the normalized text was substantially better than the parse of the original raw text in all domains, with absolute performance increases ranging from about 18-25% on subjects and objects. Furthermore, the results suggest that, as hypothesized, preparing an informal text for a parsing task requires more than simple word-to-word normalization. The proposed approach significantly outperforms the state-of-the-art word-to-word normalization approach. Perhaps most interestingly, the proposed approach performs on par with, and in several cases superior to, gold standard word-to-word annotations. This result gives strong evidence for the conclusion that parser-targeted normalization requires a broader understanding of the scope of the normalization task.

While the work presented here gives promising results, there are still many behaviors found in informal text that prove challenging. One such example is the word reordering seen in Figure 4. Although word reordering could be incorporated into the model as a combination of a deletion and an insertion, the model as currently devised cannot easily link these two replacements to one another. Additionally, instances of reordering proved hard to detect in practice. As such, no reordering-based replacement generators were implemented in the presented system. Another case that proved difficult was the insertion of missing tokens. For instance, the informal sentence “Day 3 still don’t freaking

feel good!:(” could be formally rendered as “**It is** day 3 **and I** still do not feel good!”. Attempts to address missing tokens in the model resulted in frequent false positives. Similarly, punctuation insertion proved to be challenging, often requiring a deep analysis of the sentence. For example, contrast the sentence “I’m watching a movie I don’t know its name.” which would benefit from inserted punctuation, with “I’m watching a movie I don’t know.”, which would not. We feel that the work presented here provides a foundation for future work to more closely examine these challenges.

## 7 Conclusions

This work presents a framework for normalization with an eye towards domain adaptation. The proposed framework builds a statistical model over a series of replacement generators. By doing so, it allows a designer to quickly adapt a generic model to a new domain with the inclusion of a small set of domain-specific generators. Tests over three different domains suggest that, using this model, only a small amount of domain-specific data is necessary to tailor an approach towards a new domain.

Additionally, this work introduces a parser-centric view of normalization, in which the performance of the normalizer is directly tied to the performance of a downstream dependency parser. This evaluation metric allows for a deeper understanding of how certain normalization actions impact the output of the parser. Using this metric, this work established that, when dependency parsing is the goal, typical word-to-word normalization approaches are insufficient. By taking a broader look at the normalization task, the approach presented here is able to outperform not only state-of-the-art word-to-word normalization approaches but also manual word-to-word annotations.

Although the work presented here established that more than word-to-word normalization was necessary to produce parser-ready normalizations, it remains unclear which specific normalization tasks are most critical to parser performance. We leave this interesting area of examination to future work.

## Abstract

This paper presents an unsupervised random walk approach to alleviate data sparsity for selectional preferences. Based on the measure of preferences between predicates and arguments, the model aggregates all the transitions from a given predicate to its nearby predicates, and propagates their argument preferences as the given predicate's smoothed preferences. Experimental results show that this approach outperforms several state-of-the-art methods on the pseudo-disambiguation task, and it better correlates with human plausibility judgements.

## 1 Introduction

Selectional preferences (SP) or selectional restrictions capture the plausibility of predicates and their arguments for a given relation. Kaze and Fodor (1963) describe that predicates and their arguments have strict *boolean restrictions*, either satisfied or violated. Sentences are semantically anomalous and not consistent in reading if they violated the restrictions. Wilks (1973) argues that “rejecting utterances is just what humans do not. They try to understand them.” He further states selectional restrictions as *preferences* between the predicates and arguments, where the violation can be less preferred, but not fatal. For instance, given the predicate word *eat*, word *food* is likely to be its object, *iPhone* is likely to be implausible for it, and *tiger* is less preferred but not curious.

SP have been proven to help many natural language processing tasks that involve attachment de-

terminations, such as semantic role labeling (Resnik, 1993; Gildea and Jurafsky, 2002), word sense disambiguation (Resnik, 1997), human plausibility judgements (Spasić and Ananiadou, 2004), syntactic disambiguation (Toutanova et al., 2005), word compositionality (McCarthy et al., 2007), textual entailment (Pantel et al., 2007) and pronoun resolution (Bergsma et al., 2008) etc.

A direct approach to acquire SP is to extract triples  $(q, r, a)$  of predicates, relations, and arguments from a syntactically analyzed corpus, and then conduct maximum likelihood estimation (MLE) on the data. However, this strategy is infeasible for many plausible triples due to data sparsity. For example, given the relation  $\langle \textit{verb-dobj-noun} \rangle$  in a corpus, we may see plausible triples:

*eat* - {*food, cake, apple, banana, candy...*}

But we may not see plausible and implausible triples such as:

*eat* - {*watermelon, ziti, escarole, iPhone...*}

Then how to use a smooth model to alleviate data sparsity for SP?

Random walk models have been successfully applied to alleviate the data sparsity issue on collaborative filtering in recommender systems. Many online businesses, such as Netflix, Amazon.com, and Facebook, have used recommender systems to provide personalized suggestions on the movies, books, or friends that the users may prefer and interested in (Liben-Nowell and Kleinberg, 2007; Yildirim and Krishnamoorthy, 2008).

In this paper, we present an extension of using the random walk model to alleviate data sparsity for SP. The main intuition is to aggregate all the transitions from a given predicate to its nearby predicates, and propagate their preferences on arguments as the given predicate's smoothed argu-

\*Partial of this work was done when the first author visiting at Language Technologies Institute of Carnegie Mellon University sponsored by the China Scholarship Council.

ment preferences. Our work and contributions are summarized as follows:

- We present a framework of random walk approach to SP. It contains four components with *flexible* configurations. Each component is corresponding to a specific functional operation on the bipartite and monopartite graphs which representing the SP data;
- We propose an adjusted *preference ranking* method to measure SP based on the popularity and association of predicate-argument pairs. It better correlates with human plausibility judgements. It also helps to discover similar predicates more precisely;
- We introduce a *probability function* for random walk based on the predicate distances. It controls the influence of nearby and distant predicates to achieve more accurate results;
- We find out that *propagate* the measured preferences of predicate-argument pairs is more proper and natural for SP smooth. It helps to improve the final performance significantly.

We conduct experiments using two sections of the LDC English gigaword corpora as the generalization data. For the *pseudo-disambiguation* task, we evaluate it on the Penn TreeBank-3 data. Results show that our model outperforms several previous methods. We further investigate the correlations of smoothed scores with *human plausibility judgements*. Again our method achieves better correlations on two third party data.

The remainder of the paper is organized as follows: Section 2 introduces related work. Section 3 briefly formulates the overall framework of our method. Section 4 describes the detailed model configurations, with discussions on their roles and implications. Section 5 provides experiments on both the pseudo-disambiguation task and human plausibility judgements. Finally, Section 6 summarizes the conclusions and future work.

## 2 Related Work

### 2.1 WordNet-based Approach

Resnik (1996) conducts the pioneer work on corpus-driven SP induction. For a given predicate  $q$ , the system firstly computes its distribution of argument semantic classes based on WordNet. Then for a given argument  $a$ , the system collects

the set of candidate semantic classes which contain the argument  $a$ , and ensures they are seen in  $q$ . Finally the system picks a semantic class from the candidates with the maximal selectional association score, and defines the score as smoothed score of  $(q, a)$ .

Many researchers have followed the so-called WordNet-based approach to SP. One of the key issues is to induce the set of argument semantic classes that are acceptable by the given predicate. Li and Abe (1998) propose a tree cut model based on minimal description length (MDL) principle for the induction of semantic classes. Clark and Weir (2002) suggest a hypothesis testing method by ascending the noun hierarchy of WordNet. Ciaramita and Johnson (2000) model WordNet as a Bayesian network to solve the “explain away” ambiguity. Beyond induction on argument classes only, Agirre and Martinez (2001) propose a class-to-class model that simultaneously learns SP on both the predicate and argument classes.

WordNet-based approach produces human interpretable output, but suffers the poor lexical coverage problem. Gildea and Jurafsky (2002) show that clustering-based approach has better coverage than WordNet-based approach. Brockmann and Lapata (2003) find out that sophisticated WordNet-based methods do not always outperform simple frequency-based methods.

### 2.2 Distributional Models without WordNet

Alternatively, Rooth et al. (1999) propose an EM-based *clustering* smooth for SP. The key idea is to use the latent clusterings to take the place of WordNet semantic classes. Where the latent clusterings are automatically derived from distributional data based on EM algorithm. Recently, more sophisticated methods are innovated for SP based on topic models, where the *latent variables* (topics) take the place of semantic classes and distributional clusterings (Séaghdha, 2010; Ritter et al., 2010).

Without introducing semantic classes and latent variables, Keller and Lapata (2003) use the web to obtain frequencies for unseen bigrams smooth. Pantel et al. (2007) apply a collection of rules to filter out incorrect inferences for SP. Specifically, Dagan et al. (1999) introduce a general similarity-based model for word co-occurrence probabilities, which can be interpreted for SP. Similarly, Erk et al. propose an argument-oriented similarity model based on semantic or syntactic vector spaces (Erk,

2007; Erk et al., 2010). They compare several similarity functions and weighting functions in their model. Furthermore, instead of employing various similarity functions, Bergsma et al. (2008) propose a discriminative approach to learn the weights between the predicates, based on the *verb-noun* co-occurrences and other kinds of features.

Random walk model falls into the non-class based distributional approach. Previous literatures have fully studied the selection of distance or similarity functions to find out similar predicates and arguments (Dagan et al., 1999; Erk et al., 2010), or learn the weights between the predicates (Bergsma et al., 2008). Instead, we put effort in following issues: 1) how to measure SP; 2) how to transfer between predicates using random walk; 3) how to propagate the preferences for smooth. Experiments show these issues are important for SP and they should be addressed properly to achieve better results.

### 3 RSP: A Random Walk Model for SP

In this section, we briefly introduce how to address SP using random walk. We propose a framework of RSP with four components (functions). Each of them are flexible to be configured. In summary, Algorithm 1 describes the overall process.

---

#### Algorithm 1 RSP: Random walk model for SP

---

**Require:** Init bipartite graph  $G$  with raw counts

- 1: // Ranking on the bipartite graph  $G$ ;
  - 2:  $R = \Psi(G)$ ; // ranking function
  - 3: // Project  $R$  to monopartite graph  $D$
  - 4:  $D = \Phi(R)$ ; // distance function
  - 5: // Transform  $D$  to stochastic matrix  $P$
  - 6:  $P = \Delta(D)$ ; // probability function
  - 7: // Get the convergence  $\tilde{P}$
  - 8:  $\tilde{P} = \sum_{t=1}^{\infty} \frac{(dP)^t}{|(dP)^t|} = dP(I - dP)^{-1}$ ;
  - 9: **return** Smoothed bipartite graph  $\tilde{R}$
  - 10:  $\tilde{R} = \tilde{P} * R$ ; // propagation function
- 

**Bipartite Graph Construction:** For a given relation  $r$ , the observed predicate-argument pairs can be represented by a bipartite graph  $G=(X, Y, E)$ . Where  $X=\{q_1, q_2, \dots, q_m\}$  are the  $m$  predicates, and  $Y=\{a_1, a_2, \dots, a_n\}$  are the  $n$  arguments. We initiate the links  $E$  with the raw co-occurrence counts of seen predicate-argument pairs in a given generalization data. We represent the graph by an adjacency matrix with rows representing predicates and columns as arguments. For

convenience, we use indices  $i, j$  to represent predicates  $q_i, q_j$ , and  $k, l$  for arguments  $a_k, a_l$ .

We employ a preference *ranking function*  $\Psi$  to measure the SP between the predicates and arguments. It transforms  $G$  to a corresponding bipartite graph  $R$ , with links representing the strength of SP. Each row of the adjacency matrix  $R$  denotes the predicate vector  $\vec{q}_i$  or  $\vec{q}_j$ . We discuss the selection of  $\Psi$  in section 4.1.

$$\Psi := G \mapsto R \quad (1)$$

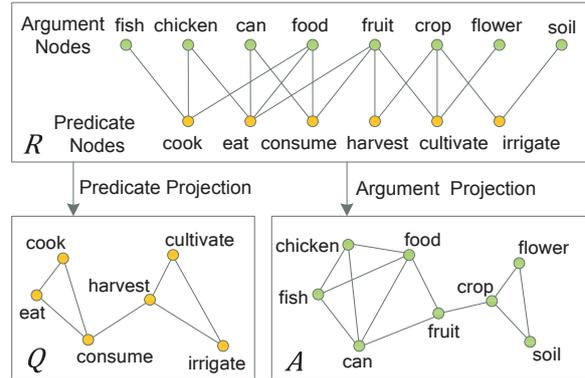

Figure 1: Illustration of  $(R)$  the bipartite graph of the *verb-dobj-noun* relation,  $(Q)$  the predicate-projection monopartite graph, and  $(A)$  the argument-projection monopartite graph.

**Monopartite Graph Projection:** In order to conduct random walk on the graph, we project the bipartite graph  $R$  onto a monopartite graph  $Q=(X, E)$  between the predicates, or  $A=(Y, E)$  between the arguments (Zhou et al., 2007). Figure 1 illustrates the intuition of the projection. The links in  $Q$  represent the indirect connects between the predicates in  $R$ . Two predicates are connected in  $Q$  if they share at least one common neighbor argument in  $R$ . The weight of the links in  $Q$  could be set by arbitrary distance measures. We refer  $D$  as an instance of the projection  $Q$  by a given *distance function*  $\Phi$ .

$$\Phi := R \mapsto D \quad (2)$$

**Stochastic Walking Strategy:** We introduce a *probability function*  $\Delta$  to transform the predicate distances  $D$  into transition probabilities  $P$ . Where  $P$  is a stochastic matrix, with each element  $p_{ij}$  represents the transition probability from predicate  $q_i$  to  $q_j$ . Generally speaking, nearby predicates gain higher probabilities to be visited, while distant predicates will be penalized.

$$\Delta := D \mapsto P \quad (3)$$

Follow Equation 4, we aggregate over all orders of the transition probabilities  $P$  as the final stationary probabilities  $\tilde{P}$ . According to the *Perron-Frobenius* theory, one can verify that it converges to  $dP(I - dP)^{-1}$  when  $P$  is non-negative and regular matrix (Li et al., 2009). Where  $t$  represents the orders: the length of the path between two nodes in terms of edges. The damp factor  $d \in (0, 1)$ , and its value mainly depends on the data sparsity level. Typically  $d$  prefers small values such as 0.005. It means higher order transitions are much less reliable than lower orders (Liben-Nowell and Kleinberg, 2007).

$$\tilde{P} = \sum_{t=1}^{\infty} \frac{(dP)^t}{|(dP)^t|} = dP(I - dP)^{-1} \quad (4)$$

**Preference Propagation:** in Equation 5, we combine the converged transition probabilities  $\tilde{P}$  with the measured preferences  $R$  as the *propagation function*: 1) for a given predicate, firstly it transfers to all nearby predicates with designed probabilities; 2) then it sums over the arguments preferred by these predicates with quantified scores to get smoothed  $\tilde{R}$ . We further describe its configuration details in Section 4.4 and Equation 12 with two propagation modes.

$$\tilde{R} = \tilde{P} * R \quad (5)$$

## 4 Model Configurations

### 4.1 Preference Ranking: Measure the Selectional Preferences

In collaborative filtering, usually there are *explicit* and *scaled* user ratings on their item preferences. For instance, a user ratings a movie with a score  $\in [0, 10]$  on IMDB site. But in SP, the preferences between the predicates and arguments are implicit: their co-occurrence counts follow the power law distribution and vary greatly.

Therefore, we employ a ranking function  $\Psi$  to measure the SP of the *seen* predicate-argument pairs. We suppose this could bring at least two benefits: 1) a proper measure on the preferences can make the discovering of nearby predicates with similar preferences to be more accurate; 2) while propagation, we propagate the scored preferences, rather than the raw counts or conditional probabilities, which could be more proper and agree with the nature of SP smooth. We denote  $\text{SelPref}(q, a)$  as  $\text{Pr}(q, a)$  for short.

$$\text{SelPref}(q, a) = \Psi(q, a) \quad (6)$$

Previous literatures have well studied on various smooth models for SP. However, they vary greatly on the measure of preferences. It is still not clear how to do this best. Lapata et al. investigate the correlations between the co-occurrence counts (CT)  $c(q, a)$ , or smoothed counts with the human plausibility judgements (Lapata et al., 1999; Lapata et al., 2001). Some introduce conditional probability (CP)  $p(a|q)$  for the decision of preference judgements (Chambers and Jurafsky, 2010; Erk et al., 2010; Séaghdha, 2010). Meanwhile, the pointwise mutual information (MI) is also employed by many researchers to filter out incorrect inferences (Pantel et al., 2007; Bergsma et al., 2008).

$$\begin{aligned} \Psi_{CT} &= c(q, a) & \Psi_{MI} &= \log \frac{p(q, a)}{p(q)p(a)} \\ \Psi_{CP} &= \frac{c(q, a)}{c(q, *)} & \Psi_{TD} &= c(q, a) \log \left( \frac{m}{|a|} \right) \end{aligned} \quad (7)$$

In this paper, we present an adjusted ranking function (AR) in Equation 8 to measure the SP of seen predicate-argument pairs. Intuitively, it measures the preferences by combining both the *popularity* and *association*, with parameters control the uncertainty of the trade-off between the two. We define the popularity as the joint probability  $p(q, a)$  based on MLE, and the association as MI. This is potentially similar to the process of human plausibility judgements. One may judge the plausibility of a predicate-argument collocation from two sides: 1) if it has enough evidences and commonly to be seen; 2) if it has strong association according to the cognition based on kinds of background knowledge. This metric is also similar to the TF-IDF (TD) used in information retrieval.

$$\begin{aligned} \Psi_{AR}(q, a) &= p(q, a)^{\alpha_1} \left( \frac{p(q, a)}{p(q)p(a)} \right)^{\alpha_2} \\ s.t. \quad &\alpha_1, \alpha_2 \in [0, 1] \end{aligned} \quad (8)$$

We verify if a metric is better by two tasks: 1) how well it correlates with human plausibility judgements; 2) how well it helps with the smooth inference to disambiguate plausible and implausible instances. We conduct empirical experiments on these issues in Section 5.3 and Section 5.4.

### 4.2 Distance Function: Projection of the Monopartite Graph

In Equation 9, the distance function  $\Phi$  is used to discover nearby predicates with distance  $d_{ij}$ . It weights the links on the monopartite graph  $Q$ . It

guides the walker to transfer between predicates. We calculate  $\Phi$  based on the vectors  $\vec{q}_i, \vec{q}_j$  represented by the measured preferences in  $R$ .

$$d_{ij} = \Phi(\vec{q}_i, \vec{q}_j) \quad (9)$$

Where  $\Phi$  can be distance functions such as Euclidean (norm) distance or Kullback-Leibler divergence (KL) etc., or one *minus* the similarity functions such as Jaccard and Cosine etc. The selection of distributional functions has been fully studied by previous work (Lee, 1999; Erk et al., 2010). In this paper, we do not focus on this issue due to page limits. We simply use the *Cosine* function:

$$\Phi_{\text{cosine}}(\vec{q}_i, \vec{q}_j) = 1 - \frac{\vec{q}_i \cdot \vec{q}_j}{\|\vec{q}_i\| \|\vec{q}_j\|} \quad (10)$$

### 4.3 Probability Function: the Walk Strategy

We define the probability function  $\Delta$  as Equation 11. Where the transition probability  $p(q_j|q_i)$  in  $P$  is defined as a function of the distance  $d_{ij}$  with a parameter  $\delta$ . Intuitively, it means in a given walk step, a predicate  $q_j$  which is far away from  $q_i$  will get much less probability to be visited, and  $q_i$  has high probabilities to start walk from itself and its nearby predicates to pursue good precision. Once we get the transition matrix  $P$ , we can compute  $\tilde{P}$  according to Equation 4.

$$p(q_j|q_i) = \Delta(d_{ij}) = \frac{(1 - d_{ij})^\delta}{Z(q_i)} \quad (11)$$

*s.t.*  $\delta \geq 0, \quad d_{ij} \in [0, 1]$

Where the parameter  $\delta$  is used to control the balance of nearby and distant predicates.  $Z(q_i)$  is the normalize factor. Typically,  $\delta$  around 2 can produce good enough results in most cases. We verify the settings of  $\delta$  in section 5.3.2.

### 4.4 Propagation Function

The propagation function in Equation 5 is represented by the matrix form. It can be expanded and rewritten as Equation 12. Where  $\tilde{p}(q_j|q_i)$  is the converged transition probability from predicate  $q_i$  to  $q_j$ .  $\Pr(a_k, q_j)$  is the measured preference of predicate  $q_j$  with argument  $a_k$ .

$$\tilde{\Pr}(a_k, q_i) = \sum_{j=1}^m \tilde{p}(q_j|q_i) \cdot \Pr(a_k, q_j) \quad (12)$$

We employ two propagation modes (PropMode) for the preference propagation function. One is

'CP' mode. In this mode, we always set  $\Pr(q, a)$  as the conditional probability  $p(a|q)$  for the propagation function, despite what  $\Psi$  is used for the distance function. This mode is similar to previous methods (Dagan et al., 1999; Keller and Lapata, 2003; Bergsma et al., 2008). The other is 'PP' mode. We set ranking function  $\Psi = \Pr(q, a)$  always to be the same in both the distance function and the propagation function. That means what we propagated is the designed and scored preferences. This could be more proper and agree with the nature of SP smooth. We show the improvement of this extension in section 5.3.1.

## 5 Experiments

### 5.1 Data Set

**Generalization Data:** We parsed the Agence France-Presse (AFP) and New York Times (NYT) sections of the LDC English Gigaword corpora (Parker et al., 2011), each from year 2001-2010. The parser is provided by the Stanford CoreNLP package<sup>1</sup>. We filter out all tokens containing non-alphabetic characters, collect the *<verb-dobj-noun>* triples from the syntactically analyzed data. Predicates (verbs) whose frequency lower than 30 and arguments (noun headwords) whose frequency less than 5 are excluded out. No other filters have been done. The resulting data consist of:

- **AFP:** 26, 118, 892 verb-dobj-noun observations with 1, 918, 275 distinct triples, totally 4, 771 predicates and 44, 777 arguments.
- **NYT:** 29, 149, 574 verb-dobj-noun observations with 3, 281, 391 distinct triples, totally 5, 782 predicates and 57, 480 arguments.

**Test Data:** For pseudo-disambiguation, we employ Penn TreeBank-3 (**PTB**) as the test data (Marcus et al., 1999)<sup>2</sup>. We collect the 36, 400 manually annotated *verb-dobj-noun* dependencies (with 23, 553 distinct ones) from PTB. We keep dependencies whose predicates and arguments are seen in the generalization data. We randomly select 20% of these dependencies as the test set. We split the test set equally into two parts: one as the *development* set and the other as the *final* test set.

**Human Plausibility Judgements Data:** We employ two human plausibility judgements data

<sup>1</sup><http://nlp.stanford.edu/software/corenlp.shtml>

<sup>2</sup>PTB includes 2, 499 stories from the Wall Street Journal (WSJ). It is different with our two generalization data.

for the correlation evaluation. In each they collect a set of predicate-argument pairs, and annotate with two kinds of human ratings: one for an argument takes the role as the *patient* of a predicate, and the other for the argument as the *agent*. The rating values are between 1 and 7: e.g. they assign *hunter-subj-shoot* with a rating 6.9 but 2.8 for *shoot-dobj-hunter*.

- **PBP**: Padó et al. (2007) develop a set of human plausibility ratings on the basis of the Penn TreeBank and FrameNet respectively. We refer PBP as their 212 patient ratings from the Penn TreeBank.
- **MRP**: This data are originally contributed by McRae et al. (1998). We use all their 723 *patient-nn* ratings.

Without explicit explanation, we remove all the selected PTB tests and human plausibility pairs from AFP and NYT to treat them unseen.

## 5.2 Comparison Methods

Since RSP falls into the unsupervised distributional approach, we compare it with previous similarity-based methods and unsupervised generative topic model<sup>3</sup>.

**Erk** et al. (Erk, 2007; Erk et al., 2010) are the pioneers to address SP using similarity-based method. For a given  $(q, a)$  in relation  $r$ , the model sums over the similarities between  $a$  and the seen headwords  $a' \in Seen(q, r)$ . They investigated several similarity functions  $sim(a, a')$  such as Jaccard, Cosine, Lin, and nGCM etc., and different weighting functions  $wt_{q,r}(a')$ .

$$S(q, r, a) = \sum_{a'} \frac{wt_{q,r}(a')}{Z_{q,r}} \cdot sim(a, a') \quad (13)$$

For comparison, we suppose the primary corpus and generalization corpus in their model to be the same. We set the similarity function of their model as nGCM, use both the **FREQ** and **DISCR** weighting functions. The vector space is in **SYN-PRIMARY** setting with 2,000 basis elements.

**Dagan** et al. (1999) propose state-of-the-art similarity based model for word co-occurrence probabilities. Though it is not intended for SP, but it can be interpreted and rewritten for SP as:

$$\Pr(a|q) = \sum_{q' \in Simset(q)} \frac{sim(q, q')}{Z(q)} p(a|q') \quad (14)$$

<sup>3</sup>The implementation of RSP and listed previous methods are available at <https://github.com/ZhenhuaTian/RSP>

They use the  $k$ -closest nearbys as  $Simset(q)$ , with a parameter  $\beta$  to revise the similarity function. For comparison, we use the Jensen-Shannon divergence (Lin, 1991) which shows the best performance in their work as  $sim(q, q')$ , and optimize the settings of  $k$  and  $\beta$  in our experiments.

**LDA-SP**: Another kind of sophisticated unsupervised approaches for SP are latent variable models based on Latent Dirichlet Allocation (LDA). Ó Séaghdha (2010) applies topic models for the SP induction with three variations: LDA, Rooth-LDA, and Dual-LDA; Ritter et al. (2010) focus on inferring latent topics and their distributions over multiple arguments and relations (e.g., the subject and direct object of a verb).

In this work, we compare with Ó Séaghdha’s original LDA approach to SP. We use the Matlab Topic Modeling Toolbox<sup>4</sup> for the inference of latent topics. The hyper parameters are set as suggested  $\alpha=50/T$  and  $\beta=200/n$ , where  $T$  is the number of topics and  $n$  is the number of arguments. We test  $T=100, 200, 300$ , each with 1,000 iterations of Gibbs sampling.

## 5.3 Pseudo-Disambiguation

*Pseudo-disambiguation* has been used for SP evaluation by many researchers (Rooth et al., 1999; Erk, 2007; Bergsma et al., 2008; Chambers and Jurafsky, 2010; Ritter et al., 2010). First the system removes a portion of seen predicate-argument pairs from the generalization data to treat them as unseen positive tests  $(q, a^+)$ . Then it introduces confounder selection to create a *pseudo* negative test  $(q, a^-)$  for each positive  $(q, a^+)$ . Finally it evaluates a SP model by how well the model disambiguates these positive and negative tests.

**Confounder Selection**: for a given  $(q, a^+)$ , the system selects an argument  $a'$  from the argument vocabulary. Then by ensure  $(q, a')$  is *unseen* in the generalization data, it treats  $a'$  as pseudo  $a^-$ . This process guarantees that  $(q, a^-)$  to be negative in real case with very high probability. Previous work have made advances on confounder selection with random, bucket and nearest confounders. Random confounder (RND) most closes to the realistic case; While nearest confounder (NER) is reproducible and it avoids frequency bias (Chambers and Jurafsky, 2010).

In this work, we employ both RND and NER confounders: 1) for RND, we randomly select

<sup>4</sup>[psiexp.ss.uci.edu/research/programs\\_data/toolbox.htm](https://psiexp.ss.uci.edu/research/programs_data/toolbox.htm)

confounders according to the occurrence probability of arguments. We sample confounders on both the development and final test data with 100 iterations. 2) for NER, firstly we sort the arguments by their frequency. Then we select the nearest confounders with two iterations. One iteration selects the confounder whose frequency is more than or equal to  $a^+$ , and the other iteration with frequency lower than or equal to  $a^+$ .

**Evaluation Metric:** we evaluate performance on both the *pairwise* and *pointwise* settings:

1) On pairwise setting, we combine corresponding  $(q, a^+, a^-)$  together as test instances. The performance is evaluated based on the accuracy (ACC) metric. It computes the portion of test instances  $(q, a^+, a^-)$  which correctly predicted by the smooth model with  $\text{score}(q, a^+) > \text{score}(q, a^-)$ . We weight each instance equally for **macroACC**, and weight each by the frequency of the positive pair  $(q, a^+)$  for **microACC**.

2) On pointwise setting, we use each positive test  $(q, a^+)$  or negative test  $(q, a^-)$  as test instances independently. We treat it as a binary classification task, and evaluate using the standard area-under-the-curve (AUC) metric. This metric is firstly employed for the SP evaluation by Ritter et al (2010). For **macroAUC**, we weight each instance equally; for **microAUC**, we weight each by its argument frequency (Bergsma et al., 2008).

**Parameters Tuning:** The parameters are tuned on the PTB *development* set, using AFP as the generalization data. We report the overall performance on the *final* test set. While using NYT as the generalization data, we hold the same parameter settings as AFP to ensure the results are robust. Note that indeed the parameter settings would vary among different generalization and test data.

### 5.3.1 Verify Ranking Function and Propagation Method

This experiment is conducted on the PTB *development* set with RND confounders. We use AFP and NYT as the generalization data. For comparison, we set the distance function  $\Phi$  as *Cosine*, with default  $d=0.005$ , and  $\delta=1$ .

In Table 1, the evaluation metric is Accuracy. The first 4 rows are the results of 'CP' PropMode, and the latter 3 rows are the 'PP' PropMode. With respect to the ranking function  $\Psi$ , CP performs the worst as it considers only the popularity rather than association. The heavy bias on frequent predicates and arguments has two major drawbacks: a)

The computation of predicate distances would rely much more on frequent arguments, rather than those arguments they preferred; b) While propagation, it may bias more on frequent arguments, too. Even these frequent arguments are less preferred and not proper to be propagated.

Crit.	AFP		NYT	
	macro	micro	macro	micro
$\Psi_{CP}$	71.7	76.7	78.2	81.2
$\Psi_{MI}$	70.9	75.8	79.1	81.8
$\Psi_{TD}$	73.4	78.2	80.9	83.4
$\Psi_{AR}$	72.9	77.8	81.0	83.5
$\Psi_{MI}$	76.8	80.6	81.9	83.8
$\Psi_{TD}$	74.4	79.1	81.8	84.2
$\Psi_{AR}$	82.5	85.2	87.7	88.6

Table 1: Comparing different ranking functions.

For MI, it biases infrequent arguments with strong association, without regarding to the popular arguments with more evidences. Furthermore, the generalization data is automatically parsed and kind of noisy, especially on infrequent predicates and arguments. The noises could yield unreliable estimations and decrease the performance. For TD, it outperforms MI method on 'CP' PropMode, but it not always outperforms MI on 'PP' PropMode. It is no surprise to find out the adjusted ranking AR achieves better results on both AFP and NYT data, with  $\alpha_1=0.2$  and  $\alpha_2=0.6$ . Finally, it shows the 'PP' mode, which propagating the designed preference scores, gains significantly better performance as discussed in Section 4.4.

### 5.3.2 Verify $\delta$ of the Probability Function

This experiment is conducted on the PTB *development* tests with both RND and NER confounders. The generalization data is AFP.

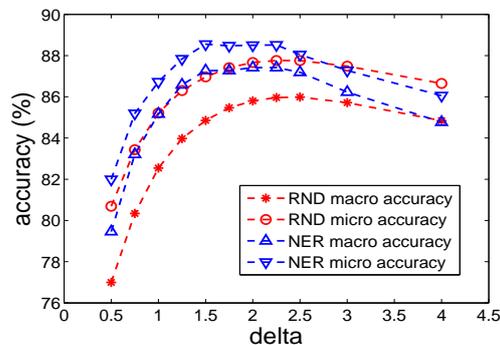

Figure 2: Performance variation on different  $\delta$ .

+Rank+PP+Delta	<b>86.2</b>	<b>87.3</b>	<b>88.4</b>	<b>88.1</b>	<b>90.6</b>	<b>90.1</b>	<b>91.1</b>	<b>89.3</b>

Table 2: Pseudo-disambiguation results of different smooth models. Macro and micro Accuracy.

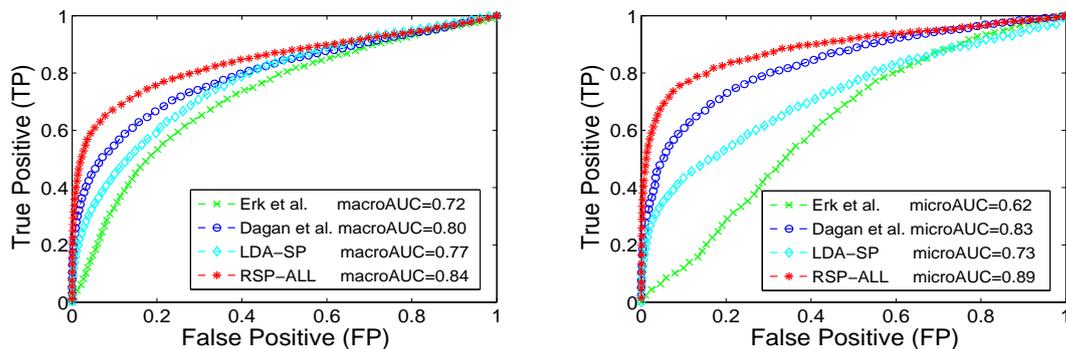

Figure 3: Marco and micro ROC curves of different smooth models.

We set the ranking function  $\Psi$  as AR (with tuned  $\alpha_1=0.2$  and  $\alpha_2=0.6$ ), the distance function  $\Phi$  as *Cosine*, default  $d=0.005$ , and we restrict  $\delta \in [0.5, 4]$ . Figure 2 shows  $\delta$  has significant impact on the performance. Starting from  $\delta=0.5$ , the system gains better performance while  $\delta$  increasing. It achieves good results around  $\delta=2$ . This means for a given predicate, the penalty on its distant predicates helps to get more accurate smooth. The performance will drop if  $\delta$  becomes too big. This means closest predicates are useful for smooth. It is not better to penalize them heavily.

### 5.3.3 Overall Performance

Finally we compare the overall performance of different models. We report the results on the PTB *final* test set, with RND and NER confounders.

Table 2 shows the overall performance on Accuracy metric. Among previous methods in the first 4 rows, LDA-SP performs the best in most cases. In the last 4 rows, RSP<sub>naive</sub> means both the ranking function and PropMode are set as 'CP' and  $\delta=1$ . This configuration yields poor performance. Iteratively, by employing the adjusted

ranking function, smoothing with preference propagation method, and revising the probability function with the parameter  $\delta$ , RSP outperforms all previous methods. The parameter settings of RSP-All are  $\alpha_1=0.2$ ,  $\alpha_2=0.6$ ,  $\delta=1.75$  and  $d=0.005$ .

Figure 3 show the macro (left) and micro (right) receiver-operating-characteristic (ROC) curves of different models, using AFP as the generalization data and RND confounders. For each kind of previous methods, we show the best AUC they achieved. RASP-All still performs the best on the terms of AUC metric, achieving macroAUC at 84% and microAUC at 89%. We also verified the AUC metric using NYT as the generalization data. The results are similar to the AFP data. It is also interesting to find out that the ACC metric is not always bring into correspondence with the AUC metric. The difference mainly raise on the pointwise and pairwise test settings of pseudo-disambiguation.

Table 3: Correlation results on the human plausibility judgements data.

tions and human ratings. Follow Lapata et al. (2001), we first collect the co-occurrence counts of predicate-argument pairs in the human plausibility data from AFP and NYT (before removing them as unseen pairs). Then we score them with different ranking functions (described in Section 4.1) based on MLE. Inspired by Erk et al. (2010), we do not suppose linear correlations between the estimated scores and human ratings. We use the Spearman's  $\rho$  and Kendall's  $\tau$  **rank correlation** coefficient.

We also compare the correlations between the *smoothed scores* of different models with human ratings. With respect to **upper bounds**, Padó et al. (2007) suggest that the typical agreement of human participants is around a correlation of 0.7 on their plausibility data. We hold that automatic models of plausibility can not be expected to surpass this upper bound.

In Table 3, all coefficients are verified at significant level  $p < 0.01$ . The first 5 rows are the correlations between the preference ranking functions and human ratings based on MLE. On both the PBP and MRP data, the proposed AR metric better correlates with human ratings than others, with  $\alpha_2 > 0.5$  and  $\alpha_1$  around  $[0.2, 0.35]$ . The latter 6 rows are the results of smooth models. It shows LDA-SP performs good correlation with human ratings, where LDA-SP<sub>+Bayes</sub> refers to the Bayes prediction method of Ritter et al. (2010). RSP model gains the best correlation on the two plausibility data in most cases, where the parameter settings are the same as pseudo-disambiguation.

## 6 Conclusions and Future Work

In this work we present a random walk approach to SP. Experiments show it is efficient and effective to address data sparsity for SP. It is also flexible to be applied to new data. We find out that a proper measure on SP between the predicates and arguments is important for SP. It helps with the discovering of nearby predicates and it makes the preference propagation to be more accurate. Another issue is that it is not good enough to directly apply the similarity or distance functions for smooth. Potential future work including but not limited to follows: investigate argument-oriented and personalized random walk, extend the model in heterogeneous network with multiple link types, discover soft clusters using random walk for semantic induction, and combine it with discriminative learning approach etc.

## Abstract

This paper presents a novel deterministic algorithm for implicit Semantic Role Labeling. The system exploits a very simple but relevant discursive property, the argument coherence over different instances of a predicate. The algorithm solves the implicit arguments sequentially, exploiting not only explicit but also the implicit arguments previously solved. In addition, we empirically demonstrate that the algorithm obtains very competitive and robust performances with respect to supervised approaches that require large amounts of costly training data.

## 1 Introduction

Traditionally, Semantic Role Labeling (SRL) systems have focused in searching the fillers of those explicit roles appearing within sentence boundaries (Gildea and Jurafsky, 2000, 2002; Carreras and Màrquez, 2005; Surdeanu et al., 2008; Hajič et al., 2009). These systems limited their search-space to the elements that share a syntactical relation with the predicate. However, when the participants of a predicate are implicit this approach obtains incomplete predicative structures with null arguments. The following example includes the gold-standard annotations for a traditional SRL process:

- (1) [*arg0* The network] had been expected to have [*np losses*] [*arg1* of as much as \$20 million] [*arg3* on baseball this year]. It isn't clear how much those [*np losses*] may widen because of the short Series.

The previous analysis includes annotations for the nominal predicate **loss** based on the NomBank structure (Meyers et al., 2004). In this case the annotator identifies, in the first sentence, the arguments *arg0*, the entity losing something, *arg1*, the

thing lost, and *arg3*, the source of that loss. However, in the second sentence there is another instance of the same predicate, **loss**, but in this case no argument has been associated with it. Traditional SRL systems facing this type of examples are not able to fill the arguments of a predicate because their fillers are not in the same sentence of the predicate. Moreover, these systems also let unfilled arguments occurring in the same sentence, like in the following example:

- (2) Quest Medical Inc said it adopted [*arg1* a shareholders' rights] [*np plan*] in which rights to purchase shares of common stock will be distributed as a dividend to shareholders of record as of Oct 23.

For the predicate **plan** in the previous sentence, a traditional SRL process only returns the filler for the argument *arg1*, the theme of the plan.

However, in both examples, a reader could easily infer the missing arguments from the surrounding context of the predicate, and determine that in (1) both instances of the predicate share the same arguments and in (2) the missing argument corresponds to the subject of the verb that dominates the predicate, *Quest Medical Inc*. Obviously, this additional annotations could contribute positively to its semantic analysis. In fact, Gerber and Chai (2010) pointed out that implicit arguments can increase the coverage of argument structures in NomBank by 71%. However, current automatic systems require large amounts of manually annotated training data for each predicate. The effort required for this manual annotation explains the absence of generally applicable tools. This problem has become a main concern for many NLP tasks. This fact explains a new trend to develop accurate unsupervised systems that exploit simple but robust linguistic principles (Raghuathan et al., 2010).

In this work, we study the coherence of the predicate and argument realization in discourse. In particular, we have followed a similar approach to

the one proposed by Dahl et al. (1987) who filled the arguments of anaphoric mentions of nominal predicates using previous mentions of the same predicate. We present an extension of this idea assuming that in a coherent document the different occurrences of a predicate, including both verbal and nominal forms, tend to be mentions of the same event, and thus, they share the same argument fillers. Following this approach, we have developed a deterministic algorithm that obtains competitive results with respect to supervised methods. That is, our system can be applied to any predicate without training data.

The main contributions of this work are the following:

- We empirically prove that there exists a strong discourse relationship between the implicit and explicit argument fillers of the same predicates.
- We propose a deterministic approach that exploits this discursive property in order to obtain the fillers of implicit arguments.
- We adapt to the implicit SRL problem a classic algorithm for pronoun resolution.
- We develop a robust algorithm, ImpAr, that obtains very competitive results with respect to existing supervised systems. We release an open source prototype implementing this algorithm<sup>1</sup>.

The paper is structured as follows. Section 2 discusses the related work. Section 3 presents in detail the data used in our experiments. Section 4 describes our algorithm for implicit argument resolution. Section 5 presents some experiments we have carried out to test the algorithm. Section 6 discusses the results obtained. Finally, section 7 offers some concluding remarks and presents some future research lines.

## 2 Related Work

The first attempt for the automatic annotation of implicit semantic roles was proposed by Palmer et al. (1986). This work applied selectional restrictions together with coreference chains, in a very specific domain. In a similar approach, Whittemore et al. (1991) also attempted to solve implicit

arguments using some manually described semantic constraints for each thematic role they tried to cover. Another early approach was presented by Tetreault (2002). Studying another specific domain, they obtained some probabilistic relations between some roles. These early works agree that the problem is, in fact, a special case of anaphora or coreference resolution.

Recently, the task has been taken up again around two different proposals. On the one hand, Ruppenhofer et al. (2010) presented a task in SemEval-2010 that included an implicit argument identification challenge based on FrameNet (Baker et al., 1998). The corpus for this task consisted in some novel chapters. They covered a wide variety of nominal and verbal predicates, each one having only a small number of instances. Only two systems were presented for this sub-task obtaining quite poor results (F1 below 0,02). VENSES++ (Tonelli and Delmonte, 2010) applied a rule based anaphora resolution procedure and semantic similarity between candidates and thematic roles using WordNet (Fellbaum, 1998). The system was tuned in (Tonelli and Delmonte, 2011) improving slightly its performance. SEMAFOR (Chen et al., 2010) is a supervised system that extended an existing semantic role labeler to enlarge the search window to other sentences, replacing the features defined for regular arguments with two new semantic features. Although this system obtained the best performance in the task, data sparseness strongly affected the results. Besides the two systems presented to the task, some other systems have used the same dataset and evaluation metrics. Ruppenhofer et al. (2011), Laparra and Rigau (2012), Gorinski et al. (2013) and Laparra and Rigau (2013) explore alternative linguistic and semantic strategies. These works obtained significant gains over previous approaches. Silberer and Frank (2012) adapted an entity-based coreference resolution model to extend automatically the training corpus. Exploiting this additional data, their system was able to improve previous results. Following this approach Moor et al. (2013) present a corpus of predicate-specific annotations for verbs in the FrameNet paradigm that are aligned with PropBank and VerbNet.

On the other hand, Gerber and Chai (2010, 2012) studied the implicit argument resolution on NomBank. They use a set of syntactic, semantic and coreferential features to train a logistic regres-

---

<sup>1</sup><http://adimen.si.ehu.es/web/ImpAr>

sion classifier. Unlike the dataset from SemEval-2010 (Ruppenhofer et al., 2010), in this work the authors focused on a small set of ten predicates. But for those predicates, they annotated a large amount of instances in the documents from the Wall Street Journal that were already annotated for PropBank (Palmer et al., 2005) and NomBank. This allowed them to avoid the sparseness problems and generalize properly from the training set. The results of this system were far better than those obtained by the systems that faced the SemEval-2010 dataset. This work represents the deepest study so far of the features that characterize the implicit arguments<sup>2</sup>. However, many of the most important features are lexically dependent on the predicate and cannot be generalized. Thus, specific annotations are required for each new predicate to be analyzed.

All the works presented in this section agree that implicit arguments must be modeled as a particular case of coreference together with features that include lexical-semantic information, to build selectional preferences. Another common point is the fact that these works try to solve each instance of the implicit arguments independently, without taking into account the previous realizations of the same implicit argument in the document. We propose that these realizations, together with the explicit ones, must maintain a certain coherence along the document and, in consequence, the filler of an argument remains the same along the following instances of that argument until a stronger evidence indicates a change. We also propose that this feature can be exploited independently from the predicate.

### 3 Datasets

In our experiments, we have focused on the dataset developed in Gerber and Chai (2010, 2012). This dataset (hereinafter BNB which stands for "Beyond NomBank") extends existing predicate annotations for NomBank and PropBank.

BNB presented the first annotation work of implicit arguments based on PropBank and NomBank frames. This annotation was an extension of the standard training, development and testing sections of Penn TreeBank that have been typically used for SRL evaluation and were already annotated with PropBank and NomBank predicate

<sup>2</sup>Gerber and Chai (2012) includes a set of 81 different features.

structures. The authors selected a limited set of predicates. These predicates are all nominalizations of other verbal predicates, without sense ambiguity, that appear frequently in the corpus and tend to have implicit arguments associated with their instances. These constraints allowed them to model enough occurrences of each implicit argument in order to cover adequately all the possible cases appearing in a test document. For each missing argument position they went over all the preceding sentences and annotated all mentions of the filler of that argument. In tables 3 and 4 we show the list of predicates and the resulting figures of this annotation.

In this work we also use the corpus provided for the CoNLL-2008 task. These corpora cover the same BNB documents and include annotated predictions for syntactic dependencies and SuperSense labels as semantic tags. Unlike Gerber and Chai (2010, 2012) we do not use the constituent analysis from the Penn TreeBank.

## 4 ImpAr algorithm

### 4.1 Discursive coherence of predicates

Exploring the training dataset of BNB, we observed a very strong discourse effect on the implicit and explicit argument fillers of the predicates. That is, if several instances of the same predicate appear in a well-written discourse, it is very likely that they maintain the same argument fillers. This property holds when joining the different parts-of-speech of the predicates (nominal or verbal) and the explicit or implicit realizations of the argument fillers. For instance, we observed that 46% of all implicit arguments share the same filler with the previous instance of the same predicate while only 14% of them have a different filler. The remaining 40% of all implicit arguments correspond to first occurrences of their predicates. That is, these fillers can not be recovered from previous instances of their predicates.

The rationale behind this phenomena seems to be simple. When referring to different aspects of the same event, the writer of a coherent document does not repeat redundant information. They refer to previous predicate instances assuming that the reader already recalls the involved participants. That is, the filler of the different instances of a predicate argument maintain a certain discourse coherence. For instance, in example (1), all the argument positions of the second occurrence of the

predicate **loss** are missing, but they can be easily inferred from the previous instance of the same predicate.

- (1) [*arg0* The network] had been expected to have [*np losses*] [*arg1* of as much as \$20 million] [*arg3* on baseball this year]. It isn't clear how much those [*np losses*] may widen because of the short Series.

Therefore, we propose to exploit this property in order to capture correctly how the fillers of all predicate arguments evolve through a document.

Our algorithm, **ImpAr**, processes the documents sentence by sentence, assuming that sequences of the same predicate (in its nominal or verbal form) share the same argument fillers (explicit or implicit)<sup>3</sup>. Thus, for every **core** argument  $arg_n$  of a predicate, ImpAr stores its previous known filler as a **default** value. If the arguments of a predicate are explicit, they always replace default fillers previously captured. When there is no antecedent for a particular implicit argument  $arg_n$ , the algorithm tries to find in the surrounding context which participant is the most likely to be the filler according to some salience factors (see Section 4.2). For the following instances, without an explicit filler for a particular argument position, the algorithm repeats the same selection process and compares the new implicit candidate with the default one. That is, the default implicit argument of a predicate with no antecedent can change every time the algorithm finds a filler with a greater salience. A damping factor is applied to reduce the salience of distant predicates.

#### 4.2 Filling arguments without explicit antecedents

Filling the implicit arguments of a predicate has been identified as a particular case of coreference, very close to pronoun resolution (Silberer and Frank, 2012). Consequently, for those implicit arguments that have not explicit antecedents, we propose an adaptation of a classic algorithm for deterministic pronoun resolution. This component of our algorithm follows the RAP approach (Lapin and Leass, 1994). When our algorithm needs to fill an implicit predicate argument without an explicit antecedent it considers a set of candidates within a window formed by the sentence of the predicate and the two previous sentences. Then, the algorithm performs the following steps:

1. Apply two constraints to the candidate list:
  - (a) All candidates that are already explicit arguments of the predicate are ruled out.
  - (b) All candidates commanded by the predicate in the dependency tree are ruled out.
2. Select those candidates that are semantically consistent with the semantic category of the implicit argument.
3. Assign a salience score to each candidate.
4. Sort the candidates by their proximity to the predicate of the implicit argument.
5. Select the candidate with the highest salience value.

As a result, the candidate with the highest salience value is selected as the filler of the implicit argument. Thus, this filler with its corresponding salience weight will be also considered in subsequent instances of the same predicate.

Now, we explain each step in more detail using example (2). In this example,  $arg_0$  is missing for the predicate **plan**:

- (2) Quest Medical Inc said it adopted [*arg1* a shareholders' rights] [*np plan*] in which rights to purchase shares of common stock will be distributed as a dividend to shareholders of record as of Oct 23.

**Filtering.** In the first step, the algorithm filters out the candidates that are actual explicit arguments of the predicate or have a syntactic dependency with the predicate, and therefore, they are in the search space of a traditional SRL system.

In our example, the filtering process would remove [*a shareholders' rights*] because it is already the explicit argument  $arg_1$ , and [*in which rights to purchase shares of common stock will be distributed as a dividend to shareholders of record as of Oct 23*] because it is syntactically commanded by the predicate **plan**.

**Semantic consistency.** To determine the semantic coherence between the potential candidates and a predicate argument  $arg_n$ , we have exploited the selectional preferences in the same way as in previous SRL and implicit argument resolution works. First, we have designed a list of very general semantic categories. Second, we have semi-automatically assigned one of them to every predicate argument  $arg_n$  in PropBank and NomBank. For this, we have used the semantic annotation provided by the training documents of the CoNLL-2008 dataset. This annotation was performed automatically using the *SuperSense-Tagger* (Ciaramita and Altun, 2006) and includes

<sup>3</sup>Note that the algorithm could also consider sequences of closely related predicates.

named-entities and WordNet Super-Senses<sup>4</sup>. We have also defined a mapping between the semantic classes provided by the SuperSenseTagger and our seven semantic categories (see Table 1 for more details). Then, we have acquired the most common categories of each predicate argument  $arg_n$ . ImpAr algorithm also uses the *SuperSenseTagger* over the documents to be processed from BNB to check if the candidate belongs to the expected semantic category of the implicit argument to be filled.

Following the example above, [*Quest Medical Inc*] is tagged as an *ORGANIZATION* by the *SuperSenseTagger*. Therefore, it belongs to our semantic category *COGNITIVE*. As the semantic category for the implicit argument  $arg_0$  for the predicate **plan** has been recognized to be also *COGNITIVE*, [*Quest Medical Inc*] remains in the list of candidates as a possible filler.

Semantic category	Name-entities	Super-Senses
COGNITIVE	<i>PERSON</i>	noun.person
	<i>ORGANIZATION</i>	noun.group
	<i>ANIMAL</i>	noun.animal
	...	...
TANGIBLE	<i>PRODUCT</i>	noun.artifact
	<i>SUBSTANCE</i>	noun.object
	...	...
EVENTIVE	<i>GAME</i>	noun.act
	<i>DISEASE</i>	noun.communication
	...	...
RELATIVE	...	noun.shape
	...	noun.attribute
	...	...
LOCATIVE	<i>LOCATION</i>	noun.location
TIME	<i>DATE</i>	noun.time
	<i>QUANTITY</i>	noun.quantity
MESURABLE	<i>PERCENT</i>	...
	...	...

**Table 1:** Links between the semantic categories and some name-entities and super-senses.

**Saliency weighting.** In this process, the algorithm assigns to each candidate a set of saliency factors that scores its prominence. The *sentence recency* factor prioritizes the candidates that occur close to the same sentence of the predicate. The *subject*, *direct object*, *indirect object* and *non-adverbial* factors weight the saliency of the candidate depending on the syntactic role they belong to. Additionally, the head of these syntactic roles are prioritized by the *head* factor. We have used the same weights, listed in table 2, proposed by Lappin and Leass (1994).

In the example, candidate [*Quest Medical Inc*] is in the same sentence as the predicate **plan**, it

<sup>4</sup>Lexicographic files according to WordNet terminology.

Factor type	weight
Sentence recency	100
Subject	80
Direct object	50
Indirect object	40
Head	80
Non-adverbial	50

**Table 2:** Weights assigned to each saliency factor.

belongs to a subject, and, indeed, it is the head of that subject. Hence, the saliency score for this candidate is:  $100 + 80 + 80 = 260$ .

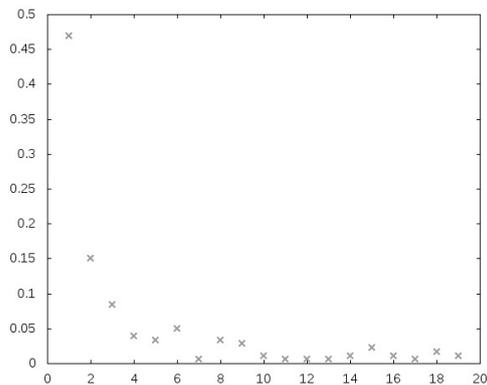

### 4.3 Damping the saliency of the default candidate

As the algorithm maintains the default candidate until an explicit filler appears, potential errors produced in the automatic selection process explained above can spread to distant implicit instances, specially when the saliency score of the default candidate is high. In order to reduce the impact of these errors we have included a damping factor that is applied sentence by sentence to the saliency value of the default candidate. ImpAr applies that damping factor,  $r$ , as follows. It assumes that, independently of the initial saliency assigned, 100 points of the saliency score came from the *sentence recency* factor. Then, the algorithm changes this value multiplying it by  $r$ . So, given a saliency score  $s$ , the value of the score in a following sentence,  $s'$ , is:

$$s' = s - 100 + 100 \cdot r$$

Obviously, the value of  $r$  must be defined without harming excessively those cases where the default candidate has been correctly identified. For this, we studied in the training dataset the cases of implicit arguments filled with the default candidate. Figure 1 shows that the influence of the default filler is much higher in near sentences that in more distance ones.

We tried to mimic a damping factor following this distribution. That is, to maintain high score saliency for the near sentences while strongly decreasing them in the subsequent ones. In this way, if the filler of the implicit argument is wrongly identified, the error only spreads to the nearest instances. If the identification is correct, a lower score for more distance sentences is not too harmful. The distribution shown in figure 1 follows an exponential decay, therefore we have described the damping factor as a curve like the following, where  $\alpha$  must be a value within 0 and 1:

**Figure 1:** Distances between the implicit argument and the default candidate. The  $y$  axis indicate the percentage of cases occurring in each sentence distance, expressed in  $x$

$$r = \alpha^d$$

In this function,  $d$  stands for the sentence distance and  $r$  for the damping factor to apply in that sentence. In this paper, we have decided to set the value of  $\alpha$  to 0.5.

$$r = 0.5^d$$

This value maintains the influence of the default fillers with high salience in near sentences. But it decreases that influence strongly in the following.

In order to illustrate the whole process we will use the previous example. In that case, *[Quest Medical Inc]* is selected as the  $arg_0$  of **plan** with a salience score of 260. Therefore *[Quest Medical Inc]* becomes the default  $arg_0$  of **plan**. In the following sentence the damping factor is:

$$0.5 = 0.5^1$$

Therefore, its salience score changes to  $260 - 100 + 100 \cdot 0.5 = 210$ . Then, the algorithm changes the default filler for  $arg_0$  only if it finds a candidate that scores higher in their current context. At two sentence distance, the resulting score for the default filler is  $260 - 100 + 100 \cdot 0.25 = 185$ . In this way, at more distance sentences, the influence of the default filler of  $arg_0$  becomes smaller.

## 5 Evaluation

In order to evaluate the performance of the ImpAr algorithm, we have followed the evaluation method presented by Gerber and Chai (2010, 2012). For every argument position in the gold-standard the scorer expects a single predicted constituent to fill in. In order to evaluate the correct span of a constituent, a prediction is scored using the Dice coefficient:

$$\frac{2|Predicted \cap True|}{|Predicted| + |True|}$$

The function above relates the set of tokens that form a predicted constituent, *Predicted*, and the set of tokens that are part of an annotated constituent in the gold-standard, *True*. For each missing argument, the gold-standard includes the whole coreference chain of the filler. Therefore, the scorer selects from all coreferent mentions the highest Dice value. If the predicted span does not cover the head of the annotated filler, the scorer returns zero. Then, *Precision* is calculated by the sum of all prediction scores divided by the number of attempts carried out by the system. *Recall* is equal to the sum of the prediction scores divided by the number of actual annotations in the gold-standard. F-measure is calculated as the harmonic mean of recall and precision.

Traditionally, there have been two approaches to develop SRL systems, one based on constituent trees and the other one based on syntactic dependencies. Additionally, the evaluation of both types of systems has been performed differently. For constituent based SRL systems the scorers evaluate the correct span of the filler, while for dependency based systems the scorer just check if the systems are able to capture the head token of the filler. As shown above, previous works in implicit argument resolution proposed a metric that involves the correct identification of the whole span of the filler. ImpAr algorithm works with syntactic dependencies and therefore it only returns the head token of the filler. In order to compare our results with previous works, we had to apply some simple heuristics to guess the correct span of the filler. Obviously, this process inserts some noise in the final evaluation.

We have performed a first evaluation over the test set used in (Gerber and Chai, 2010). This dataset contains 437 predicate instances but just 246 argument positions are implicitly filled. Table 3 includes the results obtained by ImpAr, the results of the system presented by Gerber and Chai (2010) and the baseline proposed for the task. Best results are marked in bold<sup>5</sup>. For all predicates, ImpAr improves over the baseline (19.3 points higher in the overall  $F_1$ ). Our system also outperforms the one presented by Gerber and Chai (2010). Interestingly, both systems present very different performances predicate by predicate. For

<sup>5</sup>No proper significance test can be carried out without the the full predictions of all systems involved.

**Table 4:** Evaluation with the full dataset. The results from (Gerber and Chai, 2012) are included.

instance, our system obtains much higher results for the predicates **bid** and **fund**, while much lower for **loss** and **loan**. In general, ImpAr seems to be more robust since it obtains similar performances for all predicates. In fact, the standard deviation,  $\sigma$ , of  $F_1$  measure is 10.98 for ImpAr while this value for the (Gerber and Chai, 2010) system is 20.00.

In a more recent work, Gerber and Chai (2012) presented some improvements of their previous results. In this work, they extended the evaluation of their model using the whole dataset and not just the testing documents. Applying a cross-validated approach they tried to solve some problems that they found in the previous evaluation, like the small size of the testing set. For this work, they also studied a wider set of features, specially, they experimented with some statistics learnt from parts of GigaWord automatically annotated. Table 4 shows that the improvement over their previous system was remarkable. The system also seems to be more stable across predicates. For comparison purposes, we also included the performance of ImpAr applied over the whole dataset.

The results in table 4 show that, although ImpAr still achieves the best results in some cases, this time, it cannot beat the overall results obtained by

the supervised model. In fact, both systems obtain a very similar recall, but the system from (Gerber and Chai, 2012) obtains much higher precision. In both cases, the  $\sigma$  value of  $F_1$  is reduced, 8.81 for ImpAr and 8.21 for (Gerber and Chai, 2012). However, ImpAr obtains very similar performance independently of the testing dataset what proves the robustness of the algorithm. This suggests that our algorithm can obtain strong results also for other corpus and predicates. Instead, the supervised approach would need a large amount of manual annotations for every predicate to be processed.

## 6 Discussion

### 6.1 Component Analysis

In order to assess the contribution of each system component, we also tested the performance of ImpAr algorithm when disabling only one of its components. With this evaluations we pretend to sight the particular contribution of each component. In table 5 we present the results obtained in the following experiments for the two testing sets explained in section 5:

- Exp1: The damping factor is disabled. All selected fillers maintain the same salience over

all sentences.

- Exp2: Only explicit fillers are considered as candidates<sup>6</sup>.
- Exp3: No default fillers are considered as candidates.

As expected, we observe a very similar performances in both datasets. Additionally, the highest loss appears when the default fillers are ruled out (Exp3). In particular, it also seems that the explicit information from previous predicates provides the most correct evidence (Exp2). Also note that for Exp2, the system obtains the highest precision. This means that the most accurate cases are obtained by previous explicit antecedents.

	test			full		
	<i>P</i>	<i>R</i>	<i>F</i> <sub>1</sub>	<i>P</i>	<i>R</i>	<i>F</i> <sub>1</sub>
full	47.9	<b>43.8</b>	<b>45.8</b>	47.7	<b>43.0</b>	<b>45.3</b>
Exp1	45.7	41.8	43.6	47.1	42.5	44.8
Exp2	<b>51.2</b>	24.6	33.2	<b>55.3</b>	25.5	34.9
Exp3	34.6	29.7	31.9	34.8	28.9	31.5
Exp4	<b>42.6</b>	<b>37.9</b>	<b>40.1</b>	<b>37.5</b>	<b>31.2</b>	<b>34.1</b>
Exp5	38.8	34.5	36.5	35.7	29.7	32.4
Exp6	53.3	48.7	50.9	52.4	47.2	49.6

**Table 5:** Exp1, Exp2 and Exp3 correspond to ablations of the components. Exp3 and Exp4 are experiments over the cases that are not solved by explicit antecedents. Exp6 evaluates the system capturing just the head tokens of the constituents.

As Exp1 also includes instances with explicit antecedents, and for these cases the damping factor component has no effect, we have designed two additional experiments:

- Exp4: Full system for the cases not solved by explicit antecedents.
- Exp5: As in Exp4 but with the damping factor disabled.

As expected, now the contribution of the dumping factor seems to be more relevant, in particular, for the *test* dataset.

## 6.2 Correct span of the fillers

As explained in Section 5, our algorithm works with syntactic dependencies and its predictions only return the head token of the filler. Obtaining the correct constituents from syntactic dependencies is not trivial. In this work we have applied a simple heuristic that returns all the descendant

<sup>6</sup>That is, implicit arguments without explicit antecedents are not filled.

tokens of the predicted head token. This naive process inserts some noise to the evaluation of the system. For example, from the following sentence our system gives the following prediction for an implicit  $arg_1$  of an instance of the predicate **sale**:

Ports of Call Inc. reached agreements to sell its remaining seven aircraft [ $arg_1$  to buyers] that weren't disclosed.

But the actual gold-standard annotation is: [ $arg_1$  buyers that weren't disclosed]. Although the head of the constituent, *buyers*, is correctly captured by ImpAr, the final prediction is heavily penalized by the scoring method. Table 5 presents the results of ImpAr when evaluating the head tokens of the constituents only (Exp6). These results show that the current performance of our system can be easily improved applying a more accurate process for capturing the correct span.

## 7 Conclusions and Future Work

In this work we have presented a robust deterministic approach for implicit Semantic Role Labeling. The method exploits a very simple but relevant discursive coherence property that holds over explicit and implicit arguments of closely related nominal and verbal predicates. This property states that if several instances of the same predicate appear in a well-written discourse, it is very likely that they maintain the same argument fillers. We have shown the importance of this phenomenon for recovering the implicit information about semantic roles. To our knowledge, this is the first empirical study that proves this phenomenon.

Based on these observations, we have developed a new deterministic algorithm, ImpAr, that obtains very competitive and robust performances with respect to supervised approaches. That is, it can be applied where there is no available manual annotations to train. The code of this algorithm is publicly available and can be applied to any document. As input it only needs the document with explicit semantic role labeling and Super-Sense annotations. These annotations can be easily obtained from plain text using available tools<sup>7</sup>, what makes this algorithm the first effective tool available for implicit SRL.

As it can be easily seen, ImpAr has a large margin for improvement. For instance, providing more accurate spans for the fillers. We also plan

<sup>7</sup>We recommend mate-tools (Björkelund et al., 2009) and SuperSenseTagger (Ciaramita and Altun, 2006).

to test alternative approaches to solve the arguments without explicit antecedents. For instance, our system can also profit from additional annotations like coreference, that has proved its utility in previous works. Finally, we also plan to study our approach on different languages and datasets (for instance, the SemEval-2010 dataset).

## Abstract

Semantic Role Labeling (SRL) has become one of the standard tasks of natural language processing and proven useful as a source of information for a number of other applications. We address the problem of transferring an SRL model from one language to another using a shared feature representation. This approach is then evaluated on three language pairs, demonstrating competitive performance as compared to a state-of-the-art unsupervised SRL system and a cross-lingual annotation projection baseline. We also consider the contribution of different aspects of the feature representation to the performance of the model and discuss practical applicability of this method.

## 1 Background and Motivation

Semantic role labeling has proven useful in many natural language processing tasks, such as question answering (Shen and Lapata, 2007; Kaisser and Webber, 2007), textual entailment (Sammons et al., 2009), machine translation (Wu and Fung, 2009; Liu and Gildea, 2010; Gao and Vogel, 2011) and dialogue systems (Basili et al., 2009; van der Plas et al., 2009).

Multiple models have been designed to automatically predict semantic roles, and a considerable amount of data has been annotated to train these models, if only for a few more popular languages. As the annotation is costly, one would like to leverage existing resources to minimize the human effort required to construct a model for a new language.

A number of approaches to the construction of semantic role labeling models for new languages

have been proposed. On one end of the scale is unsupervised SRL, such as Grenager and Manning (2006), which requires some expert knowledge, but no labeled data. It clusters together arguments that should bear the same semantic role, but does not assign a particular role to each cluster. On the other end is annotating a new dataset from scratch. There are also intermediate options, which often make use of similarities between languages. This way, if an accurate model exists for one language, it should help simplify the construction of a model for another, related language.

The approaches in this third group often use parallel data to bridge the gap between languages. Cross-lingual annotation projection systems (Padó and Lapata, 2009), for example, propagate information directly via word alignment links. However, they are very sensitive to the quality of parallel data, as well as the accuracy of a source-language model on it.

An alternative approach, known as cross-lingual model transfer, or cross-lingual model adaptation, consists of modifying a source-language model to make it directly applicable to a new language. This usually involves constructing a shared feature representation across the two languages. McDonald et al. (2011) successfully apply this idea to the transfer of dependency parsers, using part-of-speech tags as the shared representation of words. A later extension of Täckström et al. (2012) enriches this representation with cross-lingual word clusters, considerably improving the performance.

In the case of SRL, a shared representation that is purely syntactic is likely to be insufficient, since structures with different semantics may be realized by the same syntactic construct, for example “in August” vs “in Britain”. However with the help of recently introduced cross-lingual word represen-

tations, such as the cross-lingual clustering mentioned above or cross-lingual distributed word representations of Klementiev et al. (2012), we may be able to transfer models of shallow semantics in a similar fashion.

In this work we construct a shared feature representation for a pair of languages, employing cross-lingual representations of syntactic and lexical information, train a semantic role labeling model on one language and apply it to the other one. This approach yields an SRL model for a new language at a very low cost, effectively requiring only a source language model and parallel data.

We evaluate on five (directed) language pairs – EN-ZH, ZH-EN, EN-CZ, CZ-EN and EN-FR, where EN, FR, CZ and ZH denote English, French, Czech and Chinese, respectively. The transferred model is compared against two baselines: an unsupervised SRL system and a model trained on the output of a cross-lingual annotation projection system.

In the next section we will describe our setup, then in section 3 present the shared feature representation we use, discuss the evaluation data and other technical aspects in section 4, present the results and conclude with an overview of related work.

## 2 Setup

The purpose of the study is not to develop a yet another semantic role labeling system – any existing SRL system can (after some modification) be used in this setup – but to assess the practical applicability of cross-lingual model transfer to this problem, compare it against the alternatives and identify its strong/weak points depending on a particular setup.

### 2.1 Semantic Role Labeling Model

We consider the dependency-based version of semantic role labeling as described in Hajič et al. (2009) and transfer an SRL model from one language to another. We only consider verbal predicates and ignore the predicate disambiguation stage. We also assume that the predicate identification information is available – in most languages it can be obtained using a relatively simple heuristic based on part-of-speech tags.

The model performs argument identification and classification (Johansson and Nugues, 2008) separately in a pipeline – first each candidate is

classified as being or not being a head of an argument phrase with respect to the predicate in question and then each of the arguments is assigned a role from a given inventory. The model is factorized over arguments – the decisions regarding the classification of different arguments are made independently of each other.

With respect to the use of syntactic annotation we consider two options: using an existing dependency parser for the target language and obtaining one by means of cross-lingual transfer (see section 4.2).

Following McDonald et al. (2011), we assume that a part-of-speech tagger is available for the target language.

### 2.2 SRL in the Low-resource Setting

Several approaches have been proposed to obtain an SRL model for a new language with little or no manual annotation. Unsupervised SRL models (Lang and Lapata, 2010) cluster the arguments of predicates in a given corpus according to their semantic roles. The performance of such models can be impressive, especially for those languages where semantic roles correlate strongly with syntactic relation of the argument to its predicate. However, assigning meaningful role labels to the resulting clusters requires additional effort and the model’s parameters generally need some adjustment for every language.

If the necessary resources are already available for a closely related language, they can be utilized to facilitate the construction of a model for the target language. This can be achieved either by means of cross-lingual annotation projection (Yarowsky et al., 2001) or by cross-lingual model transfer (Zeman and Resnik, 2008).

This last approach is the one we are considering in this work, and the other two options are treated as baselines. The unsupervised model will be further referred to as UNSUP and the projection baseline as PROJ.

### 2.3 Evaluation Measures

We use the  $F_1$  measure as a metric for the argument identification stage and accuracy as an aggregate measure of argument classification performance. When comparing to the unsupervised SRL system the clustering evaluation measures are used instead. These are purity and collocation

$$PU = \frac{1}{N} \sum_i \max_j |G_j \cap C_i|$$

$$CO = \frac{1}{N} \sum_j \max_i |G_j \cap C_i|,$$

where  $C_i$  is the set of arguments in the  $i$ -th induced cluster,  $G_j$  is the set of arguments in the  $j$ th gold cluster and  $N$  is the total number of arguments. We report the harmonic mean of the two (Lang and Lapata, 2011) and denote it  $F_1^c$  to avoid confusing it with the supervised metric.

### 3 Model Transfer

The idea of this work is to abstract the model away from the particular source language and apply it to a new one. This setup requires that we use the same feature representation for both languages, for example part-of-speech tags and dependency relation labels should be from the same inventory.

Some features are not applicable to certain languages because the corresponding phenomena are absent in them. For example, consider a strongly inflected language and an analytic one. While the latter can usually convey the information encoded in the word form in the former one (number, gender, etc.), finding a shared feature representation for such information is non-trivial. In this study we will confine ourselves to those features that are applicable to all languages in question, namely: part-of-speech tags, syntactic dependency structures and representations of the word’s identity.

#### 3.1 Lexical Information

We train a model on one language and apply it to a different one. In order for this to work, the words of the two languages have to be mapped into a common feature space. It is also desirable that closely related words from both languages have similar representations in this space.

*Word mapping.* The first option is simply to use the source language words as the shared representation. Here every source language word would have itself as its representation and every target word would map into a source word that corresponds to it. In other words, we supply the model with a gloss of the target sentence.

The mapping (bilingual dictionary) we use is derived from a word-aligned parallel corpus, by identifying, for each word in the target language,

the word in the source language it is most often aligned to.

*Cross-lingual clusters.* There is no guarantee that each of the words in the evaluation data is present in our dictionary, nor that the corresponding source-language word is present in the training data, so the model would benefit from the ability to generalize over closely related words. This can, for example, be achieved by using cross-lingual word clusters induced in Täckström et al. (2012). We incorporate these clusters as features into our model.

#### 3.2 Syntactic Information

*Part-of-speech Tags.* We map part-of-speech tags into the universal tagset following Petrov et al. (2012). This may have a negative effect on the performance of a monolingual model, since most part-of-speech tagsets are more fine-grained than the universal POS tags considered here. For example Penn Treebank inventory contains 36 tags and the universal POS tagset – only 12. Since the finer-grained POS tags often reflect more language-specific phenomena, however, they would only be useful for very closely related languages in the cross-lingual setting.

The universal part-of-speech tags used in evaluation are derived from gold-standard annotation for all languages except French, where predicted ones had to be used instead.

*Dependency Structure.* Another important aspect of syntactic information is the dependency structure. Most dependency relation inventories are language-specific, and finding a shared representation for them is a challenging problem. One could map dependency relations into a simplified form that would be shared between languages, as it is done for part-of-speech tags in Petrov et al. (2012). The extent to which this would be useful, however, depends on the similarity of syntactic-semantic interfaces of the languages in question.

In this work we discard the dependency relation labels where the inventories do not match and only consider the unlabeled syntactic dependency graph. Some discrepancies, such as variations in attachment order, may be present even there, but this does not appear to be the case with the datasets we use for evaluation. If a target language is poor in resources, one can obtain a dependency parser for the target language by means of cross-lingual model transfer (Zeman and Resnik, 2008). We

take this into account and evaluate both using the original dependency structures and the ones obtained by means of cross-lingual model transfer.

### 3.3 The Model

The model we use is based on that of Björkelund et al. (2009). It is comprised of a set of linear classifiers trained using Liblinear (Fan et al., 2008). The feature model was modified to accommodate the cross-lingual cluster features and the reranker component was not used.

We do not model the interaction between different argument roles in the same predicate. While this has been found useful, in the cross-lingual setup one has to be careful with the assumptions made. For example, modeling the sequence of roles using a Markov chain (Thompson et al., 2003) may not work well in the present setting, especially between distant languages, as the order or arguments is not necessarily preserved. Most constraints that prove useful for SRL (Chang et al., 2007) also require customization when applied to a new language, and some rely on language-specific resources, such as a valency lexicon. Taking into account the interaction between different arguments of a predicate is likely to improve the performance of the transferred model, but this is outside the scope of this work.

### 3.4 Feature Selection

Compatibility of feature representations is necessary but not sufficient for successful model transfer. We have to make sure that the features we use are predictive of similar outcomes in the two languages as well.

Depending on the pair of languages in question, different aspects of the feature representation will retain or lose their predictive power. We can be reasonably certain that the identity of an argument word is predictive of its semantic role in any language, but it might or might not be true of, for example, the word directly preceding the argument word. It is therefore important to pre-

POS	part-of-speech tags
Synt	unlabeled dependency graph
Cls	cross-lingual word clusters
Gloss	glossed word forms
Deprel	dependency relations

Table 1: Feature groups.

vent the model from capturing overly specific aspects of the source language, which we do by confining the model to first-order features. We also avoid feature selection, which, performed on the source language, is unlikely to help the model to better generalize to the target one. The experiments confirm that feature selection and the use of second-order features degrade the performance of the transferred model.

### 3.5 Feature Groups

For each word, we use its part-of-speech tag, cross-lingual cluster id, word identity (glossed, when evaluating on the target language) and its dependency relation to its parent. Features associated with an argument word include the attributes of the predicate word, the argument word, its parent, siblings and children, and the words directly preceding and following it. Also included are the sequences of part-of-speech tags and dependency relations on the path between the predicate and the argument.

Since we are also interested in the impact of different aspects of the feature representation, we divide the features into groups as summarized in table 1 and evaluate their respective contributions to the performance of the model. If a feature group is enabled – the model has access to the corresponding source of information. For example, if only POS group is enabled, the model relies on the part-of-speech tags of the argument, the predicate and the words to the right and left of the argument word. If Synt is enabled too, it also uses the POS tags of the argument’s parent, children and siblings.

Word order information constitutes an implicit group that is always available. It includes the Position feature, which indicates whether the argument is located to the left or to the right of the predicate, and allows the model to look up the attributes of the words directly preceding and following the argument word. The model we compare against the baselines uses all applicable feature groups (Deprel is only used in EN-CZ and CZ-EN experiments with original syntax).

## 4 Evaluation

### 4.1 Datasets and Preprocessing

Evaluation of the cross-lingual model transfer requires a rather specific kind of dataset. Namely, the data in both languages has to be annotated

with the same set of semantic roles following the same (or compatible) guidelines, which is seldom the case. We have identified three language pairs for which such resources are available: English-Chinese, English-Czech and English-French.

The evaluation datasets for English and Chinese are those from the CoNLL Shared Task 2009 (Hajič et al., 2009) (henceforth CoNLL-ST). Their annotation in the CoNLL-ST is not identical, but the guidelines for “core” semantic roles are similar (Kingsbury et al., 2004), so we evaluate only on core roles here. The data for the second language pair is drawn from the Prague Czech-English Dependency Treebank 2.0 (Hajič et al., 2012), which we converted to a format similar to that of CoNLL-ST<sup>1</sup>. The original annotation uses the tectogrammatical representation (Hajič, 2002) and an inventory of semantic roles (or *functions*), most of which are interpretable across various predicates. Also note that the syntactic annotation of English and Czech in PCEDT 2.0 is quite similar (to the extent permitted by the difference in the structure of the two languages) and we can use the dependency relations in our experiments.

For English-French, the English CoNLL-ST dataset was used as a source and the model was evaluated on the manually annotated dataset from van der Plas et al. (2011). The latter contains one thousand sentences from the French part of the Europarl (Koehn, 2005) corpus, annotated with semantic roles following an adapted version of PropBank (Palmer et al., 2005) guidelines. The authors perform annotation projection from English to French, using a joint model of syntax and semantics and employing heuristics for filtering. We use a model trained on the output of this projection system as one of the baselines. The evaluation dataset is relatively small in this case, so we perform the transfer only one-way, from English to French.

The part-of-speech tags in all datasets were replaced with the universal POS tags of Petrov et al. (2012). For Czech, we have augmented the mappings to account for the tags that were not present in the datasets from which the original mappings were derived. Namely, tag “t” is mapped to “VERB” and “Y” – to “PRON”.

We use parallel data to construct a bilingual dictionary used in word mapping, as well as in the projection baseline. For English-Czech

and English-French, the data is drawn from Europarl (Koehn, 2005), for English-Chinese – from MultiUN (Eisele and Chen, 2010). The word alignments were obtained using GIZA++ (Och and Ney, 2003) and the intersection heuristic.

## 4.2 Syntactic Transfer

In the low-resource setting, we cannot always rely on the availability of an accurate dependency parser for the target language. If one is not available, the natural solution would be to use cross-lingual model transfer to obtain it.

Unfortunately, the models presented in the previous work, such as Zeman and Resnik (2008), McDonald et al. (2011) and Täckström et al. (2012), were not made available, so we reproduced the direct transfer algorithm of McDonald et al. (2011), using Malt parser (Nivre, 2008) and the same set of features. We did not reimplement the projected transfer algorithm, however, and used the default training procedure instead of perceptron-based learning. The dependency structure thus obtained is, of course, only a rough approximation – even a much more sophisticated algorithm may not perform well when transferring syntax between such languages as Czech and English, given the inherent difference in their structure. The scores are shown in table 2.

We will henceforth refer to the syntactic annotations that were provided with the datasets as *original*, as opposed to the annotations obtained by means of syntactic transfer.

## 4.3 Baselines

*Unsupervised Baseline:* We are using a version of the unsupervised semantic role induction system of Titov and Klementiev (2012a) adapted to

Setup	UAS, %
EN-ZH	35
ZH-EN	42
EN-CZ	36
CZ-EN	39
EN-FR	67

Table 2: Syntactic transfer accuracy, unlabeled attachment score (percent). Note that in case of French we evaluate against the output of a supervised system, since manual annotation is not available for this dataset. This score does not reflect the true performance of syntactic transfer.

<sup>1</sup>see <http://www.ml4nlp.de/code-and-data/treeex2conll>

the shared feature representation considered in order to make the scores comparable with those of the transfer model and, more importantly, to enable evaluation on transferred syntax. Note that the original system, tailored to a more expressive language-specific syntactic representation and equipped with heuristics to identify active/passive voice and other phenomena, achieves higher scores than those we report here.

*Projection Baseline:* The projection baseline we use for English-Czech and English-Chinese is a straightforward one: we label the source side of a parallel corpus using the source-language model, then identify those verbs on the target side that are aligned to a predicate, mark them as predicates and propagate the argument roles in the same fashion. A model is then trained on the resulting training data and applied to the test set.

For English-French we instead use the output of a fully featured projection model of van der Plas et al. (2011), published in the CLASSiC project.

## 5 Results

In order to ensure that the results are consistent, the test sets, except for the French one, were partitioned into five equal parts (of 5 to 10 thousand sentences each, depending on the dataset) and the evaluation performed separately on each one. All evaluation figures for English, Czech or Chinese below are the average values over the five subsets. In case of French, the evaluation dataset is too small to split it further, so instead we ran the evaluation five times on a randomly selected 80% sample of the evaluation data and averaged over those. In both cases the results are consistent over the subsets, the standard deviation does not exceed 0.5% for the transfer system and projection baseline and 1% for the unsupervised system.

### 5.1 Argument Identification

We summarize the results in table 3. Argument identification is known to rely heavily on syntactic information, so it is unsurprising that it proves inaccurate when transferred syntax is used. Our simple projection baseline suffers from the same problem. Even with original syntactic information available, the performance of argument identification is moderate. Note that the model of (van der Plas et al., 2011), though relying on more expressive syntax, only outperforms the transferred system by 3% ( $F_1$ ) on this task.

Setup	Syntax	TRANS	PROJ
EN-ZH	trans	34.5	13.9
ZH-EN	trans	32.6	15.6
EN-CZ	trans	46.3	12.4
CZ-EN	trans	42.3	22.2
EN-FR	trans	61.6	43.5
EN-ZH	orig	51.7	19.6
ZH-EN	orig	53.2	29.7
EN-CZ	orig	63.9	59.3
CZ-EN	orig	67.3	60.9
EN-FR	orig	71.0	51.3

Table 3: Argument identification, transferred model vs. projection baseline,  $F_1$ .

Most unsupervised SRL approaches assume that the argument identification is performed by some external means, for example heuristically (Lang and Lapata, 2011). Such heuristics or unsupervised approaches to argument identification (Abend et al., 2009) can also be used in the present setup.

### 5.2 Argument Classification

In the following tables, TRANS column contains the results for the transferred system, UNSUP – for the unsupervised baseline and PROJ – for projection baseline. We highlight in bold the higher score where the difference exceeds twice the maximum of the standard deviation estimates of the two results.

Table 4 presents the unsupervised evaluation results. Note that the unsupervised model performs as well as the transferred one or better where the

Setup	Syntax	TRANS	UNSUP

CZ-EN	orig	61.0	60.8
EN-FR	orig	63.0	<b>68.0</b>

Table 5: Argument classification, transferred model vs. projection baseline, accuracy.

original syntactic dependencies are available. In the more realistic scenario with transferred syntax, however, the transferred model proves more accurate.

In table 5 we compare the transferred system with the projection baseline. It is easy to see that the scores vary strongly depending on the language pair, due to both the difference in the annotation scheme used and the degree of relatedness between the languages. The drop in performance when transferring the model to another language is large in every case, though, see table 6.

Setup	Target	Source
EN-ZH	71.7	87.1
ZH-EN	66.1	86.2
EN-CZ	59.0	80.1
CZ-EN	61.0	75.4
EN-FR	63.0	82.5

Table 6: Model accuracy on the source and target language using original syntax. The source language scores for English vary between language pairs because of the difference in syntactic annotation and role subset used.

We also include the individual  $F_1$  scores for the top-10 most frequent labels for EN-CZ transfer with original syntax in table 7. The model provides meaningful predictions here, despite low overall accuracy.

Most of the labels<sup>2</sup> are self-explanatory: Patient (PAT), Actor (ACT), Time (TWHEN), Effect (EFF), Location (LOC), Manner (MANN), Addressee (ADDR), Extent (EXT). CPHR marks the

<sup>2</sup><http://ufal.mff.cuni.cz/~toman/pcedt/en/functors.html>

Label	Freq.	$F_1$	Re.	Pr.
PAT	14707	69.4	70.0	68.7
ACT	14303	81.1	81.7	80.4

nominal part of a complex predicate, as in “to have [a plan]<sub>CPHR</sub>”, and DIR3 indicates destination.

### 5.3 Additional Experiments

We now evaluate the contribution of different aspects of the feature representation to the performance of the model. Table 8 contains the results for English-French.

Features	Orig	Trans
POS	47.5	47.5
POS, Synt	53.0	53.1
POS, Cls	53.7	53.7
POS, Gloss	63.7	63.7
POS, Synt, Cls	55.9	56.4
POS, Synt, Gloss	65.2	66.3
POS, Cls, Gloss	61.5	61.5
POS, Synt, Cls, Gloss	63.0	65.1

Table 8: EN-FR model transfer accuracy with different feature subsets, using original and transferred syntactic information.

The fact that the model performs slightly better with transferred syntax may be explained by two factors. Firstly, as we already mentioned, the original syntactic annotation is also produced automatically. Secondly, in the model transfer setup it is more important how closely the syntactic-semantic interface on the target side resembles that on the source side than how well it matches the “true” structure of the target language, and in this respect a transferred dependency parser may have an advantage over one trained on target-language data.

The high impact of the Gloss features here

may be partly attributed to the fact that the mapping is derived from the same corpus as the evaluation data – Europarl (Koehn, 2005) – and partly by the similarity between English and French in terms of word order, usage of articles and prepositions. The moderate contribution of the cross-lingual cluster features are likely due to the insufficient granularity of the clustering for this task.

For more distant language pairs, the contributions of individual feature groups are less interpretable, so we only highlight a few observations. First of all, both EN-CZ and CZ-EN benefit noticeably from the use of the original syntactic annotation, including dependency relations, but not from the transferred syntax, most likely due to the low syntactic transfer performance. Both perform better when lexical information is available, although the improvement is not as significant as in the case of French – only up to 5%.

The situation with Chinese is somewhat complicated in that adding lexical information here fails to yield an improvement in terms of the metric considered. This is likely due to the fact that we consider only the core roles, which can usually be predicted with high accuracy based on syntactic information alone.

## 6 Related Work

Development of robust statistical models for core NLP tasks is a challenging problem, and adaptation of existing models to new languages presents a viable alternative to exhaustive annotation for each language. Although the models thus obtained are generally imperfect, they can be further refined for a particular language and domain using techniques such as active learning (Settles, 2010; Chen et al., 2011).

Cross-lingual annotation projection (Yarowsky et al., 2001) approaches have been applied extensively to a variety of tasks, including POS tagging (Xi and Hwa, 2005; Das and Petrov, 2011), morphology segmentation (Snyder and Barzilay, 2008), verb classification (Merlo et al., 2002), mention detection (Zitouni and Florian, 2008), LFG parsing (Wróblewska and Frank, 2009), information extraction (Kim et al., 2010), SRL (Padó and Lapata, 2009; van der Plas et al., 2011; Annesi and Basili, 2010; Tonelli and Pianta, 2008), dependency parsing (Naseem et al., 2012; Ganchev et al., 2009; Smith and Eisner, 2009; Hwa et al., 2005) or temporal relation pre-

diction (Spreyer and Frank, 2008). Interestingly, it has also been used to propagate morphosyntactic information between old and modern versions of the same language (Meyer, 2011).

Cross-lingual model transfer methods (McDonald et al., 2011; Zeman and Resnik, 2008; Durrett et al., 2012; Søgaard, 2011; Lopez et al., 2008) have also been receiving much attention recently. The basic idea behind model transfer is similar to that of cross-lingual annotation projection, as we can see from the way parallel data is used in, for example, McDonald et al. (2011).

A crucial component of direct transfer approaches is the unified feature representation. There are at least two such representations of lexical information (Klementiev et al., 2012; Täckström et al., 2012), but both work on word level. This makes it hard to account for phenomena that are expressed differently in the languages considered, for example the syntactic function of a certain word may be indicated by a preposition, inflection or word order, depending on the language. Accurate representation of such information would require an extra level of abstraction (Hajič, 2002).

A side-effect of using adaptation methods is that we are forced to use the same annotation scheme for the task in question (SRL, in our case), which in turn simplifies the development of cross-lingual tools for downstream tasks. Such representations are also likely to be useful in machine translation.

Unsupervised semantic role labeling methods (Lang and Lapata, 2010; Lang and Lapata, 2011; Titov and Klementiev, 2012a; Lorenzo and Cerisara, 2012) also constitute an alternative to cross-lingual model transfer.

For an overview of semi-supervised approaches we refer the reader to Titov and Klementiev (2012b).

## 7 Conclusion

We have considered the cross-lingual model transfer approach as applied to the task of semantic role labeling and observed that for closely related languages it performs comparably to annotation projection approaches. It allows one to quickly construct an SRL model for a new language without manual annotation or language-specific heuristics, provided an accurate model is available for one of the related languages along with a certain amount of parallel data for the two languages. While an-

notation projection approaches require sentence- and word-aligned parallel data and crucially depend on the accuracy of the syntactic parsing and SRL on the source side of the parallel corpus, cross-lingual model transfer can be performed using only a bilingual dictionary.

Unsupervised SRL approaches have their advantages, in particular when no annotated data is available for any of the related languages and there is a syntactic parser available for the target one, but the annotation they produce is not always sufficient. In applications such as Information Retrieval it is preferable to have precise labels, rather than just clusters of arguments, for example.

Also note that when applying cross-lingual model transfer in practice, one can improve upon the performance of the simplistic model we use for evaluation, for example by picking the features manually, taking into account the properties of the target language. Domain adaptation techniques can also be employed to adjust the model to the target language.

## Acknowledgments

The authors would like to thank Alexandre Klementiev and Ryan McDonald for useful suggestions and Täckström et al. (2012) for sharing the cross-lingual word representations. This research is supported by the MMCI Cluster of Excellence.

## Abstract

Derivational models are still an under-researched area in computational morphology. Even for German, a rather resource-rich language, there is a lack of large-coverage derivational knowledge. This paper describes a rule-based framework for inducing *derivational families* (i.e., clusters of lemmas in derivational relationships) and its application to create a high-coverage German resource, DERIVBASE, mapping over 280k lemmas into more than 17k non-singleton clusters. We focus on the rule component and a qualitative and quantitative evaluation. Our approach achieves up to 93% precision and 71% recall. We attribute the high precision to the fact that our rules are based on information from grammar books.

## 1 Introduction

Morphological processing is generally recognized as an important step for many NLP tasks. Morphological analyzers such as lemmatizers and part of speech (POS) taggers are commonly the first NLP tools developed for any language (Koskenniemi, 1983; Brill, 1992). They are also applied in NLP applications where little other linguistic analysis is performed, such as linguistic annotation of corpora or terminology acquisition; see Daille et al. (2002) for an informative summary.

Most work on computational morphology has focused on inflectional morphology, that is, the handling of grammatically determined variation of form (Bickel and Nichols, 2001), which can be understood, overimplying somewhat, as a normalization step. Derivational morphology, which is concerned with the formation of new words from existing ones, has received less attention. Exam-

ples are nominalization (*to understand* → *the understanding*), verbalization (*the shelf* → *to shelve*), and adjectivization (*the size* → *sizable*). Part of the reason for the relative lack of attention lies in the morphological properties of English, such as the presence of many zero derivations (*the fish* → *to fish*), the dominance of suffixation, and the relative absence of stem changes in derivation. For these reasons, simple *stemming* algorithms (Porter, 1980) provide a cheap and accurate approximation to English derivation.

Two major NLP resources deal with derivation. WordNet lists so-called “morphosemantic” relations (Fellbaum et al., 2009) for English, and a number of proposals exist for extending WordNets in other languages with derivational relations (Bilgin et al., 2004; Pala and Hlaváčková, 2007). CatVar, the “Categorial Variation Database of English” (Habash and Dorr, 2003), is a lexicon aimed specifically at derivation. It groups English nouns, verbs, adjectives, and adverbs into derivational equivalence classes or *derivational families* such as

*ask<sub>V</sub> asker<sub>N</sub> asking<sub>N</sub> asking<sub>A</sub>*

Derivational families are commonly understood as groups of derivationally related lemmas (Daille et al., 2002; Milin et al., 2009). The lemmas in CatVar come from various open word classes, and multiple words may be listed for the same POS. The above family lists two nouns: an event noun (*asking*) and an agentive noun (*asker*). However, CatVar does not consider prefixation, which is why, e.g., the adjective *unasked* is missing.

CatVar has found application in different areas of English NLP. Examples are the acquisition of paraphrases that cut across POS lines, applied, for example, in textual entailment (Szpektor and Dagan, 2008; Berant et al., 2012). Then there is the induction and extension of semantic roles resources for predicates of various parts of speech (Meyers et al., 2004; Green et al., 2004). Finally, CatVar has

been used as a lexical resource to generate sentence intersections (Thadani and McKeown, 2011).

In this paper, we describe the project of obtaining derivational knowledge for German to enable similar applications. Even though there are two derivational resources for this language, IMSLEX (Fitschen, 2004) and CELEX (Baayen et al., 1996), both have shortcomings. The former does not appear to be publicly available, and the latter has a limited coverage (50k lemmas) and does not explicitly represent derivational relationships within families, which are necessary for fine-grained optimization of families. For this reason, we look into building a novel derivational resource for German. Unfortunately, the approach used to build CatVar cannot be adopted: it builds on a collection of high-quality lexical-semantic resources such as NOMLEX (Macleod et al., 1998), which are not available for German.

Instead, we employ a rule-based framework to define derivation rules that cover both suffixation and prefixation and describes stem changes. Following the work of Šnajder and Dalbelo Bašić (2010), we define the derivational processes using derivational rules and higher-order string transformation functions. The derivational rules induce a partition of the language’s lemmas into derivational families. Our method is applicable to many languages if the following are available: (1) a comprehensive set of lemmas (optionally including gender information); (2) knowledge about admissible derivational patterns, which can be gathered, for example, from linguistics textbooks.

The result is a freely available high-precision high-coverage resource for German derivational morphology that has a structure parallel to CatVar, but was obtained without using manually constructed lexical-semantic resources. We conduct a thorough evaluation of the induced derivational families both regarding precision and recall.

**Plan of the paper.** Section 2 discusses prior work. Section 3 defines our derivation model that is applied to German in Section 4. Sections 5 and 6 present our evaluation setup and results. Section 7 concludes the paper and outlines future work.

## 2 Related Work

Computational models of morphology have a long tradition. Koskenniemi (1983) was the first who analyzed and generated morphological phenomena computationally. His two-level theory has been

applied in finite state transducers (FST) for several languages (Karttunen and Beesley, 2005).

Many recent approaches automatically induce morphological information from corpora. They are either based solely on corpus statistics (Déjean, 1998), measure semantic similarity between input and output lemma (Schone and Jurafsky, 2000), or bootstrap derivation rules starting from seed examples (Piasecki et al., 2012). Hammarström and Borin (2011) give an extensive overview of state-of-the-art unsupervised learning of morphology. Unsupervised approaches operate at the level of word-forms and have complementary strengths and weaknesses to rule-based approaches. On the upside, they do not require linguistic knowledge; on the downside, they have a harder time distinguishing between derivation and inflection, which may result in lower precision, and are not guaranteed to yield analyses that correspond to linguistic intuition. An exception is the work by Gaussier (1999), who applies an unsupervised model to construct derivational families for French.

For German, several morphological tools exist. Morphix is a classification-based analyzer and generator of German words on the inflectional level (Finkler and Neumann, 1988). SMOR (Schmid et al., 2004) employs a finite-state transducer to analyze German words at the inflectional, derivational, and compositional level, and has been used in other morphological analyzers, e.g., Morphisto (Zielinski and Simon, 2008). The site *canoonet*<sup>1</sup> offers broad-coverage information about the German language including derivational word formation.

## 3 Framework

In this section, we describe our rule-based model of derivation, its operation to define derivational families, and the application of the model to German. We note that the model is purely surface-based, i.e., it does not model any semantic regularities beyond those implicit in string transformations. We begin by outlining the characteristics of German derivational morphology.

### 3.1 German Derivational Morphology

As German is a morphologically complex language, we analyzed its derivation processes before implementing our rule-based model. We relied on traditional grammar books and lexicons, e.g., Hoepfner (1980) and Augst (1975), in order to linguistically

<sup>1</sup><http://canoonet.net>

justify our assumptions as well as to achieve the best possible precision and coverage.

We concentrate on German derivational processes that involve nouns, verbs, and adjectives.<sup>2</sup> Nouns are simple to recognize due to capitalization: *stauen*<sub>V</sub> – *Stau*<sub>N</sub> (to jam – jam), *essen*<sub>V</sub> – *Essen*<sub>N</sub> (to eat – food). Verbs bear three typical suffixes (-en, -eln, -ern). An example of a derived verb is *fest*<sub>A</sub> – *festigen*<sub>V</sub> (tight – to tighten), where -ig is the derivational suffix. Adjectivization works similarly: *Tag*<sub>N</sub> – *täglich*<sub>A</sub> (day – daily).

This example shows that derivation can also involve stem changes in the form of umlaut (e.g., *a* → *ä*) and ablaut shift, e.g., *sieden*<sub>V</sub> – *Sud*<sub>N</sub> (to boil – infusion). Other frequent processes in German derivation are circumfixation (*Haft*<sub>N</sub> – *inhaftieren*<sub>V</sub> (arrest – to arrest)) and prefixation (*heben*<sub>V</sub> – *beheben*<sub>V</sub> (to raise – to remedy)). Prefixation often indicates a semantic shift, either in terms of the general meaning (as above) or in terms of the polarity (*klar*<sub>A</sub> – *unklar*<sub>A</sub> (clear – unclear)). Also note that affixes can be either Germanic, e.g., *ölen* – *Ölung* (to oil – oiling), or Latin/Greek, e.g., *generieren* – *Generator* (to generate – generator).

As this analysis shows, derivation in German involves transformation as well as affixation processes, which has to be taken into account when modeling a derivational resource.

### 3.2 A Rule-based Derivation Model

The purpose of a derivational model is to define a set of transformations that correspond to valid derivational word formation rules. Rule-based frameworks offer convenient representations for derivational morphology because they can take advantage of linguistic knowledge about derivation, have interpretable representations, and can be fine-tuned for high precision. The choice of the framework is in principle arbitrary, as long as it can conveniently express the derivational phenomena of a language. Typically used for this purpose are two-level formalism rules (Karttunen and Beesley, 1992) or XFST replace rules (Beesley and Karttunen, 2003).

In this paper, we adopt the modeling framework proposed by Šnajder and Dalbello Bašić (2010). The framework corresponds closely to simple, human-readable descriptions in traditional gram-

<sup>2</sup>We ignore adverb derivation; the German language distinguishes between adverbial adjectives and adverbs, the latter being a rather unproductive class and thus of no interest for derivation (Schiller et al., 1999).

mar books. The expressiveness of the formalism is equivalent to the replacement rules commonly used in finite state frameworks, thus the rules can be compiled into FSTs for efficient processing.

The framework makes a clear distinction between inflectional and derivational morphology and provides separate modeling components for these two; we only make use of the derivation modeling component. We use an implementation of the modeling framework in Haskell. For details, see the studies by Šnajder and Dalbello Bašić (2008) and Šnajder and Dalbello Bašić (2010).

The building blocks of the derivational component are *derivational rules (patterns)* and *transformation functions*. A derivational rule describes the derivation of a *derived* word from a *basis* word. A derivational rule *d* is defined as a triple:

$$d = (t, \mathcal{P}_1, \mathcal{P}_2) \quad (1)$$

where *t* is the transformation function that maps the word’s stem (or lemma) into the derived word’s stem (or lemma), while  $\mathcal{P}_1$  and  $\mathcal{P}_2$  are the sets of inflectional paradigms of the basis word and the derived word, respectively, which specify the morphological properties of the rule’s input and output. For German, our study assumes that inflectional paradigms are combinations of part-of-speech and gender information (for nouns).

A transformation function  $t : S \rightarrow \wp(S)$  maps strings to a set of strings, representing possible transformations. At the lowest level, *t* is defined in terms of atomic string replacement operations (replacement of prefixes, suffixes, and infixes). The framework then uses the notion of higher-order functions – functions that take other transformations as arguments and return new transformations as results – to succinctly define common derivational processes such as prefixation, suffixation, and stem change. More complex word-formation rules, such as those combining prefixation and suffixation, can be obtained straightforwardly by functional composition.

Table 1 summarizes the syntax we use for transformation functions and shows two example derivational rules. Rule 1 defines an English adjectivization rule. It uses the conditional *try* operator to apply to nouns with and without the -ion suffix (*action* – *active*, *instinct* – *instinctive*). Infix replacement is used to model stem alternation, as shown in rule 2 for German nominalization, e.g., *vermacht*<sub>A</sub> – *Vermächtnis*<sub>N</sub> (*bequeathed* – *bequest*).

Function	Description
$sfx(s)$	concatenate the suffix $s$
$dsfx(s)$	delete the suffix $s$
$aifx(s1, s2)$	alternate the infix $s1$ to $s2$
$try(t)$	perform transformation $t$ , if possible
$opt(t)$	optionally perform transformation $t$
$uml$	alternate infixes for an umlaut shift: $uml = aifx(\{(a, ä), (o, ö), (u, ü)\})$
Examples	
1 (EN)	$(sfx(ive) \circ try(dsfx(ion)), \mathcal{N}, \mathcal{A})$ “derive <i>-ive</i> adjectives from nouns potentially ending in <i>-ion</i> ”
2 (DE)	$(sfx(nis) \circ try(uml), \mathcal{A}, \mathcal{N})$ “derive <i>-nis</i> nouns from adjectives with optional umlaut creation”

Table 1: Transformation functions and exemplary derivational rules in the framework by Šnajder and Dalbelo Bašić (2010)

$\mathcal{N}$  and  $\mathcal{A}$  denote the paradigms for nouns (without gender restriction) and adjectives, respectively.

### 3.3 Induction of Derivational Families

Recall that our goal is to induce derivational families, that is, classes of derivationally related words. We define derivational families on the basis of derivational rules as follows.

Given a lemma-paradigm pair  $(l, p)$  as input, a single derivational rule  $d = (t, \mathcal{P}_1, \mathcal{P}_2)$  generates a set of possible derivations  $L_d(l, p) = \{(l_1, p_1), \dots, (l_n, p_n)\}$ , where  $p \in \mathcal{P}_1$  and  $p_i \in \mathcal{P}_2$  for all  $i$ . Given a set of derivational rules  $\mathcal{D}$ , we define a binary derivation relation  $\rightarrow_{\mathcal{D}}$  between two lemma-paradigm pairs that holds if the second pair can be derived from the first one as:

$$(l_1, p_1) \rightarrow_{\mathcal{D}} (l_2, p_2) \quad (2)$$

iff  $\exists d \in \mathcal{D}. (l_2, p_2) \in L_d(l_1, p_1)$

Let  $\mathcal{L}$  denote the set of lemma-paradigm pairs. The set of *derivational families defined by  $\mathcal{D}$  on  $\mathcal{L}$*  is given by the equivalence classes of the transitive, symmetric, and reflexive closure of  $\rightarrow_{\mathcal{D}}$  over  $\mathcal{L}$ .

Note that in addition to the quality of the rules, the properties of  $\mathcal{L}$  plays a central role in the quality of the induced families. High coverage of  $\mathcal{L}$  is important because the transitivity of  $\rightarrow_{\mathcal{D}}$  ranges only over lemmas in  $\mathcal{L}$ , so low coverage of  $\mathcal{L}$  may result in fragmented derivational families. However,  $\mathcal{L}$  should also not contain erroneous lemma-paradigm pairs. The reason is that the derivational rules only define *admissible* derivations, which need not be morphologically valid, and therefore routinely over-

generate;  $\mathcal{L}$  plays an important role in filtering out derivations that are not attested in the data.

## 4 Building the Resource

### 4.1 Derivational Rules

We implemented the derivational rules from Hoepfner (1980) for verbs, nouns, and adjectives, covering all processes described in Section 3.1 (zero derivation, prefixation, suffixation, circumfixation, and stem changes). We found many derivational patterns in German to be conceptually simple (e.g., verb-noun zero derivation) so that substantial coverage can already be achieved with very simple transformation functions. However, there are many more complex patterns (e.g., suffixation combined with optional stem changes) that in sum also affect a considerable number of lemmas, which required us to either implement low-coverage rules or generalize existing rules. In order to preserve precision as much as possible, we restricted rule application by using *try* instead of *opt*, and by using gender information from the noun paradigms (for example, some rules only apply to masculine nouns and produce female nouns). As a result, we end up with high-coverage rules, such as derivations of person-denoting nouns ( $Schule_N - Schüler_N$  (*school - pupil*)) as well as high-accuracy rules such as negation prefixes ( $Pol_N - Gegenpol_N$  (*pole - antipole*)).

Even though we did not focus on the explanatory relevance of rules, we found that the underlying modeling formalism, and the methodology used to develop the model, offer substantial linguistic plausibility in practice. We had to resort to heuristics mostly for words with derivational transformations that are motivated by Latin or Greek morphology and do not occur regularly in German, e.g.,  $selegieren_V - Selektion_N$  (*select - selection*).

In the initial development phase, we implemented 154 rules, which took about 22 person-hours. We then revised the rules with the aim of increasing both precision and recall. To this end, we constructed a development set comprised of a sample of 1,000 derivational families induced using our rules. On this set, we inspected the derivational families for false positives, identified the problematic rules, and identified unused and redundant rules. In order to identify the false negatives, we additionally sampled a list of 1,000 lemmas and used string distance measures (cf. Section 5.1) to retrieve the 10 most similar words for each lemma not

Process	N-N	N-A	N-V	A-A	A-V	V-V
Zero derivation	–	1	5	–	–	–
Prefixation	10	–	5	5	2	9
+ Stem change	–	–	3	–	1	–
Suffixation	15	35	20	1	14	–
+ Stem change	2	8	7	–	3	1
Circumfixation	–	–	1	–	–	–
+ Stem change	–	–	1	–	–	–
Stem change	–	–	7	–	–	2
<i>Total</i>	27	44	49	6	20	12

Table 2: Breakdown of derivation rules by category of the basis and the derived word

already covered by the derivational families. The refinement process took another 8 person-hours. It revealed three redundant rules and seven missing rules, leading us to a total of 158 rules.

Table 2 shows the distribution of rules with respect to the derivational processes they implement and the part of speech combinations for the basis and the derived words. All affixations occur both with and without stem changes, mostly umlaut shifts. Suffixation is by far the most frequently used derivation process, and noun-verb derivation is most diverse in terms of derivational processes.

We also estimated the reliability of derivational rules by analyzing the accuracy of each rule on the development set. We assigned each rule a confidence rating on a three-level scale: L3 – very reliable (high-accuracy rules), L2 – generally reliable, and L1 – less reliable (low-accuracy rules). We manually analyzed the correctness of rule applications for 100 derivational families of different size (counting 2 up to 114 lemmas), and assigned 55, 79, and 24 rules to L3, L2 and L1, respectively.

## 4.2 Data and Preprocessing

For an accurate application of nominal derivation rules, we need a lemma list with POS and gender information. We POS-tag and lemmatize SDEWAC, a large German-language web corpus from which boilerplate paragraphs, ungrammatical sentences, and duplicate pages were removed (Faaß et al., 2010). For POS tagging and lemmatization, we use TreeTagger (Schmid, 1994) and determine grammatical gender with the morphological layer of the MATE Tools (Bohnet, 2010). We treat proper nouns like common nouns.

We apply three language-specific filtering steps based on observations in Section 3.1. First, we discard non-capitalized nominal lemmas. Second, we deleted verbal lemmas not ending in verb suffixes.

Third, we removed frequently occurring erroneous comparative forms of adjectives (usually formed by adding *-er*, like *neuer / newer*) by checking for the presence of lemmas without *-er* (*neu / new*).

An additional complication in German concerns prefix verbs, because prefix is separated in tensed instances. For example, the 3rd person male singular of *aufhören* (*to stop*) is *er hört auf* (*he stops*). Since most prefixes double as prepositions, the correct lemmas can only be reconstructed by parsing. We parse the corpus using the MST parser (McDonald et al., 2006) and recover prefix verbs by searching for instances of the dependency relation labeled PTKVZ.

Since SDEWAC, as a web corpus, still contains errors, we only take into account lemmas that occur three times or more in the corpus. Considering the size of SDEWAC, we consider this as a conservative filtering step that preserves high recall and provides a comprehensive basis for evaluation. After preprocessing and filtering, we run the induction of the derivational families as explained in Section 3 to obtain the DERIVBASE resource.

## 4.3 Statistics on DERIVBASE

The preparation of the SDEWAC corpus as explained in Section 4.2 yields 280,336 lemmas, which we cover with our resource. We induced a total of 239,680 derivational families from this data, with 17,799 non-singletons and 221,881 singletons (most of them due to compound nouns). 11,039 of the families consist of two lemmas, while the biggest contains 116 lemmas (an overgenerated family). The biggest family with perfect precision (i.e., it contains only morphologically related lemmas) contains 40 lemmas, e.g., *halten<sub>V</sub>*, *erhalten<sub>V</sub>*, *Verhältnis<sub>N</sub>* (*to hold, to uphold, relation*), etc. For comparison, CatVar v2.1 contains only 82,676 lemmas in 13,368 non-singleton clusters and 38,604 singletons.

The following sample family has seven members across all three POSes and includes prefixation, suffixation, and infix umlaut shifts:

*taub<sub>A</sub>* (*numb<sub>A</sub>*), *Taubheit<sub>Nf</sub>* (*numbness<sub>N</sub>*), *betäuben<sub>V</sub>* (*to anesthetize<sub>V</sub>*), *Betäubung<sub>Nf</sub>* (*anesthesia<sub>N</sub>*), *betäubt<sub>A</sub>* (*anesthetized<sub>A</sub>*), *betäubend<sub>A</sub>* (*anesthetic<sub>A</sub>*), *Betäuben<sub>Nn</sub>* (*act of anesthetizing<sub>N</sub>*)

## 5 Evaluation

### 5.1 Baselines

We use two baselines against which we compare the induced derivational families: (1) clusters obtained with the German version of Porter’s stemmer (Porter, 1980)<sup>3</sup> and (2) clusters obtained using string distance-based clustering. We have considered a number of string distance measures and tested them on the development set (cf. Section 4.1). The measure proposed by Majumder et al. (2007) turned out to be the most effective in capturing suffixal variation. For words  $X$  and  $Y$ , it is defined as

$$D_4(X, Y) = \frac{n - m + 1}{n + 1} \sum_{i=m}^n \frac{1}{2^{i-m}} \quad (3)$$

where  $m$  is the position of left-most character mismatch, and  $n + 1$  is the length of the longer of the two strings. To capture prefixal variation and stem changes, we use the  $n$ -gram based measure proposed by Adamson and Boreham (1974):

$$Dice_n(X, Y) = 1 - \frac{2c}{x + y} \quad (4)$$

where  $x$  and  $y$  are the total number of distinct  $n$ -grams in  $X$  and  $Y$ , respectively, and  $c$  is the number of distinct  $n$ -grams shared by both words. In our experiments, the best performance was achieved with  $n = 3$ .

We used hierarchical agglomerative clustering with average linkage. To reduce the computational complexity, we performed a preclustering step by recursively partitioning the set of lemmas sharing the same prefix into partitions of manageable size (1000 lemmas). Initially, we set the number of clusters to be roughly equal to the number of induced derivational families. For the final evaluation, we optimized the number of clusters based on  $F_1$  score on calibration and validation sets (cf. Section 5.3).

### 5.2 Evaluation Methodology

The induction of derivational families could be evaluated globally as a clustering problem. Unfortunately, cluster evaluation is a non-trivial task for which there is no consensus on the best approach (Amigó et al., 2009). We decided to perform our evaluation at the level of pairs: we manually judge for a set of pairs whether they are derivationally related or not.

<sup>3</sup><http://snowball.tartarus.org>

We obtain the gold standard for this evaluation by sampling lemmas from the lemma list. With random sampling, the evaluation would be unrealistic because a vast majority of pairs would be derivationally unrelated and count as true negatives in our analysis. Moreover, in order to reliably estimate the overall precision of the obtained derivational families, we need to evaluate on pairs sampled from these families. On the other hand, in order to assess recall, we need to sample from pairs that are not included in our derivational families.

To obtain reliable estimates of both precision and recall, we decided to draw two different samples: (1) a sample of lemma pairs sampled from the induced derivational families, on which we estimate precision (*P-sample*) and (2) a sample of lemma pairs sampled from the set of possibly derivationally related lemma pairs, on which we estimate recall (*R-sample*). In both cases, pairs  $(l_1, l_2)$  are sampled in two steps: first a lemma  $l_1$  is drawn from a non-singleton family, then the second lemma  $l_2$  is drawn from the derivational family of  $l_1$  (*P-sample*) or the set of lemmas possibly related to  $l_1$  (*R-sample*). The set of possibly related lemmas is a union of the derivational family of  $l_1$ , the clusters of  $l_1$  obtained with the baseline methods, and  $k$  lemmas most similar to  $l_1$  according to the two string distance measures. We use  $k = 7$  in our experiments. This is based on preliminary experiments on the development set (cf. Section 4.1), which showed that  $k = 7$  retrieves about 92% of the related lemmas retrieved for  $k = 20$  with a much smaller number of true negatives. Thus, the evaluation on the *R-sample* might overestimate the recall, but only slightly so, while the *P-sample* yields a reliable estimate of precision by reducing the number of true negatives in the sample.

Both samples contain 2400 lemma pairs each. Lemmas included in the development set (Section 4.1) were excluded from sampling.

### 5.3 Gold Standard Annotation

Two German native speakers annotated the pairs from the *P-sample* and *R-samples*. We defined five categories into which all lemma pairs are classified as shown in Table 3. We count *R* and *M* as positives and *N*, *C*, *L* as negatives (cf. Section 3).<sup>4</sup> Note that this binary distinction would be sufficient to compute recall and precision. However, the more

<sup>4</sup>Ambiguous lemmas are categorized as positive (*R* or *M*) if there is a matching sense.

Label	Description	Example
<b>R</b>	$l_1$ and $l_2$ are morphologically and semantically related	<i>kratzig<sub>A</sub> – verkratz<sub>A</sub></i> ( <i>scratchy – scuffed</i> )
<b>M</b>	$l_1$ and $l_2$ are morphologically but not semantically related	<i>bomben<sub>V</sub> – bombig<sub>A</sub></i> ( <i>to bomb – smashing</i> )
<b>N</b>	no morphological relation	<i>belebt<sub>A</sub> – loben<sub>V</sub></i> ( <i>lively – to praise</i> )
<b>C</b>	no derivational relation, but the pair is compositionally related	<i>Filmende<sub>N</sub> – filmen<sub>V</sub></i> ( <i>end of film – to film</i> )
<b>L</b>	not a valid lemma (mis-lemmatization, wrong gender, foreign words)	<i>Haufe<sub>N</sub> – Häufung<sub>N</sub></i> ( <i>N/A – accumulation</i> )

Table 3: Categories for lemma pair classification

	Agreement	Cohen’s $\kappa$
R-sample	0.85	0.79
P-sample	0.86	0.70

Table 4: Inter-annotator agreement on validation sample

fine-grained five-class annotation scheme provides a more detailed picture. The separation between R and M gives a deeper insight into the semantics of the derivational families. Distinguishing between C and N, in turn, allows us to identify the pairs that are derivationally unrelated, but compositionally related, e.g., *Ehemann<sub>N</sub> – Ehefrau<sub>N</sub>* (*husband – wife*).

We first carried out a calibration phase in which the annotators double-annotated 200 pairs from each of the two samples and refined the annotation guidelines. In a subsequent validation phase, we computed inter-annotator agreements on the annotations of another 200 pairs each from the P- and the R-samples. Table 4 shows the proportion of identical annotations by both annotators as well as Cohen’s  $\kappa$  score (Cohen, 1968). We achieve substantial agreement for  $\kappa$  (Carletta, 1996). On the P-sample,  $\kappa$  is a little lower because the distribution of the categories is skewed towards R, which makes an agreement by chance more probable.

In our opinion, the IAA results were sufficiently high to switch to single annotation for the production phase. Here, each annotator annotated another 1000 pairs from the P-sample and R-sample so that the final test set consists of 2000 pairs from each sample. The P-sample contains 1663 positive (R+M) and 337 negative (N+C+L) pairs, respectively, the R-sample contains 575 positive and 1425 negative pairs. As expected, there are more positive

Method	Precision		Recall	
	P-sample	R-sample	P-sample	R-sample
DERIVBASE (initial)	0.83		0.58	
DERIVBASE-L123	0.83		<b>0.71</b>	
DERIVBASE-L23	0.88		0.61	
DERIVBASE-L3	<b>0.93</b>		0.35	
		R-sample		
Stemming	0.66		0.07	
String distance $D_4$	0.36		0.20	
String distance $Dice_3$	0.23		0.23	

Table 5: Precision and recall on test samples

pairs in the P-sample and more negative pairs in the R-sample.

## 6 Results

### 6.1 Quantitative Evaluation

Table 5 presents the overall results. We evaluate four variants of the induced derivational families: those obtained before rule refinement (DERIVBASE initial), and three variants after rule refinement: using all rules (DERIVBASE-L123), excluding the least reliable rules (DERIVBASE-L23), and using only highly reliable rules (DERIVBASE-L3).

We measure the precision of our method on the P-sample and recall on the R-sample. For the baselines, precision was also computed on the R-sample (computing it on P-sample, which is obtained from the induced derivational families, would severely underestimate the number of false positives). We omit the  $F_1$  score because its use for precision and recall estimates from different samples is unclear.

DERIVBASE reaches 83% precision when using all rules and 93% precision when using only highly reliable rules. DERIVBASE-L123 achieves the highest recall, outperforming other methods and variants by a large margin. Refinement of the initial model has produced a significant improvement in recall without losses in precision. The baselines perform worse than our method: the stemmer we use is rather conservative, which fragments the families and leads to a very low recall. The string distance-based approaches achieve more balanced precision and recall scores. Note that for these methods, precision and recall can be traded off against each other by varying the number of clusters; we chose the number of clusters by optimizing the  $F_1$  score on the calibration and validation sets.

All subsequent analyses refer to DERIVBASE-

Coverage	Accuracy		
	High	Low	Total
High	18	–	18
Low	53	21	74
<i>Total</i>	71	21	92

Table 6: Proportions of accuracy and coverage for direct derivations (measured on P-sample)

	P	R	P	R
N-N	0.78	0.68	N-A	<b>0.89</b> <b>0.83</b>
A-A	0.87	0.70	N-V	0.79 0.68
V-V	0.55	0.24	A-V	0.88 0.73

Table 7: Precision and recall across different part of speech (first POS: basis; second POS: derived word)

L123, which is the model with the highest recall. If optimal precision is required, DERIVBASE-L3 should however be preferred.

**Analysis by frequency.** We cross-classified our rules according to high/low accuracy and high/low coverage based on the pairs in the P-sample. We only considered directly derivationally related ( $\rightarrow_D$ ) pairs and defined “high accuracy” and “high coverage” as all rules above the 25th percentile in terms of accuracy and coverage, respectively. The results are shown in Table 6: all high-coverage rules are also highly accurate. Most rules are accurate but infrequent. Only 21 rules have a low accuracy, but all of them apply infrequently.

**Analysis by parts of speech.** Table 7 shows precision and recall values for different part of speech combinations for the basis and derived words. High precision and recall are achieved for N-A derivations. The recall is lowest for V-V derivations, suggesting that the derivational phenomena for this POS combination are not yet covered satisfactorily.

## 6.2 Error analysis

Table 8 shows the frequencies of true positives and false positives on the P-sample and false negatives on the R-sample for each annotated category. True negatives are not reported, since their analysis gives no deeper insight.

**True positives.** In our analysis we treated both R and M pairs as related, but it is interesting to see how many of the true positives are in fact semantically unrelated. Out of 1,663 pairs, 90% are semantically as well as morphologically related (R), e.g.,

Label	TPs	FPs	FNs
	P-sample	P-sample	R-sample
R	1,492	–	107
M	171	–	60
N	–	216	–
C	–	7	–
L	–	114	–
<i>Total</i>	1,663	337	167

Table 8: Predictions over annotated categories

*alkoholisieren<sub>V</sub> – antialkoholisch<sub>A</sub> (to alcoholize – nonalcoholic), Beschuldigung<sub>N</sub> – unschuldig<sub>A</sub> (accusation – innocent).* Most R pairs result from high-accuracy rules, i.e., zero derivation, negation prefixation and simple suffixation. The remaining 10% are only morphologically related (M), e.g., *beschwingt<sub>A</sub> – schwingen<sub>V</sub> (cheerful – to swing), Stolzieren<sub>N</sub> – stolz<sub>A</sub> (strut – proud).* In both pairs, the two lemmas share a common semantic concept – i.e., being in motion or being proud – but nowadays meanings have grown apart from each other. Among the M true positives, we observe prefixation derivations in 66% of the cases, often involving prefixation at both lemmas, e.g., *Erdenkliche<sub>N</sub> – bedenklich<sub>A</sub> (imaginable – questionable).*

**False positives.** We observe many errors in pairs involving short lemmas, e.g., *Gen<sub>N</sub> – genieren<sub>V</sub> (gene – to be embarrassed)*, where orthographic context is insufficient to reject the derivation. About 64% of the 337 incorrect pairs are of class N (unrelated lemmas). For example, the rule for deriving nouns denoting a male person incorrectly links *Morse<sub>N</sub> – Mörser<sub>N</sub> (Morse – mortar)*. Transitively applied rules often produce incorrect pairs; e.g., *Speiche<sub>N</sub> – speicherbar<sub>A</sub> (spoke – storable)* results from the rule chain *Speiche<sub>N</sub> → Speicher<sub>N</sub> → speichern<sub>V</sub> → speicherbar<sub>A</sub> (spoke → storage → to store → storable)*. Chains that involve ablaut shifts (cf. Section 3.1) can lead to surprising results, e.g., *Erringung<sub>N</sub> – rangiert<sub>A</sub> (achievement – shunted)*. Meanwhile, some pairs judged as unrelated by the annotators might conceivably be weakly related, such as *schlürfen<sub>V</sub> and schlurfen<sub>V</sub> (to sip – to shuffle)*, both of which refer to specific long drawn out sounds. About 20% out of these unrelated lemma pairs is due to derivations between proper nouns (PNs) and common nouns. This happens especially for short PNs (cf. the above example of *Morse*). However, since PNs also participate in valid derivations (e.g., *Chaplin – chaplinesque*),

one could investigate their impact on derivations rather than omitting them.

Errors of the category L – 34% of the false positives – are caused during preprocessing by the lemmatizer. They cannot be blamed on our derivational model, but of course form part of the output.

**False negatives.** Errors of this type are due to missing derivation rules, erroneous rules that leave some lemmas undiscovered, or the absence of lemmas in the corpus required for transitive closure. About 64% of the 167 missed pairs are of category R. About half of these pairs result from a lack of prefixation rules – mainly affecting verbs – with a wide variety of prefixes (*zu-*, *um-*, etc.), including prepositional prefixes like *herum-* (*around*) or *über-* (*over*). We intentionally ignored these derivations, since they frequently lead to semantically unrelated pairs. In fact, merely five of the remaining 36% false negative pairs (M) do not involve prefixation. However, this analysis as well as the rather low coverage for verb-involved rules (cf. Table 7) shows that DERIVBASE might benefit from more prefix rules. Apart from the lack of prefixation coverage and a few other, rather infrequent rules, we did not find any substantial deficits. Most of the remaining errors are due to German idiosyncrasies and exceptional derivations, e.g., *fahren<sub>V</sub>* – *Fahrt<sub>N</sub>* (*drive* – *trip*), where the regular zero derivation would result in *Fahr*.

## 7 Conclusion and Future Work

In this paper, we present DERIVBASE, a derivational resource for German based on a rule-based framework. A few work days were enough to build the underlying rules with the aid of grammar textbooks. We collected derivational families for over 280,000 lemmas with high accuracy as well as solid coverage. The resource is freely available.<sup>5</sup>

Our approach for compiling a derivational resource is not restricted to German. In addition to the typologically most similar Germanic and Romance languages, it is also applicable to agglutinative languages like Finnish, or other fusional languages like Russian. Its main requirements are a large list of lemmas for the language (optionally with further morphological features) and linguistic literature on morphological patterns.

We have employed an evaluation method that uses two separate samples to assess precision and

recall to deal with the high number of false negatives. Our analyses indicate two interesting directions for future work: (a) specific handling of proper nouns, which partake in specific derivations; and (b) the use of graph clustering instead of the transitive closure to avoid errors resulting from long transitive chains.

Finally, we plan to employ distributional semantics methods (Turney and Pantel, 2010) to help remove semantically unrelated pairs as well as distinguish automatically between only morphologically (M) or both morphologically and semantically (R) related pairs. Last, but not least, this allows us to group derivation rules according to their semantic properties. For example, nouns with *-er* suffixes often denote persons and are agentivizations of a basis word (Bilgin et al., 2004).

## Abstract

We report on the construction of the Webis text reuse corpus 2012 for advanced research on text reuse. The corpus compiles manually written documents obtained from a completely controlled, yet representative environment that emulates the web. Each of the 297 documents in the corpus is about one of the 150 topics used at the TREC Web Tracks 2009–2011, thus forming a strong connection with existing evaluation efforts. Writers, hired at the crowdsourcing platform oDesk, had to retrieve sources for a given topic and to reuse text from what they found. Part of the corpus are detailed interaction logs that consistently cover the search for sources as well as the creation of documents. This will allow for in-depth analyses of *how text is composed* if a writer is at liberty to reuse texts from a third party—a setting which has not been studied so far. In addition, the corpus provides an original resource for the evaluation of text reuse and plagiarism detectors, where currently only less realistic resources are employed.

## 1 Introduction

The web has become one of the most common sources for text reuse. When reusing text from the web, humans may follow a three step approach shown in Figure 1: searching for appropriate sources on a given topic, copying of text from selected sources, modification and paraphrasing of the copied text. A considerable body of research deals with the detection of text reuse, and, in particular, with the detection of cases of plagiarism (i.e., the reuse of text with the intent of disguising the fact that text has been reused). Similarly, a large number of commercial software systems is

being developed whose purpose is the detection of plagiarism. Both the developers of these systems as well as researchers working on the subject matter frequently claim their approaches to be searching the entire web or, at least, to be scalable to web size. However, there is hardly any evidence to substantiate this claim—rather the opposite can be observed: commercial plagiarism detectors have not been found to reliably identify plagiarism from the web (Köhler and Weber-Wulff, 2010), and the evaluation of research prototypes even under laboratory conditions shows that there is still a long way to go (Potthast et al., 2010b). We explain the disappointing state of the art by the lack of realistic, large-scale evaluation resources.

With our work, we want to contribute to closing the gap. In this regard the paper in hand introduces the Webis text reuse corpus 2012 (Webis-TRC-12), which, for the first time, emulates the *entire process* of reusing text from the web, both at scale and in a controlled environment. The corpus comprises a number of features that set it apart from previous ones: (1) the topic of each document in the corpus is derived from a topic of the TREC Web Track, and the sources to copy from have been retrieved manually from the ClueWeb corpus. (2) The search for sources is logged, including click-through and browsing data. (3) A fine-grained edit history has been recorded for each document. (4) A total of 297 documents were written with an average length of about 5700 words, whereas diversity is ensured via crowdsourcing. Altogether, this corpus forms the current most realistic sample of writers reusing text. The corpus is publicly available.<sup>1</sup>

### 1.1 Related Work

As organizers of the annual PAN plagiarism detection competitions,<sup>2</sup> we have introduced the first standardized evaluation framework for that pur-

<sup>1</sup><http://www.webis.de/research/corpora>

<sup>2</sup><http://pan.webis.de>

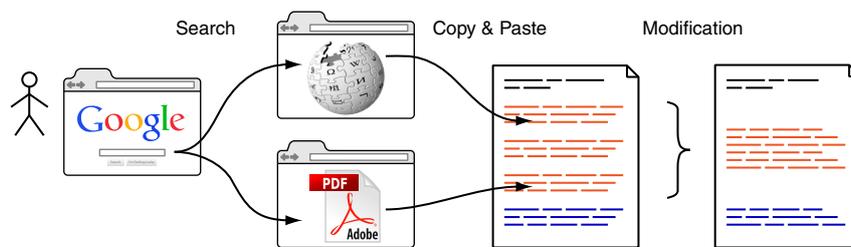

Figure 1: The basic steps of reusing text from the web (Potthast, 2011).

pose (Potthast et al., 2010b). Among others, it comprises a series of corpora that consist of automatically generated cases of plagiarism, provided in the form of the PAN plagiarism corpora 2009-2011. The corpora have been used to evaluate dozens of plagiarism detection approaches within the respective competitions in these years;<sup>3</sup> but even though they have been adopted by the community, a number of shortcomings render them less realistic:

1. All plagiarism cases were generated by randomly selecting text passages from documents and inserting them at random positions in a host document. This way, the reused passages do not match the topic of the host document.
2. The majority of the reused passages were modified in order to obfuscate the reuse. However, the applied modification strategies, again, are basically random: shuffling, replacing, inserting, or deleting words randomly. An effort was made to avoid non-readable text, yet none of it bears any semantics.
3. The corpus documents are parts of books from the Project Gutenberg. Many of these books are pretty old, whereas today the web is the predominant source for text reuse.

To overcome the second issue, about 4 000 passages were rewritten manually via crowdsourcing on Amazon’s Mechanical Turk for the 2011 corpus. But, because of the first issue (random passage insertion), a topic drift analysis can spot a reused passage more easily than a search within the document set containing the original source (Potthast et al., 2011). From these observations it becomes clear that there are limits for the automatic construction of such kinds of corpora. The Webis text reuse corpus 2012 addresses all of the mentioned issues since it has been constructed manually.

<sup>3</sup>See (Potthast et al., 2009; Potthast et al., 2010a; Potthast et al., 2011) for overviews of approaches and evaluation results of each competition.

Besides the PAN corpora, there are two other corpora that comprise “genuinely reused” text: the Clough09 corpus, and the Meter corpus. The former corpus consists of 57 answers to one of five computer science questions that were reused from a respective Wikipedia article (Clough and Stevenson, 2011). While the text was genuinely written by a number of volunteer students, the choice of topics is narrow, and text lengths range from 200 to 300 words, which is hardly more than 2-3 paragraphs. Also, the sources from which text was reused were given up front, so that there is no data about their retrieval. The Meter corpus annotates 445 cases of text reuse among 1 716 news articles (Clough et al., 2002). The cases of text reuse in this corpus are realistic for the news domain; however, they have not been created by the reuse process outlined in Figure 1. Note that in the news domain, text is often reused directly from a news wire without the need for retrieval. Our new corpus complements these two resources.

## 2 Corpus Construction

Two data sets form the basis for constructing our corpus, namely (1) a set of topics to write about and (2) a set of web pages to research about a given topic. With regard to the former, we resort to topics used at TREC, specifically to those used at the Web Tracks 2009–2011. With regard to the latter, we employ the ClueWeb corpus from 2009<sup>4</sup> (and not the “web in the wild”). The ClueWeb comprises more than one billion documents from ten languages and can be considered as a representative cross-section of the real web. It is a widely accepted resource among researchers and became one of the primary resources to evaluate the retrieval performance of search engines within several TREC tracks. Our corpus’s strong connection to TREC will allow for unforeseen synergies. Based on these decisions our

<sup>4</sup><http://lemurproject.org/clueweb09>

corpus construction steps can be summarized as follows:

1. Rephrasing of the 150 topics used at the TREC Web Tracks 2009–2011 so that they explicitly invite people to write an essay.
2. Indexing of the ClueWeb corpus category A (the entire English portion with about 0.5 billion documents) using the BM25F retrieval model plus additional features.
3. Development of a search interface that allows for answering queries within milliseconds and that is designed along the lines of commercial search interfaces.
4. Development of a browsing API for the ClueWeb, which serves ClueWeb pages on demand and which rewrites links of delivered pages, now pointing to their corresponding ClueWeb pages on our servers (instead of to the originally crawled URL).
5. Recruiting 27 writers, 17 of whom with a professional writing background, hired at the crowdsourcing platform oDesk from a wide range of hourly rates for diversity.
6. Instructing the writers to write one essay at a time of at least 5000 words length (corresponding to an average student’s homework assignment) about an open topic of their choice, using our search engine—hence browsing only ClueWeb pages.
7. Logging all writers’ interactions with the search engine and the ClueWeb on a per-essay basis at our site.
8. Logging all writers’ edits to their essays in a fine-grained edit log: a snapshot was taken whenever a writer stopped writing for more than 300ms.
9. Double-checking all of the essays for quality.

After having deployed the search engine and completed various usability tests, the actual corpus construction took nine months, from April 2012 through December 2012.

Obviously, the outlined experimental setup can serve different lines of research and is publicly available as well. The remainder of the section presents elements of our setup in greater detail.

## 2.1 Topic Preparation

Since the topics used at the TREC Web Tracks were not amenable for our purpose as is, we rephrased them so that they ask for writing an essay instead of searching for facts. Consider for example topic 001 of the TREC Web Track 2009:

*Query.* obama family tree

*Description.* Find information on President Barack Obama’s family history, including genealogy, national origins, places and dates of birth, etc.

*Sub-topic 1.* Find the TIME magazine photo essay “Barack Obama’s Family Tree.”

*Sub-topic 2.* Where did Barack Obama’s parents and grandparents come from?

*Sub-topic 3.* Find biographical information on Barack Obama’s mother.

This topic is rephrased as follows:

*Obama’s family.* Write about President Barack Obama’s family history, including genealogy, national origins, places and dates of birth, etc. Where did Barack Obama’s parents and grandparents come from? Also include a brief biography of Obama’s mother.

In the example, Sub-topic 1 is considered too specific for our purposes while the other sub-topics are retained. TREC Web Track topics divide into faceted and ambiguous topics. While topics of the first kind can be directly rephrased into essay topics, from topics of the second kind one of the available interpretations was chosen.

## 2.2 A Controlled Web Search Environment

To give the oDesk writers a familiar search experience while maintaining reproducibility at the same time, we developed a tailored search engine called ChatNoir (Potthast et al., 2012b).<sup>5</sup> Besides ours, the only other public search engine for the ClueWeb is Carnegie Mellon’s Indri,<sup>6</sup> which, unfortunately, is far from our efficiency requirements. Moreover, its search interface does not follow the standard in terms of result page design, and it does not give access to interaction logs. Our search engine is on the order of milliseconds in terms of retrieval

<sup>5</sup><http://chatnoir.webis.de>

<sup>6</sup><http://lemurproject.org/clueweb09.php/index.php#Services>

time, its interface follows industry standards, and it features an API that allows for user tracking.

ChatNoir is based on the BM25F retrieval model (Robertson et al., 2004), uses the anchor text list provided by (Hiemstra and Hauff, 2010), the PageRanks provided by the Carnegie Mellon University alongside the ClueWeb corpus, and the Spam rank list provided by (Cormack et al., 2011). ChatNoir comes with a proximity feature with variable-width buckets as described by (Elsayed et al., 2011). Our choice of retrieval model and ranking features is intended to provide a reasonable baseline performance. However, it is neither near as mature as those of commercial search engines nor does it compete with the best-performing models from TREC. Yet, it is among the most widely accepted models in information retrieval, which underlines our goal of reproducibility.

In addition to its retrieval model, ChatNoir implements two search facets: text readability scoring and long text search. The first facet, similar to that provided by Google, scores the readability of a text found on a web page via the well-known Flesch-Kincaid grade level formula (Kincaid et al., 1975): it estimates the number of years of education required in order to understand a given text. This number is mapped onto the three categories “Simple” (up to 5 years), “Intermediate” (between 5 and 9 years) and “Expert” (at least 9 years). The “Long Text” search facet omits search results which do not contain at least one continuous paragraph of text that exceeds 300 words. The two facets can be combined with each other.

When clicking on a search result, ChatNoir does not link into the real web but redirects into the ClueWeb. Though the ClueWeb provides the original URLs from which the web pages have been obtained, many of these pages have gone or been updated since. We hence set up an API that serves web pages from the ClueWeb on demand: when accessing a web page, it is pre-processed before being shipped, removing automatic referrers and replacing all links to the real web with links to their counterpart inside the ClueWeb. This way, the ClueWeb can be browsed as if surfing the real web, whereas it becomes possible to track a user. The ClueWeb is stored in the HDFS of our 40 node Hadoop cluster, and web pages are fetched directly from there with latencies of about 200ms. ChatNoir’s inverted index has been optimized to guarantee fast response times, and it is deployed alongside Hadoop on the same cluster.

Table 1: Demographics of the 12 Batch 2 writers.

Writer Demographics					
<i>Age</i>		<i>Gender</i>		<i>Native language(s)</i>	
Minimum	24	Female	67%	English	67%
Median	37	Male	33%	Filipino	25%
Maximum	65			Hindi	17%
<i>Academic degree</i>		<i>Country of origin</i>		<i>Second language(s)</i>	
Postgraduate	41%	UK	25%	English	33%
Undergraduate	25%	Philippines	25%	French	17%
None	17%	USA	17%	Afrikaans, Dutch,	
n/a	17%	India	17%	German, Spanish,

Minimum	2	Google	92%	Daily	83%
Median	8	Bing	33%	Weekly	8%
Standard dev.	6	Yahoo	25%	n/a	8%
Maximum	20	Others	8%		

### 2.3 Two Batches of Writing

In order to not rely only on the retrieval model implemented in our controlled web search environment, we divided the task into two batches, so that two essays had to be written for each of the 150 topics, namely one in each batch. In Batch 1, our writers did not search for sources themselves, but they were provided up front with an average of 20 search results to choose from for each topic. These results were obtained from the TREC Web Track relevance judgments (so-called “qrels”): only documents that were found to be relevant or key documents for a given topic by manual inspection of the NIST assessors were provided to our writers. These documents result from the combined wisdom of all retrieval models of the TREC Web Tracks 2009–2011, and hence can be considered as optimum retrieval results produced by the state of the art in search engine technology. In Batch 2, in order to obtain realistic search interaction logs, our writers were instructed to search for source documents using ChatNoir.

### 2.4 Crowdsourcing Writers

Our ideal writer has experience in writing, is capable of writing about a diversity of topics, can complete a text in a timely manner, possesses decent English writing skills, and is well-versed in using the aforementioned technologies. After bootstrapping our setup with 10 volunteers recruited at our university, it became clear that, because of the workload involved, accomplishing our goals would not be possible with volunteers only. Therefore, we resorted to hiring (semi-)professional writers and made use of the crowdsourcing platform oDesk.<sup>7</sup> Crowdsourcing has quickly become one of the

<sup>7</sup><http://www.odesk.com>

Sources / Writer	5	169.7	1 065	269.6	

cornerstones for constructing evaluation corpora, which is especially true for paid crowdsourcing. Compared to Amazon’s Mechanical Turk (Barr and Cabrera, 2006), which is used more frequently than oDesk, there are virtually no workers at oDesk submitting fake results because of its advanced rating features for workers and employers. Moreover, oDesk tracks their workers by randomly taking screenshots, which are provided to employers in order to check whether the hours logged correspond to work-related activity. This allowed us to check whether our writers used our environment instead of other search engines and editors.

During Batch 2, we have conducted a survey among the twelve writers who worked for us at that time. Table 1 gives an overview of the demographics of these writers, based on a questionnaire and their resumes at oDesk. Most of them come from an English-speaking country, and almost all of them speak more than one language, which suggests a reasonably good education. Two thirds of the writers are female, and all of them have years of writing experience. Hourly wages were negotiated individually and range from 3 to 34 US dollars (dependent on skill and country of residence), with an average of about 12 US dollars. For ethical reasons, we payed at least the minimum wage of the respective countries involved. In total, we spent 20 468 US dollars to pay the writers—an amount that may be considered large compared to other scientific crowdsourcing efforts from the literature, but small in terms of the potential of crowdsourcing to make a difference in empirical science.

### 3 Corpus Analysis

This section presents selected results of a preliminary corpus analysis. We overview the data and shed some light onto the search and writing behavior of writers.

#### 3.1 Corpus Statistics

Table 2 shows key figures of the collected interaction logs, including the absolute numbers of queries, relevance judgments, working times, number of edits, words, and retrieved sources, as well as their relation to essays, writers, and work time, where applicable. On average, each writer wrote 2 essays while the standard deviation is 15.9, since one very prolific writer managed to write 66 essays.

From a total of 13 655 queries submitted by the writers within Batch 2, each essay got an average of 91 queries. The average number of results clicked per query is 2.3. For comparison, we computed the average number of clicks per query in the AOL query log (Pass et al., 2006), which is 2.0. In this regard, the behavior of our writers on individual queries does not differ much from that of the average AOL user in 2006. Most of the clicks that we recorded are search result clicks, whereas 2 457 of them are browsing clicks on web page links. Among the browsing clicks, 11.3% are clicks on links that point to the same web page (i.e., anchor links using the hash part of a URL). The longest click trail contains 51 unique web pages, but most trails are very short. This is a surprising result, since we expected a larger proportion of browsing clicks, but it also shows that our writers

relied heavily on the ChatNoir’s ranking. Regarding search facets, we observed that our writers used them only for about 7% of their queries. In these cases, the writers used either the “Long Text” facet, which retrieves web pages containing at least one continuous passage of at least 300 words, or set the desired reading level to “Expert.”

The query log of each writer in Batch 2 divides into 931 search sessions with an average of 12.3 sessions per topic. Here, a session is defined as a sequence of queries recorded for a given topic which is not divided by a break longer than 30 minutes. Despite other claims in the literature (Jones and Klinkner, 2008; Hagen et al., 2013) we argue that, in our case, sessions can be reliably identified by timeouts because we have a priori knowledge about which query belongs to which essay. Typically, completing an essay took 4.9 days, which includes to a long-lasting exploration of the topic at hand.

The 297 essays submitted within the two batches were written with a total of 633 334 edits. Each topic was edited 2 132 times on average, whereas the standard deviation gives an idea about how diverse the modifications of the reused text were. Writers were not specifically instructed to modify a text as much as possible—rather they were encouraged to paraphrase in order to foreclose the detection by an automatic text reuse detector. This way, our corpus captures each writer’s idea of the necessary modification effort to accomplish this goal. The average lengths of the essays is 5 739 words, but there are also some short essays if hardly any useful information could be found on the respective topics. About 15 sources have been reused in each essay, whereas some writers reused text from as many as 69 unique documents.

### 3.2 Relevance Judgments

In the essays from Batch 2, writers reused texts from web pages they found during their search. This forms an interesting relevance signal which allows us to separate web pages relevant to a given topic from those which are irrelevant. Following the terminology of TREC, we consider web pages from which text is reused as *key documents* for the respective essay’s topic, while web pages that are on a click trail leading to a key document are termed *relevant*. The unusually high number of key documents compared to relevant documents is explained by the fact that there are only few click trails of this kind, whereas most web pages

Table 3: Confusion matrix of TREC judgments versus writer judgments.

TREC judgment	Writer judgment			
	irrelevant	relevant	key	unjudged
spam (-2)	3	0	1	2 446
spam (-1)	64	4	18	16 657
irrelevant (0)	219	13	73	33 567
relevant (1)	114	8	91	10 676
relevant (2)	44	5	56	3 711
key (3)	12	0	8	526
unjudged	5 506	221	1 690	–

have been retrieved directly. The remainder of web pages that were viewed but discarded by our writers are considered as irrelevant.

Each year, the NIST assessors employed for the TREC conference manually review hundreds of web pages that have been retrieved by experimental retrieval systems that are submitted to the various TREC tracks. This was also the case for the TREC Web Tracks from which the topics of our corpus are derived. We have compared the relevance judgments provided by TREC for these tracks with the implicit judgments from our writers. Table 3 contrasts the two judgment scales in the form of a confusion matrix. TREC uses a six-point Likert scale ranging from -2 (extreme Spam) to 3 (key document). For 733 of the documents visited by our writers, TREC relevance judgments can be found. From these, 456 documents (62%) have been considered irrelevant for the purposes of reuse by our writers, however, the TREC assessor disagree with this judgment in 170 cases. Regarding the documents considered as key documents for reuse by our writers, the TREC assessors disagree on 92 of the 247 documents. An explanation for the disagreement can be found in the differences between the TREC ad hoc search task and our text reuse task: the information nuggets (small chunks of text) that satisfy specific factual information needs from the original TREC topics are not the same as the information “ingots” (big chunks of text) that satisfy our writers’ needs.

### 3.3 Research Behavior

To analyze the writers’ search behavior during essay writing in Batch 2, we have recorded detailed search logs of their queries while they used our search engine. Figure 2 shows for each of the 150 essays of this batch a curve of the percentage of queries at times between a writer’s first query and an essay’s completion. We have normalized the time axis and excluded working breaks of more

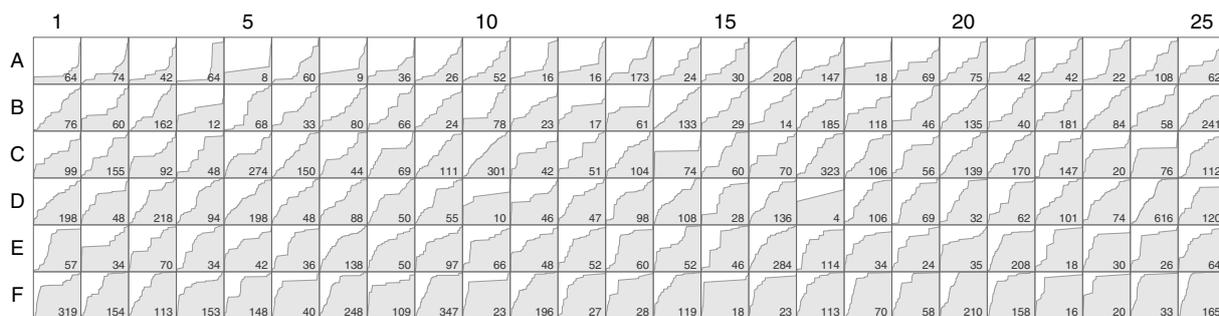

Figure 2: Spectrum of writer search behavior. Each grid cell corresponds to one of the 150 essays of Batch 2 and shows a curve of the percentage of submitted queries (y-axis) at times between the first query until the essay was finished (x-axis). The numbers denote the amount of queries submitted. The cells are sorted by area under the curve, from the smallest area in cell A1 to the largest area in cell F25.

than five minutes. The curves are organized so as to highlight the spectrum of different search behaviors we have observed: in row A, 70-90% of the queries are submitted toward the end of the writing task, whereas in row F almost all queries are submitted at the beginning. In between, however, sets of queries are often submitted in the form of “bursts,” followed by extended periods of writing, which can be inferred from the steps in the curves (e.g., cell C12). Only in some cases (e.g., cell C10) a linear increase of queries over time can be observed for a non-trivial amount of queries, which indicates continuous switching between searching and writing. From these observations, it can be inferred that our writers sometimes conducted a “first fit” search and reused the first texts they found easily. However, as the essay progressed and the low hanging fruit in terms of search were used up, they had to search more intensively in order to complete their essay. More generally, this data gives an idea of how humans perform exploratory search in order to learn about a given topic. Our current research on this aspect focuses on the prediction of search mission types, since we observe that the search mission type does not simply depend on the writer or the perceived topic difficulty.

### 3.4 Visualizing Edit Histories

To analyze the writers’ writing style, that is to say, how writers reuse texts and how the essay is completed in both batches, we have recorded the edit logs of their essays. Whenever a writer stopped writing for more than 300ms, a new edit was stored in a version control system at our site. The edit logs document the entire text evolution, from first the keystroke until an essay was completed. We have used the so-called history flow visualization to analyze the writing process (Vié-

gas et al., 2004). Figure 3 shows four examples from the set of 297 essays. Based on these visualizations, a number of observations can be made. In general, we identify two distinct writing-style types to perform text reuse, namely to *build up* an essay during writing, or, to first gather material and then to *boil down* a text until the essay is completed. Later in this section, we will analyze this observation in greater detail. Within the plots, a number of events can be spotted that occurred during writing: in the top left plot, encircled as area A, the insertion of a new piece of text can be observed. Though marked as original text at first, the writer worked on this passage and then revealed that it was reused from another source. At area B in the top right plot, one can observe the reorganization of two passages as they exchange places from one edit to another. Area C in the bottom right plot shows that the writer, shortly before completing this essay, reorganized substantial parts. Area D in the same plot shows how the writer went about boiling down the text by incorporating contents from different passages that have been collected beforehand and, then, from one edit to another, discarded most of the rest. The saw-tooth shaped pattern in area E in the bottom left plot reveals that, even though the writer of this essay adopts a build-up style, she still pastes passages from her sources into the text one at a time, and then individually boils down each. Our visualizations also include information about the text positions where writers have been working at a given point in time; these positions are shown as blue dots in the plots. In this regard distinct writing patterns are discernible of writers who go through a text linearly versus those who do not. Future work will include an analysis of these writing patterns.

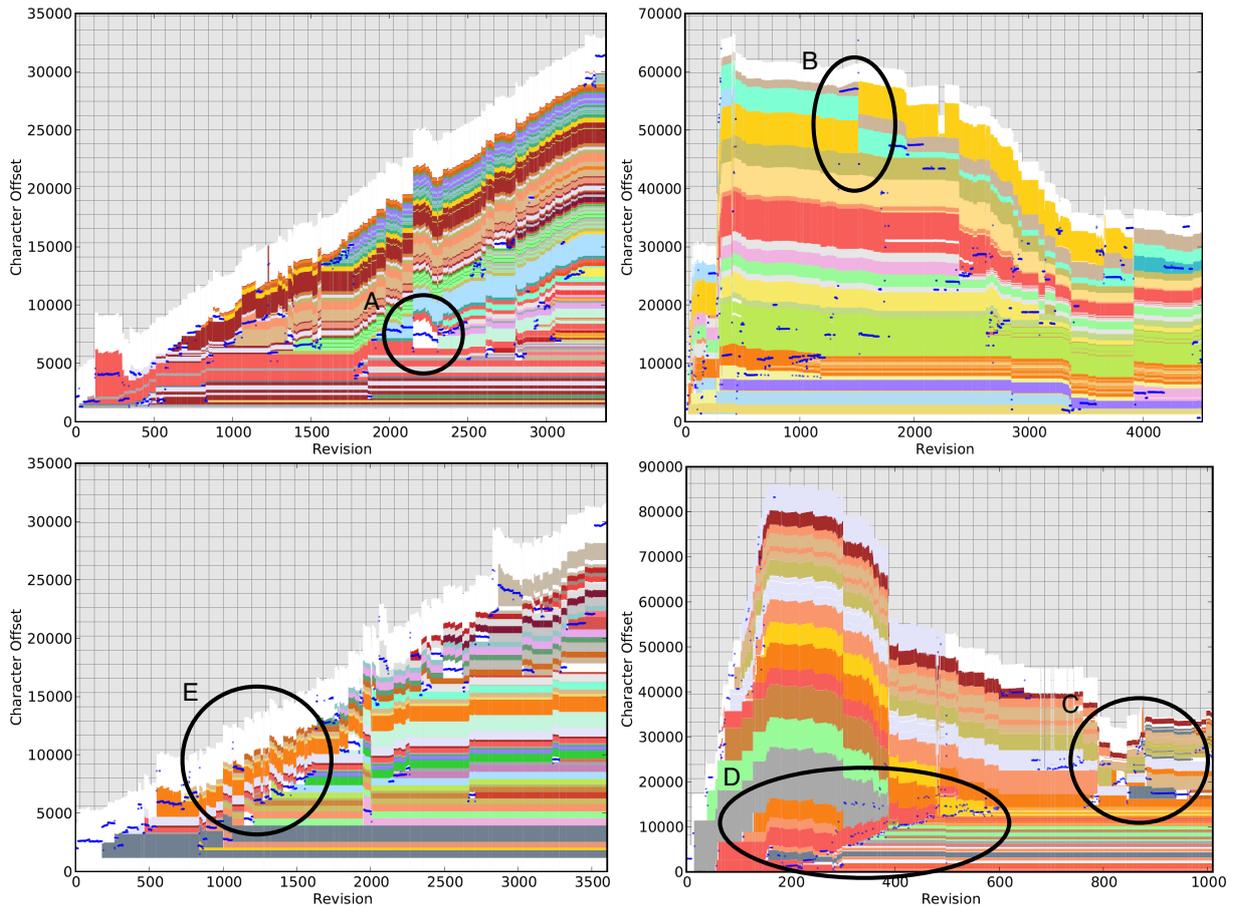

Figure 3: Types of text reuse: build-up reuse (left) versus boil-down reuse (right). Each plot shows the text length at text edit between first keystroke and essay completion; edits have been recorded during writing whenever a writer stopped for more than 300ms. Colors encode different source documents. Original text is white; blue dots indicate the text position of the writer’s last edit.

### 3.5 Build-up Reuse versus Boil-down Reuse

Based on the edit history visualizations, we have manually classified the 297 essays of both batches into two categories, corresponding to the two styles build-up reuse and boil-down reuse. We found that 40% are instances of build-up reuse, 45% are instances of boil-down reuse, and 13% fall in between, excluding 2% of the essays as outliers due to errors or for being too short. The in-between cases show that a writer actually started one way and then switched to the respective other style of reuse so that the resulting essays could not be attributed to a single category. An important question that arises out of this observation is whether different writers habitually exert different reuse styles or whether they apply them at random. To obtain a better overview, we envision the applied reuse style of an essay by the skyline curve of its edit history visualization (i.e., by the curve that plots the length of an essay after each edit). Aggregating these curves on a per-writer basis reveals distinct

Table 4: Contingency table: writers over reuse style.

Reuse Style	Writer ID											
	A02	A05	A06	A07	A10	A17	A18	A19	A20	A21	A24	
build-up	4	27	11	4	9	13	12	4	9	18	2	
boil-down	52	5	0	14	2	13	11	3	0	0	24	
mixed	10	3	0	1	1	7	6	0	0	3	1	

patterns. For eight of our writers Figure 4 shows this characteristic. The plots are ordered by the shape of the averaged curve, starting from a linear increase (left) to a compound of steep increase to a certain length after which the curve levels out (right). The former shape corresponds to writers who typically apply build-up reuse, while the latter can be attributed to writers who typically apply boil-down reuse.

When comparing the plots we notice a very interesting effect: it appears that writers who conduct boil-down reuse vary more wildly in their behavior. The reuse style of some writers, however, falls in between the two extremes. Besides the visual analysis, Table 4 shows the distribution of reuse styles

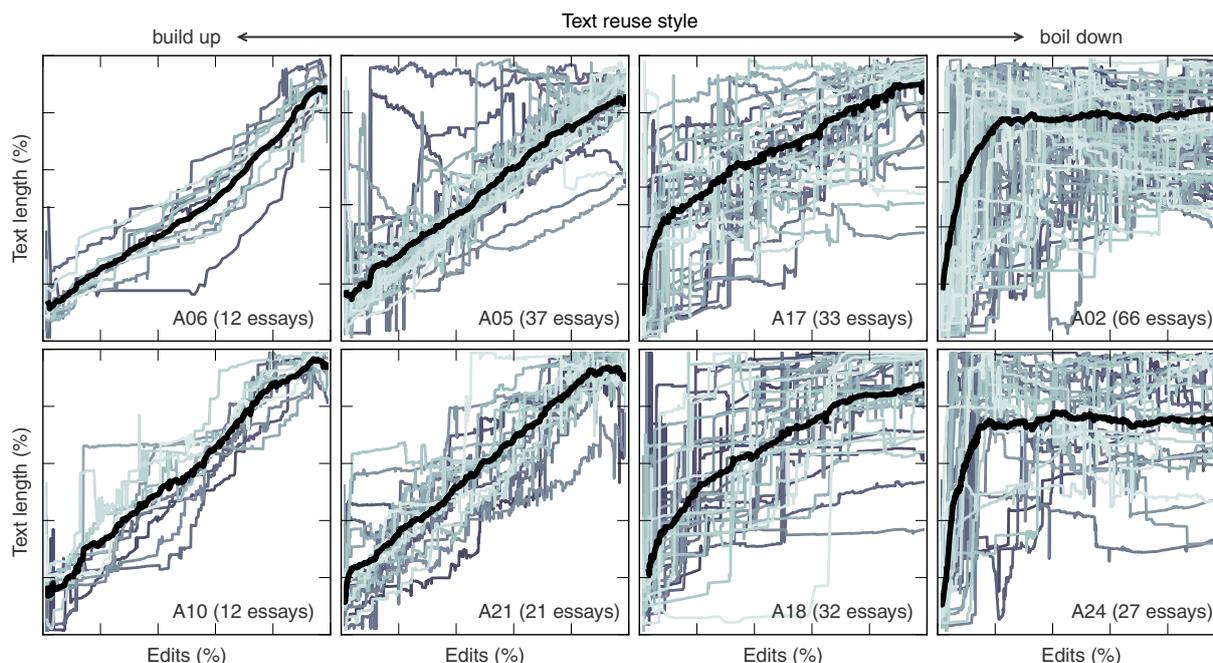

Figure 4: Text reuse styles ranging from build-up reuse (left) to boil-down reuse (right). A gray curve shows the normalized length of an essay over the edits that went into it during writing. Curves are grouped by writers. The black curve marks the average of all other curves in a plot.

for the eleven writers who contributed at least five essays. Most writers use one style for about 80% of their essays, whereas two writers (A17, A18) are exactly on par between the two styles. Based on Pearson’s chi-squared test, one can safely reject the null hypothesis that writers and text reuse styles are independent:  $\chi^2 = 139.0$  with  $p = 7.8 \cdot 10^{-20}$ . Since our sample of authors and essays is sparse, Pearson’s chi-squared test may not be perfectly suited which is why we have also applied Fisher’s exact test, which computes probability  $p = 0.0005$  that the null hypothesis is true.

#### 4 Summary and Outlook

This paper details the construction of the Webis text reuse corpus 2012 (Webis-TRC-12), a new corpus for text reuse research that has been created entirely manually on a large scale. We have recorded consistent interaction logs of human writers with a search engine as well as with the used text processor; these logs serve the purpose of studying how texts from the web are being reused for essay writing. Our setup is entirely reproducible: we have built a static web search environment consisting of a search engine along with a means to browse a large corpus of web pages as if it were the “real” web. Yet, in terms of scale, this environment is representative of the real web. Besides our corpus also this infrastructure is available to other researchers.

The corpus itself goes beyond existing resources in that it allows for a much more fine-grained analysis of text reuse, and in that it significantly improves the realism of the data underlying evaluations of automatic tools to detect text reuse and plagiarism.

Our analysis gives an overview of selected aspects of the new corpus. This includes corpus statistics about important variables, but also exploratory studies of search behaviors and strategies for reusing text. We present new insights about how text is composed, revealing two types of writers: those who build up a text as they go, and those who first collect a lot of material which then is boiled down until the essay is finished.

Parts of our corpus have been successfully employed to evaluate plagiarism detectors in the PAN plagiarism detection competition 2012 (Potthast et al., 2012a). Future work will include analyses that may help to understand the state of mind of writers when reusing text as well as of plagiarists. We also expect insights with regard to the development of algorithms for detection purposes and for linguists studying the process of writing.

#### Acknowledgements

We thank our writers at oDesk and all volunteers for their contribution. We also thank Jan Graßegger and Martin Tippmann who kept the search engine up and running during corpus construction.

# SPred: Large-scale Harvesting of Semantic Predicates

Tiziano Flati and Roberto Navigli

Dipartimento di Informatica

Sapienza Università di Roma

{flati,navigli}@di.uniroma1.it

## Abstract

We present SPred, a novel method for the creation of large repositories of semantic predicates. We start from existing collocations to form lexical predicates (e.g., *break* \*) and learn the semantic classes that best fit the \* argument. To do this, we extract all the occurrences in Wikipedia which match the predicate and abstract its arguments to general semantic classes (e.g., *break* BODY PART, *break* AGREEMENT, etc.). Our experiments show that we are able to create a large collection of semantic predicates from the Oxford Advanced Learner's Dictionary with high precision and recall, and perform well against the most similar approach.

## 1 Introduction

Acquiring semantic knowledge from text automatically is a long-standing issue in Computational Linguistics and Artificial Intelligence. Over the last decade or so the enormous abundance of information and data that has become available has made it possible to extract huge amounts of patterns and named entities (Etzioni et al., 2005), semantic lexicons for categories of interest (Thelen and Riloff, 2002; Igo and Riloff, 2009), large domain glossaries (De Benedictis et al., 2013) and lists of concepts (Katz et al., 2003). Recently, the availability of Wikipedia and other collaborative resources has considerably boosted research on several aspects of knowledge acquisition (Hovy et al., 2013), leading to the creation of several large-scale knowledge resources, such as DBpedia (Bizer et al., 2009), BabelNet (Navigli and Ponzetto, 2012), YAGO (Hoffart et al., 2013), MENTA (de Melo and Weikum, 2010), to name but a few. This wealth of acquired knowledge is known to have a positive impact on important fields such as Information Retrieval (Chu-Carroll and Prager, 2007), Information Extraction (Krause

et al., 2012), Question Answering (Ferrucci et al., 2010) and Textual Entailment (Berant et al., 2012; Stern and Dagan, 2012).

Not only are these knowledge resources obtained by acquiring concepts and named entities, but they also provide semantic relations between them. These relations are extracted from unstructured or semi-structured text using ontology learning from scratch (Velardi et al., 2013) and Open Information Extraction techniques (Etzioni et al., 2005; Yates et al., 2007; Wu and Weld, 2010; Fader et al., 2011; Moro and Navigli, 2013) which mainly stem from seminal work on *is-a* relation acquisition (Hearst, 1992) and subsequent developments (Girju et al., 2003; Pasca, 2004; Snow et al., 2004, among others).

However, these knowledge resources still lack semantic information about language units such as phrases and collocations. For instance, which semantic classes are expected as a direct object of the verb *break*? What kinds of noun does the adjective *amazing* collocate with? Recognition of the need for systems that are aware of the selectional restrictions of verbs and, more in general, of textual expressions, dates back to several decades (Wilks, 1975), but today it is more relevant than ever, as is testified by the current interest in semantic class learning (Kozareva et al., 2008) and supertype acquisition (Kozareva and Hovy, 2010). These approaches leverage lexico-syntactic patterns and input seeds to recursively learn the semantic classes of relation arguments. However, they require the manual selection of one or more seeds for each pattern of interest, and this selection influences the amount and kind of semantic classes to be learned. Furthermore, the learned classes are not directly linked to existing resources such as WordNet (Fellbaum, 1998) or Wikipedia.

The goal of our research is to create a large-scale repository of semantic predicates whose lexical arguments are replaced by their semantic classes. For example, given the textual expression *break a toe* we want to create the correspond-

ing semantic predicate *break a BODY PART*, where BODY PART is a class comprising several lexical realizations, such as *leg, arm, foot*, etc.

This paper provides three main contributions:

- We propose SPred, a novel approach which harvests predicates from Wikipedia and generalizes them by leveraging core concepts from WordNet.
- We create a large-scale resource made up of semantic predicates.
- We demonstrate the high quality of our semantic predicates, as well as the generality of our approach, also in comparison with our closest competitor.

## 2 Preliminaries

We introduce two preliminary definitions which we use in our approach.

**Definition 1 (lexical predicate).** A lexical predicate  $w_1 w_2 \dots w_i * w_{i+1} \dots w_n$  is a regular expression, where  $w_j$  are tokens ( $j = 1, \dots, n$ ),  $*$  matches any sequence of one or more tokens, and  $i \in \{0, \dots, n\}$ . We call the token sequence which matches  $*$  the filling argument of the predicate.

For example,  $a * \textit{of milk}$  matches occurrences such as *a full bottle of milk, a glass of milk, a carton of milk*, etc. While in principle  $*$  could match any sequence of words, since we aim at generalizing nouns, in what follows we allow  $*$  to match only noun phrases (e.g., *glass, hot cup, very big bottle*, etc.).

**Definition 2 (semantic predicate).** A semantic predicate is a sequence  $w_1 w_2 \dots w_i c w_{i+1} \dots w_n$ , where  $w_j$  are tokens ( $j = 1, \dots, n$ ),  $c \in C$  is a semantic class selected from a fixed set  $C$  of classes, and  $i \in \{0, \dots, n\}$ .

As an example, consider the semantic predicate *cup of BEVERAGE*,<sup>1</sup> where BEVERAGE is a semantic class representing beverages. This predicate matches phrases like *cup of coffee, cup of tea*, etc., but not *cup of sky*. Other examples include: *MUSICAL INSTRUMENT is played by*, *a CONTAINER of milk, break AGREEMENT*, etc.

Semantic predicates mix the lexical information of a given lexical predicate with the explicit semantic modeling of its argument. Importantly, the same lexical predicate can have different classes as its argument, like *cup of FOOD* vs. *cup of BEVERAGE*. Note, however, that different classes might convey different semantics for the same lexical

predicate, such as *cup of COUNTRY*, referring to cup as a prize instead of cup as a container.

## 3 Large-Scale Harvesting of Semantic Predicates

The goal of this paper is to provide a fully automatic approach for the creation of a large repository of semantic predicates in three phases. For each lexical predicate of interest (e.g., *break \**):

1. We extract all its possible filling arguments from Wikipedia, e.g., *lease, contract, leg, arm*, etc. (Section 3.1).
2. We disambiguate as many filling arguments as possible using Wikipedia, obtaining a set of corresponding Wikipedia pages, e.g., *Lease, Contract*, etc. (Section 3.2).
3. We create the semantic predicates by generalizing the Wikipedia pages to their most suitable semantic classes, e.g., *break AGREEMENT, break LIMB*, etc. (Section 3.3).

We can then exploit the learned semantic predicates to assign the most suitable semantic class to new filling arguments for the given lexical predicate (Section 3.4).

### 3.1 Extraction of Filling Arguments

Let  $\pi$  be an input lexical predicate (e.g., *break \**). We search the English Wikipedia for all the token sequences which match  $\pi$ , resulting in a list of noun phrases filling the  $*$  argument. We show an excerpt of the output obtained when searching Wikipedia for the arguments of the lexical predicate  $a * \textit{of milk}$  in Table 1. As can be seen, a wide range of noun phrases are extracted, from quantities such as *glass* and *cup* to other aspects, such as *brand* and *constituent*.

The output of this first step is a set  $L_\pi$  of triples  $(a, s, l)$  of filling arguments  $a$  matching the lexical predicate  $\pi$  in a sentence  $s$  of the Wikipedia corpus, with  $a$  potentially linked to a page  $l$  (e.g., see the top 3 rows in Table 1;  $l = \epsilon$  if no link is provided, see bottom rows of the Table).<sup>2</sup> Note that Wikipedia is the only possible corpus that can be used here for at least two reasons: first, in order to extract relevant arguments, we need a large corpus of a definitional nature; second, we need wide-coverage semantic annotations of filling arguments.

### 3.2 Disambiguation of Filling Arguments

The objective of the second step is to disambiguate as many arguments in  $L_\pi$  as possible for the lex-

<sup>1</sup>In what follows we denote the SEMANTIC CLASS in small capitals and the *lexical predicate* in italics.

<sup>2</sup>We will also refer to  $l$  as the *sense* of  $a$  in sentence  $s$ .

a	full [[bottle]]	of milk
a	nice hot [[cup]]	of milk
a	cold [[glass]]	of milk
a	very big bottle	of milk
a	brand	of milk
a	constituent	of milk

Table 1: An excerpt of the token sequences which match the lexical predicate  $a * of\ milk$  in Wikipedia (filling argument shown in the second column; following the Wikipedia convention we provide links in double square brackets).

ical predicate  $\pi$ . We denote  $D_\pi = \{(a, s, l) : l \neq \epsilon\} \subseteq L_\pi$  as the set of those arguments originally linked to the corresponding Wikipedia page (like the top three linked arguments in Table 1). Therefore, in the rest of this section we will focus only on the remaining triples  $(a, s, \epsilon) \in U_\pi$ , where  $U_\pi = L_\pi \setminus D_\pi$ , i.e., those triples whose arguments are not semantically annotated. Our goal is to replace  $\epsilon$  with an appropriate sense, i.e., page, for  $a$ . For each such triple  $(a, s, \epsilon) \in U_\pi$ , we apply the following disambiguation heuristics:

- **One sense per page:** if another occurrence of  $a$  in the same Wikipedia page (independent of the lexical predicate) is linked to a page  $l$ , then remove  $(a, s, \epsilon)$  from  $U_\pi$  and add  $(a, s, l)$  to  $D_\pi$ . In other words, we propagate an existing annotation of  $a$  in the same Wikipedia page and apply it to our ambiguous item. For instance, *cup of coffee* appears in the Wikipedia page *Energy drink* in the sentence “[...] energy drinks contain more caffeine than a strong *cup of coffee*”, but this occurrence of *coffee* is not linked. However the second paragraph contains the sentence “[[Coffee]], tea and other naturally caffeinated beverages are usually not considered energy drinks”, where *coffee* is linked to the *Coffee* page. This heuristic naturally reflects the broadly known assumption about lexical ambiguity presented in (Yarowsky, 1995), namely the one-sense-per-discourse heuristic.
- **One sense per lexical predicate:** if  $\exists(a, s', l) \in D_\pi$ , then remove  $(a, s, \epsilon)$  from  $U_\pi$  and add  $(a, s, l)$  to  $D_\pi$ . If multiple senses of  $a$  are available, choose the most frequent one in  $D_\pi$ . For example, in the page *Singaporean cuisine* the occurrence of *coffee* in the sentence “[...] combined with a *cup of coffee* and a half-boiled egg” is not linked, but we have collected many other occurrences, all linked to the *Coffee* page, so this link

gets propagated to our ambiguous item as well. This heuristic mimes the one-sense-per-collocation heuristic presented in (Yarowsky, 1995).

- **Trust the inventory:** if Wikipedia provides only one sense for  $a$ , i.e., only one page title whose lemma is  $a$ , link  $a$  to that page. Consider the instance “At that point, Smith threw down a *cup of Gatorade*” in page *Jimmy Clausen*; there is only one sense for *Gatorade* in Wikipedia, so we link the unannotated occurrence to it.

As a result, the initial set of disambiguated arguments in  $D_\pi$  is augmented with all those triples for which any of the above three heuristics apply. Note that  $D_\pi$  might contain the same argument several times, occurring in different sentences and linked many times to the same page or to different pages. Notably, the discovery of new links is made through one scan of Wikipedia per heuristic. The three disambiguation strategies, applied in the same order as presented above, contribute to promoting the most relevant sense for a given word.

Finally, let  $A$  be the set of arguments in  $D_\pi$ , i.e.,  $A := \{a : \exists(a, s, l) \in D_\pi\}$ . For each argument  $a \in A$  we select the majority sense  $sense(a)$  of  $a$  and collect the corresponding set of sentences  $sent(a)$  marked with that sense. Formally,  $sense(a) := \arg \max_l |\{(x, y, z) \in D_\pi : x = a \wedge z = l\}|$  and  $sent(a) := \{s : (a, s, sense(a)) \in D_\pi\}$ .

### 3.3 Generalization to Semantic Classes

Our final objective is to generalize the annotated arguments to semantic classes picked out from a fixed set  $C$  of classes. As explained below, we assume the set  $C$  to be made up of representative synsets from WordNet. We perform this in two substeps: we first link all our disambiguated arguments to WordNet (Section 3.3.1) and then leverage the WordNet taxonomy to populate the semantic classes in  $C$  (Section 3.3.2).

#### 3.3.1 Linking to WordNet

So far the arguments in  $D_\pi$  have been semantically annotated with the Wikipedia pages they refer to. However, using Wikipedia as our sense inventory is not desirable; in fact, contrarily to other commonly used lexical-semantic networks such as WordNet, Wikipedia is not formally organized in a structured, taxonomic hierarchy. While it is true that attached to each Wikipedia page there are one or more categories, these categories just provide shallow information about the class the page

belongs to. Indeed, categories are not ideal for representing the semantic classes of a Wikipedia page for at least three reasons: i) many categories do not express taxonomic information (e.g., the English page *Albert Einstein* provides categories such as DEATHS FROM ABDOMINAL AORTIC ANEURYSM and INSTITUTE FOR ADVANCED STUDY FACULTY); ii) categories are mostly structured in a directed acyclic graph with multiple parents per category (even worse, cycles are possible in principle); iii) there is no clear way of identifying core semantic classes from the large set of available categories. Although efforts towards the automatic taxonomization of Wikipedia categories do exist in the literature (Ponzetto and Strube, 2011; Nastase and Strube, 2013), the results are of a lower quality than a hand-built lexical resource. Therefore, as was done in previous work (Mihalcea and Moldovan, ; Ciaramita and Altun, 2006; Izquierdo et al., 2009; Erk and McCarthy, 2009; Huang and Riloff, 2010), we pick out our semantic classes  $C$  from WordNet and leverage its manually-curated taxonomy to associate our arguments with the most suitable class. This way we avoid building a new taxonomy and shift the problem to that of projecting the Wikipedia pages – associated with annotated filling arguments – to synsets in WordNet. We address this problem in two steps:

**Wikipedia-WordNet mapping.** We exploit an existing mapping implemented in BabelNet (Navigli and Ponzetto, 2012), a wide-coverage multilingual semantic network that integrates Wikipedia and WordNet.<sup>3</sup> Based on a disambiguation algorithm, BabelNet establishes a mapping  $\mu : \text{Wikipages} \rightarrow \text{Synsets}$  which links about 50,000 pages to their most suitable WordNet senses.<sup>4</sup>

**Mapping extension.** Nevertheless, BabelNet is able to solve the problem only partially, because it still leaves the vast majority of the 4 million English Wikipedia pages unmapped. This is mainly due to the encyclopedic nature of most pages, which do not have a counterpart in the WordNet dictionary. To address this issue, for each unmapped Wikipedia page  $p$  we obtain its textual definition as the first sentence of the page.<sup>5</sup> Next,

<sup>3</sup><http://babelnet.org>

<sup>4</sup>We follow (Navigli, 2009) and denote with  $w_p^i$  the  $i$ -th sense of  $w$  in WordNet with part of speech  $p$ .

<sup>5</sup>According to the Wikipedia guidelines, “The article should begin with a short declarative sentence, answering two questions for the nonspecialist reader: *What (or who) is the subject?* and *Why is this subject notable?*”, extracted from <http://en.wikipedia.org/wiki/>

we extract the hypernym from the textual definition of  $p$  by applying Word-Class Lattices (Navigli and Velardi, 2010, WCL<sup>6</sup>), a domain-independent hypernym extraction system successfully applied to taxonomy learning from scratch (Velardi et al., 2013) and freely available online (Faralli and Navigli, 2013). If a hypernym  $h$  is successfully extracted and  $h$  is linked to a Wikipedia page  $p'$  for which  $\mu(p')$  is defined, then we extend the mapping by setting  $\mu(p) := \mu(p')$ . For instance, the mapping provided by BabelNet does not provide any link for the page *Peter Spence*; thanks to WCL, though, we are able to set the page *Journalist* as its hypernym, and link it to the WordNet synset *journalist* <sub>$n$</sub> <sup>1</sup>.

This way our mapping extension now covers 539,954 pages, i.e., more than an order of magnitude greater than the number of pages originally covered by the BabelNet mapping.

### 3.3.2 Populating the Semantic Classes

We now proceed to populating the semantic classes in  $C$  with the annotated arguments obtained for the lexical predicate  $\pi$ .

**Definition 3 (semantic class of a synset).** The semantic class for a WordNet synset  $S$  is the class  $c$  among those in  $C$  which is the most specific hypernym of  $S$  according to the WordNet taxonomy.

For instance, given the synset *tap water* <sub>$n$</sub> <sup>1</sup>, its semantic class is *water* <sub>$n$</sub> <sup>1</sup> (while the other more general subsumers in  $C$  are not considered, e.g., *compound* <sub>$n$</sub> <sup>2</sup>, *chemical* <sub>$n$</sub> <sup>1</sup>, *liquid* <sub>$n$</sub> <sup>3</sup>, etc).

For each argument  $a \in A$  for which a Wikipedia-to-WordNet mapping  $\mu(\text{sense}(a))$  could be established as a result of the linking procedure described above, we associate  $a$  with the semantic class of  $\mu(\text{sense}(a))$ . For example, consider the case in which  $a$  is equal to *tap water* and  $\text{sense}(a)$  is equal to the Wikipedia page *Tap water*, in turn mapped to *tap water* <sub>$n$</sub> <sup>1</sup> via  $\mu$ ; we thus associate *tap water* with its semantic class *water* <sub>$n$</sub> <sup>1</sup>. If more than one class can be found we add  $a$  to each of them.<sup>7</sup>

Ultimately, for each class  $c \in C$ , we obtain a set  $\text{support}(c)$  made up of all the arguments  $a \in A$  associated with  $c$ . For instance,  $\text{support}(\text{beverage}_n^1) = \{ \text{chinese tea}, \text{3.2\% beer}, \text{hot cocoa}, \text{cider}, \dots, \text{orange juice} \}$ . Note that, thanks to our extended mapping (cf. Section 3.3.1), the support of a class can also contain arguments not covered in WordNet (e.g., *hot cocoa* and *tejuino*).

Wikipedia:Writing\_better\_articles.

<sup>6</sup><http://lcl.uniroma1.it/wcl>

<sup>7</sup>This can rarely happen due to multiple hypernyms available in WordNet for the same synset.

$P_{class}(c \pi)$	$c$	$support(c)$
0.1896	wine <sub>n</sub> <sup>1</sup>	wine, sack, white wine, red wine, wine in china, madeira wine, claret, kosher wine
0.1805	coffee <sub>n</sub> <sup>1</sup>	turkish coffee, drip coffee, espresso, coffee, cappucino, caffè latte, decaffeinated coffee, latte
0.1143	herb <sub>n</sub> <sup>2</sup>	green tea, indian tea, black tea, orange pekoe tea, tea
0.1104	water <sub>n</sub> <sup>1</sup>	water, seawater
0.0532	beverage <sub>n</sub> <sup>1</sup>	chinese tea, 3.2% beer, orange soda, boiled water, hot chocolate, hot cocoa, tejuino, cider, beverage, cocoa, coffee milk, lemonade, orange juice
0.0403	milk <sub>n</sub> <sup>1</sup>	skim milk, milk, cultured buttermilk, whole milk
0.0351	beer <sub>n</sub> <sup>1</sup>	3.2% beer, beer
0.0273	alcohol <sub>n</sub> <sup>1</sup>	mead, umeshu, kava, rice wine, jägermeister, kvass, sake, gin, rum
0.0182	poison <sub>n</sub> <sup>1</sup>	poison

Table 2: Highest-probability semantic classes for the lexical predicate  $\pi = \text{cup of } *$ , according to our set  $C$  of semantic classes.

Since not all classes are equally relevant to the lexical predicate  $\pi$ , we estimate the conditional probability of each class  $c \in C$  given  $\pi$  on the basis of the number of sentences which contain an argument in that class. Formally:

$$P_{class}(c|\pi) = \frac{\sum_{a \in support(c)} |sent(a)|}{Z}, \quad (1)$$

where  $Z$  is a normalization factor calculated as  $Z = \sum_{c' \in C} \sum_{a \in support(c')} |sent(a)|$ . As an example, in Table 2 we show the highest-probability classes for the lexical predicate *cup of*  $*$ .

As a result of the probabilistic association of each semantic class  $c$  with a target lexical predicate  $w_1 w_2 \dots w_i * w_{i+1} \dots w_n$ , we obtain a semantic predicate  $w_1 w_2 \dots w_i c w_{i+1} \dots w_n$ .

### 3.4 Classification of new arguments

Once the semantic predicates for the input lexical predicate  $\pi$  have been learned, we can classify a new filling argument  $a$  of  $\pi$ . However, the class probabilities calculated with Formula 1 might not provide reliable scores for several classes, including unseen ones whose probability would be 0.

To enable wide coverage we estimate a second conditional probability based on the distributional semantic profile of each class. To do this, we perform three steps:

1. For each WordNet synset  $S$  we create a distributional vector  $\vec{S}$  summing the noun occurrences within all the Wikipedia pages  $p$  such that  $\mu(p) = S$ . Next, we create a distributional vector for each class  $c \in C$  as follows:

$$\vec{c} = \sum_{S \in desc(c)} \vec{S},$$

where  $desc(c)$  is the set of all synsets which are descendants of the semantic class  $c$  in WordNet. As a result we obtain a predicate-independent distributional description for each semantic class in  $C$ .

2. Now, given an argument  $a$  of a lexical predicate  $\pi$ , we create a distributional vector  $\vec{a}$  by summing the noun occurrences of all the sentences  $s$  such that  $(a, s, l) \in L_\pi$  (cf. Section 3.1).
3. Let  $C_a$  be the set of candidate semantic classes for argument  $a$ , i.e.,  $C_a$  contains the semantic classes for the WordNet synsets of  $a$  as well as the semantic classes associated with  $\mu(p)$  for all Wikipedia pages  $p$  whose lemma is  $a$ . For each candidate class  $c \in C_a$ , we determine the cosine similarity between the distributional vectors  $\vec{c}$  and  $\vec{a}$  as follows:

$$sim(\vec{c}, \vec{a}) = \frac{\vec{c} \cdot \vec{a}}{\|\vec{c}\| \|\vec{a}\|}.$$

Then, we determine the most suitable semantic class  $c \in C_a$  of argument  $a$  as the class with the highest distributional probability, estimated as:

$$P_{distr}(c|\pi, a) = \frac{sim(\vec{c}, \vec{a})}{\sum_{c' \in C_a} sim(\vec{c}', \vec{a})}. \quad (2)$$

We can now choose the most suitable class  $c \in C_a$  for argument  $a$  which maximizes the probability mixture of the distributional probability in Formula 2 and the class probability in Formula 1:

$$P(c|\pi, a) = \alpha P_{distr}(c|\pi, a) + (1 - \alpha) P_{class}(c|\pi), \quad (3)$$

where  $\alpha \in [0, 1]$  is an interpolation factor.

We now illustrate the entire process of our algorithm on a real example. Given a textual expression such as *virus replicate*, we: (i) extract all the filling arguments of the lexical predicate  $* \text{replicate}$ ; (ii) link and disambiguate the extracted filling arguments; (iii) query our system for the available *virus* semantic classes (i.e.,  $\{virus_n^1, virus_n^3\}$ ); (iv) build the distributional vectors for

the candidate semantic classes and the given input argument; (v) calculate the probability mixture. As a result we obtain the following ranking,  $virus_n^1:0.250$ ,  $virus_n^3:0.000894$ , so that the first sense of *virus* in WordNet 3.0 is preferred, being an “ultramicroscopic infectious agent that replicates itself only within cells of living hosts”.

## 4 Experiment 1: Oxford Lexical Predicates

We evaluate on the two forms of output produced by SPred: (i) the top-ranking semantic classes of a lexical predicate, as obtained with Formula 1, and (ii) the classification of a lexical predicate’s argument with the most suitable semantic class, as produced using Formula 3. For both evaluations, we use a lexical predicate dataset built from the Oxford Advanced Learner’s Dictionary (Crowther, 1998).

### 4.1 Set of Semantic Classes

The selection of which semantic classes to include in the set  $C$  is of great importance. In fact, having too many classes will end up in an overly fine-grained inventory of meanings, whereas an excessively small number of classes will provide little discriminatory power. As our set  $C$  of semantic classes we selected the standard set of 3,299 core nominal synsets available in WordNet.<sup>8</sup> However, our approach is flexible and can be used with classes of an arbitrary level of granularity.

### 4.2 Datasets

The Oxford Advanced Learner’s Dictionary provides usage notes that contain typical predicates in various semantic domains in English, e.g., Traveling.<sup>9</sup> Each predicate is made up of a fixed part (e.g., a verb) and a generalizable part which contains one or more nouns.

Examples include *fix an election/the vote*, *bacteria/microbes/viruses spread*, *spend money/savings/a fortune*. In the case that more than one noun was provided, we split the textual expression into as many items as the number of nouns. For instance, from *spend money/savings/a fortune* we created three items in our dataset, i.e., *spend money*, *spend savings*, *spend a fortune*. The splitting procedure generated 6,220 instantiated lexical predicate items overall.

20	0.75	671	892

Table 3: Precision@ $k$  for ranking the semantic classes of lexical predicates.

### 4.3 Evaluating the Semantic Class Ranking

**Dataset.** Given the above dataset, we generalized each item by pairing its fixed verb part with \* (i.e., we keep “verb predicates” only, since they are more informative). For instance, the three items *bacteria/microbes/viruses spread* were generalized into the lexical predicate \* *spread*. The total number of different lexical predicates obtained was 1,446, totaling 1,429 distinct verbs (note that the dataset might contain the lexical predicate \* *spread* as well as *spread* \*).<sup>10</sup>

**Methodology.** For each lexical predicate we calculated the conditional probability of each semantic class using Formula 1, resulting in a ranking of semantic classes. To evaluate the top ranking classes, we calculated precision@ $k$ , with  $k$  ranging from 1 to 20, by counting all applicable classes as correct, e.g.,  $location_n^1$  is a valid semantic class for *travel to* \* while  $emotion_n^1$  is not.

**Results.** We show in Table 3 the precision@ $k$  calculated over a random sample of 50 lexical predicates.<sup>11</sup> As can be seen, while the classes quality is pretty high with low values of  $k$ , performance gradually degrades as we let  $k$  increase. This is mostly due to the highly polysemous nature of the predicates selected (e.g., *occupy* \*, *leave* \*, *help* \*, *attain* \*, *live* \*, etc.). We note that high performance, attaining above 80%, can be achieved

<sup>10</sup>The low number of items per predicate is due to the original Oxford resource.

<sup>11</sup>One lexical predicate did not have any semantic class ranking.

by focusing up to the first 7 classes output by our system, with a 94% precision@1.

#### 4.4 Evaluating Classification Performance

**Dataset.** Starting from the lexical predicate items obtained as described in Section 4.2, we selected those items belonging to a random sample of 20 usage notes among those provided by the Oxford dictionary, totaling 3,245 items. We then manually tagged each item’s argument (e.g., *virus* in *viruses spread*) with the most suitable semantic class (e.g., *virus<sub>n</sub><sup>1</sup>*), obtaining a gold standard dataset for the evaluation of our argument classification algorithm (cf. Section 3.4).

**Methodology.** In this second evaluation we measure the accuracy of our method at assigning the most suitable semantic class to the argument of a lexical predicate item in our gold standard. We use three customary measures to determine the quality of the acquired semantic classes, i.e., precision, recall and F1. Precision is the number of items which are assigned the correct class (as evaluated by a human) over the number of items which are assigned a class by the system. Recall is the number of items which are assigned the correct class over the number of items to be classified. F1 is the harmonic mean of precision and recall.

**Tuning.** The only parameter to be tuned is the factor  $\alpha$  that we use to mix the two probabilities in Formula 3 (cf. Section 3.4). For tuning  $\alpha$  we used a held-out set of 8 verbs, randomly sampled from the lexical predicates not used in the dataset. We created a tuning set using the annotated arguments in Wikipedia for these verbs: we trained the model on 80% of the annotated lexical predicate arguments (i.e., the class probability estimates in Formula 1) and then applied the probability mixture (i.e., Formula 3) for classifying the remaining 20% of arguments. Finally, we calculated the performance in terms of precision, recall and F1 with 11 different values of  $\alpha \in \{0, 0.1, \dots, 1.0\}$ , achieving optimal performance with  $\alpha = 0.2$ .

**Results.** Table 4 shows the results on the semantic class assignments. Our system shows very high precision, above 85%, while at the same time attaining an adequate 68% recall. We also compared against a random baseline that randomly selects one out of all the candidate semantic classes for each item, achieving only moderate results. A subsequent error analysis revealed the common types of error produced by our system: terms for which we could not provide (1) any WordNet concept

Method	Precision	Recall	F1
SPred	85.61	68.01	75.80
Random	40.96	40.96	40.96

Table 4: Performance on semantic class assignment.

(e.g., *political corruption*) or (2) any candidate semantic class (e.g., *immune system*).

#### 4.5 Disambiguation heuristics impact

As a follow-up analysis, for each dataset we considered the impact of each disambiguation heuristic described in Section 3.2 according to how many times it was triggered. Starting from the entire set of 1,446 lexical predicates from the Oxford dictionary (see Section 4.3), we counted the number of argument triples  $(a, s, l)$  already disambiguated in Wikipedia (i.e.,  $l \neq \epsilon$ ) and those disambiguated thanks to our disambiguation strategies. Table 5 shows the statistics. We note that, while the amount of originally linked arguments is very low (about 2.5% of total), our strategies are able to considerably increase the size of the initial set of linked instances. The most effective strategies appear to be the *One sense per page* and the *Trust the inventory*, which contribute 26.16% and 31.33% of the total links, respectively.

Even though most of the triples (i.e., 68 out of almost 74 million) remain unlinked, the ratio of distinct arguments which we linked to WordNet is considerably higher, calculated as 3,723,979 linked arguments over 12,431,564 distinct arguments, i.e., about 30%.

### 5 Experiment 2: Comparison with Kozareva & Hovy (2010)

Due to the novelty of the task carried out by SPred, the resulting output may be compared with only a limited number of existing approaches. The most similar approach is that of Kozareva and Hovy (2010, K&H) who assign supertypes to the arguments of arbitrary relations, a task which resembles our semantic predicate ranking. We therefore performed a comparison on the quality of the most highly-ranked supertypes (i.e., semantic classes) using their dataset of 24 relation patterns (i.e., lexical predicates).

**Dataset.** The dataset contained 14 lexical predicates (e.g., *work for \** or *\* fly to*), 10 of which were expanded in order to semantify their left- and right-side arguments (e.g., *\* work for* and *work for \**); for the remaining 4 predicates just a single

Total triples	Linked in Wikipedia	One sense per page	One sense per lexical predicate	Trust the inventory	Not linked

20	0.89	429	480

Table 6: Precision@ $k$  for the semantic classes of the relations of Kozareva and Hovy (2010).

side was generalized (e.g., *\*dress*). While most of the relations apply to persons as a supertype, our method could find arguments for each of them.

**Methodology.** We carried out the same evaluation as in Section 4.3. We calculated precision@ $k$  of the semantic classes obtained for each relation in the dataset of K&H. Because the set of applicable classes was potentially unbounded, we were not able to report recall directly.

**Results.** K&H reported an overall accuracy of the top-20 superclasses of 92%. As can be seen in Table 6 we exhibit very good performance with increasing values of  $k$ . A comparison of Table 3 with Table 6 shows considerable differences in performance between the two datasets. We attribute this difference to the higher average WordNet polysemy of the verbal component of the Oxford predicates (on average 2.64 senses for K&H against 6.52 for the Oxford dataset).

Although we cannot report recall, we list the number of Wikipedia arguments and associated classes in Table 7, which provides an estimate of the extraction capability of SPred. The large number of classes found for the arguments demonstrates the ability of our method to generalize to a variety of semantic classes.

Predicate	Number of args	Number of classes
cause *	181,401	1,339
live in *	143,628	600
go to *	134,712	867

## 6 Related work

The availability of Web-scale corpora has led to the production of large resources of relations (Etzioni et al., 2005; Yates et al., 2007; Wu and Weld, 2010; Carlson et al., 2010; Fader et al., 2011). However, these resources often operate purely at the lexical level, providing no information on the semantics of their arguments or relations. Several studies have examined adding semantics through grouping relations into sets (Yates and Etzioni, 2009), ontologizing the arguments (Chklovski and Pantel, 2004), or ontologizing the relations themselves (Moro and Navigli, 2013). However, analysis has largely been either limited to ontologizing a small number of relation types with a fixed inventory, which potentially limits coverage, or has used implicit definitions of semantic categories (e.g., clusters of arguments), which limits interpretability. For example, Mohamed et al. (2011) use the semantic categories of the NELL system (Carlson et al., 2010) to learn roughly 400 valid ontologized relations from over 200M web pages, whereas WiSeNet (Moro and Navigli, 2012) leverages Wikipedia to acquire relation synsets for an open set of relations. Despite these efforts, no large-scale resource has existed to date that contains ontologized lexical predicates. In contrast, the present work provides a high-coverage method for learning argument superclasses from a broad-coverage ontology (WordNet), which can potentially be leveraged in relation extraction to ontolo-

gize relation arguments.

Our method for identifying the different semantic classes of predicate arguments is closely related to the task of identifying selectional preferences. The most similar approaches to it are taxonomy-based ones, which leverage the semantic types of the relations arguments (Resnik, 1996; Li and Abe, 1998; Clark and Weir, 2002; Pennacchiotti and Pantel, 2006). Nevertheless, despite their high quality sense-tagged data, these methods have often suffered from lack of coverage. As a result, alternative approaches have been proposed that eschew taxonomies in favor of rating the quality of potential relation arguments (Erk, 2007; Chambers and Jurafsky, 2010) or generating probability distributions over the arguments (Rooth et al., 1999; Pantel et al., 2007; Bergsma et al., 2008; Ritter et al., 2010; Séaghdha, 2010; Bouma, 2010; Jang and Mostow, 2012) in order to obtain higher coverage of preferences.

In contrast, we overcome the data sparsity of class-based models by leveraging the large quantity of collaboratively-annotated Wikipedia text in order to connect predicate arguments with their semantic class in WordNet using BabelNet (Navigli and Ponzetto, 2012); because we map directly to WordNet synsets, we provide a more readily-interpretable collocation preference model than most similarity-based or probabilistic models.

Verb frame extraction (Green et al., 2004) and predicate-argument structure analysis (Surdeanu et al., 2003; Yakushiji et al., 2006) are two areas that are also related to our work. But their generality goes beyond our intentions, as we focus on semantic predicates, which is much simpler and free from syntactic parsing.

Another closely related work is that of Hanks (2013) concerning the Theory of Norms and Exploitations, where norms (exploitations) represent expected (unexpected) classes for a given lexical predicate. Although our semantified predicates do, indeed, provide explicit evidence of norms obtained from collective intelligence and would provide support for this theory, exploitations present a more difficult task, different from the one addressed here, due to its focus on identifying property transfer between the semantic class and the exploited instance.

The closest technical approach to ours is that of Kozareva and Hovy (2010), who use recursive patterns to induce semantic classes for the arguments of relational patterns. Whereas their approach requires both a relation pattern and one or more seeds, which bias the types of semantic classes that are learned, our proposed method re-

quires only the pattern itself, and as a result is capable of learning an unbounded number of different semantic classes.

## 7 Conclusions

In this paper we present SPred, a novel approach to large-scale harvesting of semantic predicates. In order to semantify lexical predicates we exploit the wide coverage of Wikipedia to extract and disambiguate lexical predicate occurrences, and leverage WordNet to populate the semantic classes with suitable predicate arguments. As a result, we are able to ontologize lexical predicate instances like those available in existing dictionaries (e.g., *break a toe*) into semantic predicates (such as *break* a BODY PART).

For each lexical predicate (such as *break* \*), our method produces a probability distribution over the set of semantic classes (thus covering the different expected meanings for the filling arguments) and is able to classify new instances with the most suitable class. Our experiments show generally high performance, also in comparison with previous work on argument supertyping.

We hope that our semantic predicates will enable progress in different Natural Language Processing tasks such as Word Sense Disambiguation (Navigli, 2009), Semantic Role Labeling (Fürstenau and Lapata, 2012) or even Textual Entailment (Stern and Dagan, 2012) – each of which is in urgent need of reliable semantics. While we focused on semantifying lexical predicates, as future work we will apply our method to the ontologization of large amounts of sequences of words, such as phrases or textual relations (e.g., considering Google n-grams appearing in Wikipedia). Notably, our method should, in principle, generalize to any semantically-annotated corpus (e.g., Wikipedias in other languages), provided lexical predicates can be extracted with associated semantic classes.

In order to support future efforts we are releasing our semantic predicates as a freely available resource.<sup>12</sup>

## Abstract

In automatic summarization, *centrality* is the notion that a summary should contain the core parts of the source text. Current systems use centrality, along with redundancy avoidance and some sentence compression, to produce mostly extractive summaries. In this paper, we investigate how summarization can advance past this paradigm towards robust abstraction by making greater use of the domain of the source text. We conduct a series of studies comparing human-written model summaries to system summaries at the semantic level of *caseframes*. We show that model summaries (1) are more abstractive and make use of more sentence aggregation, (2) do not contain as many topical caseframes as system summaries, and (3) cannot be reconstructed solely from the source text, but can be if texts from in-domain documents are added. These results suggest that substantial improvements are unlikely to result from better optimizing centrality-based criteria, but rather more domain knowledge is needed.

## 1 Introduction

In automatic summarization, *centrality* has been one of the guiding principles for content selection in extractive systems. We define centrality to be the idea that a summary should contain the parts of the source text that are most similar or representative of the source text. This is most transparently illustrated by the Maximal Marginal Relevance (MMR) system of Carbonell and Goldstein (1998), which defines the summarization objective

to be a linear combination of a centrality term and a non-redundancy term.

Since MMR, much progress has been made on more sophisticated methods of measuring centrality and integrating it with non-redundancy (See Nenkova and McKeown (2011) for a recent survey). For example, term weighting methods such as the signature term method of Lin and Hovy (2000) pick out salient terms that occur more often than would be expected in the source text based on frequencies in a background corpus. This method is a core component of the most successful summarization methods (Conroy et al., 2006).

While extractive methods based on centrality have thus achieved success, there has long been recognition that abstractive methods are ultimately more desirable. One line of work is in text simplification and sentence fusion, which focus on the ability of abstraction to achieve a higher compression ratio (Knight and Marcu, 2000; Barzilay and McKeown, 2005). A less examined issue is that of aggregation and information synthesis. A key part of the usefulness of summaries is that they provide some synthesis or analysis of the source text and make a more general statement that is of direct relevance to the user. For example, a series of related events can be aggregated and expressed as a trend.

The position of this paper is that centrality is not enough to make substantial progress towards abstractive summarization that is capable of this type of semantic inference. Instead, summarization systems need to make more use of domain knowledge. We provide evidence for this in a series of studies on the TAC 2010 guided summarization data set that examines how the behaviour of automatic summarizers can or cannot be distinguished from human summarizers. First, we confirm that abstraction is a desirable goal, and

provide a quantitative measure of the degree of sentence aggregation in a summarization system. Second, we show that centrality-based measures are unlikely to lead to substantial progress towards abstractive summarization, because current top-performing systems already produce summaries that are more “central” than humans do. Third, we consider how domain knowledge may be useful as a resource for an abstractive system, by showing that key parts of model summaries can be reconstructed from the source plus related in-domain documents.

Our contributions are novel in the following respects. First, our analyses are performed at the level of *caseframes*, rather at the level of words or syntactic dependencies as in previous work. Caseframes are shallow approximations of semantic roles which are well suited to characterizing a domain by its slots. Furthermore, we take a *developmental* rather than *evaluative* perspective—our goal is not to develop a new evaluation measure as defined by correlation with human responsiveness judgments. Instead, our studies reveal useful criteria with which to distinguish human-written and system summaries, helping to guide the development of future summarization systems.

## 2 Related Work

Domain-dependent template-based summarization systems have been an alternative to extractive systems which make use of rich knowledge about a domain and information extraction techniques to generate a summary, possibly using a natural language generation system (Radev and McKeown, 1998; White et al., 2001; McKeown et al., 2002). This paper can be seen as a first step towards reconciling the advantages of domain knowledge with the resource-lean extraction approaches popular today.

As noted above, Lin and Hovy’s (2000) signature terms have been successful in discovering terms that are specific to the source text. These terms are identified by a log-likelihood ratio test based on their relative frequencies in relevant and irrelevant documents. They were originally proposed in the context of single-document summarization, where they were calculated using in-domain (relevant) vs. out-of-domain (irrelevant) text. In multi-document summarization, the in-domain text has been replaced by the source text cluster (Conroy et al., 2006), thus they are now

used as a form of centrality-based features. In this paper, we use guided summarization data as an opportunity to reopen the investigation into the effect of domain, because multiple document clusters from the same domain are available.

Summarization evaluation is typically done by comparing system output to human-written model summaries, and are validated by their correlation with user responsiveness judgments. The comparison can be done at the word level, as in ROUGE (Lin, 2004), at the syntactic level, as in Basic Elements (Hovy et al., 2006), or at the level of summary content units, as in the Pyramid method (Nenkova and Passonneau, 2004). There are also automatic measures which do not require model summaries, but compare against the source text instead (Louis and Nenkova, 2009; Saggion et al., 2010).

Several studies complement this paper by examining the best possible extractive system using current evaluation measures, such as ROUGE (Lin and Hovy, 2003; Conroy et al., 2006). They find that the best possible extractive systems score higher or as highly than human summarizers, but it is unclear whether this means the oracle summaries are actually as useful as human ones in an extrinsic setting. Genest et al. (2009) ask humans to create extractive summaries, and find that they score in between current automatic systems and human-written abstracts on responsiveness, linguistic quality, and Pyramid score. In the lecture domain, He et al. (1999; 2000) find that lecture transcripts that have been manually highlighted with key points improve students’ quiz scores more than when using automated summarization techniques or when providing only the lecture transcript or slides.

Jing and McKeown (2000) manually analyzed 30 human-written summaries, and find that 19% of sentences cannot be explained by *cut-and-paste* operations from the source text. Saggion and Lapalme (2002) similarly define a list of transformations necessary to convert source text to summary text, and manually analyzed their frequencies. Copeck and Szpakowicz (2004) find that at most 55% of vocabulary items found in model summaries occur in the source text, but they do not investigate where the other vocabulary items might be found.

<b>Sentence:</b>	
<i>At one point, two bomb squad trucks sped to the school after a backpack scare.</i>	
<b>Dependencies:</b>	
<i>num(point, one)</i>	<i>prep_at(sped, point)</i>
<i>num(trucks, two)</i>	<i>nn(trucks, bomb)</i>
<i>nn(trucks, squad)</i>	<i>nsubj(sped, trucks)</i>
<i>root(ROOT, sped)</i>	<i>det(school, the)</i>
<i>prep_to(sped, school)</i>	<i>det(scare, a)</i>
<i>nn(scare, backpack)</i>	<i>prep_after(sped, scare)</i>
<b>Caseframes:</b>	
<i>(speed, prep_at)</i>	<i>(speed, nsubj)</i>
<i>(speed, prep_to)</i>	<i>(speed, prep_after)</i>

Table 1: A sentence decomposed into its dependency edges, and the caseframes derived from those edges that we consider (in black).

### 3 Theoretical basis of our analysis

Many existing summarization evaluation methods rely on word or N-gram overlap measures, but these measures are not appropriate for our analysis. Word overlap can occur due to shared proper nouns or entity mentions. Good summaries should certainly contain the salient entities in the source text, but when assessing the effect of the domain, different domain instances (i.e., different document clusters in the same domain) would be expected to contain different salient entities. Also, the realization of entities as noun phrases depends strongly on context, which would confound our analysis if we do not also correctly resolve coreference, a difficult problem in its own right. We leave such issues to other work (Nenkova and McKeown, 2003, e.g.).

Domains would rather be expected to share *slots* (a.k.a. *aspects*), which require a more semantic level of analysis that can account for the various ways in which a particular slot can be expressed. Another consideration is that the structures to be analyzed should be extracted automatically. Based on these criteria, we selected *caseframes* to be the appropriate unit of analysis. A caseframe is a shallow approximation of the semantic role structure of a proposition-bearing unit like a verb, and are derived from the dependency parse of a sentence<sup>1</sup>.

<sup>1</sup>Note that caseframes are distinct from (though directly

<b>Relation</b>	<b>Caseframe Pair</b>	<b>Sim.</b>
Degree	<i>(kill, dobj)</i> <i>(wound, dobj)</i>	0.82
Causal	<i>(kill, dobj)</i> <i>(die, nsubj)</i>	0.80
Type	<i>(rise, dobj)</i> <i>(drop, prep_to)</i>	0.81

Figure 1: Sample pairs of similar caseframes by relation type, and the similarity score assigned to them by our distributional model.

In particular, they are *(gov, role)* pairs, where *gov* is a proposition-bearing element, and *role* is an approximation of a semantic role with *gov* as its head (See Figure 1 for examples). Caseframes do not consider the dependents of the semantic role approximations.

The use of caseframes is well grounded in a variety of NLP tasks relevant to summarization such as coreference resolution (Bean and Riloff, 2004), and information extraction (Chambers and Jurafsky, 2011), where they serve the central unit of semantic analysis. Related semantic representations are popular in Case Grammar and its derivative formalisms such as frame semantics (Fillmore, 1982).

We use the following algorithm to extract caseframes from dependency parses. First, we extract those dependency edges with a relation type of subject, direct object, indirect object, or prepositional object (with the preposition indicated), along with their governors. The governor must be a verb, event noun (as defined by the hyponyms of the WordNet EVENT synset), or nominal or adjectival predicate. Then, a series of deterministic transformations are applied to the syntactic relations to account for voicing alternations, control, raising, and copular constructions.

#### 3.1 Caseframe Similarity

Direct caseframe matches account for some variation in the expression of slots, such as voicing alternations, but there are other reasons different caseframes may indicate the same slot (Figure 1). For example, *(kill, dobj)* and *(wound, dobj)* both indicate the victim of an attack, but differ by the degree of injury to the victim. *(kill, dobj)* and *(die, nsubj)* also refer to a victim, but are linked by a causal relation. *(rise, dobj)* and

inspired by) the similarly named *case frames* of Case Grammar (Fillmore, 1968).

(*drop, prep\_to*) on the other hand simply share a named entity type (in this case, numbers). To account for these issues, we measure caseframe similarity based on their distributional similarity in a large training corpus.

First, we construct vector representations of each caseframe, where the dimensions of the vector correspond to the lemma of the head word that fills the caseframe in the training corpus. For example, *kicked the ball* would result in a count of 1 added to the caseframe (*kick, dobj*) for the context word *ball*. Then, we rescale the counts into pointwise mutual information values, which has been shown to be more effective than raw counts at detecting semantic relatedness (Turney, 2001). Similarity between caseframes can then be compared by cosine similarity between their vector representations.

For training, we use the AFP portion of the Gigaword corpus (Graff et al., 2005), which we parsed using the Stanford parser’s typed dependency tree representation with collapsed conjunctions (de Marneffe et al., 2006). For reasons of sparsity, we only considered caseframes that appear at least five times in the guided summarization corpus, and only the 3000 most common lemmata in Gigaword as context words.

### 3.2 An Example

To illustrate how caseframes indicate the slots in a summary, we provide the following fragment of a model summary from TAC about the *Unabomber trial*:

- (1) *In Sacramento, Theodore Kaczynski faces a 10-count federal indictment for 4 of the 16 mail bomb attacks attributed to the Unabomber in which two people were killed. If found guilty, he faces a death penalty. ... He has pleaded innocent to all charges. U.S. District Judge Garland Burrell Jr. presides in Sacramento.*

All of the slots provided by TAC for the *Investigations and Trials* domain can be identified by one or more caseframes. The DEFENDANT can be identified by (*face, nsubj*), and (*plead, nsubj*); the CHARGES by (*face, dobj*); the REASON by (*indictment, prep\_for*); the SENTENCE by (*face, dobj*); the PLEAD by (*plead, dobj*); and the INVESTIGATOR by (*preside, nsubj*).

## 4 Experiments

We conducted our experiments on the data and results of the TAC 2010 summarization workshop. This data set contains 920 newspaper articles in 46 topics of 20 documents each. Ten are used in an initial guided summarization task, and ten are used in an update summarization task, in which a summary must be produced assuming that the original ten documents had already been read. All summaries have a word length limit of 100 words. We analyzed the results of the two summarization tasks separately in our experiments.

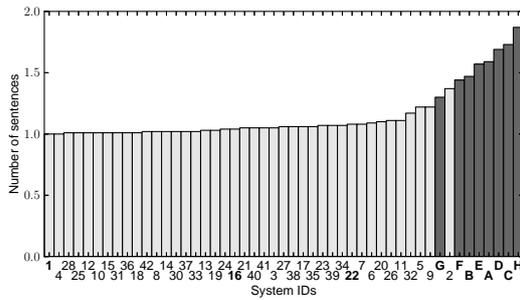

The 46 topics belong to five different categories or domains: *Accidents and natural disasters*, *Criminal or terrorist attacks*, *Health and safety*, *Endangered resources*, and *Investigations and trials*. Each domain is associated with a template specifying the type of information that is expected in the domain, such as the participants in the event or the time that the event occurred.

In our study, we compared the characteristics of summaries generated by the eight human summarizers with those generated by the peer summaries, which are basically extractive systems. There are 43 peer summarization systems, including two baselines defined by NIST. We refer to systems by their ID given by NIST, which are alphabetical for the human summarizers (A to H), and numeric for the peer summarizers (1 to 43). We removed two peer systems (systems 29 and 43) which did not generate any summary text in the workshop, presumably due to software problems. For each measure that we consider, we compare the average among the human-written summaries to the three individual peer systems, which we chose in order to provide a representative sample of the average and best performance of the automatic systems according to current evaluation methods. These systems are all primarily extractive, like most of the systems in the workshop:

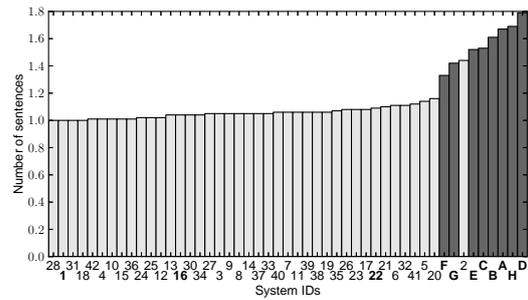

**Peer average** The average of the measure among the 41 peer summarizers.

**Peer 16** This system scored the highest in responsiveness scores on the original summarization task and in ROUGE-2, responsiveness, and Pyramid score in the update task.

**Peer 22** This system scored the highest in ROUGE-2 and Pyramid score in the original summarization task.

(a) Initial guided summarization task

(b) Update summarization task

Figure 2: Average sentence cover size: the average number of sentences needed to generate the caseframes in a summary sentence (Study 1). Model summaries are shown in darker bars. Peer system numbers that we focus on are in bold.

Condition	Initial	Update
Model average	1.58	1.57
Peer average	1.06	1.06
Peer 1	1.00	1.00
Peer 16	1.04	1.04
Peer 22	1.08	1.09

Table 2: The average number of source text sentences needed to cover a summary sentence. The model average is statistically significantly different from all the other conditions  $p < 10^{-7}$  (Study 1).

**Peer 1** The NIST-defined baseline, which is the leading sentence baseline from the most recent document in the source text cluster. This system scored the highest on linguistic quality in both tasks.

#### 4.1 Study 1: Sentence aggregation

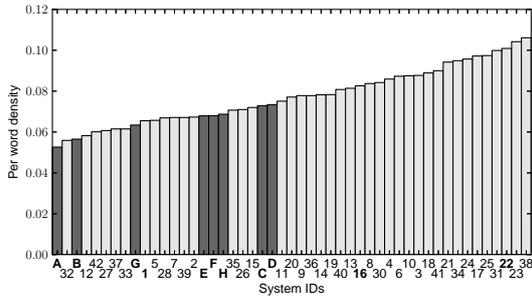

We first confirm that human summarizers are more prone to sentence aggregation than system summarizers, showing that abstraction is indeed a desirable goal. To do so, we propose a measure to quantify the degree of sentence aggregation exhibited by a summarizer, which we call **average sentence cover size**. This is defined to be the minimum number of sentences from the source text needed to cover all of the caseframes found in a summary sentence (for those caseframes that can be found in the source text at all), averaged over all of the summary sentences. Purely extractive systems would thus be expected to score 1.0, as would systems that perform text compression by remov-

ing constituents of a source text sentence. Human summarizers would be expected to score higher, if they actually aggregate information from multiple points in the source text.

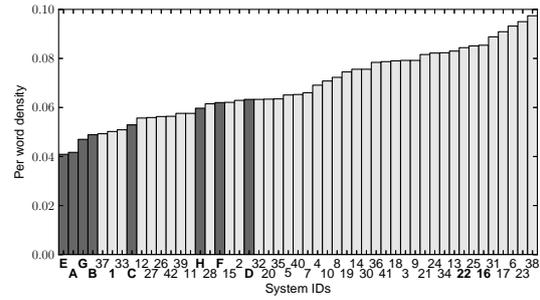

To illustrate, suppose we assign arbitrary indices to caseframes, a summary sentence contains caseframes  $\{1, 2, 3, 4, 5\}$ , and the source text contains three sentences with caseframes, which can be represented as a nested set  $\{\{1, 3, 4\}, \{2, 5, 6\}, \{1, 4, 7\}\}$ . Then, the summary sentence can be covered by two sentences from the source text, namely  $\{\{1, 3, 4\}, \{2, 5, 6\}\}$ .

This problem is actually an instance of the minimum set cover problem, in which sentences are sets, and caseframes are set elements. Minimum set cover is NP-hard in general, but the standard integer programming formulation of set cover sufficed for our data set; we used ILOG CPLEX 12.4’s mixed integer programming mode to solve all the set cover problems optimally.

**Results** Figure 2 shows the ranking of the summarizers by this measure. Most peer systems have a low average sentence cover size of close to 1, which reflects the fact that they are purely or almost purely extractive. Human model summarizers show a higher degree of aggregation in their summaries. The averages of the tested conditions are shown in Table 2, and are statistically significant. Peer 2 shows a relatively high level of aggregation despite being an extractive system. Upon inspection of its summaries, it appears that Peer 2 tends to select many datelines, and without punctuation to separate them from the rest of the summary, our automatic analysis tools incorrectly merged many sentences together, resulting in incorrect parses and novel caseframes not found in

(a) Initial guided summarization task

the source text.

#### 4.2 Study 2: Signature caseframe density

Study 1 shows that human summarizers are more abstractive in that they aggregate information from multiple sentences in the source text, but how is this aggregation performed? One possibility is that human summary writers are able to pack a greater number of salient caseframes into their summaries. That is, humans are fundamentally relying on centrality just as automatic summarizers do, and are simply able to achieve higher compression ratios by being more succinct. If this is true, then sentence fusion methods over the source text alone might be able to solve the problem. Unfortunately, we show that this is false and that system summaries are actually more central than model ones.

To extract topical caseframes, we use Lin and Hovy’s (2000) method of calculating signature terms, but extend the method to apply it at the caseframe rather than the word level. We follow Lin and Hovy (2000) in using a significance

Condition	Initial	Update
Model average	0.065	0.052
Peer average	0.080*	0.072*
Peer 1	0.066	0.050
Peer 16	0.083*	0.085*
Peer 22	0.101*	0.084*

Table 3: Signature caseframe densities for different sets of summarizers, for the initial and update guided summarization tasks (Study 2). \*:  $p < 0.005$ .

threshold of 0.001 to determine signature caseframes<sup>2</sup>. Figure 4 shows examples of signature caseframes for several topics. Then, we calculate the **signature caseframe density** of each of the summarization systems. This is defined to be the number of signature caseframes in the set of summaries divided by the number of words in that set of summaries.

**Results** Figure 3 shows the density for all of the summarizers, in ascending order of density. As can be seen, the human abstractors actually tend to use fewer signature caseframes in their summaries than automatic systems. Only the leading baseline is indistinguishable from the model average. Table 3 shows the densities for the conditions that we described earlier. The differences in density between the human average and the non-baseline conditions are highly statistically significant, according to paired two-tailed Wilcoxon signed-rank tests for the statistic calculated for each topic cluster.

These results show that human abstractors do

<sup>2</sup>We tried various other thresholds, but the results were much the same.

Threshold	0.9		0.8	
Condition	Init.	Up.	Init.	Up.
Model average	0.066	0.052	0.062	0.047
Peer average	0.080	0.071	0.071	0.063
Peer 1	0.068	0.050	0.060	0.044
Peer 16	0.083	0.086	0.072	0.077
Peer 22	0.100	0.086	0.084	0.075

Table 4: Density of signature caseframes after merging to various threshold for the initial (**Init.**) and update (**Up.**) summarization tasks (Study 2).

not merely repeat the caseframes that are indicative of a topic cluster or use minor grammatical alternations in their summaries. Rather, a genuine sort of abstraction or distillation has taken place, either through paraphrasing or semantic inference, to transform the source text into the final informative summary.

**Merging Caseframes** We next investigate whether simple paraphrasing could account for the above results; it may be the case that human summarizers simply replace words in the source text with synonyms, which can be detected with distributional similarity. Thus, we merged similar caseframes into clusters according to the distributional semantic similarity defined in Section 3.1, and then repeated the previous experiment. We chose two relatively high levels of similarity (0.8 and 0.9), and used complete-link agglomerative (i.e., bottom-up) clustering to merge similar caseframes. That is, each caseframe begins as a separate cluster, and the two most similar clusters are merged at each step until the desired similarity threshold is reached. Cluster similarity is defined to be the minimum similarity (or equivalently, maximum distance) between elements in the two clusters; that is,  $\max_{c \in C_1, c' \in C_2} \text{sim}(c, c')$ . Complete-link agglomerative clustering tends to form coherent clusters where the similarity between any pair within a cluster is high (Manning et al., 2008).

**Cluster Results** Table 4 shows the results after the clustering step, with similarity thresholds of 0.9 and 0.8. Once again, model summaries contain a lower density of signature caseframes. The statistical significance results are unchanged. This indicates that simple paraphrasing alone cannot account for the difference in the signature caseframe

densities, and that some deeper abstraction or semantic inference has occurred.

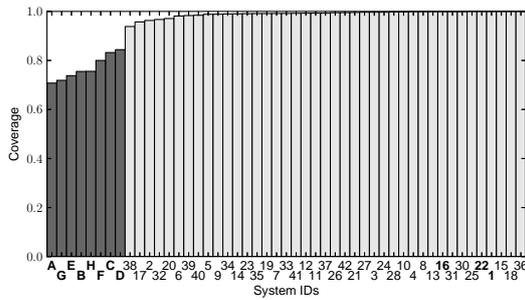

Note that we are not claiming that a lower density of signature caseframes necessarily correlates with a more informative summary. For example, some automatic summarizers are comparable to the human abstractors in their relatively low density of signature caseframes, but these turn out to be the lowest performing summarization systems by all measures in the workshop, and they are unlikely to rival human abstractors in any reasonable evaluation of summary informativeness. It does, however, appear that further optimizing centrality-based measures alone is unlikely to produce better informative summaries, even if we analyze the summary at a syntactic/semantic rather than lexical level.

### 4.3 Study 3: Summary Reconstruction

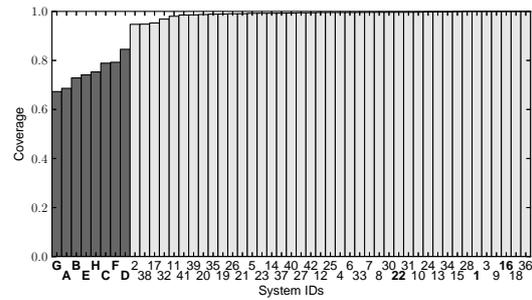

The above studies show that the higher degree of abstraction in model summaries cannot be explained by better compression of topically salient caseframes alone. We now switch perspectives to ask how model summaries might be automatically generated at all. We will show that they cannot be reconstructed solely from the source text, extending Copeck and Szpakowicz (2004)’s result to caseframes. However, we also show that if articles from the same domain are added, reconstruction then becomes possible. Our measure of whether a model summary can be reconstructed is **caseframe coverage**. We define this to be the proportion of caseframes in a summary that is contained by some reference set. This is thus a score between 0 and 1. Unlike in the previous study, we use the full set of caseframes, not just signature caseframes, because our goal now to create a hypothesis space from which it is in principle possible to generate the model summaries.

**Results** We first calculated caseframe coverage with respect to the source text alone (Figure 5). As expected, automatic systems show close to perfect coverage, because of their basically extractive nature, while model summaries show much lower coverage. These statistics are summarized by Table 5. These results present a fundamental limit to extractive systems, and also text simplification and sentence fusion methods based solely on the source text.

**The Impact of Domain Knowledge** How might automatic summarizers be able to acquire these

(a) Initial guided summarization task

caseframes from other sources? Traditional systems that perform semantic inference do so from a set of known facts about the domain in the form of a knowledge base, but as we have seen, most extractive summarization systems do not make much use of in-domain corpora. We examine adding in-domain text to the source text to see how this would affect coverage.

Recall that the 46 topics in TAC 2010 are categorized into five domains. To calculate the impact of domain knowledge, we add all the documents that belong in the same domain to the source text to calculate coverage. To ensure that coverage does not increase simply due to increasing the size of the reference set, we compare to the baseline of adding the same number of documents that belong to another domain. As shown in Table 6, the effect of adding more in-domain text on caseframe coverage is substantial, and noticeably more than using out-of-domain text. In fact, nearly all caseframes can be found in the expanded set of articles. The implication of this result is that it may be possible to generate better summaries by mining in-domain text for relevant caseframes.

Reference corpus	Initial	Update
Source text only	0.77	0.75
+out-of-domain	0.91	0.91
+in-domain	0.98	0.97

Table 6: The effect on caseframe coverage of adding in-domain and out-of-domain documents. The difference between adding in-domain and out-of-domain text is significant  $p < 10^{-3}$  (Study 3).

## 5 Conclusion

We have presented a series of studies to distinguish human-written informative summaries from the summaries produced by current systems. Our studies are performed at the level of caseframes, which are able to characterize a domain in terms of its slots. First, we confirm that model summaries are more abstractive and aggregate information from multiple source text sentences. Then, we show that this is not simply due to summary writers packing together source text sentences containing topical caseframes to achieve a higher compression ratio, even if paraphrasing is taken into account. Indeed, model summaries cannot be reconstructed from the source text alone. However, our results are also positive in that we find that nearly all model summary caseframes can be found in the source text together with some in-domain documents.

Current summarization systems have been heavily optimized towards centrality and lexical-semantic reasoning, but we are nearing the bottom of the barrel. Domain inference, on the other hand, and a greater use of in-domain documents as a knowledge source for domain inference, are very promising indeed. Mining useful caseframes

for a sentence fusion-based approach has the potential, as our experiments have shown, to deliver results in just the areas where current approaches are weakest.

## Abstract

This paper presents HEADY: a novel, *abstractive* approach for headline generation from news collections. From a web-scale corpus of English news, we mine syntactic patterns that a Noisy-OR model generalizes into event descriptions. At inference time, we query the model with the patterns observed in an unseen news collection, identify the event that better captures the gist of the collection and retrieve the most appropriate pattern to generate a headline. HEADY improves over a state-of-the-art open-domain title abstraction method, bridging half of the gap that separates it from extractive methods using human-generated titles in manual evaluations, and performs comparably to human-generated headlines as evaluated with ROUGE.

## 1 Introduction

**Motivation.** News events are rarely reported only in one way, from a single point of view. Different news agencies will interpret the event in different ways; various countries or locations may highlight different aspects of it depending on how they are affected; and opinions and in-depth analyses will be written after the fact.

The variety of contents and styles is both an opportunity and a challenge. On the positive side, we have the same events described in different ways; this redundancy is useful for summarization, as the information content reported by the majority of news sources most likely represents the central part of the event. On the other hand, variability and subjectivity can be difficult to isolate. For some applications it is important to understand, given a collection of related news articles and re-

ports, how to formulate in an objective way what has happened.

As a motivating example, Table 1 shows the different headlines observed in news reporting the wedding between basketball player Carmelo Anthony and actress LaLa Vazquez. As can be seen, there is a wide variety of ways to report the same event, including different points of view, highlighted aspects, and opinionated statements on the part of the reporter. When presenting this event to a user in a news-based information retrieval or recommendation system, different event descriptions may be more appropriate. For example, a user may only be interested in objective, informative summaries without any interpretation on the part of the reporter. In this case, *Carmelo Anthony, ac-*

\*Work done during an internship at Google Zurich.

*tress LaLa Vazquez wed in NYC* would be a good choice.

**Goal.** Our final goal in this research is to build a headline generation system that, given a news collection, is able to describe it with the most compact, objective and informative headline. In particular, we want the system to be able to:

- Generate headlines in an open-domain, unsupervised way, so that it does not need to rely on training data which is expensive to produce.
- Generalize across synonymous expressions that refer to the same event.
- Do so in an abstractive fashion, to enforce novelty, objectivity and generality.

In order to advance towards this goal, this paper explores the following questions:

- What is a good way of using syntactic patterns to represent events for generating headlines?
- Can we have satisfactory readability with an open-domain abstractive approach, not relying on training data nor on manually predefined generation templates?
- How far can we get in terms of informativeness, compared to the human-produced headlines, i.e., extractive approaches?

**Contributions.** In this paper we present HEADY, which is at the same time a novel system for abstractive headline generation, and a smooth clustering of patterns describing the same events. HEADY is fully open-domain and can scale to web-sized data. By learning to generalize events across the boundaries of a single news story or news collection, HEADY produces compact and effective headlines that objectively convey the relevant information.

When compared to a state-of-the-art open-domain headline abstraction system (Filippova, 2010), the new headlines are statistically significantly better both in terms of readability and informativeness. Also, automatic evaluations using ROUGE, having objective headlines for the news as references, show that the abstractive headlines are on par with human-produced headlines.

## 2 Related work

### Headline generation and summarization.

Most headline generation work in the past has focused on the problem of single-document summarization: given the main passage of a single news article, generate a very short summary of the article. From early in the field, it was pointed out that a purely extractive approach is not good enough to generate headlines from the body text (Banko et al., 2000). Sometimes the most important information is distributed across several sentences in the document. More importantly, quite often, the single sentence selected as the most informative for the news collection is already longer than the desired headline size. For this reason, most early headline generation work focused on either extracting and reordering  $n$ -grams from the document to be summarized (Banko et al., 2000), or extracting one or two informative sentences from the document and performing linguistically-motivated transformations to them in order to reduce the summary length (Dorr et al., 2003). The first approach is not guaranteed to produce grammatical headlines, whereas the second approach is tightly tied to the actual wording found in the document. Single-document headline generation was also explored at the Document Understanding Conferences between 2002 and 2004<sup>1</sup>.

In later years, there has been more interest in problems such as sentence compression (Galley and McKeown, 2007; Clarke and Lapata, 2008; Cohn and Lapata, 2009; Napoles et al., 2011; Berg-Kirkpatrick et al., 2011), text simplification (Zhu et al., 2010; Coster and Kauchak, 2011; Woodsend and Lapata, 2011) and sentence fusion (Barzilay and McKeown, 2005; Wan et al., 2007; Filippova and Strube, 2008; Elsner and Santhanam, 2011). All of them have direct applications for headline generation, as it can be construed as selecting one or a few sentences from the original document(s), and then reducing them to the target title size. For example, Wan et al. (2007) generate novel utterances by combining Prim’s maximum-spanning-tree algorithm with an  $n$ -gram language model to enforce fluency. Unlike HEADY, the method by Wan and colleagues is an extractive method that can summarize single documents into a sentence, as opposed to generating a sentence that can stand for a whole collec-

<sup>1</sup><http://duc.nist.gov/>

tion of news. Filippova (2010) reports a system that is very close to our settings: the input is a collection of related news articles, and the system generates a headline that describes the main event. This system uses sentence compression techniques and benefits from the redundancy in the collection. One difference with respect to HEADY is that it does not use any syntactic information aside from part-of-speech tags, and it does not require a training step. We have used this approach as a baseline for comparison.

There are not many fully abstractive systems for news summarization. The few that exist, such as the work by Genest and Lapalme (2012), rely on manually written generation templates. In contrast, HEADY automatically learns the templates or headline patterns automatically, which allows it to work in open-domain settings without relying on supervision or manual annotations.

**Open-domain pattern learning.** Pattern learning for relation extraction is an active area of research that is very related to our problem of event pattern learning for headline generation. TextRunner (Yates et al., 2007), ReVerb (Fader et al., 2011) and NELL (Carlson et al., 2010; Mohamed et al., 2011) are some examples of open-domain systems that learn surface patterns that express relations between pairs of entities. PATTY (Nakashole et al., 2012) generalizes the patterns to also include syntactic information and ontological (class membership) constraints. Our patterns are more similar to the ones used by PATTY, which also produces clusters of synonymous patterns. The main differences are that (a) HEADY is not limited to consider patterns expressing relations between pairs of entities; (b) we identify synonym patterns using a probabilistic, Bayesian approach that takes advantage of the multiplicity of news sources reporting the same events. Chambers and Jurafsky (2009) present an unsupervised method for learning narrative schemas from news, i.e., coherent sets of events that involve specific entity types (semantic roles). Similarly to them, we move from the assumptions that 1) utterances involving the same entity types within the same document (in our case, a collection of related documents) are likely describing aspects of the same event, and 2) meaningful representations of the underlying events can be learned by clustering these utterances in a principled way.

**Noisy-OR networks.** Noisy-OR Bayesian networks (Pearl, 1988) have been applied in the past to a wide class of large-scale probabilistic inference problems, from the medical domain (Middleton et al., 1991; Jaakkola and Jordan, 1999; Onisko et al., 2001), to synthetic image-decomposition and co-citation data analysis (Šingliar and Hauskrecht, 2006). By assuming independence between the causes of the hidden variables, noisy-OR models tend to be reliable (Friedman and Goldszmidt, 1996) as they require a relatively small number of parameters to be estimated (linear with the size of the network).

### 3 Headline generation

In this section, we describe the HEADY system for news headline abstraction. Our approach takes as input, for training, a corpus of news articles organized in news collections. Once the model is trained, it can generate headlines for new collections. An outline of HEADY’s main components follows (details of each component are provided in Sections 3.1, 3.2 and 3.3):

**Pattern extraction.** Identify, in each of the news collections, syntactic patterns connecting  $k$  entities, for  $k \geq 1$ . These will be the candidate patterns expressing events.

**Training.** Train a Noisy-OR Bayesian network on the co-occurrence of syntactic patterns. Each pattern extracted in the previous step is added as an observed variable, and latent variables are used to represent the hidden events that generate patterns. An additional *noise* variable links to every terminal node, allowing every terminal to be generated by language background (noise) instead of by an actual event.

**Inference.** Generate a headline from an unseen news collection. First, patterns are extracted using the pattern extraction procedure mentioned above. Given the patterns, the posterior probability of the hidden *event* variables is estimated. Then, from the activated hidden events, the likelihood of every pattern can be estimated, even if they do not appear in the collection. The single pattern with the maximum probability is selected to generate a new headline from it. Being the product of extra-news collection generalization, the retrieved pattern is more likely to be objective and informative than patterns directly observed in the news collection.

**Algorithm 1** COLLECTIONTOPATTERNS $_{\Psi}(\mathcal{N})$ :  
 $\mathcal{N}$  is a repository of news collections,  $\Psi$  is a set of parameters controlling the extraction process.

### 3.1 Pattern extraction

In this section we detail the process for obtaining the event patterns that constitute the building blocks of learning and inference.

Patterns are extracted from a large repository  $\mathcal{N}$  of news collections  $N_1, \dots, N_{|\mathcal{N}|}$ . Each news collection  $N = \{n_i\}$  is an unordered collection of related news, each of which can be seen as an ordered sequence of sentences, i.e.:  $n = [s_0, \dots, s_{|n|}]$ .

Algorithm 1 presents a high-level view of the pattern extraction process. The different steps are described below:

**PREPROCESSDATA:** We start by preprocessing all the news in the news collections with a standard NLP pipeline: tokenization and sentence boundary detection (Gillick, 2009), part-of-speech tagging, dependency parsing (Nivre, 2006), coreference resolution (Haghighi and Klein, 2009) and entity linking based on Wikipedia and Freebase. Using the Freebase dataset, each entity is annotated with all its Freebase types (class labels). In the end, for each entity mentioned in the document we have a unique identifier, a list with all its mentions in the document and a list of class labels from Freebase.

As a result of this process, we obtain for each sentence in the corpus a representation as exemplified in Figure 1 (1). In this example, the mentions of three distinct entities have been identified, i.e.,  $e_1, \dots, e_3$ . In the Freebase list of types (class labels),  $e_1$  is a *person* and a *celebrity*, and  $e_3$  is a *state* and a *location*.

**GETRELEVANTENTITIES:** For each news collection  $N$  we collect the set  $E$  of the entities mentioned most often within the collection. Next, we generate the set COMBINATIONS $_{\Psi}(E)$  consisting

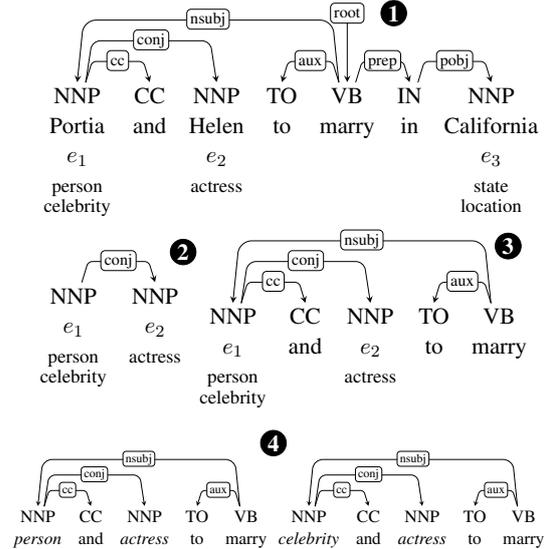

Figure 1: Pattern extraction process from an annotated dependency parse. (1): an MST is extracted from the entity pair  $e_1, e_2$  (2); nodes are heuristically added to the MST to enforce grammaticality (3); entity types are recombined to generate the final patterns (4).

of non-empty subsets of  $E$ , without repeated entities. The number of entities to consider in each collection, and the maximum size for the subsets of entities to consider are meta-parameters embedded in  $\Psi$ .<sup>2</sup>

**EXTRACTPATTERNS:** For each subset of relevant entities  $E_i$ , event patterns are mined from the articles in the news collection. The process by which patterns are extracted from a news is explained in Algorithm 2 and exemplified graphically in Figure 1 (2–4).

**GETMENTIONNODES:** Using the dependency parse  $T$  for a sentence  $s$ , we first identify the set of nodes  $M_i$  that mention the entities in  $E_i$ . If  $T$  does not contain exactly one mention of each target entity in  $E_i$ , then the sentence is ignored. Otherwise, we obtain the minimum spanning tree for the nodeset  $P_i$ , i.e., the shortest path in the dependency tree connecting all the nodes in  $M_i$  (Figure 1, 2).  $P_i$  is the set of nodes around which the patterns will be constructed.

**APPLYHEURISTICS:** With very high probability, the MST  $P_i$  that we obtain does not constitute a grammatical or useful extrapolation of the original sentence  $s$ . For example, the MST for the en-

<sup>2</sup>As our objective is to generate very short titles (under 10 words), we only consider combinations of up to three elements of  $E$ .

---

**Algorithm 2**  $\text{EXTRACTPATTERNS}_\Psi(\mathbf{n}, E_i)$ :  $\mathbf{n}$  is the list of sentences in a news article. Sentences are POS-tagged, dependency parsed and annotated with respect to a set of entities  $E \supseteq E_i$

return  $\mathcal{P}$ 

```

---

tity pair  $\langle e_1, e_2 \rangle$  in the example does not provide a good description of the event as it is neither adequate nor fluent. For this reason, we apply a set of post-processing heuristic transformations that aim at including a minimal set of meaningful nodes. These include making sure that both the root of the clause and its subject appear in the extracted pattern, and that conjunctions between entities should not be dropped (Figure 1, 3).

**COMBINEENTITYTYPES**: Finally, a distinct pattern is generated from each possible combination of entity type assignments for the participating entities. (Figure 1, 4).

It is important to note that both at training and test time, for pattern extraction we only consider the title and the first sentence of the article body. The reason is that we want to limit ourselves, in each news collection, to the most relevant event reported in the collection, which appears most of the times in these two sentences. Unlike titles, first sentences do not extensively use puns or rhetorics as they tend to be grammatical and informative rather than catchy.

The patterns mined from the same news collection and for the same set of entities are grouped together, and constitute the building blocks of the clustering algorithm which is described below.

### 3.2 Training

The extracted patterns are used to learn a Noisy-OR (Pearl, 1988) model by estimating the probability that each (observed) pattern activates one or many (hidden) *events*. Figure 2 represents the two levels: the hidden event variables at the top, and the observed pattern variables at the bottom. An additional *noise* variable links to every termi-

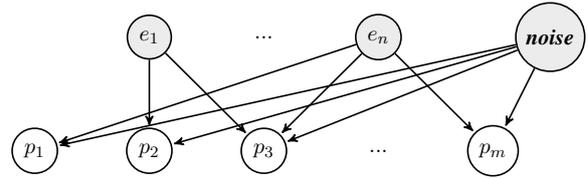

Figure 2: Probabilistic model. The associations between latent event variables and observed pattern variables are modeled by noisy-OR gates. Events are assumed to be marginally independent, and patterns conditionally independent given the events.

nal node, allowing all terminals to be generated by language background (noise) instead of by an actual event. The associations between latent events and observed patterns are modeled by noisy-OR gates.

In this model, the conditional probability of a hidden event  $e_i$  given a configuration of observed patterns  $\mathbf{p} \in \{0, 1\}^{|\mathcal{P}|}$  is calculated as:

$$\begin{aligned}
 P(e_i = 0 \mid \mathbf{p}) &= (1 - q_{i0}) \prod_{j \in \pi_j} (1 - q_{ij})^{p_j} \\
 &= \exp \left( -\theta_{i0} - \sum_{j \in \pi_i} \theta_{ij} p_j \right),
 \end{aligned}$$

where  $\pi_i$  is the set of active events (i.e.,  $\pi_i = \cup_j \{p_j\} \mid p_j = 1$ ), and  $q_{ij} = P(e_i = 1 \mid p_j = 1)$  is the estimated probability that the observed pattern  $p_i$  can, in isolation, activate the event  $e$ . The term  $q_{i0}$  is the so-called “noise” term of the model, and it accounts for the fact that an observed event  $e_i$  might be activated by some pattern that has never been observed (Jaakkola and Jordan, 1999).

In Algorithm 1, at the end of the process we group in  $\mathcal{R}[N, E_i]$  all the patterns extracted from the same news collection  $N$  and entity sub-set  $E_i$ . These groups represent rough clusters of patterns, that we can use to bootstrap the optimization of the model parameters  $\theta_{ij} = -\log(1 - q_{ij})$ . We initiate the training process by randomly selecting 100,000 of these groups, and optimize the weights of the model through 40 EM (Dempster et al., 1977) iterations.

### 3.3 Inference (generation of new headlines)

Given an unseen news collection  $N$ , the inference component of HEADY generates a single headline that captures the main event reported by the news in  $N$ . In order to do so, we first need to select a

single event-pattern  $p^*$  that is especially relevant for  $N$ . Having selected  $p^*$ , in order to generate a headline it is sufficient to replace the entity placeholders in  $p^*$  with the surface forms observed in  $N$ .

To identify  $p^*$ , we start from the assumption that the most descriptive event encoded by  $N$  must describe an important situation in which some subset of the relevant entities  $E$  in  $N$  are involved.

The basic inference algorithm is a two-step random walk in the Bayesian network. Given a set of entities  $E$  and sentences  $\mathbf{n}$ ,  $\text{EXTRACTPATTERNS}_\Psi(\mathbf{n}, E)$  collects patterns involving those entities. By normalizing the frequency of the extracted patterns, we get a probability distribution over the observed variables in the network. A two-step random walk traversing to the latent event nodes and back to the pattern nodes allows us to generalize across events. We call this algorithm  $\text{INFERENCE}(\mathbf{n}, E)$ .

In order to decide which is the most relevant set of events that should appear in the headline, we use the following procedure:

1. Given the set of entities  $E$  mentioned in the news collection, we consider each entity subset  $E_i \subseteq E$  including up to three entities<sup>3</sup>. For each  $E_i$ , we run  $\text{INFERENCE}(\mathbf{n}, E_i)$ , which computes a distribution  $\mathbf{w}_i$  over patterns involving the entities in  $E_i$ .
2. We invoke again  $\text{INFERENCE}$ , now using at the same time all the patterns extracted for every subset of  $E_i \subseteq E$ . This computes a probability distribution  $\mathbf{w}$  over all patterns involving any admissible subset of the entities mentioned in the collection.
3. Third, we select the entity-specific distribution that approximates better the overall distribution

$$\mathbf{w}^* = \arg \max_i \cos(\mathbf{w}, \mathbf{w}_i)$$

We assume that the corresponding set of entities  $E_i$  are the most central entities in the collection and therefore any headline should make sure to mention them all.

<sup>3</sup>As we noted before, we impose this limitation to keep the generated headlines relatively short and to limit data sparsity issues.

4. Finally, we select the pattern with the highest weight in  $\mathbf{w}^*$  as the pattern that better captures the main event reported in the news collection:

$$p^* = p_j \mid w_j = \arg \max_j w_j^*$$

The headline is then produced from  $p^*$ , replacing placeholders with the entities in the document from which the pattern was extracted.

While in many cases information about entity types would be sufficient to decide about the order of the entities in the generated sentences (e.g., “[person] married in [location]” for the entity set  $\{e_a = \text{“Mr. Brown”}, e_b = \text{“Los Angeles”}\}$ ), in other cases class assignment can be ambiguous (e.g., “[person] killed [person]” for  $\{e_a = \text{“Mr. A”}, e_b = \text{“Mr. B”}\}$ ). To handle these cases, when extracting patterns for an entity set  $\{e_a, e_b\}$ , we keep track of the alphabetical ordering of the entities, e.g., from a news collection about “Mr. B” killing “Mr. A” we would produce patterns such as “[person:2] killed [person:1]” or “[person:1] was killed by [person:2]” since  $e_a = \text{“Mr. A”} < e_b = \text{“Mr. B”}$ . At inference time, when we query the model with such patterns we can only activate events whose assignments are compatible with the entities observed in the text, making the replacement straightforward and unambiguous.

## 4 Experiment settings

In our method we use patterns that are fully lexicalized (with the exception of entity placeholders) and enriched with syntactic data. Under these circumstances, the Noisy-OR can effectively generalize and learn meaningful clusters only if provided with large amounts of data. To our best knowledge, available data sets for headline generation are not large enough to support this kind of inference.

For this reason, we rely on a corpus of news crawled from the web between 2008 and 2012 which have been clustered based on closeness in time and cosine similarity, using the vector-space model and tf.idf weights. News collections with less than 5 documents are discarded<sup>4</sup>, and those

<sup>4</sup>There is a very long tail of singleton articles, which do not offer useful examples of lexical or syntactic variation, and many very small collections that tend to be especially noisy, hence the decision to consider only collections with at least 5 documents.

larger than 50 documents are capped, by randomly picking 50 documents from the collection<sup>5</sup>. The total number of news collections after clustering is 1.7 million. From this set, we have set aside a few hundred collections that will remain unseen until the final evaluation.

As we have no development set, we have done no tuning of the parameters for pattern extraction nor for the Bayesian network training (100,000 latent variables to represent the different events, 40 EM iterations, as mentioned in Section 3.2). The EM iterations on the noisy-OR were distributed across 30 machines with 16 GB of memory each.

#### 4.1 Systems used

One of the questions we wanted to answer in this research was whether it was possible to obtain the same quality with automatically abstracted headlines as with human-generated headlines. For every news collection we have as many human-generated headlines as documents. To decide which human-generated headline should be used in this comparison, we used three different methods that pick one of the collection headlines:

- **Latest headline:** selects the headline from the latest document in the collection. Intuitively this should be the most relevant one for news about sport matches and competitions, where the earlier headlines offer previews and predictions, and the later headlines report who won and the final scores.
- **Most frequent headline:** some headlines are repeated across the collection, and this method chooses the most frequent one. If there are several with the same frequency, one is taken at random<sup>6</sup>.
- **TopicSum:** we use TopicSum (Haghighi and Vanderwende, 2009), a 3-layer hierarchical topic model, to infer the language model that is most central for the collection. The news title that has the smallest Kullback-Leibler

<sup>5</sup>Even though we did not run any experiment to find an optimal value for this parameter, 50 documents seems like a reasonable choice to avoid redundancy while allowing for considerable lexical and syntactic variation.

<sup>6</sup>The most frequent headline only has a tie in 6 collections in the whole test set. In 5 cases two headlines are tied at frequencies around 4, and in one case three headlines are tied at frequency 2. All six are large collections with 50 news articles, so this baseline is significantly different from a random baseline.

	R-1	R-2	R-SU4
HEADY	0.3565	0.1903	0.1966
Most frequent pattern	0.3560	0.1864	0.1959
TopicSum	0.3594	0.1821	0.1935
MSC	0.3470	0.1765	0.1855
Most frequent headline	0.3177	0.1401	0.1668
Latest headline	0.2814	0.1191	0.1425

Table 2: Results from the automatic evaluation, sorted according to the ROUGE-2 and ROUGE-SU4 scores.

divergence with respect the collection language model is the one chosen.

A headline generation system that addresses the same application as ours is (Filippova, 2010), which generates a graph from the collection sentences and selects the shortest path between the begin and the end node traversing words in the same order in which they were found in the original documents. We have used this system, called Multi-Sentence Compression (**MSC**), for comparisons.

Finally, in order to understand whether the noisy-OR Bayesian network is useful for generalizing across patterns into *latent events*, we added a baseline that extracts all patterns from the test collection following the same COLLECTIONTOPATTERNS algorithm (including the application of the linguistically motivated heuristics), and then produces a headline straightaway from the most frequent pattern extracted. In other words, the only difference with respect to HEADY is that in this case no generalization through the Noisy-OR network is carried out, and that headlines are generated from patterns directly observed in the test news collections. We call this system **Most frequent pattern**.

#### 4.2 Annotation activities

In order to evaluate HEADY’s performance, we carried out two annotation activities.

First, from the set of collections that we had set aside at the beginning, we randomly chose 50 collections for which all the systems could generate an output, and we asked raters to manually write titles for them. As this is not a simple task to be crowdsourced, for this evaluation we relied on eight trained raters. We collected between four and five reference titles for each of the fifty news collections, to be used to compare the headline

	Readability	Informativeness
TopicSum	<b>4.86</b>	<b>4.63</b>
Most freq. headline	†‡4.61	†‡◊4.43
Latest headline	†‡4.55	†4.00
HEADY	†4.28	†3.75
Most freq. pattern	†3.95	†3.82
MSC	3.00	3.05

Table 3: Results from the manual evaluation. At 95% confidence, TopicSum is significantly better than all others for readability, and only indistinguishable from the most frequent pattern for informativeness. For the rest, ◊ means being significantly better than HEADY, ‡ than the most frequent pattern, and † than MSC.

generation methods using automatic summarization metrics.

Then, we took the output of the systems for the 50 test collections and asked human raters to evaluate the headlines:

1. Raters were shown one headline and asked to rate it in terms of **readability** on a 5-point Likert scale. In the instructions, the raters were provided with examples of ungrammatical and grammatical titles to guide them in this annotation.
2. After the previous rating is done, raters were shown a selection of five documents from the collection, and they were asked to judge the **informativeness** of the previous headline for the news in the collection, again on a 5-point Likert scale.

This second annotation was carried out by independent raters in a crowd-sourcing setting. The raters did not have any involvement with the inception of the model or the writing of the paper. They did not know that the headlines they were rating were generated according to different methods. We measured inter-judge agreement on the Likert-scale annotations using their Intra-Class Correlation (ICC) (Cicchetti, 1994). The ICC for readability is 0.76 (0.95 confidence interval [0.71, 0.80]), and for informativeness it is 0.67 (0.95 confidence interval [0.60, 0.73]). This means strong agreement for readability, and moderate agreement for informativeness.

## 5 Results

The COLLECTIONTOPATTERNS algorithm was run on the training set, producing a 230 million

event patterns. Patterns that were obtained from the same collection and involving the same entities were grouped together, for a total of 1.7 million pattern collections. The pattern groups are used to bootstrap the Noisy-OR model training. Training the HEADY model that we used for the evaluation took around six hours on 30 cores.

Table 2 shows the results of the comparison of the headline generation systems using ROUGE (R-1, R-2 and R-SU4) (Lin, 2004) with the collected references. According to Owczarzak et al. (2012), ROUGE is still a competitive metric that correlates well with human judgements for ranking summarizers. The significance tests for ROUGE are performed using bootstrap resampling and a graphical significance test (Minka, 2002). The human annotators that created the references for this evaluation were explicitly instructed to write objective titles, which is the kind of headlines that the abstractive systems aim at generating. It is common to see real headlines that are catchy, joking, or with a double meaning, and therefore they use a different vocabulary than objective titles that simply mention what happened. TopicSum sometimes selects objective titles amongst the human-made titles and that is why it also scores very well with the ROUGE scores. But the other two criteria for choosing human-made headlines select non-objective titles much more often, and this lowers their performance when measured with ROUGE with respect to the objective references.

Table 3 lists the results of the manual evaluation of readability and informativeness of the generated headlines. The first result that we can see is the difference in the rankings between the two evaluations. Part of this difference might be due to the fact that ROUGE is not as good for discriminating between human-made and automatic summaries. In fact, in the DUC competitions, the gap between human summaries and automatic summaries was also more apparent in the manual evaluations than using ROUGE. Another part of the observed difference may be due to the design of the evaluation. The manual evaluation is asking raters to judge whether real, human-written titles that were actually used for those news are grammatical and informative. As could be expected, as these are published titles, the real titles score very good on the manual evaluation.

Some other interesting results are:

Model	Generated title
TopicSum	Modern Family's Eric Stonestreet laughs off Charlize Theron rumours
MSC	Modern Family star Eric Stonestreet is dating Charlize Theron.
Latest headline	Eric laughs off Theron dating rumours
Frequent pattern	Eric Stonestreet jokes about Charlize relationship
Frequent headline	Charlize Theron dating Modern Family star
HEADY	Eric Stonestreet not dating Charlize Theron
TopicSum	McFadzean rescues point for Crawley Town
MSC	Crawley side challenging for a point against Oldham Athletic.
Latest headline	Reds midfielder victim of racist tweet
Frequent pattern	Kyle McFadzean fired a equaliser Crawley were made
Frequent headline	Latics halt Crawley charge
HEADY	Kyle McFadzean rescues point for Crawley Town F.C.
TopicSum	UCI to strip Lance Armstrong of his 7 Tour titles
MSC	The international cycling union said today.
Latest headline	Letters: elderly drivers and Lance Armstrong
Frequent pattern	Lance Armstrong stripped of Tour de France titles
Frequent headline	Today in the news: third debate is tonight
HEADY	Lance Armstrong was stripped of Tour de France titles

Table 4: A comparison of the titles generated by the different models for three news collections.

- Amongst the automatic systems, HEADY performed better than MSC, with statistical significance at 95% for all the metrics. Headlines based on the most frequent patterns were better than MSC for all metrics but ROUGE-2.
- The most frequent pattern baseline and HEADY have comparable performance across all the metrics (not statistically significantly different), although HEADY has slightly better scores for all metrics except for informativeness.

While we do not take any step to explicitly model stylistic variation, estimating the weights of the Noisy-OR network turns out to be a very effective way of filtering out sensational wording to the advantage of plainer, more objective style. This may not clearly emerge from the evaluation, as we did not explicitly ask the raters to annotate the items based on their objectivity, but a manual inspection of the clusters suggests that the generalization is working in the right direction.

Table 4 presents a selection of outputs produced by the six models for three different news collections. The first example shows a news collection containing news about a rumour that was immediately denied. In the second example, HEADY generalization improves over the most frequent pattern. In the third case, HEADY generates a

good title from a noisy collection (containing different but related events). The examples also show that TopicSum is very effective in selecting a good human-generated headline for each collection. This opens the possibility of using TopicSum to automatically generate ROUGE references for future evaluations of abstractive methods.

## 6 Conclusions

We have presented HEADY, an abstractive headline generation system based on the generalization of syntactic patterns by means of a Noisy-OR Bayesian network. We evaluated the model both automatically and through human annotations. HEADY performs significantly better than a state-of-the-art open domain abstractive model (Filippova, 2010) in all evaluations, and is in par with human-generated headlines in terms of ROUGE scores. We have shown that it is possible to achieve high quality generation of news headlines in an open-domain, unsupervised setting by successfully exploiting syntactic and ontological information. The system relies on a standard NLP pipeline, requires no manual data annotation and can effectively scale to web-sized corpora.

For feature work, we plan to improve all components of HEADY in order to fill in the gap with the human-generated titles in terms of readability and informativeness. One of the directions in which we plan to move is the removal of the syntactic heuristics that currently enforce pattern well-formedness and to automatically learn the necessary transformations from the data.

Two other lines of work that we plan to explore are the possibility of personalizing the headlines to user interests (as stored in user profiles or expressed as user queries), and to investigate further applications of the Bayesian network of event patterns, such as its use for relation extraction and knowledge base population.

## Acknowledgments

The research leading to these results has received funding from: the EU's 7<sup>th</sup> Framework Programme (FP7/2007-2013) under grant agreement number 257790; the Spanish Ministry of Science and Innovation's project Holopedia (TIN2010-21128-C02); and the Regional Government of Madrid's MA2VICMR (S2009/TIC1542). # Conditional Random Fields for Responsive Surface Realisation using Global Features

Nina Dethlefs, Helen Hastie, Heriberto Cuayahuitl and Oliver Lemon

## Abstract

Surface realisers in spoken dialogue systems need to be more responsive than conventional surface realisers. They need to be sensitive to the utterance context as well as robust to partial or changing generator inputs. We formulate surface realisation as a sequence labelling task and combine the use of conditional random fields (CRFs) with semantic trees. Due to their extended notion of context, CRFs are able to take the global utterance context into account and are less constrained by local features than other realisers. This leads to more natural and less repetitive surface realisation. It also allows generation from partial and modified inputs and is therefore applicable to incremental surface realisation. Results from a human rating study confirm that users are sensitive to this extended notion of context and assign ratings that are significantly higher (up to 14%) than those for taking only local context into account.

## 1 Introduction

Surface realisation typically aims to produce output that is grammatically well-formed, natural and cohesive. Cohesion can be characterised by lexical or syntactic cues such as repetitions, substitutions, ellipses, or connectives. In automatic language generation, such properties can sometimes be difficult to model, because they require rich context-awareness that keeps track of all (or much) of what was generated before, i.e. a growing generation history. In text generation, cohesion can span over the entire text. In interactive settings such as generation within a spoken dialogue system (SDS), a

challenge is often to keep track of cohesion over several utterances. In addition, since interactions are dynamic, generator inputs from the dialogue manager can sometimes be partial or subject to subsequent modification. This has been addressed by work on incremental processing (Schlangen and Skantze, 2009). Since dialogue acts are passed on to the generation module as soon as possible, this can sometimes lead to incomplete generator inputs (because the user is still speaking), or inputs that are subject to later modification (because of an initial ASR mis-recognition).

In this paper, we propose to formulate surface realisation as a sequence labelling task. We use conditional random fields (Lafferty et al., 2001; Sutton and McCallum, 2006), which are suitable for modelling rich contexts, in combination with semantic trees for rich linguistic information. This combination is able to keep track of dependencies between syntactic, semantic and lexical features across multiple utterances. Our model can be trained from minimally labelled data, which reduces development time and may (in the future) facilitate an application to new domains.

The domain used in this paper is a pedestrian walking around a city looking for information and recommendations for local restaurants from an SDS. We describe here the module for surface realisation. Our main hypothesis is that the use of global context in a CRF with semantic trees can lead to surface realisations that are better phrased, more natural and less repetitive than taking only local features into account. Results from a human rating study confirm this hypothesis. In addition, we compare our system with alternative surface realisation methods from the literature, namely, a rank and boost approach and  $n$ -grams.

Finally, we argue that our approach lends itself

to surface realisation within incremental systems, because CRFs are able to model context across full as well as partial generator inputs which may undergo modifications during generation. As a demonstration, we apply our model to incremental surface realisation in a proof-of-concept study.

## 2 Related Work

Our approach is most closely related to Lu et al. (2009) who also use CRFs to find the best surface realisation from a semantic tree. They conclude from an automatic evaluation that using CRF-based generation which takes long-range dependencies into account outperforms several baselines. However, Lu et al.'s generator does not take context beyond the current utterance into account and is thus restricted to local features. Furthermore, their model is not able to modify generation results on the fly due to new or updated inputs.

In terms of surface realisation from graphical models (and within the context of SDSs), our approach is also related to work by Georgila et al. (2002) and Dethlefs and Cuayáhuitl (2011b), who use HMMs, Dethlefs and Cuayáhuitl (2011a) who use Bayes Nets, and Mairesse et al. (2010) who use Dynamic Bayes Nets within an Active Learning framework. The last approach is also concerned with generating restaurant recommendations within an SDS. Specifically, their system optimises its performance online, during the interaction, by asking users to provide it with new textual descriptions of concepts, for which it is unsure of the best realisation. In contrast to these related approaches, we use undirected graphical models which are useful when the natural directionality between the input variables is unknown.

In terms of surface realisation for SDSs, Oh and Rudnicky (2000) present foundational work in using an  $n$ -gram-based system. They train a surface realiser based on a domain-dependent language model and use an overgeneration and ranking approach. Candidate utterances are ranked according to a penalty function which penalises too long or short utterances, repetitious utterances and utterances which either contain more or less information than required by the dialogue act. While their approach is fast to execute, it has the disadvantage of not being able to model long-range dependencies. They show that humans rank their output equivalently to template-based generation.

Further, our approach is related to the SPaRKY

sentence generator (Walker et al., 2007). SPaRKY was also developed for the domain of restaurant recommendations and was shown to be equivalent to or better than a carefully designed template-based generator which had received high human ratings in the past (Stent et al., 2002). It generates sentences in two steps. First, it produces a randomised set of alternative realisations, which are then ranked according to a mapping from sentence plans to predicted human ratings using a boosting algorithm. As in our approach, SPaRKY distinguishes local and global features. Local features take only information of the current tree node into account, including its parents, siblings and children, while global features take information of the entire utterance into account. While SPaRKY is shown to reach high output quality in comparison to a template-based baseline, the authors acknowledge that generation with SPaRKY is rather slow when applied in a real-time SDS. This could present a problem in incremental settings, where generation speed is of particular importance.

The SPaRKY system is also used by Rieser et al. (2011), who focus on information presentation strategies for restaurant recommendations, summaries or comparisons within an SDS. Their surface realiser is informed by the highest ranked SPaRKY outputs for a particular information presentation strategy and will constitute one of our baselines in the evaluation.

More work on trainable realisation for SDSs generally includes Bulyko and Ostendorf (2002) who use finite state transducers, Nakatsu and White (2006) who use supervised learning, Varges (2006) who uses chart generation, and Konstas and Lapata (2012) who use weighted hypergraphs, among others.

## 3 Cohesion across Utterances

### 3.1 Tree-based Semantic Representations

The restaurant recommendations we generate can include any of the attributes shown in Table 1. It is then the task of the surface realiser to find the best realisation, including whether to present them in one or several sentences. This often is a sentence planning decision, but in our approach it is handled using CRF-based surface realisation. The semantic forms underlying surface realisation can be produced in many ways. In our case, they are produced by a reinforcement learning agent which orders semantic attributes in the tree ac-

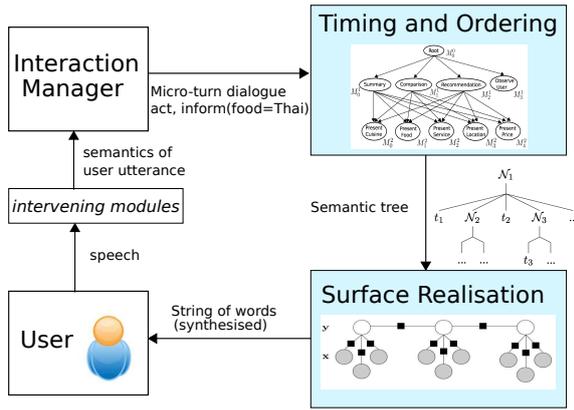

Figure 1: Architecture of our SDS with a focus on the NLG components. While the user is speaking, the dialogue manager sends dialogue acts to the NLG module, which uses reinforcement learning to order semantic attributes and produce a semantic tree (see Dethlefs et al. (2012b)). This paper focuses on surface realisation from these trees using a CRF as shown in the surface realisation module.

SIGNATURE	The venue specialises in ...
VENUE	This venue is a ...

Table 1: Semantic slots required for our domain along with example realisations. Attributes can be combined in all possible ways during generation.

according to their confidence in the dialogue. This is because SDSs can often have uncertainties with regard to the user's actual desired attribute values due to speech recognition inaccuracies. We therefore model all semantic slots as probability distributions, such as  $inform(food=Indian, 0.6)$  or  $inform(food=Italian, 0.4)$  and apply reinforcement learning to finding the optimal sequence for presentation. Please see Dethlefs et al. (2012b) for details. Here, we simply assume that a semantic form has been produced by a previous processing module.

As shown in the architecture diagram in Figure 1, a CRF surface realiser takes a semantic tree as input. We represent these as context-free trees which can be defined formally as 4-tuples

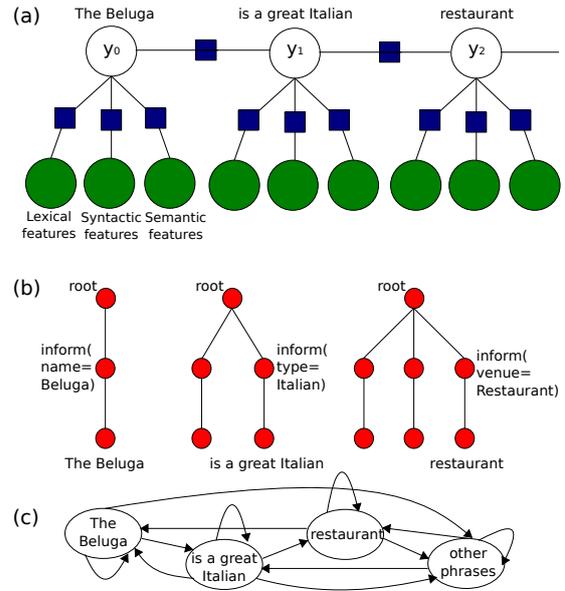

Figure 2: (a) Graphical representation of a linear-chain Conditional Random Field (CRF), where empty nodes correspond to the labelled sequence, shaded nodes to linguistic observations, and dark squares to feature functions between states and observations; (b) Example semantic trees that are updated at each time step in order to provide linguistic features to the CRF (only one possible surface realisation is shown and parse categories are omitted for brevity); (c) Finite state machine of phrases (labels) for this example.

$\{S, T, N, H\}$ , where  $S$  is a start symbol, typically the root node of the tree;  $T = \{t_0, t_1, t_2 \dots t_{|T|}\}$  is a set of terminal symbols, corresponding to single phrases;  $N = \{n_0, n_1, n_2 \dots n_{|N|}\}$  is a set of non-terminal symbols corresponding to semantic categories, and  $H = \{h_0, h_1, h_2 \dots h_{|H|}\}$  is a set of production rules of the form  $n \rightarrow \alpha$ , where  $n \in N$ ,  $\alpha \in T \cup N$ . The production rules represent alternatives at each branching node where the CRF is consulted for the best available expansion from the subset of possible ones. All nodes in the tree are annotated with a semantic concept (obtained from the semantic form) as well as their parse category.

### 3.2 Conditional Random Fields for Phrase-Based Surface Realisation

The main idea of our approach is to treat surface realisation as a sequence labelling task in which a sequence of semantic inputs needs to be labelled with appropriate surface realisations. The task is therefore to find a mapping between (observed)

lexical, syntactic and semantic features and a (hidden) best surface realisation.

We use the linear-chain Conditional Random Field (CRF) model for statistical phrase-based surface realisation, see Figure 2 (a). This probabilistic model defines the posterior probability of labels (surface realisation phrases)  $\mathbf{y}=\{y_1, \dots, y_{|\mathbf{y}|}\}$  given features  $\mathbf{x}=\{x_1, \dots, x_{|\mathbf{x}|}\}$  (informed by a semantic tree, see Figure 2 (b)), as

$$P(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \prod_{t=1}^T \exp \left\{ \sum_{k=1}^K \theta_k \Phi_k(y_t, y_{t-1}, \mathbf{x}_t) \right\},$$

where  $Z(\mathbf{x})$  is a normalisation factor over all possible realisations (i.e. labellings) of  $\mathbf{x}$  such that the sum of all terms is one. The parameters  $\theta_k$  are weights corresponding to feature functions  $\Phi_k(\cdot)$ , which are real values describing the label state  $y$  at time  $t$  based on the previous label state  $y_{t-1}$  and features  $\mathbf{x}_t$ . For example: from Figure 2 (c),  $\Phi_k$  might have the value  $\Phi_k = 1.0$  for the transition from “*The Beluga*” to “*is a great Italian*”, and 0.0 elsewhere. The parameters  $\theta_k$  are set to maximise the conditional likelihood of phrase sequences in the training data set. They are estimated using the gradient ascent algorithm.

After training, labels can be predicted for new sequences of observations. The most likely phrase sequence is expressed as

$$\mathbf{y}^* = \arg \max_{\mathbf{y}} P(\mathbf{y}|\mathbf{x}),$$

which is computed using the Viterbi algorithm. We use the Mallet package<sup>1</sup> (McCallum, 2002) for parameter learning and inference.

### 3.3 Feature Selection and Training

The following features define the generation context used during training of the CRF. The generation context includes everything that has been generated for the current utterance so far. All features can be obtained from a semantic input tree.

- Lexical items of parents and siblings,
- Semantic types in expansion,
- Semantic types of parents and siblings,
- Parse category of expansion,
- Parse categories of parents and siblings.

We use the StanfordParser<sup>2</sup> (Marneffe et al., 2006) to obtain the parse category for each tree node.

<sup>1</sup><http://mallet.cs.umass.edu/>

<sup>2</sup><http://nlp.stanford.edu/software/lex-parser.shtml>

The semantics for each node are derived from the input dialogue acts (these are listed in Table 1) and are associated with nodes. The lexical items are present in the generation context and are mapped to semantic tree nodes.

As an example, for generating an utterance (label sequence) such as *The Beluga is a great restaurant. It is located in the city centre.*, each generation step needs to take the features of the entire generation history into account. This includes all individual lexical items generated, the semantic types used and the parse categories for each tree node involved. For the first constituent, *The Beluga*, this corresponds to the features  $\{\hat{\text{BEGIN NAME}}\}$  indicating the beginning of a sentence (where empty features are omitted), the beginning of a new generation context and the next semantic slot required. For the second constituent, *is a great restaurant*, the features are  $\{\text{THE BELUGA NAME NP VENUE}\}$ , i.e. including the generation history (with lexical items and parse category added for the first constituent) and the semantics of the next required slot, VENUE. In this way, a sequence of surface form constituents is generated corresponding to latent states in the CRF.

Since global utterance features capture the full generation context (i.e. beyond the current utterance), we are also able to model phenomena such as co-references and pronouns. This is useful for longer restaurant recommendations which may span over more than one utterance. If the generation history already contains a semantic attribute, e.g. the restaurant name, the CRF may afterwards choose a pronoun, e.g. *it*, which has a higher likelihood than using the proper name again. Similarly, the CRF may decide to realise a new attribute as constituents of different order, such as a sentence or PP, depending on the length, number and parse categories of previously generated output. In this way, our approach implicitly treats sentence planning decisions such as the distribution of content over a set of messages in the same way as (or as part of) surface realisation. A further capability of our surface realiser is that it can generate complete phrases from full as well as partial dialogue acts. This is useful in interactive contexts, where we need as much robustness as possible. A demonstration of this is given in Section 5 in an application to incremental surface realisation.

To train the CRF, we used a data set of 552 restaurant recommendations from the website The

List.<sup>3</sup> The data contains recommendations such as *Located in the city centre, Beluga is a stylish yet laid-back restaurant with a smart menu of modern European cuisine.*

### 3.4 Grammar Induction

The grammar  $g$  of surface realisation candidates is obtained through an automatic grammar induction algorithm which can be run on unlabelled data and requires only minimal human intervention. This grammar defines the surface realisation space for the CRFs. We provide the human corpus of restaurant recommendations from Section 3.3 as input to grammar induction. The algorithm is shown in Algorithm 1. It first identifies all semantic attributes of interest in an utterance, in our case those specified in Table 1, and replaces them by a variable. These attributes include food types, such as *Mexican*, *Chinese*, particular parts of town, prices, etc. About 45% of them can be identified based on heuristics. The remainder needs to be hand-annotated at the moment, which includes mainly attributes like restaurant names or quality attributes, such as *delicate*, *exquisite*, etc. Subsequently, all utterances are parsed using the Stanford parser to obtain constituents and are integrated into the grammar under construction. The non-terminal symbols are named after the automatically annotated semantic attributes contained in their expansion, e.g.  $\text{NAME\_QUALITY} \rightarrow \textit{The } \$name\$ \textit{ is of } \$quality\$ \textit{ quality}$ . In this way, each non-terminal symbol has a semantic representation and an associated parse category. In total, our induced grammar contains more than 800 rules.

## 4 Evaluation

To evaluate our approach, we focus on a subjective human rating study which aims to determine whether CRF-based surface realisation that takes the full generation context into account, called **CRF (global)**, is perceived better by human judges than one that uses a CRF but just takes local context into account, called **CRF (local)**. While CRF (global) uses features from the entire generation history, CRF (local) uses only features from the current tree branch. We assume that cohesion can be identified by untrained judges as natural, well-phrased and non-repetitive surface forms. To examine differences in methodology between

CRFs and other state-of-the-art methods, we also compare our system to two other baselines:

- **CLASSiC** corresponds to the system reported in Rieser et al. (2011),<sup>4</sup> which generates restaurant recommendations based on the SPaRKY system (Walker et al., 2007), and has received high ratings in the past. SPaRKY uses global utterance features.
- **$n$ -grams** represents a simple 5-gram baseline that is similar to Oh and Rudnicky (2000)’s system. We will sample from the most likely slot realisations that do not contain a repetition and include exactly the required slot values. Local context only is taken into account.

### 4.1 Human Rating Study

We carried out a user rating study on the CrowdFlower crowd sourcing platform.<sup>5</sup> Each participant was shown part of a real human-system dialogue that emerged as part of the CLASSiC project evaluation (Rieser et al., 2011). All dialogues and data are freely available from <http://www.classic-project.org>. Each dialogue contained two variations for one of the utterances. These variations were generated from two out of the four systems described above. The order that these were presented to the participant was counterbalanced. Table 2 gives an example of a dialogue segment presented to the participants.

<sup>4</sup>In Rieser et al. (2011), this system is referred to as the TIP system, which generates summaries, comparisons or recommendations for restaurants. For the present study, we com-

**SYS** Thank you for calling the Cambridge Information system. Your call will be recorded for research purposes. You may ask for information about a place to eat, such as a restaurant, a pub, or a cafe. How may I help you?

**USR** I want to find an American restaurant which is in the very expensive area.

**SYS A** *The restaurant Gourmet Burger is an outstanding, expensive restaurant located in the central area.*

**SYS B** *Gourmet Burger is a smart and welcoming restaurant. Gourmet Burger provides an expensive dining experience with great food and friendly service. If you're looking for a central meal at an expensive price.*

**USR** What is the address and phone number?

**SYS** Gourmet Burger is on Regent Street and its phone number is 01223 312598.

**USR** Thank you. Good bye.

Table 2: Example dialogue for participants to compare alternative outputs in italics, USR=user, SYS A=CRF (global), SYS B=CRF(local).

System	Natural	Phrasing	Repetit.
CRF global	<b>3.65</b>	<b>3.64</b>	<b>3.65</b>
CRF local	3.10*	3.19*	3.13*
CLASSiC	3.53*	3.59	3.48*
<i>n</i> -grams	3.01*	3.09*	3.32*

Table 3: Subjective user ratings. Significance with CRF (global) at  $p < 0.05$  is indicated as \*.

44 participants gave a total of 1,830 ratings of utterances produced across the four systems. Fluent speakers of English only were requested and the participants were from the United States. They were asked to rate each utterance on a 5 point Likert scale in response to the following questions (where 5 corresponds to *totally agree* and 1 corresponds to *totally disagree*):

- The utterance was natural, i.e. it could have been produced by a human. (*Natural*)
- The utterance was phrased well. (*Phrasing*)
- The utterance was repetitive. (*Repetitive*)

## 4.2 Results

We can see from Table 3 that across all the categories, the CRF (global) gets the highest overall ratings. This difference is significant for all categories compared with CRF (local) and *n*-grams (using a 1-sided Mann Whitney U-test,  $p < 0.001$ ).

pare only with the subset of recommendations.

<sup>5</sup><http://www.crowdfunder.com>

Possibly this is because the local context taken into account by both systems was not enough to ensure cohesion across surface phrases. It is not possible, e.g., to cover co-references within a local context only or discourse markers that refer beyond the current utterance. This can lead to short and repetitive phrases, such as *Make your way to Gourmet Burger. The food quality is outstanding. The prices are expensive.* generated by the *n*-gram baseline.

The CLASSiC baseline, based on SPaRKY, was the most competitive system in our comparison. None-the-less CRF (global) is rated higher across categories and significantly so for *Natural* ( $p < 0.05$ ) and *Repetitive* ( $p < 0.005$ ). For *Phrasing*, there is a trend but not a significant difference ( $p < 0.16$ ). All comparisons are based on a 1-sided Mann Whitney U-test. A qualitative comparison between the CRF (global) and CLASSiC outputs showed the following. CLASSiC utterances tend to be longer and contain more sentences than CRF (global) utterances. While CRF (global) often decides to aggregate attributes into one sentence, such as *the Beluga is an outstanding restaurant in the city centre*, CLASSiC tends to rely more on individual messages, such as *The Beluga is an outstanding restaurant. It is located in the city centre.* A possible reason is that while CRF (global) is able to take features beyond an utterance into account, CLASSiC/SPaRKY is restricted to global features of the current utterance.

We can further compare our results with Rieser et al. (2011) and Mairesse et al. (2010) who also generate restaurant recommendations and asked similar questions to participants as we did. Rieser et al. (2011)'s system received an average rating of 3.58<sup>6</sup> in terms of *Phrasing* which compares to our 3.64. This difference is not significant, and in line with the user ratings we observed for the CLASSiC system above (3.59). Mairesse et al. (2010) achieved an average score of 4.05 in terms of *Natural* in comparison to our 3.65. This difference is significant at  $p < 0.05$ . Possibly their better performance is due to the data set being more "in domain" than ours. They collected data from humans that was written specifically for the task that the system was tested on. In contrast, our system was trained on freely available data that was written by professional restaurant reviewers. Unfortunately, we cannot compare across other categories,

<sup>6</sup>This was rescaled from a 1-6 scale.

USR1 I'm looking for a nice restaurant in the centre.  
 SYS1 *inform(area=centre [0.2], food=Thai [0.3])*  
*inform(name=Bangkok [0.3])*  
 So you're looking for a Thai ...  
 USR2 [*bares in*] No, I'm looking for a restaurant  
 with good quality food.  
 SYS2 *inform(quality=good [0.6], name=Beluga [0.6])*  
 Oh sorry, so a nice restaurant located ...  
 USR3 [*bares in*] ... in the city centre.  
 SYS3 *inform(area=centre [0.8])*

Table 4: Example dialogue where the dialogue manager needs to send incremental updates to the NLG. Incremental surface realisation from semantic trees for this dialogue is shown in Figure 3.

because the authors tested only for *Phrasing* and *Natural*, respectively.

## 5 Incremental Surface Realisation

Recent years have seen increased interest in incremental dialogue processing (Skantze and Schlangen, 2009; Schlangen and Skantze, 2009). The main characteristic of incremental architectures is that instead of waiting for the end of a user turn, they begin to process the input stream as soon as possible, updating their processing hypotheses as more information becomes available. From a dialogue perspective, they can be said to work on partial rather than full dialogue acts.

With respect to surface realisation, incremental NLG systems have predominantly relied on pre-defined templates (Purver and Otsuka, 2003; Skantze and Hjalmarsson, 2010; Dethlefs et al., 2012a), which limits the flexibility and quality of output generation. Buschmeier et al. (2012) have presented a system which systematically takes the user's acoustic understanding problems into account by pausing, repeating or re-phrasing if necessary. Their approach is based on SPUD (Stone et al., 2003), a constraint satisfaction-based NLG architecture and marks important progress towards more flexible incremental surface realisation. However, given the human labour involved in constraint specification, cohesion is often limited to a local context. Especially for long utterances or such that are separated by user turns, this may lead to surface form increments that are not well connected and lack cohesion.

### 5.1 Application to Incremental SR

This section will discuss a proof-of-concept application of our approach to incremental surface realisation. Table 4 shows an example dialogue between a user and system that contains a number of incremental phenomena that require hypothesis updates, system corrections and user barge-ins. Incremental surface realisation for this dialogue is shown in Figure 3, where processing steps are indicated as bold-face numbers and are triggered by partial dialogue acts that are sent from the dialogue manager, such as *inform(area=centre [0.2])*. The numbers in square brackets indicate the system's confidence in the attribute-value pair. Once a dialogue act is observed by the NLG system, a reinforcement learning agent determines the order of attributes and produces a semantic tree, as described in Section 3.1. Since the semantic forms are constructed incrementally, new tree nodes can be attached to and deleted from an existing tree, depending on what kind of update is required.

In the dialogue in Table 4, the user first asks for a *nice restaurant in the centre*. The dialogue manager constructs a first attribute-value slot, *inform(area=centre [0.2], ...)*, and passes it on to NLG.<sup>7</sup> In Figure 3, we can observe the corresponding NLG action, a first tree is created with just a root node and a node representing the area slot (step 1). In a second step, the semantically annotated node gets **expanded** into a surface form that is chosen from a set of candidates (shown in curly brackets). The CRF is responsible for this last step. Since there is no preceding utterance, the best surface form is chosen based on the semantics alone. Active tree nodes, i.e. those currently under generation, are indicated as asterisks in Figure 3. Currently inactive nodes are shown as circles.

Step 3 then further expands the current tree adding a node for the food type and the name of a restaurant that the dialogue manager had passed. We see here that attributes can either be primitive or complex. Primitive attributes contain a single semantic type, such as *area*, whereas complex attributes contain multiple types, such as *food*, *name* and need to be decomposed in a later processing step (see steps 4 and 6). Step 5 again uses the CRF

<sup>7</sup>Note here that the information passed on to the NLG is distinct from the dialogue manager's own actions. In the example, the NLG is asked to generate a recommendation, but the dialogue manager actually decides to clarify the user's preferences due to low confidence. This scenario is an example of generator inputs that may get revised afterwards.

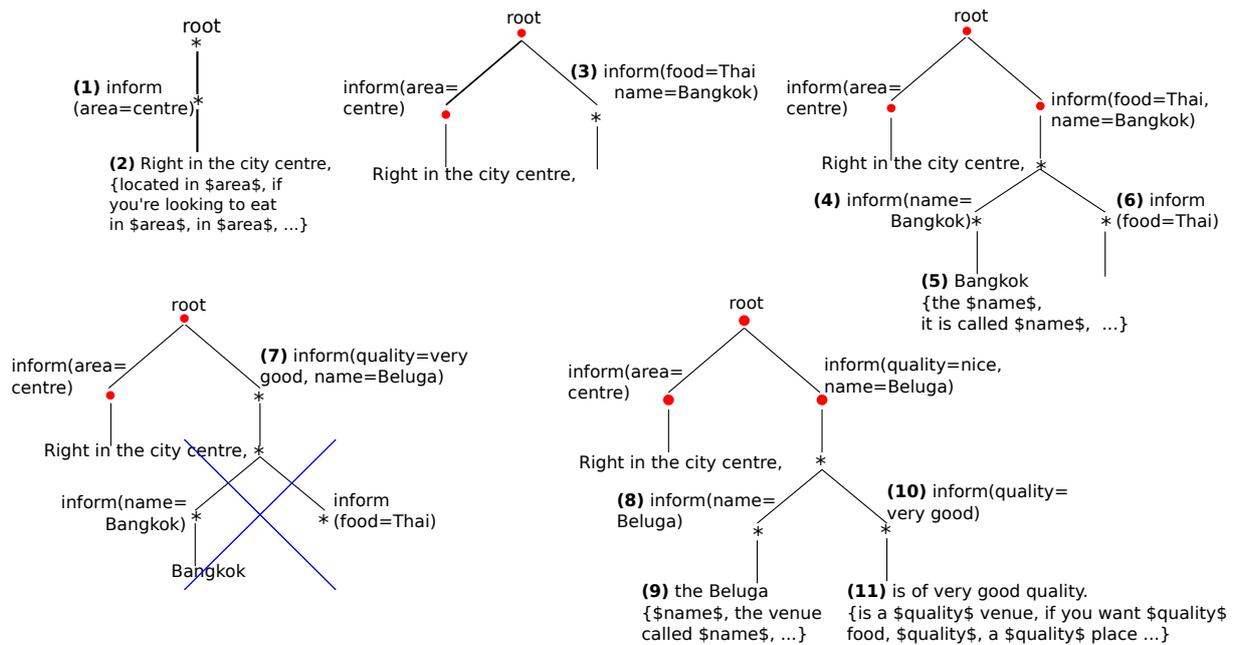

Figure 3: Example of incremental surface realisation, where each generation step is indicated by a number. Active generation nodes are shown as asterisks and deletions are shown as crossed out. Lexical and semantic features are associated with their respective nodes. Syntactic information in the form of parse categories are also taken into account for surface realisation, but have been omitted in this figure.

to obtain the next surface realisation that connects with the previous one (so that a sequence of realisation “labels” appears: *Right in the city centre* and *Bangkok*). It takes the full generation context into account to ensure a globally optimal choice. This is important, because the local context would otherwise be restricted to a partial dialogue act, which can be much smaller than a full dialogue act and thus lead to short, repetitive sentences.

The dialogue continues as the system implicitly confirms the user’s preferred restaurant (SYS1). At this point, we encounter a user barge-in correcting the desired choice. As a consequence, the dialogue manager needs to **update** its initial hypotheses and communicate this to NLG. Here, the last three tree nodes need to be **deleted** from the tree because the information is no longer valid. This update and the deletion is shown in step 7. Afterwards, the dialogue continues and NLG involves mainly expanding the current tree into a full sequence of surface realisations for partial dialogue acts which come together into a full utterance.

This example illustrates three incremental processing steps: expansions, updates and deletions. **Expansions** are the most frequent operation. They add new partial dialogue acts to the semantic tree. They also consult the CRF for the best surface

realisation. Since CRFs are not restricted by the Markov condition, they are less constrained by local context than other models and can take non-local dependencies into account. For our application, the maximal context is 9 semantic attributes (for a surface form that uses all possible 10 attributes). While their extended context awareness can often make CRFs slow to train, they are fast at execution and therefore very applicable to the incremental scenario. For applications involving longer-spanning alternatives, such as texts or paragraphs, the context of the CRF would likely have to be constrained. **Updates** are triggered by the hypothesis updates of the dialogue manager. Whenever a new attribute comes in, it is checked against the generator’s existing knowledge. If it is inconsistent with previous knowledge, an update is triggered and often followed by a **deletion**. Whenever generated output needs to be modified, old expansions and surface forms are deleted first, before new ones can be expanded in their place.

## 5.2 Updates and Processing Speed Results

Since fast responses are crucial in incremental systems, we measured the average time our system took for a surface realisation. The time is 100ms on a MacBook Intel Core 2.6 Duo with 8GB in

RAM. This is slightly better than other incremental systems (Skantze and Schlangen, 2009) and much faster than state-of-the-art non-incremental systems such as SPaRKY (Walker et al., 2007). In addition, we measured the number of necessary generation updates in comparison to a non-incremental setting. Since updates take effect directly on partial dialogue acts, rather than the full generated utterance, we require around 50% less updates as if generating from scratch for every changed input hypothesis. A qualitative analysis of the generated outputs showed that the quality is comparable to the non-incremental case.

## 6 Conclusion and Future Directions

We have presented a novel technique for surface realisation that treats generation as a sequence labelling task by combining a CRF with tree-based semantic representations. An essential property of interactive surface realisers is to keep track of the utterance context including dependencies between linguistic features to generate cohesive utterances. We have argued that CRFs are well suited for this task because they are not restricted by independence assumptions. In a human rating study, we confirmed that judges rated our output as better phrased, more natural and less repetitive than systems that just take local features into account. This also holds for a comparison with state-of-the-art rank and boost or  $n$ -gram approaches. Keeping track of the global context is also important for incremental systems since generator inputs can be incomplete or subject to modification. In a proof-of-concept study, we have argued that our approach is applicable to incremental surface realisation. This was supported by preliminary results on the speed, number of updates and quality during generation. As future work, we plan to test our model in a task-based setting using an end-to-end SDS in an incremental and non-incremental setting. This study will contain additional evaluation categories, such as the understandability or informativeness of system utterances. In addition, we may compare different sequence labelling algorithms for surface realisation (Nguyen and Guo, 2007) or segmented CRFs (Sarawagi and Cohen, 2005) and apply our method to more complex surface realisation domains such as text generation or summarisation. Finally, we would like to explore methods for unsupervised data labelling so as to facilitate portability across domains further.

## Abstract

Long distance reordering remains one of the greatest challenges in statistical machine translation research as the key contextual information may well be beyond the confine of translation units. In this paper, we propose Two-Neighbor Orientation (TNO) model that jointly models the orientation decisions between anchors and two neighboring multi-unit chunks which may cross phrase or rule boundaries. We explicitly model the longest span of such chunks, referred to as Maximal Orientation Span, to serve as a global parameter that constrains underlying local decisions. We integrate our proposed model into a state-of-the-art string-to-dependency translation system and demonstrate the efficacy of our proposal in a large-scale Chinese-to-English translation task. On NIST MT08 set, our most advanced model brings around +2.0 BLEU and -1.0 TER improvement.

## 1 Introduction

Long distance reordering remains one of the greatest challenges in Statistical Machine Translation (SMT) research. The challenge stems from the fact that an accurate reordering hinges upon the model's ability to make many local and global reordering decisions accurately. Often, such reordering decisions require contexts that span across multiple translation units.<sup>1</sup> Unfortunately, previous approaches fall short in capturing such cross-unit contextual information that could be

<sup>1</sup>We define translation units as phrases in phrase-based SMT, and as translation rules in syntax-based SMT.

critical in reordering. Specifically, the popular distortion or lexicalized reordering models in phrase-based SMT focus only on making good local prediction (i.e. predicting the orientation of immediate neighboring translation units), while translation rules in syntax-based SMT come with a strong context-free assumption, which model only the reordering within the confine of the rules. In this paper, we argue that reordering modeling would greatly benefit from richer cross-boundary contextual information

We introduce a reordering model that incorporates such contextual information, named the Two-Neighbor Orientation (TNO) model. We first identify *anchors* as regions in the source sentences around which ambiguous reordering patterns frequently occur and *chunks* as regions that are consistent with word alignment which may span multiple translation units at decoding time. Most notably, anchors and chunks in our model may not necessarily respect the boundaries of translation units. Then, we jointly model the orientations of chunks that immediately precede and follow the anchors (hence, the name “two-neighbor”) along with the maximal span of these chunks, to which we refer as Maximal Orientation Span (MOS).

As we will elaborate further in next sections, our models provide a stronger mechanism to make more accurate global reordering decisions for the following reasons. First of all, we consider the orientation decisions on both sides of the anchors simultaneously, in contrast to existing works that only consider one-sided decisions. In this way, we hope to upgrade the unigram formulation of existing reordering models to a higher order formulation. Second of all, we capture the reordering of chunks that may cross translation units and may be composed of multiple units, in contrast to ex-

isting works that focus on the reordering between individual translation units. In effect, MOS acts as a global reordering parameter that guides or constrains the underlying local reordering decisions.

To show the effectiveness of our model, we integrate our TNO model into a state-of-the-art syntax-based SMT system, which uses synchronous context-free grammar (SCFG) rules to jointly model reordering and lexical translation. The introduction of nonterminals in the SCFG rules provides some degree of generalization. However as mentioned earlier, the context-free assumption ingrained in the syntax-based formalism often limits the model’s ability to influence global reordering decision that involves cross-boundary contexts. In integrating TNO, we hope to strengthen syntax-based system’s ability to make more accurate global reordering decisions.

Our other contribution in this paper is a practical method for integrating the TNO model into syntax-based translations. The integration is non-trivial since the decoding of syntax-based SMT proceeds in a bottom-up fashion, while our model is more natural for top-down parsing, thus the model’s full context sometimes is often available only at the latest stage of decoding. We implement an efficient shift-reduce algorithm that facilitates the accumulation of partial context in a bottom-up fashion, allowing our model to influence the translation process even in the absence of full context.

We show the efficacy of our proposal in a large-scale Chinese-to-English translation task where the introduction of our TNO model provides a significant gain over a state-of-the-art string-to-dependency SMT system (Shen et al., 2008) that we enhance with additional state-of-the-art features. Even though the experimental results carried out in this paper employ SCFG-based SMT systems, we would like to point out that our models is applicable to other systems including phrase-based SMT systems.

The rest of the paper is organized as follows. In Section 2, we introduce the formulation of our TNO model. In Section 3, we introduce and motivate the concept of Maximal Orientation Span. In Section 4, we introduce four variants of the TNO model with different model complexities. In Section 5, we describe the training procedure to estimate the parameters of our models. In Section 6, we describe our shift-reduce algorithm which inte-

grates our proposed TNO model into syntax-based SMT. In Section 7, we describe our experiments and present our results. We wrap up with related work in Section 8 and conclusion in Section 9.

## 2 Two-Neighbor Orientation Model

Given an aligned sentence pair  $\Theta = (F, E, \sim)$ , let  $\Delta(\Theta)$  be all possible chunks that can be extracted from  $\Theta$  according to:<sup>2</sup>

$$\{(f_{j_1}^{j_2}/e_{i_1}^{i_2}) : \forall j_1 \leq j_2, \exists i : (j, i) \in \sim, i_i \leq i \leq i_2 \wedge \forall i_1 \leq i \leq i_2, \exists j : (j, i) \in \sim, j_i \leq j \leq j_2\}$$

Our Two-Neighbor Orientation model (TNO) designates  $\mathcal{A} \subset \Delta(\Theta)$  as anchors and *jointly* models the orientation of chunks that appear *immediately* to the left and to the right of the anchors as well as the identities of these chunks. We define anchors as chunks, around which ambiguous reordering patterns frequently occur. Anchors can be learnt automatically from the training data or identified from the linguistic analysis of the source sentence. In our experiments, we use a simple heuristics based on part-of-speech tags which will be described in Section 7.

More concretely, given  $\mathcal{A} \subset \Delta(\Theta)$ , let  $a = (f_{j_1}^{j_2}/e_{i_1}^{i_2}) \in \mathcal{A}$  be a particular anchor. Then, let  $\mathcal{C}_L(a) \subset \Delta(\Theta)$  be  $a$ ’s left neighbors and let  $\mathcal{C}_R(a) \subset \Delta(\Theta)$  be  $a$ ’s right neighbors, iff:

$$\forall \mathcal{C}_L = (f_{j_3}^{j_4}/e_{i_3}^{i_4}) \in \mathcal{C}_L(a) : j_4 + 1 = j_1 \quad (1)$$

$$\forall \mathcal{C}_R = (f_{j_5}^{j_6}/e_{i_5}^{i_6}) \in \mathcal{C}_R(a) : j_2 + 1 = j_5 \quad (2)$$

Given  $\mathcal{C}_L(a)$  and  $\mathcal{C}_R(a)$ , let  $C_L = (f_{j_3}^{j_4}/e_{i_3}^{i_4})$  and  $C_R = (f_{j_5}^{j_6}/e_{i_5}^{i_6})$  be a particular pair of left and right neighbors of  $a = (f_{j_1}^{j_2}/e_{i_1}^{i_2})$ . Then, the orientation of  $C_L$  and  $C_R$  are  $O_L(C_L, a)$  and  $O_R(C_R, a)$  respectively and each may take one of the following four orientation values (similar to (Nagata et al., 2006)):

- **Monotone Adjacent (MA)**, if  $(i_4 + 1) = i_1$  for  $O_L$  and if  $(i_2 + 1) = i_5$  for  $O_R$
- **Reverse Adjacent (RA)**, if  $(i_2 + 1) = i_3$  for  $O_L$  and if  $(i_6 + 1) = i_1$  for  $O_R$
- **Monotone Gap (MG)**, if  $(i_4 + 1) < i_1$  for  $O_L$  and if  $(i_2 + 1) < i_5$  for  $O_R$

<sup>2</sup>We represent a chunk as a source and target phrase pair  $(f_{j_1}^{j_2}/e_{i_1}^{i_2})$  where the subscript and the superscript indicate the starting and the ending indices as such  $f_{j_1}^{j_2}$  denotes a source phrase that spans from  $j_1$  to  $j_2$ .

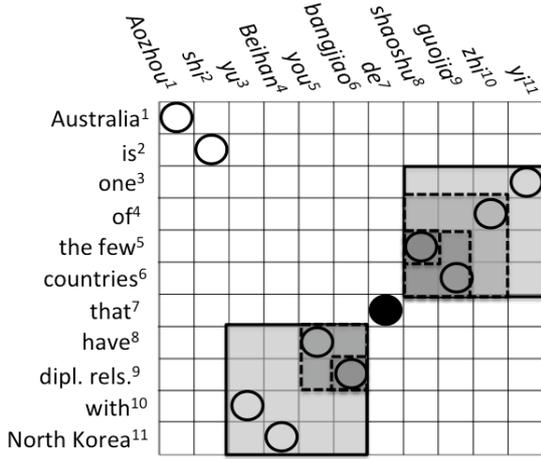

Figure 1: An aligned Chinese-English sentence pair. Circles represent alignment points. Black circle represents the anchor; boxes represent the anchor’s neighbors.

- **Reverse Gap (RG)**, if  $(i_2 + 1) < i_3$  for  $O_L$  and if  $(i_6 + 1) < i_1$  for  $O_R$ . (1)

The first clause (monotone, reverse) indicates whether the target order of the chunks follows the source order; the second (adjacent, gap) indicates whether the chunks are adjacent or separated by an intervening phrase when projected.

To be more concrete, let us consider an aligned sentence pair in Fig. 1, which is adapted from (Chiang, 2005). Suppose there is only one anchor, i.e.  $a = (f_7^7/e_7^7)$  which corresponds to the word *de(that)*. By applying Eqs. 1 and 2, we can infer that  $a$  has three left neighbors and four right neighbors, i.e.  $C_L(a) = (f_6^6/e_9^9), (f_5^6/e_8^9), (f_3^6/e_8^{11})$  and  $C_R(a) = (f_8^8/e_5^5), (f_8^9/e_5^6), (f_8^{10}/e_4^6), (f_8^{11}/e_3^6)$  respectively. Then, by applying Eq. 1, we can compute the orientation values of each of these neighbors, which are  $O_L(C_L(a), a) = RG, RA, RA$  and  $O_R(C_R(a), a) = RG, RA, RA, RA$ . As shown, most of the neighbors have Reverse Adjacent (RA) orientation except for the smallest left and right neighbors (i.e.  $(f_6^6/e_9^9)$  and  $(f_8^8/e_5^5)$ ) which have Reverse Gap (RG) orientation.

Given the anchors together with its neighboring chunks and their orientations, the Two-Neighbor Orientation model takes the following form:

$$\prod_{a \in \mathcal{A}} \sum_{\substack{C_L \in \mathcal{C}_L(a), \\ C_R \in \mathcal{C}_R(a)}} P_{TNO}(C_L, O_L, C_R, O_R | a; \Theta) \quad (2)$$

For conciseness, references that are clear from context, such the reference to  $C_L$  and  $a$  in  $O_L(C_L, a)$ , are dropped.

### 3 Maximal Orientation Span

As shown in Eq. 2, the TNO model has to enumerate all possible pairing of  $C_L \in \mathcal{C}_L(a)$  and  $C_R \in \mathcal{C}_R(a)$ . To make the TNO model more tractable, we simplify the TNO model to consider only the largest left and right neighbors, referred to as the Maximal Orientation Span/MOS ( $M$ ).

More formally, given  $a = (f_{j_1}^{j_2}/e_{i_1}^{i_2})$ , the left and the right MOS of  $a$  are:

$$M_L(a) = \arg \max_{(f_{j_3}^{j_4}/e_{i_3}^{i_4}) \in \mathcal{C}_L(a)} (j_4 - j_3)$$

$$M_R(a) = \arg \max_{(f_{j_5}^{j_6}/e_{i_5}^{i_6}) \in \mathcal{C}_R(a)} (j_6 - j_5)$$

Coming back to our example, the left and right MOS of the anchor are  $M_L(a) = (f_3^6/e_8^{11})$  and  $M_R(a) = (f_8^{11}/e_3^6)$ . In Fig. 1, they are denoted as the largest boxes delineated by solid lines.

As such, we reformulate Eq. 2 into:

$$\prod_{a \in \mathcal{A}} \sum_{\substack{C_L \in \mathcal{C}_L(a), \\ C_R \in \mathcal{C}_R(a)}} P_{TNO}(M_L, O_L, M_R, O_R | a; \Theta) \cdot \delta_{C_L == M_L \wedge C_R == M_R} \quad (3)$$

where  $\delta$  returns 1 if  $(C_L == M_L \wedge C_R == M_R)$ , otherwise 0.

Beyond simplifying the computation, the key benefit of modeling MOS is that it serves as a global parameter that can guide or constrain underlying local reorderings. As a case in point, let us consider a cheating exercise where we have to translate the Chinese sentence in Fig. 1 with the following set of hierarchical phrases<sup>3</sup>:

$$\begin{aligned} X_a &\rightarrow \langle \text{Aozhou}^1 \text{shi}^2 X_1, \text{Australia}^1 \text{is}^2 X_1 \rangle \\ X_b &\rightarrow \langle \text{yu}^3 \text{Beihan}^4 X_1, X_1 \text{with}^3 \text{North}^4 \text{Korea} \rangle \\ X_c &\rightarrow \langle \text{you}^5 \text{bangjiao}^6, \text{have}^5 \text{dipl.}^6 \text{rels.} \rangle \\ X_d &\rightarrow \langle X_1 \text{de}^7 \text{shaoshu}^8 \text{guojia}^9 \text{zhi}^{10} \text{yi}^{11}, \\ &\quad \text{one}^{11} \text{of}^{10} \text{the few}^8 \text{countries}^9 \text{that}^7 X_1 \rangle \end{aligned}$$

This set of hierarchical phrases represents a translation model that has resolved all local ambiguities (i.e. local reordering and lexical mappings) except for the spans of the hierarchical phrases. With this example, we want to show that accurate local decisions (rather obviously) don’t always lead to accurate global reordering and to demonstrate that explicit MOS modeling can play a crucial role to address this issue. To do so, we will again focus on the same anchor *de* (that).

<sup>3</sup>We use hierarchical phrase-based translation system as a case in point, but the merit is generalizable to other systems.

$$\begin{aligned}
&\stackrel{d}{\Rightarrow} \langle X_1 \mathbf{de}^7 \mathbf{shaoshu}^8 \mathbf{guojia}^9 \mathbf{zhi}^{10} \mathbf{yi}^{11} \rangle, \langle \text{one}^{11} \text{of}^{10} \text{the few}^8 \text{countries}^9 \mathbf{that}^7 X_1 \rangle \\
&\stackrel{a}{\Rightarrow} \langle \langle \mathbf{Aozhou}^1 \mathbf{shi}^2 X_1 \rangle \mathbf{de}^7 \mathbf{shaoshu}^8 \mathbf{guojia}^9 \mathbf{zhi}^{10} \mathbf{yi}^{11} \rangle, \\
&\quad \langle \text{one}^{11} \text{of}^{10} \text{the few}^8 \text{countries}^9 \mathbf{that}^7 \langle \text{Australia}^1 \text{is}^2 X_1 \rangle \rangle \\
&\stackrel{b}{\Rightarrow} \langle \langle \mathbf{Aozhou}^1 \mathbf{shi}^2 \langle \mathbf{yu}^3 \mathbf{Beihan}^4 X_1 \rangle \rangle \mathbf{de}^7 \mathbf{shaoshu}^8 \mathbf{guojia}^9 \mathbf{zhi}^{10} \mathbf{yi}^{11} \rangle, \\
&\quad \langle \text{one}^{11} \text{of}^{10} \text{the few}^8 \text{countries}^9 \mathbf{that}^7 \langle \text{Australia}^1 \text{is}^2 \langle X_1 \text{with}^3 \text{North}^4 \text{Korea} \rangle \rangle \rangle \\
&\stackrel{c}{\Rightarrow} \boxed{\langle d \rangle} \langle \langle \mathbf{Aozhou}^1 \mathbf{shi}^2 \langle \mathbf{yu}^3 \mathbf{Beihan}^4 \langle \mathbf{c} \mathbf{you}^5 \mathbf{bangjiao}^6 \rangle \mathbf{c} \rangle \mathbf{de}^7 \mathbf{shaoshu}^8 \mathbf{guojia}^9 \mathbf{zhi}^{10} \mathbf{yi}^{11} \rangle \boxed{\langle d \rangle} \rangle, \\
&\quad \langle \text{one}^{11} \text{of}^{10} \text{the few}^8 \text{countries}^9 \mathbf{that}^7 \langle \text{Australia}^1 \text{is}^2 \langle \langle \text{have}^5 \text{dipl.}^6 \text{reels.} \rangle \text{with}^3 \text{North}^4 \text{Korea} \rangle \rangle \rangle
\end{aligned}$$

Table 1: Derivation of  $X_d \prec X_a \prec X_b \prec X_c$  that leads to an incorrect translation.

$$\begin{aligned}
&\stackrel{a}{\Rightarrow} \langle \mathbf{Aozhou}^1 \mathbf{shi}^2 X_1 \rangle, \langle \text{Australia}^1 \text{is}^2 X_1 \rangle \\
&\stackrel{b}{\Rightarrow} \langle \mathbf{Aozhou}^1 \mathbf{shi}^2 \langle \mathbf{yu}^3 \mathbf{Beihan}^4 X_1 \rangle \rangle, \langle \text{Australia}^1 \text{is}^2 \langle X_1 \text{with}^3 \text{North}^4 \text{Korea} \rangle \rangle \\
&\stackrel{d}{\Rightarrow} \langle \mathbf{Aozhou}^1 \mathbf{shi}^2 \langle \mathbf{yu}^3 \mathbf{Beihan}^4 \langle X_1 \mathbf{de}^7 \mathbf{shaoshu}^8 \mathbf{guojia}^9 \mathbf{zhi}^{10} \mathbf{yi}^{11} \rangle \rangle \rangle, \\
&\quad \langle \text{Australia}^1 \text{is}^2 \langle \langle \text{one}^{11} \text{of}^{10} \text{the few}^8 \text{countries}^9 \mathbf{that}^7 X_1 \rangle \text{with}^3 \text{North}^4 \text{Korea} \rangle \rangle \rangle \\
&\stackrel{c}{\Rightarrow} \langle \mathbf{Aozhou}^1 \mathbf{shi}^2 \langle \mathbf{yu}^3 \mathbf{Beihan}^4 \langle \boxed{\langle d \rangle} \langle \mathbf{c} \mathbf{you}^5 \mathbf{bangjiao}^6 \rangle \mathbf{c} \mathbf{de}^7 \mathbf{shaoshu}^8 \mathbf{guojia}^9 \mathbf{zhi}^{10} \mathbf{yi}^{11} \rangle \boxed{\langle d \rangle} \rangle \rangle, \\
&\quad \text{Australia}^1 \text{is}^2 \langle \langle \text{one}^{11} \text{of}^{10} \text{the few}^8 \text{countries}^9 \mathbf{that}^7 \langle \text{have}^5 \text{dipl.}^6 \rangle \text{with}^3 \text{North}^4 \text{Korea} \rangle \rangle \rangle
\end{aligned}$$

Table 2: Derivation of  $X_a \prec X_b \prec X_d \prec X_c$  that leads to the correct translation.

As the rule’s identifier, we attach an alphabet letter to each rule’s left hand side, as such the anchor *de* (that) appears in rule  $X_d$ . We also attach the word indices as the superscript of the source words and project the indices to the target words aligned, as such “*have*<sup>5</sup>” suggests that the word “have” is aligned to the 5-th source word, i.e. *you*. Note that to facilitate the projection, the rules must come with internal word alignment in practice. Now the indices on the target words in the rules are different from those in Fig. 1. We will also extensively use indices in this sense in the subsequent section about decoding. In such a sense,  $M_L(a) = (f_3^6/e_3^6)$  and  $M_R(a) = (f_8^{11}/e_8^{11})$ .

Given the rule set, there are three possible derivations, i.e.  $X_d \prec X_a \prec X_b \prec X_c$ ,  $X_a \prec X_b \prec X_d \prec X_c$ , and  $X_a \prec X_d \prec X_b \prec X_c$ , where  $\prec$  indicates that the first operand dominates the second operand in the derivation tree. The application of the rules would show that the first derivation will produce an incorrect reordering while the last two will produce the correct ones. Here, we would like to point out that even in this simple example where all local decisions are made accurate, this ambiguity occurs and it would occur even more so in the real translation task where local decisions may be highly inaccurate.

Next, we will show that the MOS-related information can help to resolve this ambiguity, by focusing more closely on the first and the second derivations, which are detailed in Tables 1 and 2.

Particularly, we want to show that the MOS generated by the incorrect derivation does not match the MOS learnt from Fig. 1. As shown, at the end of the derivation, we have all the information needed to compute the MOS (i.e.  $\Theta$ ) which is equivalent to that available at training time, i.e. the source sentence, the complete translation and the word alignment. Running the same MOS extraction procedure on both derivations would produce the right MOS that agrees with the right MOS previously learnt from Fig. 1, i.e.  $(f_8^{11}/e_8^{11})$ . However, that’s not the case for left MOS, which we underline in Tables 1 and 2. As shown, the incorrect derivation produces a left MOS that spans six words, i.e.  $(f_1^6/e_1^6)$ , while the correct derivation produces a left MOS that spans four words, i.e.  $(f_3^6/e_3^6)$ . Clearly, the MOS of the incorrect derivation doesn’t agree with the MOS we learnt from Fig. 1, unlike the MOS of the correct translation. This suggests that explicit MOS modeling would provide a mechanism for resolving crucial global reordering ambiguities that are beyond the ability of local models.

Additionally, this illustration also shows a case where MOS acts as a cross-boundary context which effectively relaxes the context-free assumption of hierarchical phrase-based formalism. In Tables 1 and 2’s full derivations, we indicate rule boundaries explicitly by indexing the angle brackets, e.g.  $\langle_a$  indicates the beginning of rule  $X_a$  in the derivation. As the anchor appears in  $X_d$ , we

highlight its boundaries in box frames. *de* (that)’s MOS respects rule boundaries if and only if all the words come entirely from  $X_d$ ’s antecedent or  $\langle_d$  and  $\rangle_d$  appears outside of MOS; otherwise it crosses the rule boundaries. As clearly shown in Table 2, the left MOS of the correct derivation (underlined) crosses the rule boundary (of  $X_d$ ) since  $\langle_d$  appears within the MOS.

Going back to the formulation, focusing on modeling MOS would simplify the formulation of TNO model from Eq. 2 into:

$$\prod_{a \in \mathcal{A}} P_{TNO}(M_L, O_L, M_R, O_R | a; \Theta) \quad (4)$$

which doesn’t require enumerating of all possible pairs of  $\mathcal{C}_L$  and  $\mathcal{C}_R$ .

#### 4 Model Decomposition and Variants

To make the model more tractable, we decompose  $P_{TNO}$  in Eq. 4 into the following four factors:  $P(M_R | a) \times P(O_R | M_R, a) \times P(M_L | O_R, M_R, a) \times P(O_L | M_L, O_R, M_R, a)$ . Subsequently, we will refer to them as  $P_{M_R}$ ,  $P_{O_R}$ ,  $P_{M_L}$  and  $P_{O_L}$  respectively. Each of these factors will act as an additional feature in the log-linear framework of our SMT system. The above decomposition follows a generative story that starts from generating the right neighbor first. There are other equally credible alternatives, but based on empirical results, we settle with the above.

Next, we present four different variants of the model (not to be confused with the four factors above). Each variant has a different probabilistic conditioning of the factors. We start by making strong independence assumptions in Model 1 and then relax them as we progress to Model 4. The description of the models is as follow:

- **Model 1.** We assume  $P_{M_L}$  and  $P_{M_R}$  to be equal to 1 and  $P_{O_R} \approx P(O_R | a; \Theta)$  to be independent of  $M_R$  and  $P_{O_L} \approx P(O_L | a; \Theta)$  to be independent of  $M_L, M_R$  and  $O_R$ .
- **Model 2.** On top of Model 1, we make  $P_{O_L}$  dependent on  $P_{O_R}$ , thus  $P_{O_L} \approx P(O_L | O_R, a; \Theta)$ .
- **Model 3.** On top of Model 2, we make  $P_{O_R}$  dependent on  $M_R$  and  $P_{O_L}$  on  $M_R$  and  $M_L$ , thus  $P_{O_R} \approx P(O_R | M_R, a; \Theta)$  and  $P_{O_L} \approx P(O_L | M_L, O_R, M_R; a, \Theta)$ .
- **Model 4.** On top of Model 3, we model  $P_{M_R}$  and  $P_{M_L}$  as multinomial distributions estimated from training data.

Model 1 represents a model that focuses on making accurate one-sided decisions, independent of the decision on the other side. Model 2 is designed to address the deficiency of Model 1 since Model 1 may assign non-zero probability to improbable assignment of orientation values, e.g. Monotone Adjacent for the left neighbor and Reverse Adjacent for the right neighbor. Model 2 does so by conditioning  $P_{O_L}$  on  $O_R$ . In Model 3, we start incorporating MOS-related information in predicting  $O_L$  and  $O_R$ . In Model 4, we explicitly model the MOS of each anchor.

#### 5 Training

The TNO model training consists of two different training regimes: 1) discriminative for training  $P_{O_L}, P_{O_R}$ ; and 2) generative for training  $P_{M_L}, P_{M_R}$ . Before describing the specifics, we start by describing the procedure to extract anchors and their corresponding MOS from training data, from which we collect statistics and extract features to train the model.

For each aligned sentence pair  $(F, E, \sim)$  in the training data, the training starts with the identification of the regions in the source sentences as anchors ( $\mathcal{A}$ ). For our Chinese-English experiments, we use a simple heuristic that equates as anchors, single-word chunks whose corresponding word class belongs to closed-word classes, bearing a close resemblance to (Setiawan et al., 2007). In total, we consider 21 part-of-speech tags; some of which are as follow: VC (copula), DEG, DEG, DER, DEV (*de*-related), PU (punctuation), AD (adjectives) and P (prepositions).

Next we generate all possible chunks  $\Delta(\Theta)$  as previously described in Sec. 3. We then define a function  $MinC(\Delta, j_1, j_2)$  which returns the shortest chunk that can span from  $j_1$  to  $j_2$ . If  $(f_{j_1}^{j_2} / e_{i_1}^{i_2}) \in \Delta$ , then  $MinC$  returns  $(f_{j_1}^{j_2} / e_{i_1}^{i_2})$ .

The algorithm to extract MOS takes  $\Delta$  and an anchor  $a = (f_{j_1}^{j_2} / e_{i_1}^{i_2})$  as input; and outputs the chunk that qualifies as MOS or none. Alg. 1 provides the algorithm to extract the right MOS; the algorithm to extract the left MOS is identical to Alg. 1, except that it scans for chunks to the left of the anchor. In Alg. 1, there are two intermediate parameters  $si$  and  $ei$  which represent the active search range and should initially be set to  $j_2 + 1$  and  $|F|$  respectively. Once we obtain  $a, M_L(a)$  and  $M_R(a)$ , we compute  $O_L(M_L(a), a)$  and  $O_R(M_R(a), a)$  and are ready for training.

To estimate  $P_{O_L}$  and  $P_{O_R}$ , we train discriminative classifiers that predict the orientation values and use the normalized posteriors at decoding time as additional feature scores in SMT’s log linear framework. We train the classifiers on a rich set of binary features ranging from lexical to part-of-speech (POS) and to syntactic features.

  | end
end

```

---

Suppose  $a = (f_{j_1}^{j_2}/e_{i_1}^{i_2})$ ,  $M_L(a) = (f_{j_3}^{j_4}/e_{i_3}^{i_4})$  and  $M_R(a) = (f_{j_5}^{j_6}/e_{i_5}^{i_6})$ , then based on the context’s location, the elementary features employed in our classifiers can be categorized into:

1. *anchor-related*: `slex` (the actual word of  $f_{j_1}^{j_2}$ ), `spos` (part-of-speech (POS) tag of `slex`), `sparent` (`spos`’s parent in the parse tree), `tlex` ( $e_{i_1}^{i_2}$ ’s actual target word)..
2. *surrounding*: `lslex` (the previous word /  $f_{j_1-1}^{j_1-1}$ ), `rslex` (the next word /  $f_{j_2+1}^{j_2+1}$ ), `lspos` (`lslex`’s POS tag), `rspos` (`rslex`’s POS tag), `lsparent` (`lslex`’s parent), `rsparent`

(`rslex`’s parent).

3. *non-local*: `lanchorslex` (the previous anchor’s word), `ranchorslex` (the next anchor’s word), `lanchorspos` (`lanchorslex`’s POS tag), `ranchorspos` (`ranchorslex`’s POS tag).
4. *MOS-related*: `mosl_int_slex` (the actual word of  $f_{j_3}^{j_3}$ ), `mosl_ext_slex` (the actual word of  $f_{j_3}^{j_3}$ ), `mosl_int_spos` (`mosl_int_slex`’s POS tag), `mosl_ext_spos` (`mosl_ext_spos`’s POS tag), `mosr_int_slex` (the actual word of  $f_{j_3}^{j_3}$ ), `mosr_ext_slex` (the actual word of  $f_{j_3}^{j_3}$ ), `mosr_int_spos` (`mosr_int_slex`’s POS tag), `mosr_ext_spos` (`mosr_ext_spos`’s POS tag).

For Model 1, we train one classifier each for  $P_{O_R}$  and  $P_{O_L}$ . For Model 2-4, we train four classifiers for  $P_{O_L}$  for each value of  $O_R$ . We use only the MOS features for Model 3 and 4. Additionally, we augment the feature set with compound features, e.g. conjunction of the lexical of the anchor and the lexical of the left and the right anchors. Although they increase the number of features significantly, we found that these compound features are empirically beneficial.

We come up with  $> 50$  types of features, which consist of a combination of elementary and compound features. In total, we generate hundreds of millions of such features from the training data. To keep the number features to a manageable size, we employ the L1-regularization in training to enforce sparse solutions, using the off-the-shelf LIBLINEAR toolkit (Fan et al., 2008). After training, the number of features in our classifiers decreases to below 5 million features for each classifier.

We train  $P_{M_L}$  and  $P_{M_R}$  via the relative frequency principle. To avoid the sparsity issue, we represent  $M_L$  as (`mosl_int_spos,mosl_ext_spos`) and  $M_R$  as (`mosr_int_spos,mosr_ext_spos`). We condition  $P_{M_L}$  and  $P_{M_R}$  only on `spos` and the orientation, estimating them as follow:

$$P(M_L|spos, O_L) = \frac{N(M_L, spos, O_L)}{N(spos, O_L)}$$

$$P(M_R|spos, O_R) = \frac{N(M_R, spos, O_R)}{N(spos, O_R)}$$

where  $N$  returns the count of the events in the training data.

## 6 Decoding

Integrating the TNO Model into syntax-based SMT systems is non-trivial, especially with the MOS modeling. The method described in Sec. 3 assumes  $\Theta = (F, E, \sim)$ , thus it is only applicable at training or at the last stage of decoding. Since many reordering decisions may have been made at the earlier stages, the late application of TNO model would limit the utility of the model. In this section, we describe an algorithm that facilitates the incremental construction of MOS and the computation of TNO model on partial derivations.

The algorithm bears a close resemblance to the shift-reduce algorithm where a stack is used to accumulate (partial) information about  $a$ ,  $M_L$  and  $M_R$  for each  $a \in \mathcal{A}$  in the derivation. This algorithm takes an input stream and applies either the *shift* or the *reduce* operations starting from the beginning until the end of the stream. The *shift* operation advances the input stream by one symbol and push the symbol into the stack; while the *reduce* operation applies some reduction rule to the topmost elements of the stack. The algorithm terminates at the end of the input stream where the resulting stack will be propagated to the parent for the later stage of decoding. In our case, the input stream is the target string of the rule and the symbol is the corresponding source index of the elements of the target string. The reduction rule looks at two indices and merge them if they are adjacent (i.e. has no intervening phrase). We forbid the application of the reduction rule to anchors. Table 3 shows the execution trace of the algorithm for the derivation described in Table 2.

As shown, the algorithm starts with an empty stack. It then projects the source index to the corresponding target word and then enumerates the

target string in a left to right fashion. If it finds a target word with a source index, it applies the shift operation, pushing the index to the stack. Unless the symbol corresponds to an anchor, it tries to apply the reduce operation. Line (4) indicates the special treatment to the anchor. If the symbol read is a nonterminal, then we push the entire stack that corresponds to that nonterminal. For example, when the algorithm reads  $X_d$  at line (6), it pushes the entire stack from line (5).

This algorithm facilitates the incremental construction of MOS which may cross rule boundaries. For example, at the end of the application of  $X_d$  at line (5), the current left MOS is [5-6]. However, the algorithm grows it to [3-6] after the application of rule  $X_b$  at line (7). Furthermore, it allows us to compute the models from partial hypothesis. For example, at line (5), we can compute  $P_{O_L}$  by considering [5,6] as  $M_L$  to be updated with [3,6] in line (7). This way, we expect our TNO model would play a bigger role at decoding time.

Specific to SCFG-based translation, the values of  $O_L$  and  $O_R$  are identical in the partial or in the full derivations. For example, the orientation values of *de* (that)’s left neighbor is always *RA*. This statement holds, even though at the end of Section 2, we stated that *de* (that)’s left neighbor may have other orientation values, i.e. *RG* for  $C_L(a) = (f_6^6/e_9^9)$ . The formal proof is omitted, but the intuition comes from the fact that the derivations for SCFG-based translation are subset of  $\Delta(\Theta)$  and that  $(f_6^6/e_9^9)$  will never become  $M_L$  for  $MinC(C_L(a), a)$  respectively (chunk that spans  $a$  and  $C_L$ ). Consequently, for Model 1 and Model 2, we can obtain the model score earlier in the decoding process.

## 7 Experiments

Our baseline system is a state-of-the-art string-to-dependency system (Shen et al., 2008). The system is trained on 10 million parallel sentences that are available to the Phase 1 of the DARPA BOLT Chinese-English MT task. The training corpora include a mixed genre of newswire, weblog, broadcast news, broadcast conversation, discussion forums and comes from various sources such as LDC, HK Law, HK Hansard and UN data.

In total, our baseline model employs about 40 features, including four from our proposed Two-Neighbor Orientation model. In addition to the standard features including the rule translation probabilities, we incorporate features that are found useful for developing a state-of-the-art baseline, such as the provenance features (Chiang et al., 2011). We use a large 6-gram language model, which was trained on 10 billion English words from multiple corpora, including the English side of our parallel corpus plus other corpora such as Gigaword (LDC2011T07) and Google News. We also train a class-based language model (Chen, 2009) on two million English sentences selected from the parallel corpus. As the backbone of our string-to-dependency system, we train 3-gram models for left and right dependencies and unigram for head using the target side of the bilingual training data. To train our Two-Neighbor Orientation model, we select a subset of 5 million aligned sentence pairs.

For the tuning and development sets, we set aside 1275 and 1239 sentences selected from LDC2010E30 corpus. We tune the decoding weights with PRO (Hopkins and May, 2011) to maximize BLEU-TER. As for the blind test set, we report the performance on the NIST MT08 evaluation set, which consists of 691 sentences from newswire and 666 sentences from weblog. We pick the weights that produce the highest development set scores to decode the test set.

Table 4 summarizes the experimental results on NIST MT08 newswire and weblog. In column 2, we report the classification accuracy on a subset of training data. Note that these numbers are for reference only and not directly comparable with each other since the features used in these classifiers include several gold standard information, such as the anchors’ target words, the anchors’ MOS-related features (Model 3 & 4) and the orientation of the right MOS (Model 2-4); all of which have

	Acc	MT08 nw		MT08 wb	
		BLEU	TER	BLEU	TER
S2D	-	36.77	53.28	26.34	57.41
M1	72.5	37.60	52.70	27.59	56.33
M2	77.4	37.86	52.68	27.74	56.11
M3	84.5	38.02	52.42	28.22	<b>55.82</b>
M4	84.5	<b>38.55</b>	<b>52.41</b>	<b>28.44</b>	56.45

Table 4: The NIST MT08 results on newswire (nw) and weblog (wb) genres. S2D is the baseline string-to-dependency system (line 1), on top of which Two-Neighbor Orientation Model 1 to 4 are employed (line 2-5). The best TER and BLEU results on each genre are in **bold**. For BLEU, higher scores are better, while for TER, lower scores are better.

to be predicted at decoding time.

In columns 2 and 4, we report the BLEU scores, while in columns 3 and 5, we report the TER scores. The performance of our baseline string-to-dependency syntax-based SMT is shown in the first line, followed by the performance of our Two-Neighbor Orientation model starting from Model 1 to Model 4. As shown, the empirical results confirm our intuition that SMT can greatly benefit from reordering model that incorporate cross-unit contextual information.

Model 1 provides most of the gain across the two genres of around +0.9 to +1.2 BLEU and -0.5 to -1.1 TER. Model 2 which conditions  $P_{O_L}$  on  $O_R$  provides an additional +0.2 BLEU improvement on BLEU score consistently across the two genres. As shown in line 4, we see a stronger improvement in the inclusion of MOS-related information as features in Model 3. In newswire, Model 3 gives an additional +0.4 BLEU and -0.2 TER, while in weblog, it gives a stronger improvement of an additional +0.5 BLEU and -0.3 TER. The inclusion of explicit MOS modeling in Model 4 gives a significant BLEU score improvement of +0.5 but no TER improvement in newswire. In weblog, Model 4 gives a mixed results of +0.2 BLEU score improvement and a hit of +0.6 TER. We conjecture that the weblog text has a more ambiguous orientation span that are more challenging to learn. In total, our TNO model gives an encouraging result. Our most advanced model gives significant improvement of +1.8 BLEU/-0.8 TER in newswire domain and +2.1 BLEU/-1.0 TER over a strong string-to-dependency syntax-based SMT enhanced with additional state-of-the-art features.

## 8 Related Work

Our work intersects with existing work in many different respects. In this section, we mainly focus on work related to the probabilistic conditioning of our TNO model and the MOS modeling.

Our TNO model is closely related to the Unigram Orientation Model (UOM) (Tillman, 2004), which is the *de facto* reordering model of phrase-based SMT (Koehn et al., 2007). UOM views reordering as a process of generating  $(b, o)$  in a left-to-right fashion, where  $b$  is the current phrase pair and  $o$  is the orientation of  $b$  with the previously generated phrase pair  $b'$ . UOM makes strong independence assumptions and formulates the model as  $P(o|b)$ . Tillmann and Zhang (2007) proposed a Bigram Orientation Model (BOM) to include both phrase pairs  $(b$  and  $b')$  into the model. Their original intent is to model  $P(o, b|o', b')$ , but perhaps due to sparsity concerns, they settle with  $P(o|b, b')$ , dropping the conditioning on the previous orientation  $o'$ . Subsequent improvements use the  $P(o|b, b')$  formula, for example, for incorporating various linguistics feature like part-of-speech (Zens and Ney, 2006), syntactic (Chang et al., 2009), dependency information (Bach et al., 2009) and predicate-argument structure (Xiong et al., 2012). Our TNO model is more faithful to the BOM’s original formulation.

Our MOS concept is also closely related to hierarchical reordering model (Galley and Manning, 2008) in phrase-based decoding, which computes  $o$  of  $b$  with respect to a multi-block unit that may go beyond  $b'$ . They mainly use it to avoid overestimating “discontiguous” orientation but fall short in modeling the multi-block unit, perhaps due to data sparsity issue. Our MOS is also closely related to the efforts of modeling the span of hierarchical phrases in formally syntax-based SMT. Early works reward/penalize spans that respect the syntactic parse constituents of an input sentence (Chiang, 2005), and (Marton and Resnik, 2008). (Xiong et al., 2009) learn the boundaries from parsed and aligned training data, while (Xiong et al., 2010) learn the boundaries from aligned training data alone. Recent work couples span modeling tightly with reordering decisions, either by adding an additional feature for each hierarchical phrase (Chiang et al., 2008; Shen et al., 2009) or by refining the nonterminal label (Venugopal et al., 2009; Huang et al., 2010; Zollmann and Vogel, 2011). Common to this work is that the spans

modeled may not correspond to MOS, which may be suboptimal as discussed in Sec. 3.

In equating anchors with the function word class, our work, particularly Model 1, is closely related to the function word-centered model of Setiawan et al. (2007) and Setiawan et al. (2009). However, we provide a discriminative treatment to the model to include a richer set of features including the MOS modeling. Our work in incorporating global context also intersects with existing work in Preordering Model (PM), e.g. (Niehues and Kolss, 2009; Costa-jussà and Fonollosa, 2006; Genzel, 2010; Visweswariah et al., 2011; Tromble and Eisner, 2009). The goal of PM is to reorder the input sentence  $F$  into  $F'$  whose order is closer to the target language order, whereas the goal of our model is to directly reorder  $F$  into the target language order. The crucial difference is that we have to integrate our model into SMT decoder, which is highly non-trivial.

## 9 Conclusion

We presented a novel approach to address a kind of long-distance reordering that requires global cross-boundary contextual information. Our approach, which we formulate as a Two-Neighbor Orientation model, includes the joint modeling of two orientation decisions and the modeling of the maximal span of the reordered chunks through the concept of Maximal Orientation Span. We describe four versions of the model and implement an algorithm to integrate our proposed model into a syntax-based SMT system. Empirical results confirm our intuition that incorporating cross-boundaries contextual information improves translation quality. In a large scale Chinese-to-English translation task, we achieve a significant improvement over a strong baseline. In the future, we hope to continue this line of research, perhaps by learning to identify anchors automatically from training data, incorporating a richer set of linguistics features such as dependency structure and strengthening the modeling of Maximal Orientation Span.

## Abstract

Preordering of a source language sentence to match target word order has proved to be useful for improving machine translation systems. Previous work has shown that a reordering model can be learned from high quality manual word alignments to improve machine translation performance. In this paper, we focus on further improving the performance of the reordering model (and thereby machine translation) by using a larger corpus of sentence aligned data for which manual word alignments are not available but automatic machine generated alignments are available. The main challenge we tackle is to generate quality data for training the reordering model in spite of the machine alignments being noisy. To mitigate the effect of noisy machine alignments, we propose a novel approach that improves reorderings produced given noisy alignments and also improves word alignments using information from the reordering model. This approach generates alignments that are 2.6 f-Measure points better than a baseline supervised aligner. The data generated allows us to train a reordering model that gives an improvement of 1.8 BLEU points on the NIST MT-08 Urdu-English evaluation set over a reordering model that only uses manual word alignments, and a gain of 5.2 BLEU points over a standard phrase-based baseline.

## 1 Introduction

Dealing with word order differences between source and target languages presents a significant challenge for machine translation systems. Failing to produce target words in the correct order results

in machine translation output that is not fluent and is often very hard to understand. These problems are particularly severe when translating between languages which have very different structure.

Phrase based systems (Koehn et al., 2003) use lexicalized distortion models (Al-Onaizan and Papineni, 2006; Tillman, 2004) and scores from the target language model to produce words in the correct order in the target language. These systems typically are only able to capture short range reorderings and the amount of data required to potentially capture longer range reordering phenomena is prohibitively large.

There has been a large body of work showing the efficacy of preordering source sentences using a source parser and applying hand written or automatically learned rules (Collins et al., 2005; Wang et al., 2007; Ramanathan et al., 2009; Xia and McCord, 2004; Genzel, 2010; Visweswariah et al., 2010). Recently, approaches that address the problem of word order differences between the source and target language without requiring a high quality source or target parser have been proposed (DeNero and Uszkoreit, 2011; Visweswariah et al., 2011; Neubig et al., 2012). These methods use a small corpus of manual word alignments (where the words in the source sentence are manually aligned to the words in the target sentence) to learn a model to preorder the source sentence to match target order.

In this paper, we build upon the approach in (Visweswariah et al., 2011) which uses manual word alignments for learning a reordering model. Specifically, we show that we can significantly improve reordering performance by using a large number of sentence pairs for which manual word alignments are not available. The motivation for going beyond manual word alignments is clear: the reordering model can have millions of features and estimating weights for the features on thousands of sentences of manual word alignments is

likely to be inadequate. One approach to deal with this problem would be to use only part-of-speech tags as features for all but the most frequent words. This will cut down on the number of features and perhaps the model would be learnable with a small set of manual word alignments. Unfortunately, as we will see in the experimental section, leaving out lexical information from the models hurts performance even with a relatively small set of manual word alignments. Another option would be to collect more manual word alignments but this is undesirable because it is time consuming and expensive.

The challenge in going beyond manual word alignments and using machine alignments is the noise in the machine alignments which affects the performance of the reordering model (see Section 5). We illustrate this with the help of a motivating example. Consider the example English sentence and its translation shown in Figure 1.

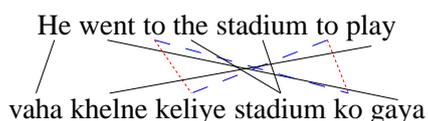

Figure 1: An example English sentence with its Urdu translation with alignment links. Red (dotted) links are incorrect links while the blue (dashed) links are the corresponding correct links.

A standard word alignment algorithm that we used (McCarley et al., 2011) made the mistake of mis-aligning the Urdu *ko* and *keliye* (it switched the two). Deriving reference reorderings from these wrong alignments would give us an incorrect reordering. A reordering model trained on such incorrect reorderings would obviously perform poorly. Our task is thus two-fold (i) improve the quality of machine alignments (ii) use these less noisy alignments to derive cleaner training data for a reordering model.

Before proceeding, we first point out that the two tasks, *viz.*, reordering and word alignment are related: Having perfect reordering makes the alignment task easier while having perfect alignments in turn makes the task of finding reorderings trivial. Motivated by this fact, we introduce models that allow us to connect the source/target reordering and the word alignments and show that these models help in mutually improving the performance of word alignments and reordering. Specifically, we build two models: the first scores

reorderings given the source sentence and noisy alignments, the second scores alignments given the noisy source and target reorderings and the source and target sentences themselves. The second model helps produce better alignments, while we use the first model to help generate better reference reordering given noisy alignments. These improved reference reorderings will then be used to train a reordering model.

Our experiments show that reordering models trained using these improved machine alignments perform significantly better than models trained only on manual word alignments. This results in a 1.8 BLEU point gain in machine translation performance on an Urdu-English machine translation task over a preordering model trained using only manual word alignments. In all, this increases the gain in performance by using the preordering model to 5.2 BLEU points over a standard phrase-based system with no preordering.

The rest of this paper is structured as follows. Section 2 describes the main reordering issues in Urdu-English translation. Section 3 introduces the reordering modeling framework that forms the basis for our work. Section 4 describes the two models we use to tie together reordering and alignments and how we use these models to generate training data for training our reordering model. Section 5 presents the experimental setup used for evaluating the models proposed in this paper on an Urdu-English machine translation task. Section 6 presents the results of our experiments. We describe related work in Section 7 and finally present some concluding remarks and potential future work in Section 8.

## 2 Reordering issues in Urdu-English translation

In this section we describe the main sources of word order differences between Urdu and English since this is the language pair we experiment with in this paper.

The typical word order in Urdu is *Subject-Object-Verb* unlike English in which the order is *Subject-Verb-Object*. Urdu has case markers that sometimes (but not always) mark the subject and the object of a sentence. This difference in the placement of verbs can often lead to movements of verbs over long distances (depending on the number of words in the object). Phrase based systems do not capture such long distance movements well.

Another difference is that Urdu uses post-positions unlike English which uses prepositions. This can also lead to long range movements depending on the length of the noun phrase that the post-position follows. The order of noun phrases and prepositional phrases is also swapped in Urdu as compared with English.

### 3 Reordering model

In this section we briefly describe the reordering model (Visweswariah et al., 2011) that forms the basis of our work. We also describe an approximation we make in the training process that significantly speeds up the training without much loss of accuracy which enables training on much larger data sets. Consider a source sentence  $\mathbf{w}$  that we would like to reorder to match the target order. Let  $\pi$  represent a candidate permutation of the source sentence  $\mathbf{w}$ .  $\pi_i$  denotes the index of the word in the source sentence that maps to position  $i$  in the candidate reordering, thus reordering with this candidate permutation  $\pi$  we will reorder the sentence  $\mathbf{w}$  to  $w_{\pi_1}, w_{\pi_2}, \dots, w_{\pi_n}$ . The reordering model we use assigns costs to candidate permutations as:

$$C(\pi|\mathbf{w}) = \sum_i c(\pi_{i-1}, \pi_i).$$

The costs  $c(m, n)$  are pairwise costs of putting  $w_m$  immediately before  $w_n$  in the reordering. We reorder the sentence  $\mathbf{w}$  according to the permutation  $\pi$  that minimizes the cost  $C(\pi|\mathbf{w})$ . We find the minimal cost permutation by converting the problem into a symmetric Travelling Salesman Problem (TSP) and then using an implementation of the chained Lin-Kernighan heuristic (Applegate et al., 2003). The costs in the reordering model  $c(m, n)$  are parameterized by a linear model:

$$c(m, n) = \theta^T \Phi(\mathbf{w}, m, n)$$

where  $\theta$  is a learned vector of weights and  $\Phi$  is a vector of binary feature functions that inspect the words and POS tags of the source sentence at and around positions  $m$  and  $n$ . We use the features ( $\Phi$ ) described in Visweswariah et al. (2011) that were based on features used in dependency parsing (McDonald et al., 2005a).

To learn the weight vector  $\theta$  we require a corpus of sentences  $\mathbf{w}$  with their desired reorderings  $\pi^*$ . Past work Visweswariah et al. (2011) used high quality manual word alignments to derive the desired reorderings  $\pi^*$  as follows. Given word

aligned source and target sentences, we drop the source words that are not aligned<sup>1</sup>. Let  $m_i$  be the mean of the target word positions that the source word at index  $i$  is aligned to. We then sort the source indices in increasing order of  $m_i$  (this order defines  $\pi^*$ ). If  $m_i = m_j$  (for example, because  $w_i$  and  $w_j$  are aligned to the same set of words) we keep them in the same order that they occurred in the source sentence.

We used the single best Margin Infused Relaxed Algorithm (MIRA) (McDonald et al. (2005b), Crammer and Singer (2003)) with online updates to our parameters given by:

$$\begin{aligned} \theta_{i+1} &= \arg \min_{\theta} \|\theta - \theta_i\| \\ \text{s.t. } & C(\pi^*|\mathbf{w}) < C(\hat{\pi}|\mathbf{w}) - L(\pi^*, \hat{\pi}). \end{aligned}$$

In the equation above,  $\hat{\pi} = \arg \min_{\pi} C(\pi|\mathbf{w})$  is the best reordering based on the current parameter value  $\theta_i$  and  $L$  is a loss function. We take  $L$  to be the number of words for which the hypothesized permutation  $\hat{\pi}$  has a different preceding word as compared with the reference permutation  $\pi^*$ .

In this paper we focus on the case where in addition to using a relatively small number of manual word aligned sentences to derive the reference permutations  $\pi^*$  used to train our model, we would like to use more abundant but noisier machine aligned sentence pairs. To handle the larger amount of training data we obtain from machine alignments, we make an approximation in training that we found empirically to not affect performance but that makes training faster by more than a factor of five. This allows us to train the reordering model with roughly 150K sentences in about two hours. The approximation we make is that instead of using the chained Lin-Kernighan heuristic to solve the TSP problem to find  $\hat{\pi} = \arg \min_{\pi} C(\pi|\mathbf{w})$ , we select greedily for each word the preceding word that has the lowest cost<sup>2</sup>. Using  $\psi_i$  to denote  $\arg \min_j c(j, i)$  and letting

$$C(\psi|\mathbf{w}) = \sum_i c(\psi_i, i),$$

<sup>1</sup>Note that the unaligned source words are dropped only at the time of training. At the time of testing all source words are retained as the alignment information is obviously not available at test time.

<sup>2</sup>It should be noted that this approximation was done only at the time of training. At the time of testing we still use the chained Lin-Kernighan heuristic to solve the TSP problem.

we do the update according to:

$$\theta_{i+1} = \underset{\theta}{\operatorname{arg\,min}} \|\theta - \theta_i\|$$

$$s.t. \quad C(\pi^*|\mathbf{w}) < C(\psi|\mathbf{w}) - L(\pi^*, \psi).$$

Again the loss  $L(\pi^*, \psi)$  is the number of positions  $i$  for which  $\pi_{i-1}^*$  is different from  $\psi_{i-1}$ .

#### 4 Generating reference reordering from parallel sentences

The main aim of our work is to improve the reordering model by using parallel sentences for which manual word alignments are not available. In other words, we want to generate relatively clean reference reorderings from parallel sentences and use them for training a reordering model. A straightforward approach for this is to use a supervised aligner to align the words in the sentences and then derive the reference reordering as we do for manual word alignments. However, as we will see in the experimental results, the quality of a reordering model trained from automatic alignments is very sensitive to the quality of alignments. This motivated us to explore if we can further improve our aligner and the method for generating reference reorderings given alignments.

We improve upon the above mentioned basic approach by coupling the tasks of reordering and word alignment. We do this by building a **reordering model** ( $C(\pi^s|\mathbf{w}^s, \mathbf{w}^t, \mathbf{a})$ ) that scores reorderings  $\pi^s$  given the source sentence  $\mathbf{w}^s$ , target sentence  $\mathbf{w}^t$  and machine alignments  $\mathbf{a}$ . Complementing this model, we build an **alignment model** ( $P(\mathbf{a}|\mathbf{w}^s, \mathbf{w}^t, \pi^s, \pi^t)$ ) that scores alignments  $\mathbf{a}$  given the source and target sentences and their predicted reorderings according to source and target reordering models. The model ( $C(\pi^s|\mathbf{w}^s, \mathbf{w}^t, \mathbf{a})$ ) helps to produce better reference reorderings for training our final reordering model given fixed machine alignments and the alignment model ( $P(\mathbf{a}|\mathbf{w}^s, \mathbf{w}^t, \pi^s, \pi^t)$ ) helps improve the machine alignments taking into account information from reordering models. In the following sections, we describe our overall approach followed by a description of the two models.

##### 4.1 Overall approach to generating training data

We first describe our overall approach to generating training data for the reordering model given a small corpus of sentences with manual

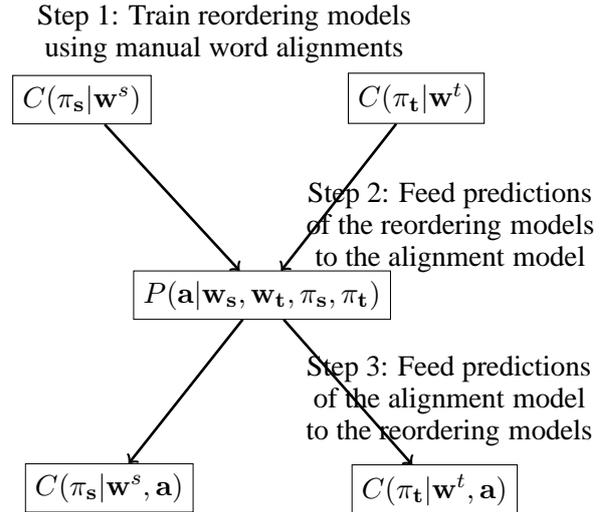

Figure 2: Overall approach: Building a sequence of reordering and alignment models.

word alignments ( $H$ ) and a much larger corpus of parallel sentences ( $U$ ) that are not word aligned. The basic idea is to chain together the two models, *viz.*, reordering model and alignment model, as illustrated in Figure 2. The steps involved are as described below:

**Step 1:** First, we use manual word alignments ( $H$ ) to train source and target reordering models as described in (Visweswariah et al., 2011).

**Step 2:** Next, we use the hand alignments to train an alignment model  $P(\mathbf{a}|\mathbf{w}^s, \mathbf{w}^t, \pi^s, \pi^t)$ . In addition to the original source and target sentence, we also feed the predictions of the reordering model trained in Step 1 to this alignment model (see section 4.2 for details of the model itself).

**Step 3:** Finally, we use the predictions of the alignment model trained in Step 2 to train reordering models  $C(\pi^s|\mathbf{w}^s, \mathbf{w}^t, \mathbf{a})$  (see section 4.3 for details on the reordering model itself).

After building the sequence of models shown in Figure 2, we apply them in sequence on the unaligned parallel data  $U$ , starting with the reordering models  $C(\pi^s|\mathbf{w}^s)$  and  $C(\pi^t|\mathbf{w}^t)$ . The reorderings obtained for the source side in  $U$  (after applying the final model  $C(\pi^s|\mathbf{w}^s, \mathbf{a})$ ) are used along with reference reorderings obtained from the manual word alignments to train our reordering model. Note that, in theory, we could iterate over steps 2 and 3 several times but, in practice we did not see a benefit of going beyond one iter-

ation in our experiments. Also, since we are interested only in the source side reorderings produced by the model  $C(\pi^s | \mathbf{w}^s, \mathbf{a})$ , the target reordering model  $C(\pi^t | \mathbf{w}^t, \mathbf{a})$  is needed only if we iterate over steps 2 and 3.

We now point to some practical considerations of our approach. Consider the case when we are training an alignment model conditioned on reorderings ( $P(\mathbf{a} | \mathbf{w}^s, \mathbf{w}^t, \pi^s, \pi^t)$ ). If the reordering model that generated these reorderings  $\pi^s, \pi^t$  were trained on the same data that we are using to train the alignment model, then the reorderings would be much better than we would expect on unseen test data, and hence the alignment model ( $P(\mathbf{a} | \mathbf{w}^s, \mathbf{w}^t, \pi^s, \pi^t)$ ) may learn to make the alignment overly consistent with the reorderings  $\pi^s$  and  $\pi^t$ . To counter this problem, we divide the training data  $H$  into  $K$  parts and at each stage we apply a model (reordering or alignment) on part  $i$  that had not seen part  $i$  in training. This ensures that the alignment model does not see very optimistic reorderings and vice versa. We now describe the individual models, viz.,  $P(\mathbf{a} | \mathbf{w}^s, \mathbf{w}^t, \pi^s, \pi^t)$  and  $C(\pi^s | \mathbf{w}^s, \mathbf{a})$ .

## 4.2 Modeling alignments given reordering

In this section we describe how we fuse information from source and target reordering models to improve word alignments.

As a base model we use the correction model for word alignments proposed by McCarley et al. (2011). This model was significantly better than the MaxEnt aligner (Ittycheriah and Roukos, 2005) and is also flexible in the sense that it allows for arbitrary features to be introduced while still keeping training and decoding tractable by using a greedy decoding algorithm that explores potential alignments in a small neighborhood of the current alignment. The model thus needs a reasonably good initial alignment to start with for which we use the MaxEnt aligner (Ittycheriah and Roukos, 2005) as in McCarley et al. (2011).

The correction model is a log-linear model:

$$P(\mathbf{a} | \mathbf{w}^s, \mathbf{w}^t) = \frac{\exp(\lambda^T \phi(\mathbf{a}, \mathbf{w}^s, \mathbf{w}^t))}{Z(\mathbf{w}^s, \mathbf{w}^t)}.$$

The  $\lambda$ s are trained using the LFBGS algorithm (Liu et al., 1989) to maximize the log-likelihood smoothed with  $L_2$  regularization. The feature functions  $\phi$  we start with are those used in McCarley et al. (2011) and include features encoding

the Model 1 probabilities between pairs of words linked in the alignment  $\mathbf{a}$ , features that inspect source and target POS tags and parses (if available) and features that inspect the alignments of adjacent words in the source and target sentence.

To incorporate information from the reordering model, we add features that use the predicted source  $\pi^s$  and target permutations  $\pi^t$ . We introduce some notation to describe these features. Let  $S_m$  and  $S_n$  be the set of indices of target words that  $w_m^s$  and  $w_n^s$  are aligned to respectively. We define the minimum signed distance (*msd*) between these two sets as:

$$msd(S_m, S_n) = i^* - j^*$$

where,  $(i^*, j^*) = \arg \min_{(i,j) \in S_m \times S_n} |i - j|$

We quantize and encode with binary features the minimum signed distance between the sets of the indices of the target words that source words adjacent in the reordering  $\pi^s$  ( $w_{\pi_i^s}^s$  and  $w_{\pi_{i+1}^s}^s$ ) are aligned to. We instantiate similar features with the roles of source and target sentences reversed. With this addition of features we use the same training and testing procedure as in McCarley et al. (2011). If the reorderings  $\pi^s$  were perfect we would learn to only allow alignments where  $w_{\pi_i^s}^s$  and  $w_{\pi_{i+1}^s}^s$  were aligned to adjacent words in the target sentence. Although the reordering model is not perfect, preferring alignments consistent with the reordering models improves the aligner.

## 4.3 Modeling reordering given alignments

To model source permutations given source ( $\mathbf{w}^s$ ) and target ( $\mathbf{w}^t$ ) sentences, and alignments ( $\mathbf{a}$ ) we reuse the reordering model framework described in Section 3 adding additional features capturing the relation between a hypothesized permutation  $\pi$  and alignments  $\mathbf{a}$ . To allow for searching via the same TSP formulation we once again assign costs to candidate permutations as:

$$C(\pi^s | \mathbf{w}^s, \mathbf{w}^t, \mathbf{a}) = \sum_i c(\pi_{i-1}, \pi_i | \mathbf{w}^s, \mathbf{a}).$$

Note that we introduce a dependence on the target sentence  $\mathbf{w}^t$  only through the alignment  $\mathbf{a}$ . Once again we parameterize the costs by a linear model:

$$c(m, n) = \theta^T \Phi(\mathbf{w}^s, \mathbf{a}, m, n).$$

For the feature functions  $\Phi$ , in addition to the features that only depend on  $\mathbf{w}^s, m, n$  (that we

use in our standard reordering model) we add binary indicator features based on  $msd(S_m, S_n)$  and  $msd(S_m, S_n)$  conjoined with  $POS(w_m^s)$  and  $POS(w_n^s)$ .

Here,  $S_m$  and  $S_n$  are the set of indices of target words that  $w_m^s$  and  $w_n^s$  are aligned to respectively. We conjoin the  $msd$  (minimum signed distance) with the POS tags to allow the model to capture the fact that the alignment error rate maybe higher for some POS tags than others (*e.g.*, we have observed verbs have a higher error rate in Urdu-English alignments).

Given these features we train the parameters  $\theta$  using the MIRA algorithm as described in Section 3. Using this model, we can find the lowest cost permutation  $C(\pi^s | \mathbf{w}^s, \mathbf{a})$  using the Lin-Kernighan heuristic as described in Section 3. This model allows us to combine features from the original reordering model along with information coming from the alignments to find source reorderings given a parallel corpus and alignments. We will see in the experimental section that this improves upon the simple heuristic for deriving reorderings described in Section 3.

## 5 Experimental setup

In this section we describe the experimental setup that we used to evaluate the models proposed in this paper. All experiments were done on Urdu-English and we evaluate reordering in two ways: Firstly, we evaluate reordering performance directly by comparing the reordered source sentence in Urdu with a reference reordering obtained from the manual word alignments using BLEU (Papineni et al., 2002) (we call this measure monolingual BLEU or mBLEU). All mBLEU results are reported on a small test set of about 400 sentences set aside from our set of sentences with manual word alignments. Additionally, we evaluate the effect of reordering on our final systems for machine translation measured using BLEU.

We use about 10K sentences (180K words) of manual word alignments which were created in house using part of the NIST MT-08 training data<sup>3</sup> to train our baseline reordering model and to train our supervised machine aligners. We use a parallel corpus of 3.9M words consisting of 1.7M words from the NIST MT-08 training data set and 2.2M words extracted from parallel news stories on the

<sup>3</sup><http://www ldc.upenn.edu>

web<sup>4</sup>. The parallel corpus is used for building our phrased based machine translation system and to add training data for our reordering model. For our English language model, we use the Gigaword English corpus in addition to the English side of our parallel corpus. Our Part-of-Speech tagger is a Maximum Entropy Markov model tagger trained on roughly fifty thousand words from the CRULP corpus (Hussain, 2008).

For our machine translation experiments, we used a standard phrase based system (Al-Onaizan and Papineni, 2006) with a lexicalized distortion model with a window size of +/-4 words<sup>5</sup>. To extract phrases we use HMM alignments along with higher quality alignments from a supervised aligner (McCarley et al., 2011). We report results on the (four reference) NIST MT-08 evaluation set in Table 4 for the News and Web conditions. The News and Web conditions each contain roughly 20K words in the test set, with the Web condition containing more informal text from the web.

## 6 Results and Discussions

We now discuss the results of our experiments.

**Need for additional data:** We first show the need for additional data in Urdu-English reordering. Column 2 of Table 1 shows mBLEU as a function of the number of sentences with manual word alignments that are used to train the reordering model. We see a roughly 3 mBLEU points drop in performance per halving of data indicating a potential for improvement by adding more data.

**Using fewer features:** We compare the performance of a model trained using lexical features for all words (Column 2 of Table 1) with a model trained using lexical features only for the 1000 most frequent words (Column 3 of Table 1). The motivation for this is to explore if a good model can be learned even from a small amount of data if we restrict the number of features in a reasonable manner. However, we see that even with only 2.4K sentences with manual word alignments our model benefits from lexical identities of more than the 1000 most frequent words.

**Effect of quality of machine alignments:** We next look at the use of automatically generated

<sup>4</sup><http://centralasiaonline.com>

<sup>5</sup>Note that the same window size of +/-4 words was used for all the systems, *i.e.*, the baseline system as well as the systems using different preordering techniques.

Data size	All features	Frequent lex only
10K	52.5	50.8
5K	49.6	49.0
2.5K	46.6	46.2

Table 1: mBLEU scores for Urdu to English re-ordering using different number of sentences of manually word aligned training data with all features and with lexical features instantiated only for the 1000 most frequent words.

machine alignments to train the reordering model and see the effect of aligner quality on the reordering model generated using this data. These experiments also form the baseline for the models we propose in this paper to clean up alignments. We experimented with two different supervised aligners : a maximum entropy aligner (Ittycheriah and Roukos, 2005) and an improved correction model that corrects the maximum entropy alignments (McCarley et al., 2011).

Aligner		Train size (words)	mBLEU
Type	f-Measure		
None		-	35.5
Manual		180K	52.5
MaxEnt	70.0	3.9M	49.5
Correction model	78.1	3.9M	55.1

Table 2: mBLEU scores for Urdu to English re-ordering using models trained on different data sources and tested on a development set of 8017 Urdu tokens.

Table 2 shows mBLEU scores when the reordering model is trained on reordering references created from aligners with different quality. We see that the quality of the alignments matter a great deal to the reordering model; using MaxEnt alignments cause a degradation in performance over just using a small set of manual word alignments. The alignments obtained using the aligner of McCarley et al. (2011) are of much better quality and hence give higher reordering performance. Note that this reordering performance is much better than that obtained using manual word alignments because the size of machine alignments is much larger (3.9M v/s 180K words).

**Improvements in reordering performance using the proposed models:** Table 3 shows improvements in the reordering model when using the models proposed in this paper. We use  $H$  to refer to the manually word aligned data and  $U$  to refer to the additional sentence pairs for which manual word alignments are not available. We report

the following numbers :

**1. Base correction model:** This is the baseline where we use the correction model of McCarley et al. (2011) for generating word alignments. The f-Measure of this aligner is 78.1% (see row 1, column 2). Corresponding to this, we also report the baseline for our reordering experiments in the third column. Here, we first generate word alignments for  $U$  using the aligner of McCarley et al. (2011) and then extract reference reorderings from these alignments. We then combine these reference reorderings with the reference reorderings derived from  $H$  and use this combined data to train a reordering model which serves as the baseline (mBLEU = 55.1).

**2. Correction model,  $C(\pi|a)$ :** Here, once again we generate alignments for  $U$  using the correction model of McCarley et al. (2011). However, instead of using the basic approach of extracting reference reorderings, we use our improved model  $C(\pi|a)$  to generate reference reorderings from  $U$ . These reference reorderings are again combined with the reference reorderings derived from  $H$  and used to train a reordering model (mBLEU = 56.4).

**3.  $P(a|\pi)$ ,  $C(\pi|a)$ :** Here, we build the entire sequence of models shown in Figure 2. The alignment model  $P(a|\pi)$  is first improved by using predictions from the reordering model. These improved alignments are then used to extract better reference reorderings from  $U$  using  $C(\pi|a)$ .

We see substantial improvements over simply adding in the data from the machine alignments. Improvements come roughly in equal parts from the two techniques we proposed in this paper : (i) using a model to generate reference reorderings from noisy alignments and (ii) using reordering information to improve the aligner.

Method	f-Measure	mBLEU
Base Correction model	78.1	55.1
Correction model, $C(\pi a)$	78.1	56.4
$P(a \pi)$ , $C(\pi a)$	80.7	57.6

Table 3: mBLEU with different methods to generate reordering model training data from a machine aligned parallel corpus in addition to manual word alignments.

**Improvements in MT performance using the proposed models:** We report results for a phrase based system with different preordering techniques. For results including a reordering model, we simply reorder the source side Urdu data both while training and at test time. In addition to

phrase based systems with different reordering methods, we also report on a hierarchical phrase based system for which we used Joshua 4.0 (Ganitkevitch et al., 2012). We see a significant gain of 1.8 BLEU points in machine translation by going beyond manual word alignments using the best reordering model reported in Table 3. We also note a gain of 2.0 BLEU points over a hierarchical phrase based system.

System type	MT-08 eval		
	Web	News	All
Baseline (no reordering)	18.4	25.6	22.2
Hierarchical phrase based	19.6	30.7	25.4
Reordering: Manual alignments	20.7	30.0	25.6
+ Machine alignments simple	21.3	30.9	26.4
+ machine alignments, model based	<b>22.1</b>	<b>32.2</b>	<b>27.4</b>

Table 4: MT performance without reordering (phrase based and hierarchical phrase based), and with reordering models using different data sources (phrase based).

## 7 Related work

Dealing with the problem of handling word order differences in machine translation has recently received much attention. The approaches proposed for solving this problem can be broadly divided into 3 sets as discussed below.

The first set of approaches handle the reordering problem as part of the decoding process. Hierarchical models (Chiang, 2007) and syntax based models (Yamada and Knight, 2002; Galley et al., 2006; Liu et al., 2006; Zollmann and Venugopal, 2006) improve upon the simpler phrase based models but with significant additional computational cost (compared with phrase based systems) due to the inclusion of chart based parsing in the decoding process. Syntax based models also require a high quality source or target language parser.

The second set of approaches rely on a source language parser and treat reordering as a separate process that is applied on the source language sentence at training and test time before using a standard approach to machine translation. Reordering the source data with hand written or automatically learned rules is effective and efficient (Collins et al., 2005; Wang et al., 2007; Ramanathan et al., 2009; Xia and McCord, 2004; Genzel, 2010; Visweswariah et al., 2010) but requires a source language parser.

Recent approaches that avoid the need for a

source or target language parser and retain the efficiency of reordering models were proposed in (Tromble and Eisner, 2009; DeNero and Uszkoreit, 2011; Visweswariah et al., 2011; Neubig et al., 2012). (DeNero and Uszkoreit, 2011; Visweswariah et al., 2011; Neubig et al., 2012) focus on the use of manual word alignments to learn reordering models and in both cases no benefit was obtained by using the parallel corpus in addition to manual word alignments. Our work is an extension of Visweswariah et al. (2011) and we focus on being able to incorporate relatively noisy machine alignments to improve the reordering model.

In addition to being related to work in reordering, our work is also more broadly related to several other efforts which we now outline. Setiawan et al. (2010) proposed the use of function word reordering to improve alignments. While this work is similar to one of our models (model of alignments given reordering) we differ in using a reordering model of all words (not just function words) and both source and target sentences (not just the source sentence). The task of directly learning a reordering model for language pairs that are very different is closely related to the task of parsing and hence work on semi-supervised parsing (Koo et al., 2008; McClosky et al., 2006; Suzuki et al., 2009) is broadly related to our work. Our work coupling reordering and alignments is also similar in spirit to approaches where parsing and alignment are coupled (Wu, 1997).

## 8 Conclusion

In the paper we showed that a reordering model can benefit from data beyond a relatively small corpus of manual word alignments. We proposed a model that scores reorderings given alignments and the source sentence that we use to generate cleaner training data from noisy alignments. We also proposed a model that scores alignments given source and target sentence reorderings that improves a supervised alignment model by 2.6 points in f-Measure. While the improvement in alignment performance is modest, the improvement does result in improved reordering models. Cumulatively, we see a gain of 1.8 BLEU points over a baseline reordering model that only uses manual word alignments, a gain of 2.0 BLEU points over a hierarchical phrase based system, and a gain of 5.2 BLEU points over a phrase based

system that uses no source reordering on a publicly available Urdu-English test set.

As future work we would like to evaluate our models on other language pairs. Another avenue of future work we would like to explore is the use of monolingual source and target data to further assist the reordering model. We hope to be able to learn lexical information such as how many arguments a verb takes, what nouns are potential subjects for a given verb by gathering statistics from an English parser and projecting to the source language via our word/phrase translation table.

# Vector Space Model for Adaptation in Statistical Machine Translation

Boxing Chen, Roland Kuhn and George Foster

National Research Council Canada

first.last@nrc-cnrc.gc.ca

## Abstract

This paper proposes a new approach to domain adaptation in statistical machine translation (SMT) based on a vector space model (VSM). The general idea is first to create a vector profile for the in-domain development (“dev”) set. This profile might, for instance, be a vector with a dimensionality equal to the number of training subcorpora; each entry in the vector reflects the contribution of a particular subcorpus to all the phrase pairs that can be extracted from the dev set. Then, for each phrase pair extracted from the training data, we create a vector with features defined in the same way, and calculate its similarity score with the vector representing the dev set. Thus, we obtain a decoding feature whose value represents the phrase pair’s closeness to the dev. This is a simple, computationally cheap form of instance weighting for phrase pairs. Experiments on large scale NIST evaluation data show improvements over strong baselines: +1.8 BLEU on Arabic to English and +1.4 BLEU on Chinese to English over a non-adapted baseline, and significant improvements in most circumstances over baselines with linear mixture model adaptation. An informal analysis suggests that VSM adaptation may help in making a good choice among words with the same meaning, on the basis of style and genre.

## 1 Introduction

The translation models of a statistical machine translation (SMT) system are trained on parallel data. Usage of language and therefore the best translation practice differs widely across genres, topics, and dialects, and even depends on a partic-

ular author’s or publication’s style; the word “domain” is often used to indicate a particular combination of all these factors. Unless there is a perfect match between the training data domain and the (test) domain in which the SMT system will be used, one can often get better performance by adapting the system to the test domain.

Domain adaptation is an active topic in the natural language processing (NLP) research community. Its application to SMT systems has recently received considerable attention. Approaches that have been tried for SMT model adaptation include mixture models, transductive learning, data selection, instance weighting, and phrase sense disambiguation, etc.

Research on mixture models has considered both linear and log-linear mixtures. Both were studied in (Foster and Kuhn, 2007), which concluded that the best approach was to combine sub-models of the same type (for instance, several different TMs or several different LMs) linearly, while combining models of different types (for instance, a mixture TM with a mixture LM) log-linearly. (Koehn and Schroeder, 2007), instead, opted for combining the sub-models directly in the SMT log-linear framework.

In transductive learning, an MT system trained on general domain data is used to translate in-domain monolingual data. The resulting bilingual sentence pairs are then used as additional training data (Ueffing et al., 2007; Chen et al., 2008; Schwenk, 2008; Bertoldi and Federico, 2009).

Data selection approaches (Zhao et al., 2004; Hildebrand et al., 2005; Lü et al., 2007; Moore and Lewis, 2010; Axelrod et al., 2011) search for bilingual sentence pairs that are similar to the in-domain “dev” data, then add them to the training data.

Instance weighting approaches (Matsoukas et al., 2009; Foster et al., 2010; Huang and Xiang, 2010; Phillips and Brown, 2011; Sennrich, 2012)

typically use a rich feature set to decide on weights for the training data, at the sentence or phrase pair level. For example, a sentence from a subcorpus whose domain is far from that of the dev set would typically receive a low weight, but sentences in this subcorpus that appear to be of a general nature might receive higher weights.

The 2012 JHU workshop on Domain Adaptation for MT <sup>1</sup> proposed phrase sense disambiguation (PSD) for translation model adaptation. In this approach, the context of a phrase helps the system to find the appropriate translation.

In this paper, we propose a new instance weighting approach to domain adaptation based on a vector space model (VSM). As in (Foster et al., 2010), this approach works at the level of phrase pairs. However, the VSM approach is simpler and more straightforward. Instead of using word-based features and a computationally expensive training procedure, we capture the distributional properties of each phrase pair directly, representing it as a vector in a space which also contains a representation of the dev set. The similarity between a given phrase pair’s vector and the dev set vector becomes a feature for the decoder. It rewards phrase pairs that are in some sense closer to those found in the dev set, and punishes the rest. In initial experiments, we tried three different similarity functions: Bhattacharyya coefficient, Jensen-Shannon divergency, and cosine measure. They all enabled VSM adaptation to beat the non-adaptive baseline, but Bhattacharyya similarity worked best, so we adopted it for the remaining experiments.

The vector space used by VSM adaptation can be defined in various ways. In the experiments described below, we chose a definition that measures the contribution (to counts of a given phrase pair, or to counts of all phrase pairs in the dev set) of each training subcorpus. Thus, the variant of VSM adaptation tested here bears a superficial resemblance to domain adaptation based on mixture models for TMs, as in (Foster and Kuhn, 2007), in that both approaches rely on information about the subcorpora from which the data originate. However, a key difference is that in this paper we explicitly capture each phrase pair’s distribution across subcorpora, and compare it to the aggregated distribution of phrase pairs in the dev set. In mixture models, a phrase pair’s distribu-

tion across subcorpora is captured only implicitly, by probabilities that reflect the prevalence of the pair within each subcorpus. Thus, VSM adaptation occurs at a much finer granularity than mixture model adaptation. More fundamentally, there is nothing about the VSM idea that obliges us to define the vector space in terms of subcorpora.

For instance, we could cluster the words in the source language into  $S$  clusters, and the words in the target language into  $T$  clusters. Then, treating the dev set and each phrase pair as a pair of bags of words (a source bag and a target bag) one could represent each as a vector of dimension  $S + T$ , with entries calculated from the counts associated with the  $S + T$  clusters (in a way similar to that described for phrase pairs below). The (dev, phrase pair) similarity would then be independent of the subcorpora. One can think of several other ways of defining the vector space that might yield even better results than those reported here. Thus, VSM adaptation is not limited to the variant of it that we tested in our experiments.

## 2 Vector space model adaptation

Vector space models (VSMs) have been widely applied in many information retrieval and natural language processing applications. For instance, to compute the sense similarity between terms, many researchers extract features for each term from its context in a corpus, define a VSM and then apply similarity functions (Hindle, 1990; Lund and Burgess, 1996; Lin, 1998; Turney, 2001).

In our experiments, we exploited the fact that the training data come from a set of subcorpora. For instance, the Chinese-English training data are made up of 14 subcorpora (see section 3 below). Suppose we have  $C$  subcorpora. The domain vector for a phrase-pair  $(f, e)$  is defined as

$$V(f, e) = \langle w_1(f, e), \dots, w_i(f, e), \dots, w_C(f, e) \rangle, \quad (1)$$

where  $w_i(f, e)$  is a standard *tf · idf* weight, i.e.

$$w_i(f, e) = tf_i(f, e) \cdot idf_i(f, e). \quad (2)$$

To avoid a bias towards longer corpora, we normalize the raw joint count  $c_i(f, e)$  in the corpus  $s_i$  by dividing by the maximum raw count of any phrase pair extracted in the corpus  $s_i$ . Let

<sup>1</sup><http://www.clsp.jhu.edu/workshops/archive/ws-12/groups/dasmt>

$$tf_i(f, e) = \frac{c_i(f, e)}{\max\{c_i(f_j, e_k), (f_j, e_k) \in s_i\}}. \quad (3)$$

The  $idf(f, e)$  is the inverse document frequency: a measure of whether the phrase-pair  $(f, e)$  is common or rare across all subcorpora. We use the standard formula:

$$idf(f, e) = \log\left(\frac{C}{df(f, e)} + \lambda\right), \quad (4)$$

where  $df(f, e)$  is the number of subcorpora that  $(f, e)$  appears in, and  $\lambda$  is an empirically determined smoothing term.

For the in-domain dev set, we first run word alignment and phrases extracting in the usual way for the dev set, then sum the distribution of each phrase pair  $(f_j, e_k)$  extracted from the dev data across subcorpora to represent its domain information. The dev vector is thus

$$V(dev) = \langle w_1(dev), \dots, w_C(dev) \rangle, \quad (5)$$

where

$$w_i(dev) = \sum_{j=0}^{j=J} \sum_{k=0}^{k=K} c_{dev}(f_j, e_k) w_i(f_j, e_k) \quad (6)$$

$J, K$  are the total numbers of source/target phrases extracted from the dev data respectively.  $c_{dev}(f_j, e_k)$  is the joint count of phrase pair  $f_j, e_k$  found in the dev set.

The vector can also be built with other features of the phrase pair. For instance, we could replace the raw joint count  $c_i(f, e)$  in Equation 3 with the raw marginal count of phrase pairs  $(f, e)$ . Therefore, even within the variant of VSM adaptation we focus on in this paper, where the definition of the vector space is based on the existence of subcorpora, one could utilize other definitions of the vectors of the similarity function than those we utilized in our experiments.

## 2.1 Vector similarity functions

VSM uses the similarity score between the vector representing the in-domain dev set and the vector representing each phrase pair as a decoder feature. There are many similarity functions we could have employed for this purpose (Cha, 2007). We

tested three commonly-used functions: the Bhattacharyya coefficient (BC) (Bhattacharyya, 1943; Kazama et al., 2010), the Jensen-Shannon divergence (JSD), and the cosine measure. According to (Cha, 2007), these belong to three different families of similarity functions: the Fidelity family, the Shannon's entropy family, and the inner Product family respectively. It was BC similarity that yielded the best performance, and that we ended up using in subsequent experiments.

To map the BC score onto a range from 0 to 1, we first normalize each weight in the vector by dividing it by the sum of the weights. Thus, we get the probability distribution of a phrase pair or the phrase pairs in the dev data across all subcorpora:

$$p_i(f, e) = \frac{w_i(f, e)}{\sum_{j=1}^{j=C} w_j(f, e)} \quad (7)$$

$$p_i(dev) = \frac{w_i(dev)}{\sum_{j=1}^{j=C} w_j(dev)} \quad (8)$$

To further improve the similarity score, we apply absolute discounting smoothing when calculating the probability distributions  $p_i(f, e)$ . We subtract a discounting value  $\alpha$  from the non-zero  $p_i(f, e)$ , and equally allocate the remaining probability mass to the zero probabilities. We carry out the same smoothing for the probability distributions  $p_i(dev)$ . The smoothing constant  $\alpha$  is determined empirically on held-out data.

The Bhattacharyya coefficient (BC) is defined as follows:

$$BC(dev; f, e) = \sum_{i=0}^{i=C} \sqrt{p_i(dev) \cdot p_i(f, e)} \quad (9)$$

The other two similarity functions we also tested are JSD and cosine (Cos). They are defined as follows:

$$JSD(dev; f, e) = \quad (10)$$

$$\frac{1}{2} \left[ \sum_{i=1}^{i=C} p_i(dev) \log \frac{2p_i(dev)}{p_i(dev) + p_i(f, e)} + \sum_{i=1}^{i=C} p_i(f, e) \log \frac{2p_i(f, e)}{p_i(dev) + p_i(f, e)} \right]$$

$$Cos(dev; f, e) = \frac{\sum_i p_i(dev) \cdot p_i(f, e)}{\sqrt{\sum_i p_i^2(dev)} \sqrt{\sum_i p_i^2(f, e)}} \quad (11)$$

### 3 Experiments

#### 3.1 Data setting

We carried out experiments in two different settings, both involving data from NIST Open MT 2012.<sup>2</sup> The first setting is based on data from the Chinese to English constrained track, comprising about 283 million English running words. We manually grouped the training data into 14 corpora according to genre and origin. Table 1 summarizes information about the training, development and test sets; we show the sizes of the training subcorpora in number of words as a percentage of all training data. Most training subcorpora consist of parallel sentence pairs. The *isi* and *lex&ne* corpora are exceptions: the former is extracted from comparable data, while the latter is a lexicon that includes many named entities. The development set (*tune*) was taken from the NIST 2005 evaluation set, augmented with some web-genre material reserved from other NIST corpora.

The second setting uses NIST 2012 Arabic to English data, but excludes the UN data. There are about 47.8 million English running words in these

training data. We manually grouped the training data into 7 groups according to genre and origin. Table 2 summarizes information about the training, development and test sets. Note that for this language pair, the comparable *isi* data represent a large proportion of the training data: 72% of the English words. We use the evaluation sets from NIST 2006, 2008, and 2009 as our development set and two test sets, respectively.

#### 3.2 System

Experiments were carried out with an in-house phrase-based system similar to Moses (Koehn et al., 2007). Each corpus was word-aligned using IBM2, HMM, and IBM4 models, and the phrase table was the union of phrase pairs extracted from these separate alignments, with a length limit of 7. The translation model (TM) was smoothed in both directions with KN smoothing (Chen et al., 2011). We use the hierarchical lexicalized reordering model (RM) (Galley and Manning, 2008), with a distortion limit of 7. Other features include lexical weighting in both directions, word count, a distance-based RM, a 4-gram LM trained on the target side of the parallel data, and a 6-gram English *Gigaword* LM. The system was tuned with batch lattice MIRA (Cherry and Foster, 2012).

#### 3.3 Results

For the baseline, we simply concatenate all training data. We have also compared our approach to two widely used TM domain adaptation ap-

proaches. One is the log-linear combination of TMs trained on each subcorpus (Koehn and Schroeder, 2007), with weights of each model tuned under minimal error rate training using MIRA. The other is a linear combination of TMs trained on each subcorpus, with the weights of each model learned with an EM algorithm to maximize the likelihood of joint empirical phrase pair counts for in-domain dev data. For details, refer to (Foster and Kuhn, 2007).

The value of  $\lambda$  and  $\alpha$  (see Eq 4 and Section 2.1) are determined by the performance on the dev set of the Arabic-to-English system. For both Arabic-to-English and Chinese-to-English experiment, these values obtained on Arabic dev were used to obtain the results below:  $\lambda$  was set to 8, and  $\alpha$  was set to 0.01. (Later, we ran an experiment on Chinese-to-English with  $\lambda$  and  $\alpha$  tuned specifically for that language pair, but the performance for the Chinese-English system only improved by a tiny, insignificant amount).

Our metric is case-insensitive IBM BLEU (Papineni et al., 2002), which performs matching of n-grams up to  $n = 4$ ; we report BLEU scores averaged across both test sets NIST06 and NIST08 for Chinese; NIST08 and NIST09 for Arabic. Following (Koehn, 2004), we use the bootstrap-resampling test to do significance testing. In tables 3 to 5, \* and \*\* denote significant gains over the baseline at  $p < 0.05$  and  $p < 0.01$  levels, respectively.

We first compare the performance of different similarity functions: cosine (COS), Jensen-Shannon divergence (JSD) and Bhattacharyya coefficient (BC). The results are shown in Table 3. All three functions obtained improvements. Both COS and BC yield statistically significant improvements over the baseline, with BC performing better than COS by a further statistically significant margin. The Bhattacharyya coefficient is explicitly designed to measure the overlap between the probability distributions of two statistical samples or populations, which is precisely what we are trying to do here: we are trying to reward phrase pairs whose distribution is similar to that of the dev set. Thus, its superior performance in these experiments is not unexpected.

In the next set of experiments, we compared VSM adaptation using the BC similarity function with the baseline which concatenates all training data and with log-linear and linear TM mixtures

system	Chinese	Arabic
baseline	31.7	46.8

Table 4: Results for variants of adaptation.

whose components are based on subcorpora. Table 4 shows that log-linear combination performs worse than the baseline: the tuning algorithm failed to optimize the log-linear combination even on dev set. For Chinese, the BLEU score of the dev set on the baseline system is 27.3, while on the log-linear combination system, it is 24.0; for Arabic, the BLEU score of the dev set on the baseline system is 46.8, while on the log-linear combination system, it is 45.4. We also tried adding the global model to the loglinear combination and it didn't improve over the baseline for either language pair. Linear mixture was significantly better than the baseline at the  $p < 0.01$  level for both language pairs. Since our approach, VSM, performed better than the linear mixture for both pairs, it is of course also significantly better than the baseline at the  $p < 0.01$  level.

This raises the question: is VSM performance significantly better than that of a linear mixture of TMs? The answer (not shown in the table) is that for Arabic to English, VSM performance is better than linear mixture at the  $p < 0.01$  level. For Chinese to English, the argument for the superiority of VSM over linear mixture is less convincing: there is significance at the  $p < 0.05$  for one of the two test sets (NIST06) but not for the other (NIST08). At any rate, these results establish that VSM adaptation is clearly superior to linear mixture TM adaptation, for one of the two language pairs.

In Table 4, the VSM results are based on the

system	Chinese	Arabic
baseline	31.7	46.8
linear tm	32.7**	47.5**
vsm, joint	33.0**	48.4**
vsm, src-marginal	32.2*	47.3*
vsm, tgt-marginal	32.6**	47.6**
vsm, src+tgt (2 feat.)	32.7**	48.2**
vsm, joint+src (2 feat.)	32.9**	48.4**
vsm, joint+tgt (2 feat.)	32.9**	48.4**
<b>vsm, joint+src+tgt (3 feat.)</b>	<b>33.1**</b>	<b>48.6**</b>

Table 5: Results for adaptation based on joint or marginal counts.

vector of the joint counts of the phrase pair. In the next experiment, we replace the joint counts with the source or target marginal counts. In Table 5, we first show the results based on source and target marginal counts, then the results of using feature sets drawn from three decoder VSM features: a joint count feature, a source marginal count feature, and a target marginal count feature. For instance, the last row shows the results when all three features are used (with their weights tuned by MIRA). It looks as though the source and target marginal counts contain useful information. The best performance is obtained by combining all three sources of information. The 3-feature version of VSM yields +1.8 BLEU over the baseline for Arabic to English, and +1.4 BLEU for Chinese to English.

When we compared two sets of results in Table 4, the joint count version of VSM and linear mixture of TMs, we found that for Arabic to English, VSM performance is better than linear mixture at the  $p < 0.01$  level; the Chinese to English significance test was inconclusive (VSM found to be superior to linear mixture at  $p < 0.05$  for NIST06 but not for NIST08). We now have somewhat better results for the 3-feature version of VSM shown in Table 5. How do these new results affect the VSM vs. linear mixture comparison? Naturally, the conclusions for Arabic don't change. For Chinese, 3-feature VSM is now superior to linear mixture at  $p < 0.01$  on NIST06 test set, but 3-feature VSM still doesn't have a statistically significant edge over linear mixture on NIST08 test set. A fair summary would be that 3-feature VSM adaptation is decisively superior to linear mixture adaptation for Arabic to English, and highly competitive with linear mixture adap-

tation for Chinese to English.

Our last set of experiments examined the question: when added to a system that already has some form of linear mixture model adaptation, does VSM improve performance? In (Foster and Kuhn, 2007), two kinds of linear mixture were described: linear mixture of language models (LMs), and linear mixture of translation models (TMs). Some of the results reported above involved linear TM mixtures, but none of them involved linear LM mixtures. Table 6 shows the results of different combinations of VSM and mixture models. \* and \*\* denote significant gains over the row *no vsm* at  $p < 0.05$  and  $p < 0.01$  levels, respectively. This means that in the table, the baseline within each box containing three results is the topmost result in the box. For instance, with an initial Chinese system that employs linear mixture LM adaptation (lin-lm) and has a BLEU of 32.1, adding 1-feature VSM adaptation (+vsm, joint) improves performance to 33.1 (improvement significant at  $p < 0.01$ ), while adding 3-feature VSM instead (+vsm, 3 feat.) improves performance to 33.2 (also significant at  $p < 0.01$ ). For Arabic, including either form of VSM adaptation always improves performance with significance at  $p < 0.01$ , even over a system including both linear TM and linear LM adaptation. For Chinese, adding VSM still always yields an improvement, but the improvement is not significant if linear TM adaptation is already in the system. These results show that combining VSM adaptation and either or both kinds of linear mixture adaptation never hurts performance, and often improves it by a significant amount.

### 3.4 Informal Data Analysis

To get an intuition for how VSM adaptation improves BLEU scores, we compared outputs from the baseline and VSM-adapted system (“vsm, joint” in Table 5) on the Chinese test data. We focused on examples where the two systems had translated the same source-language (Chinese) phrase  $s$  differently, and where the target-language (English) translation of  $s$  chosen by the VSM-adapted system,  $t_V$ , had a higher Bhattacharyya score for similarity with the dev set than did the phrase that was chosen by the baseline system,  $t_B$ . Thus, we ignored differences in the two translations that might have been due to the secondary effects of VSM adaptation (such as a different tar-

		no-lin-adap	lin-lm	lin-tm	lin-lm+lin-tm
Chinese	no vsm	31.7	32.1	32.7	33.1
	+vsm, joint	33.0**	33.1**	33.0	33.3
	+vsm, 3 feat.	33.1**	33.2**	33.1	<b>33.4</b>
Arabic	no vsm	46.8	47.0	47.5	47.7
	+vsm, joint	48.4**	48.7**	48.6**	48.8**
	+vsm, 3 feat.	48.6**	48.8**	48.7**	<b>48.9**</b>

Table 6: Results of combining VSM and linear mixture adaptation. “lin-lm” is linear language model adaptation, “lin-tm” is linear translation model adaptation. \* and \*\* denote significant gains over the row “no vsm” at  $p < 0.05$  and  $p < 0.01$  levels, respectively.

get phrase being preferred by the language model in the VSM-adapted system from the one preferred in the baseline system because of a Bhattacharyya-mediated change in the phrase preceding it).

An interesting pattern soon emerged: the VSM-adapted system seems to be better than the baseline at choosing among synonyms in a way that is appropriate to the genre or style of a text. For instance, where the text to be translated is from an informal genre such as weblog, the VSM-adapted system will often pick an informal word where the baseline picks a formal word with the same or similar meaning, and vice versa where the text to be translated is from a more formal genre. To our surprise, we saw few examples where the VSM-adapted system did a better job than the baseline of choosing between two words with different meaning, but we saw many examples where the VSM-adapted system did a better job than the baseline of choosing between two words that both have the same meaning according to considerations of style and genre.

Two examples are shown in Table 7. In the first example, the first two lines show that VSM finds that the Chinese-English phrase pair (殴打, assaulted) has a Bhattacharyya (BC) similarity of 0.556163 to the dev set, while the phrase pair (殴打, beat) has a BC similarity of 0.780787 to the dev. In this situation, the VSM-adapted system thus prefers “beat” to “assaulted” as a translation for 殴打. The next four lines show the source sentence (SRC), the reference (REF), the baseline output (BSL), and the output of the VSM-adapted system. Note that the result of VSM adaptation is that the rather formal word “assaulted” is replaced by its informal near-synonym “beat” in the translation of an informal weblog text.

“apprehend” might be preferable to “arrest” in a legal text. However, it looks as though the

VSM-adapted system has learned from the dev that among synonyms, those more characteristic of news stories than of legal texts should be chosen: it therefore picks “arrest” over its synonym “apprehend”.

What follows is a partial list of pairs of phrases (all single words) from our system’s outputs, where the baseline chose the first member of a pair and the VSM-adapted system chose the second member of the pair to translate the same Chinese phrase into English (because the second word yields a better BC score for the dev set we used). It will be seen that nearly all of the pairs involve synonyms or near-synonyms rather than words with radically different senses (one exception below is “center” vs “heart”). Instead, the differences between the two words tend to be related to genre or style: gunmen-mobsters, champion-star, updated-latest, caricatures-cartoons, spill-leakage, hiv-aids, inkling-clues, behaviour-actions, deceit-trick, brazen-shameless, aristocratic-noble, circumvent-avoid, attack-criticized, descent-born, hasten-quickly, precipice-cliff, center-heart, blessing-approval, imminent-approaching, stormed-rushed, etc.

## 4 Conclusions and future work

This paper proposed a new approach to domain adaptation in statistical machine translation, based on vector space models (VSMs). This approach measures the similarity between a vector representing a particular phrase pair in the phrase table and a vector representing the dev set, yielding a feature associated with that phrase pair that will be used by the decoder. The approach is simple, easy to implement, and computationally cheap. For the two language pairs we looked at, it provided a large performance improvement over a non-adaptive baseline, and also compared

1	phrase pairs	殴打 ↔ assaulted (0.556163) 殴打 ↔ beat (0.780787)
	SRC	...那些殴打村民的地皮流氓...
	REF	... those local ruffians and hooligans who beat up villagers ...
	BSL	... those who assaulted the villagers land hooligans ...
	VSM	... hooligans who beat the villagers ...
2	phrase pairs	缉拿 ↔ apprehend (0.286533) 缉拿 ↔ arrest (0.603342)
	SRC	... 缉拿凶手并且将之绳之以法。
	REF	... catch the killers and bring them to justice .
	BSL	... apprehend the perpetrators and bring them to justice .
	VSM	... arrest the perpetrators and bring them to justice .

Table 7: Examples show that VSM chooses translations according to considerations of style and genre.

favourably with linear mixture adaptation techniques.

Furthermore, VSM adaptation can be exploited in a number of different ways, which we have only begun to explore. In our experiments, we based the vector space on subcorpora defined by the nature of the training data. This was done purely out of convenience: there are many, many ways to define a vector space in this situation. An obvious and appealing one, which we intend to try in future, is a vector space based on a bag-of-words topic model. A feature derived from this topic-related vector space might complement some features derived from the subcorpora which we explored in the experiments above, and which seem to exploit information related to genre and style.

## Abstract

We present a method for automatically generating input parsers from English specifications of input file formats. We use a Bayesian generative model to capture relevant natural language phenomena and translate the English specification into a specification tree, which is then translated into a C++ input parser. We model the problem as a joint dependency parsing and semantic role labeling task. Our method is based on two sources of information: (1) the correlation between the text and the specification tree and (2) noisy supervision as determined by the success of the generated C++ parser in reading input examples. Our results show that our approach achieves 80.0% F-Score accuracy compared to an F-Score of 66.7% produced by a state-of-the-art semantic parser on a dataset of input format specifications from the ACM International Collegiate Programming Contest (which were written in English for humans with no intention of providing support for automated processing).<sup>1</sup>

## 1 Introduction

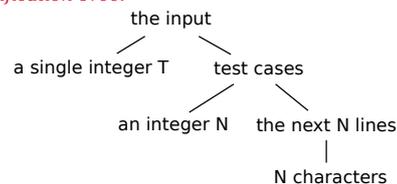

The general problem of translating natural language specifications into executable code has been around since the field of computer science was founded. Early attempts to solve this problem produced what were essentially verbose, clumsy, and ultimately unsuccessful versions of standard formal programming languages. In recent years

<sup>1</sup>The code, data, and experimental setup for this research are available at <http://groups.csail.mit.edu/rbg/code/nl2p>

### (a) Text Specification:

The input contains a single integer  $T$  that indicates the number of test cases. Then follow the  $T$  cases. Each test case begins with a line contains an integer  $N$ , representing the size of wall. The next  $N$  lines represent the original wall. Each line contains  $N$  characters. The  $j$ -th character of the  $i$ -th line figures out the color ...

Figure 1: An example of (a) one natural language specification describing program input data; (b) the corresponding specification tree representing the program input structure; and (c) two input examples

however, researchers have had success addressing specific aspects of this problem. Recent advances in this area include the successful translation of natural language commands into database queries (Wong and Mooney, 2007; Zettlemoyer and Collins, 2009; Poon and Domingos, 2009; Liang et al., 2011) and the successful mapping of natural language instructions into Windows command sequences (Branavan et al., 2009; Branavan et al., 2010).

In this paper we explore a different aspect of this general problem: the translation of natural language input specifications into executable code that correctly parses the input data and generates

data structures for holding the data. The need to automate this task arises because input format specifications are almost always described in natural languages, with these specifications then manually translated by a programmer into the code for reading the program inputs. Our method highlights potential to automate this translation, thereby eliminating the manual software development overhead.

Consider the text specification in Figure 1a. If the desired parser is implemented in C++, it should create a C++ class whose instance objects hold the different fields of the input. For example, one of the fields of this class is an integer, i.e., “a single integer T” identified in the text specification in Figure 1a. Instead of directly generating code from the text specification, we first translate the specification into a *specification tree* (see Figure 1b), then map this tree into parser code (see Figure 2). We focus on the translation from the text specification to the specification tree.<sup>2</sup>

We assume that each text specification is accompanied by a set of input examples that the desired input parser is required to successfully read. In standard software development contexts, such input examples are usually available and are used to test the correctness of the input parser. Note that this source of supervision is noisy — the generated parser may still be incorrect even when it successfully reads all of the input examples. Specifically, the parser may interpret the input examples differently from the text specification. For example, the program input in Figure 1c can be interpreted simply as a list of strings. The parser may also fail to parse some correctly formatted input files not in the set of input examples. Therefore, our goal is to design a technique that can effectively learn from this weak supervision.

We model our problem as a joint dependency parsing and role labeling task, assuming a Bayesian generative process. The distribution over the space of specification trees is informed by two sources of information: (1) the correlation between the text and the corresponding specification tree and (2) the success of the generated parser in reading input examples. Our method uses a joint probability distribution to take both of these sources of information into account, and uses a sampling framework for the inference of specifi-

<sup>2</sup>During the second step of the process, the specification tree is deterministically translated into code.

cation trees given text specifications. A specification tree is rejected in the sampling framework if the corresponding code fails to successfully read all of the input examples. The sampling framework also rejects the tree if the text/specification tree pair has low probability.

We evaluate our method on a dataset of input specifications from ACM International Collegiate Programming Contests, along with the corresponding input examples. These specifications were written for human programmers with no intention of providing support for automated processing. However, when trained using the noisy supervision, our method achieves substantially more accurate translations than a state-of-the-art semantic parser (Clarke et al., 2010) (specifically, 80.0% in F-Score compared to an F-Score of 66.7%). The strength of our model in the face of such weak supervision is also highlighted by the fact that it retains an F-Score of 77% even when only one input example is provided for each input

specification.

## 2 Related Work

### Learning Meaning Representation from Text

Mapping sentences into structural meaning representations is an active and extensively studied task in NLP. Examples of meaning representations considered in prior research include logical forms based on database query (Tang and Mooney, 2000; Zettlemoyer and Collins, 2005; Kate and Mooney, 2007; Wong and Mooney, 2007; Poon and Domingos, 2009; Liang et al., 2011; Goldwasser et al., 2011), semantic frames (Das et al., 2010; Das and Smith, 2011) and database records (Chen and Mooney, 2008; Liang et al., 2009).

**Learning Semantics from Feedback** Our approach is related to recent research on learning from indirect supervision. Examples include leveraging feedback available via responses from a virtual world (Branavan et al., 2009) or from executing predicted database queries (Chang et al., 2010; Clarke et al., 2010). While Branavan et al. (2009) formalize the task as a sequence of decisions and learns from local rewards in a Reinforcement Learning framework, our model learns to predict the whole structure at a time. Another difference is the way our model incorporates the noisy feedback. While previous approaches rely on the feedback to train a *discriminative* prediction model, our approach models a *generative process* to guide structure predictions when the feedback is noisy or unavailable.

**NLP in Software Engineering** Researchers have recently developed a number of approaches that apply natural language processing techniques to software engineering problems. Examples include analyzing API documents to infer API li-

brary specifications (Zhong et al., 2009; Pandita et al., 2012) and analyzing code comments to detect concurrency bugs (Tan et al., 2007; Tan et al., 2011). This research analyzes natural language in documentation or comments to better understand existing application programs. Our mechanism, in contrast, automatically generates parser programs from natural language input format descriptions.

## 3 Problem Formulation

The task of translating text specifications to input parsers consists of two steps, as shown in Figure 3. First, given a text specification describing an input format, we wish to infer a parse tree (which we call a *specification tree*) implied by the text. Second, we convert each specification tree into formal grammar of the input format (represented in Backus-Naur Form) and then generate code that reads the input into data structures. In this paper, we focus on the NLP techniques used in the first step, i.e., learning to infer the specification trees from text. The second step is achieved using a deterministic rule-based tool.<sup>3</sup>

As input, we are given a set of text specifications  $w = \{w^1, \dots, w^N\}$ , where each  $w^i$  is a text specification represented as a sequence of noun phrases  $\{w_k^i\}$ . We use UIUC shallow parser to preprocess each text specification into a sequence of the noun phrases.<sup>4</sup> In addition, we are given a set of input examples for each  $w^i$ . We use these examples to test the generated input parsers to re-

<sup>3</sup>Specifically, the specification tree is first translated into the grammar using a set of rules and seed words that identifies basic data types such as `int`. Our implementation then generates a top-down parser since the generated grammar is simple. In general, standard techniques such as Bison and Yacc (Johnson, 1979) can generate bottom-up parsers given such grammar.

<sup>4</sup><http://cogcomp.cs.illinois.edu/demo/shallowparse/?id=7>

ject incorrect predictions made by our probabilistic model.

We formalize the learning problem as a dependency parsing and role labeling problem. Our model predicts specification trees  $\mathbf{t} = \{t^1, \dots, t^N\}$  for the text specifications, where each specification tree  $t^i$  is a dependency tree over noun phrases  $\{w_k^i\}$ . In general many program input formats are nested tree structures, in which the tree root denotes the entire chunk of program input data and each chunk (tree node) can be further divided into sub-chunks or primitive fields that appear in the program input (see Figure 3). Therefore our objective is to predict a dependency tree that correctly represents the structure of the program input.

In addition, the role labeling problem is to assign a tag  $z_k^i$  to each noun phrase  $w_k^i$  in a specification tree, indicating whether the phrase is a *key phrase* or a *background phrase*. Key phrases are named entities that identify input fields or input chunks appear in the program input data, such as “the input” or “the following lines” in Figure 3b. In contrast, background phrases do not define input fields or chunks. These phrases are used to organize the document (e.g., “your program”) or to refer to key phrases described before (e.g., “each line”).

## 4 Model

We use two kinds of information to bias our model: (1) the quality of the generated code as measured by its ability to read the given input examples and (2) the features over the observed text  $w^i$  and the hidden specification tree  $t^i$  (this is standard in traditional parsing problems). We combine these two kinds of information into a Bayesian generative model in which the code quality of the specification tree is captured by the prior probability  $P(\mathbf{t})$  and the feature observations are encoded in the likelihood probability  $P(\mathbf{w}|\mathbf{t})$ . The inference jointly optimizes these two factors:

$$P(\mathbf{t}|\mathbf{w}) \propto P(\mathbf{t}) \cdot P(\mathbf{w}|\mathbf{t}).$$

**Modeling the Generative Process.** We assume the generative model operates by first generating the model parameters from a set of Dirichlet distributions. The model then generates text specification trees. Finally, it generates natural language feature observations conditioned on the hidden specification trees.

The generative process is described formally as follows:

- **Generating Model Parameters:** For every pair of feature type  $f$  and phrase tag  $z$ , draw a multinomial distribution parameter  $\theta_f^z$  from a Dirichlet prior  $P(\theta_f^z)$ . The multinomial parameters provide the probabilities of observing different feature values in the text.
- **Generating Specification Tree:** For each text specification, draw a specification tree  $t$  from all possible trees over the sequence of noun phrases in this specification. We denote the probability of choosing a particular specification tree  $t$  as  $P(t)$ .

Intuitively, this distribution should assign high probability to good specification trees that can produce C++ code that reads all input examples without errors, we therefore define  $P(t)$  as follows:<sup>5</sup>

$$P(t) = \frac{1}{Z} \cdot \begin{cases} 1 & \text{the input parser of tree } t \\ & \text{reads all input examples} \\ & \text{without error} \\ \epsilon & \text{otherwise} \end{cases}$$

where  $Z$  is a normalization factor and  $\epsilon$  is empirically set to  $10^{-6}$ . In other words,  $P(\cdot)$  treats all specification trees that pass the input example test as equally probable candidates and inhibits the model from generating trees which fail the test. Note that we do not know this distribution a priori until the specification trees are evaluated by testing the corresponding C++ code. Because it is intractable to test all possible trees and all possible generated code for a text specification, we never explicitly compute the normalization factor  $1/Z$  of this distribution. We therefore use sampling methods to tackle this problem during inference.

- **Generating Features:** The final step generates lexical and contextual features for each tree. For each phrase  $w_k$  associated with tag  $z_k$ , let  $w_p$  be its parent phrase in the tree and  $w_s$  be the non-background sibling phrase to its left in the tree. The model generates the corresponding set of features  $\phi(w_p, w_s, w_k)$  for each text phrase tuple  $(w_p, w_s, w_k)$ , with

<sup>5</sup>When input examples are not available,  $P(t)$  is just uniform distribution.

probability  $P(\phi(w_p, w_s, w_k))$ . We assume that each feature  $f_j$  is generated independently:

$$\begin{aligned} P(w|t) &= P(\phi(w_p, w_s, w_k)) \\ &= \prod_{f_j \in \phi(w_p, w_s, w_k)} \theta_{f_j}^{z_k} \end{aligned}$$

where  $\theta_{f_j}^{z_k}$  is the  $j$ -th component in the multinomial distribution  $\theta_f^{z_k}$  denoting the probability of observing a feature  $f_j$  associated with noun phrase  $w_k$  labeled with tag  $z_k$ . We define a range of features that capture the correspondence between the input format and its description in natural language. For example, at the unigram level we aim to capture that noun phrases containing specific words such as “cases” and “lines” may be key phrases (correspond to data chunks appear in the input), and that verbs such as “contain” may indicate that the next noun phrase is a key phrase.

The full joint probability of a set  $\mathbf{w}$  of  $N$  specifications and hidden text specification trees  $\mathbf{t}$  is defined as:

$$\begin{aligned} P(\theta, \mathbf{t}, \mathbf{w}) &= P(\theta) \prod_{i=1}^N P(t^i) P(w^i | t^i, \theta) \\ &= P(\theta) \prod_{i=1}^N P(t^i) \prod_k P(\phi(w_p^i, w_s^i, w_k^i)). \end{aligned}$$

**Learning the Model** During inference, we want to estimate the hidden specification trees  $\mathbf{t}$  given the observed natural language specifications  $\mathbf{w}$ , after integrating the model parameters out, i.e.

$$\mathbf{t} \sim P(\mathbf{t} | \mathbf{w}) = \int_{\theta} P(\mathbf{t}, \theta | \mathbf{w}) d\theta.$$

We use Gibbs sampling to sample variables  $\mathbf{t}$  from this distribution. In general, the Gibbs sampling algorithm randomly initializes the variables and then iteratively solves one subproblem at a time. The subproblem is to sample only one variable conditioned on the current values of all other variables. In our case, we sample one hidden specification tree  $t^i$  while holding all other trees  $\mathbf{t}^{-i}$  fixed:

$$t^i \sim P(t^i | \mathbf{w}, \mathbf{t}^{-i}) \quad (1)$$

where  $\mathbf{t}^{-i} = (t^1, \dots, t^{i-1}, t^{i+1}, \dots, t^N)$ .

However directly solving the subproblem (1) in our case is still hard, we therefore use a Metropolis-Hastings sampler that is similarly applied in traditional sentence parsing problems. Specifically, the Hastings sampler approximates (1) by first drawing a new  $t^{i'}$  from a tractable proposal distribution  $Q$  instead of  $P(t^i | \mathbf{w}, \mathbf{t}^{-i})$ . We choose  $Q$  to be:

$$Q(t^{i'} | \theta', w^i) \propto P(w^i | t^{i'}, \theta'). \quad (2)$$

Then the probability of accepting the new sample is determined using the typical Metropolis Hastings process. Specifically,  $t^{i'}$  will be accepted to replace the last  $t^i$  with probability:

$$\begin{aligned} R(t^i, t^{i'}) &= \min \left\{ 1, \frac{P(t^{i'} | \mathbf{w}, \mathbf{t}^{-i}) Q(t^i | \theta', w^i)}{P(t^i | \mathbf{w}, \mathbf{t}^{-i}) Q(t^{i'} | \theta', w^i)} \right\} \\ &= \min \left\{ 1, \frac{P(t^{i'}, \mathbf{t}^{-i}, \mathbf{w}) P(w^i | t^i, \theta')}{P(t^i, \mathbf{t}^{-i}, \mathbf{w}) P(w^i | t^{i'}, \theta')} \right\}, \end{aligned}$$

in which the normalization factors  $1/Z$  are cancelled out. We choose  $\theta'$  to be the parameter expectation based on the current observations, i.e.  $\theta' = E[\theta | \mathbf{w}, \mathbf{t}^{-i}]$ , so that the proposal distribution is close to the true distribution. This sampling algorithm with a changing proposal distribution has been shown to work well in practice (Johnson and Griffiths, 2007; Cohn et al., 2010; Naseem and Barzilay, 2011). The algorithm pseudo code is shown in Algorithm 1.

To sample from the proposal distribution (2) efficiently, we implement a dynamic programming algorithm which calculates marginal probabilities of all subtrees. The algorithm works similarly to the inside algorithm (Baker, 1979), except that we do not assume the tree is binary. We therefore perform one additional dynamic programming step that sums over all possible segmentations of each span. Once the algorithm obtains the marginal probabilities of all subtrees, a specification tree can be drawn recursively in a top-down manner.

Calculating  $P(\mathbf{t}, \mathbf{w})$  in  $R(t, t')$  requires integrating the parameters  $\theta$  out. This has a closed form due to the Dirichlet-multinomial conjugacy:

$$\begin{aligned} P(\mathbf{t}, \mathbf{w}) &= P(\mathbf{t}) \cdot \int_{\theta} P(\mathbf{w} | \mathbf{t}, \theta) P(\theta) d\theta \\ &\propto P(\mathbf{t}) \cdot \prod \text{Beta}(\text{count}(f) + \alpha). \end{aligned}$$

Here  $\alpha$  are the Dirichlet hyper parameters and  $\text{count}(f)$  are the feature counts observed in data  $(\mathbf{t}, \mathbf{w})$ . The closed form is a product of the Beta functions of each feature type.

Feature Type	Description	Feature Value
Word	each word in noun phrase $w_k$	lines, VAR
Verb	verbs in noun phrase $w_k$ and the verb phrase before $w_k$	contains
Distance	sentence distance between $w_k$ and its parent phrase $w_p$	1
Coreference	$w_k$ share duplicate nouns or variable names with $w_p$ or $w_s$	True

Table 1: Example of feature types and values. To deal with sparsity, we map variable names such as “N” and “X” into a category word “VAR” in word features.

**Input:** Set of text specification documents  
 $\mathbf{w} = \{w^1, \dots, w^N\}$ ,  
Number of iterations  $T$

- 1 Randomly initialize specification trees  
 $\mathbf{t} = \{t^1, \dots, t^N\}$
- 2 **for**  $iter = 1 \dots T$  **do**
- 3   *Sample tree  $t^i$  for  $i$ -th document:*
- 4   **for**  $i = 1 \dots N$  **do**
- 5     *Estimate model parameters:*
- 6      $\theta' = E[\theta' | \mathbf{w}, \mathbf{t}^{-i}]$
- 7     *Sample a new specification tree from distribution  $Q$ :*
- 8      $t' \sim Q(t' | \theta', w^i)$
- 9     *Generate and test code, and return feedback:*
- 10      $f' = \text{CodeGenerator}(w^i, t')$
- 11     *Calculate accept probability  $r$ :*
- 12      $r = R(t^i, t')$
- 13     *Accept the new tree with probability  $r$ :*
- 14     With probability  $r$ :  $t^i = t'$
- 15   **end**
- 16 **end**
- 17 *Produce final structures:*
- 18 **return**  $\{t^i \text{ if } t^i \text{ gets positive feedback}\}$

Algorithm 1: The sampling framework for learning the model.

**Model Implementation:** We define several types of features to capture the correlation between the hidden structure and its expression in natural language. For example, verb features are introduced because certain preceding verbs such as “contains” and “consists” are good indicators of key phrases. There are 991 unique features in total in our experiments. Examples of features appear in Table 1.

We use a small set of 8 seed words to bias the search space. Specifically, we require each leaf key phrase to contain at least one seed word that identifies the C++ primitive data type (such as “integer”, “float”, “byte” and “string”).

We also encourage a phrase containing the word “input” to be the root of the tree (for example, “the input file”) and each coreference phrase to be a

Total # of words	7330
Total # of noun phrases	1829
Vocabulary size	781
Avg. # of words per sentence	17.29
Avg. # of noun phrase per document	17.26
Avg. # of possible trees per document	52K
Median # of possible trees per document	79
Min # of possible trees per document	1
Max # of possible trees per document	2M

background phrase (for example, “each test case” after mentioning “test cases”), by initially adding pseudo counts to Dirichlet priors.

## 5 Experimental Setup

**Datasets:** Our dataset consists of problem descriptions from ACM International Collegiate Programming Contests.<sup>6</sup> We collected 106 problems from ACM-ICPC training websites.<sup>7</sup> From each problem description, we extracted the portion that provides input specifications. Because the test input examples are not publicly available on the ACM-ICPC training websites, for each specification, we wrote simple programs to generate 100 random input examples.

Table 2 presents statistics for the text specification set. The data set consists of 424 sentences, where an average sentence contains 17.3 words. The data set contains 781 unique words. The length of each text specification varies from a single sentence to eight sentences. The difference between the average and median number of trees is large. This is because half of the specifications are relatively simple and have a small number of possible trees, while a few difficult specifications have over thousands of possible trees (as the number of trees grows exponentially when the text length increases).

**Evaluation Metrics:** We evaluate the model

<sup>6</sup>Official Website: <http://cm.baylor.edu/welcome.icpc>

<sup>7</sup>PKU Online Judge: <http://poj.org/>; UVA Online Judge: <http://uva.onlinejudge.org/>

performance in terms of its success in generating a formal grammar that correctly represents the input format (see Figure 3c). As a gold annotation, we construct formal grammars for all text specifications. Our results are generated by automatically comparing the machine-generated grammars with their golden counterparts. If the formal grammar is correct, then the generated C++ parser will correctly read the input file into corresponding C++ data structures.

We use Recall and Precision as evaluation measures:

$$\text{Recall} = \frac{\# \text{ correct structures}}{\# \text{ text specifications}}$$

$$\text{Precision} = \frac{\# \text{ correct structures}}{\# \text{ produced structures}}$$

where the produced structures are the positive structures returned by our framework whose corresponding code successfully reads all input examples (see Algorithm 1 line 18). Note the number of produced structures may be less than the number of text specifications, because structures that fail the input test are not returned.

**Baselines:** To evaluate the performance of our model, we compare against four baselines.

The *No Learning* baseline is a variant of our model that selects a specification tree without learning feature correspondence. It continues sampling a specification tree for each text specification until it finds one which successfully reads all of the input examples.

The second baseline *Aggressive* is a state-of-the-art semantic parsing framework (Clarke et al., 2010).<sup>8</sup> The framework repeatedly predicts hidden structures (specification trees in our case) using a structure learner, and trains the structure learner based on the execution feedback of its predictions. Specifically, at each iteration the structure learner predicts the most plausible specification tree for each text document:

$$t^i = \operatorname{argmax}_t f(w^i, t).$$

Depending on whether the corresponding code reads all input examples successfully or not, the  $(w^i, t^i)$  pairs are added as an positive or negative sample to populate a training set. After each iteration the structure learner is re-trained with the training samples to improve the prediction accuracy. In our experiment, we follow (Clarke et al.,

<sup>8</sup>We take the name *Aggressive* from this paper.

Model	Recall	Precision	F-Score
No Learning	52.0	57.2	54.5
Aggressive	63.2	70.5	66.7
<b>Full Model</b>	<b>72.5</b>	<b>89.3</b>	<b>80.0</b>
Full Model (Oracle)	72.5	100.0	84.1
Aggressive (Oracle)	80.2	100.0	89.0

Table 3: Average % Recall and % Precision of our model and all baselines over 20 independent runs.

2010) and choose a structural Support Vector Machine SVM<sup>struct</sup><sup>9</sup> as the structure learner.

The remaining baselines provide an upper bound on the performance of our model. The baseline *Full Model (Oracle)* is the same as our full model except that the feedback comes from an oracle which tells whether the specification tree is correct or not. We use this oracle information in the prior  $P(t)$  same as we use the noisy feedback. Similarly the baseline *Aggressive (Oracle)* is the *Aggressive* baseline with access to the oracle.

**Experimental Details:** Because no human annotation is required for learning, we train our model and all baselines on all 106 ICPC text specifications (similar to unsupervised learning). We report results averaged over 20 independent runs. For each of these runs, the model and all baselines run 100 iterations. For baseline *Aggressive*, in each iteration the SVM structure learner predicts one tree with the highest score for each text specification. If two different specification trees of the same text specification get positive feedback, we take the one generated in later iteration for evaluation.

## 6 Experimental Results

**Comparison with Baselines** Table 3 presents the performance of various models in predicting correct specification trees. As can be seen, our model achieves an F-Score of 80%. Our model therefore significantly outperforms the *No Learning* baseline (by more than 25%). Note that the *No Learning* baseline achieves a low Precision of 57.2%. This low precision reflects the noisiness of the weak supervision - nearly one half of the parsers produced by *No Learning* are actually incorrect even though they read all of the input examples without error. This comparison shows the importance of capturing correlations between the specification trees and their text descriptions.

<sup>9</sup>[www.cs.cornell.edu/people/tj/svm\\_light/svm\\_struct.html](http://www.cs.cornell.edu/people/tj/svm_light/svm_struct.html)

- (a) The input contains several testcases. Each is specified by two strings S, T of alphanumeric ASCII characters
- (b) The next N lines of the input file contain the Cartesian coordinates of watchtowers, one pair of coordinates per line.

Figure 4: Examples of dependencies and key phrases predicted by our model. Green marks correct key phrases and dependencies and red marks incorrect ones. The missing key phrases are marked in gray.

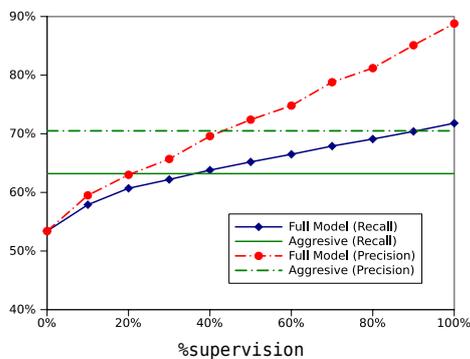

Figure 5: Precision and Recall of our model by varying the percentage of weak supervision. The green lines are the performance of *Aggressive* baseline trained with full weak supervision.

Because our model learns correlations via feature representations, it produces substantially more accurate translations.

While both the *Full Model* and *Aggressive* baseline use the same source of feedback, they capitalize on it in a different way. The baseline uses the noisy feedback to train features capturing the correlation between trees and text. Our model, in contrast, combines these two sources of information in a complementary fashion. This combination allows our model to filter false positive feedback and produce 13% more correct translations than the *Aggressive* baseline.

**Clean versus Noisy Supervision** To assess the impact of noise on model accuracy, we compare the *Full Model* against the *Full Model (Oracle)*. The two versions achieve very close performance (80% v.s 84% in F-Score), even though *Full Model* is trained with noisy feedback. This demonstrates the strength of our model in learning from such weak supervision. Interestingly, *Aggressive (Oracle)* outperforms our oracle model by a 5% margin. This result shows that when the supervision is reliable, the generative assumption limits our model’s ability to gain the same performance improvement as discriminative models.

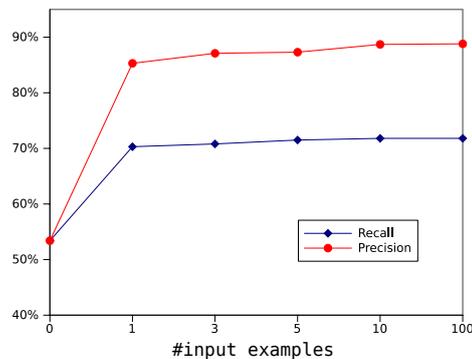

Figure 6: Precision and Recall of our model by varying the number of available input examples per text specification.

**Impact of Input Examples** Our model can also be trained in a fully unsupervised or a semi-supervised fashion. In real cases, it may not be possible to obtain input examples for all text specifications. We evaluate such cases by varying the amount of supervision, i.e. how many text specifications are paired with input examples. In each run, we randomly select text specifications and only these selected specifications have access to input examples. Figure 5 gives the performance of our model with 0% supervision (totally unsupervised) to 100% supervision (our full model). With much less supervision, our model is still able to achieve performance comparable with the *Aggressive* baseline.

We also evaluate how the number of provided input examples influences the performance of the model. Figure 6 indicates that the performance is largely insensitive to the number of input examples — once the model is given even one input example, its performance is close to the best performance it obtains with 100 input examples. We attribute this phenomenon to the fact that if the generated code is incorrect, it is unlikely to successfully parse any input.

**Case Study** Finally, we consider some text specifications that our model does not correctly trans-

late. In Figure 4a, the program input is interpreted as a list of character strings, while the correct interpretation is that the input is a list of string pairs. Note that both interpretations produce C++ input parsers that successfully read all of the input examples. One possible way to resolve this problem is to add other features such as syntactic dependencies between words to capture more language phenomena. In Figure 4b, the missing key phrase is not identified because our model is not able to ground the meaning of “pair of coordinates” to two integers. Possible future extensions to our model include using lexicon learning methods for mapping words to C++ primitive types for example “coordinates” to `<int, int>`.

## 7 Conclusion

It is standard practice to write English language specifications for input formats. Programmers read the specifications, then develop source code that parses inputs in the format. Known disadvantages of this approach include development cost, parsers that contain errors, specification misunderstandings, and specifications that become out of date as the implementation evolves.

Our results show that taking both the correlation between the text and the specification tree and the success of the generated C++ parser in reading input examples into account enables our method to correctly generate C++ parsers for 72.5% of our natural language specifications.

## Abstract

We study the task of entity linking for tweets, which tries to associate each mention in a tweet with a knowledge base entry. Two main challenges of this task are the dearth of information in a single tweet and the rich entity mention variations. To address these challenges, we propose a collective inference method that simultaneously resolves a set of mentions. Particularly, our model integrates three kinds of similarities, i.e., mention-entry similarity, entry-entry similarity, and mention-mention similarity, to enrich the context for entity linking, and to address irregular mentions that are not covered by the entity-variation dictionary. We evaluate our method on a publicly available data set and demonstrate the effectiveness of our method.

## 1 Introduction

Twitter is a widely used social networking service. With millions of active users and hundreds of millions of new published tweets every day<sup>1</sup>, it has become a popular platform to capture and transmit the human experiences of the moment. Many tweet related researches are inspired, from named entity recognition (Liu et al., 2012), topic detection (Mathioudakis and Koudas, 2010), clustering (Rosa et al., 2010), to event extraction (Grinev et al., 2009).

In this work, we study the entity linking task for tweets, which maps each entity mention in a tweet to a unique entity, i.e., an entry ID of a knowledge base like Wikipedia. Entity

linking task is generally considered as a bridge between unstructured text and structured machine-readable knowledge base, and represents a critical role in machine reading program (Singh et al., 2011). Entity linking for tweets is particularly meaningful, considering that tweets are often hard to read owing to its informal written style and length limitation of 140 characters.

Current entity linking methods are built on top of a large scale knowledge base such as Wikipedia. A knowledge base consists of a set of entities, and each entity can have a variation list<sup>2</sup>. To decide which entity should be mapped, they may compute: 1) the similarity between the context of a mention, e.g., a text window around the mention, and the content of an entity, e.g., the entity page of Wikipedia (Mihalcea and Csomai, 2007; Han and Zhao, 2009); 2) the coherence among the mapped entities for a set of related mentions, e.g. multiple mentions in a document (Milne and Witten, 2008; Kulkarni et al., 2009; Han and Zhao, 2010; Han et al., 2011).

Tweets pose special challenges to entity linking. First, a tweet is often too concise and too noisy to provide enough information for similarity computing, owing to its short and grass root nature. Second, tweets have rich variations of named entities<sup>3</sup>, and many of them fall out of the scope of the existing dictionaries mined from Wikipedia (called OOV mentions hereafter). On

<sup>2</sup>Entity variation lists can be extracted from the entity resolution pages of Wikipedia. For example, the link “<http://en.wikipedia.org/wiki/Svm>” will lead us to a resolution page, where “Svm” are linked to entities like “Space vector modulation” and “Support vector machine”. As a result, “Svm” will be added into the variation lists of “Space vector modulation” and “Support vector machine”, respectively.

<sup>3</sup>According to Liu et al. (2012), on average a named entity has 3.3 different surface forms in tweets.

<sup>1</sup><http://siteanalytics.compete.com/twitter.com/>

the other hand, the huge redundancy in tweets offers opportunities. That means, an entity mention often occurs in many tweets, which allows us to aggregate all related tweets to compute mention-mention similarity and mention-entity similarity.

We propose a collective inference method that leverages tweet redundancy to address those two challenges. Given a set of mentions, our model tries to ensure that similar mentions are linked to similar entities while pursuing the high total similarity between matched mention-entity pairs. More specifically, we define local features, including context similarity and edit distance, to model the similarity between a mention and an entity. We adopt in-link based similarity (Milne and Witten, 2008), to measure the similarity between entities. Finally, we introduce a set of features to compute the similarity between mentions, including how similar the tweets containing the mentions are, whether they come from the tweets of the same account, and their edit distance. Notably, our model can resolve OOV mentions with the help of their similar mentions. For example, for the OOV mention “LukeBryanOnline”, our model can find similar mentions like “TheLukeBryan” and “LukeBryan”. Considering that most of its similar mentions are mapped to the American country singer “Luke Bryan”, our model tends to link “LukeBryanOnline” to the same entity.

We evaluate our method on the public available data set shared by Meij et al. (2012)<sup>4</sup>. Experimental results show that our method outperforms two baselines, i.e., Wikify! (Mihalcea and Csomai, 2007) and system proposed by Meij et al. (2012). We also study the effectiveness of features related to each kind of similarity, and demonstrate the advantage of our method for OOV mention linkage.

We summarize our contributions as follows.

1. We introduce a novel collective inference method that integrates three kinds of similarities, i.e., mention-entity similarity, entity-entity similarity, and mention-mention similarity, to simultaneously map a set of tweet mentions to their proper entities.
2. We propose modeling the mention-mention similarity and demonstrate its effectiveness

<sup>4</sup><http://ilps.science.uva.nl/resources/wsdm2012-adding-semantic-to-microblog-posts/>

in entity linking for tweets, particularly for OOV mentions.

3. We evaluate our method on a public data set, and show our method compares favorably with the baselines.

Our paper is organized as follows. In the next section, we introduce related work. In Section 3, we give the formal definition of the task. In Section 4, we present our solution, including the framework, features related to different kinds of similarities, and the training and decoding procedures. We evaluate our method in Section 5. Finally in Section 6, we conclude with suggestions of future work.

## 2 Related Work

Existing entity linking work can roughly be divided into two categories. Methods of the first category resolve one mention at each time, and mainly consider the similarity between a mention-entity pair. In contrast, methods of the second category take a set of related mentions (e.g., mentions in the same document) as input, and figure out their corresponding entities simultaneously.

Examples of the first category include the first Web-scale entity linking system SemTag (Dill et al., 2003), Wikify! (Mihalcea and Csomai, 2007), and the recent work of Milne and Witten (2008). SemTag uses the TAP knowledge base<sup>5</sup>, and employs the cosine similarity with TF-IDF weighting scheme to compute the match degree between a mention and an entity, achieving an accuracy of around 82%. Wikify! identifies the important concepts in the text and automatically links these concepts to the corresponding Wikipedia pages. It introduces two approaches to define mention-entity similarity, i.e., the contextual overlap between the paragraph where the mention occurs and the corresponding Wikipedia pages, and a Naive Bayes classifier that predicts whether a mention should be linked to an entity. It achieves 80.69% F1 when two approaches are combined. Milne and Witten work on the same task of Wikify!, and also train a classifier. However, they cleverly use the

<sup>5</sup>TAB (<http://www.w3.org/2002/05/tap/>) is a shallow knowledge base that contains a broad range of lexical and taxonomic information about popular objects like music, movies, authors, sports, autos, health, etc.

links found within Wikipedia articles for training, exploiting the fact that for every link, a Wikipedian has manually selected the correct destination to represent the intended sense of the anchor. Their method achieves an F1 score of 75.0%.

Representative studies of the second category include the work of Kulkarni et al. (2009), Han et al. (2011), and Shen et al. (2012). One common feature of these studies is that they leverage the global coherence between entities. Kulkarni et al. (2009) propose a graphical model that explicitly models the combination of evidence from local mention-entity compatibility and global document-level topical coherence of the entities, and show that considering global coherence between entities significantly improves the performance. Han et al. (2011) introduce a graph-based representation, called Referent Graph, to model the global interdependence between different entity linking decisions, and jointly infer the referent entities of all name mentions in a document by exploiting the interdependence captured in Referent Graph. Shen et al. (2012) propose LIEGE, a framework to link the entities in web lists with the knowledge base, with the assumption that entities mentioned in a Web list tend to be a collection of entities of the same conceptual type.

Most work of entity linking focuses on web pages. Recently, Meij et al. (2012) study this task for tweets. They propose a machine learning based approach using n-gram features, concept features, and tweet features, to identify concepts semantically related to a tweet, and for every entity mention to generate links to its corresponding Wikipedia article. Their method belongs to the first category, in the sense that they only consider the similarity between mention (tweet) and entity (Wikipedia article).

Our method belongs to the second category. However, in contrast with existing collective approaches, our method works on tweets which are short and often noisy. Furthermore, our method is based on the “similar mention with similar entity” assumption, and explicitly models and integrates the mention similarity into the optimization framework. Compared with Meij et al. (2012), our method is collective, and integrates more features.

### 3 Task Definition

Given a sequence of mentions, denoted by  $\vec{M} = (m_1, m_2, \dots, m_n)$ , our task is to output a sequence of entities, denoted by  $\vec{E} = (e_1, e_2, \dots, e_n)$ , where  $e_i$  is the entity corresponding to  $m_i$ . Here, an entity refers to an item of a knowledge base. Following most existing work, we use Wikipedia as the knowledge base, and an entity is a definition page in Wikipedia; a mention denotes a sequence of tokens in a tweet that can be potentially linked to an entity.

Several notes should be made. First, we assume that mentions are given, e.g., identified by some named entity recognition system. Second, mentions may come from multiple tweets. Third, mentions with the same token sequence may refer to different entities, depending on mention context. Finally, we assume each entity  $e$  has a variation list<sup>6</sup>, and a unique ID through which all related information about that entity can be accessed.

Here is an example to illustrate the task. Given mentions “nbcnightlynews”, “Santiago”, “WH” and “Libya” from the following tweet “Chuck Todd: Prepping for @nbcnightlynews here in Santiago, reporting on WH handling of Libya situation.”, the expected output is “NBC Nightly News(194735)”, “Santiago Chile(51572)”, “White House(33057)” and “Libya(17633)”, where the numbers in the parentheses are the IDs of the corresponding entities.

### 4 Our Method

In this section, we first present the framework of our entity linking method. Then we introduce features related to different kinds of similarities, followed by a detailed discussion of the training and decoding procedures.

#### 4.1 Framework

Given the input mention sequence  $\vec{M} = (m_1, m_2, \dots, m_n)$ , our method outputs the entity sequence  $\vec{E}^* = (e_1^*, e_2^*, \dots, e_n^*)$  according to Formula 1:

<sup>6</sup>For example, the variation list of the entity “Obama” may contain “Barack Obama”, “Barack Hussein Obama II”, etc.

$$\vec{E}^* = \underset{\vec{E} \in C(\vec{M})}{\operatorname{argmax}} \lambda \sum_{i=1}^n \vec{w} \cdot \vec{f}(e_i, m_i) + (1 - \lambda) \sum_{i \neq j} r(e_i, e_j) s(m_i, m_j) \quad (1)$$

Where:

- $C(\vec{M})$  is the set of all possible entity sequences for the mention sequence  $\vec{M}$ ;
- $\vec{E}$  denotes an entity sequence instance, consisting of  $e_1, e_2, \dots, e_n$ ;
- $\vec{f}(e_i, m_i)$  is the feature vector that models the similarity between mention  $m_i$  and its linked entity  $e_i$ ;
- $\vec{w}$  is the feature weight vector related to  $\vec{f}$ , which is trained on the training data set;  $\vec{w} \cdot \vec{f}(e_i, m_i)$  is the similarity between mention  $m_i$  and entity  $e_i$ ;
- $r(e_i, e_j)$  is the function that returns the similarity between two entities  $e_i$  and  $e_j$ ;
- $s(m_i, m_j)$  is the function that returns the similarity between two mentions  $m_i$  and  $m_j$ ;
- $\lambda \in (0, 1)$  is a systematic parameter, which is determined on the development data set; it is used to adjust the tradeoff between local compatibility and global consistence. It is experimentally set to 0.8 in our work.

From Formula 1, we can see that: 1) our method considers the mention-entity similarity, entity-entity similarity and mention-mention similarity. Mention-entity similarity is used to model local compatibility, while entity-entity similarity and mention-mention similarity combined are to model global consistence; and 2) our method prefers configurations where similar mentions have similar entities and with high local compatibility.

$C(\vec{M})$  is worth of more discussion here. It represents the search space, which can be generated using the entity variation list. To achieve this, we first build an inverted index of all entity variation lists, with each unique variation as an entry pointing to a list of entities. Then for any mention  $m$ , we look up the index, and get all possible entities, denoted by  $C(m)$ . In this way, given a mention sequence  $\vec{M} =$

$(m_1, m_2, \dots, m_n)$ , we can enumerate all possible entity sequence  $\vec{E} = (e_1, e_2, \dots, e_n)$ , where  $e_i \in C(m_i)$ . This means  $|C(\vec{M})| = \prod_{m \in M} |C(m)|$ , which is often large. There is one special case: if  $m$  is an OOV mention, i.e.,  $|C(m)| = 0$ , then  $|C(\vec{M})| = 0$ , and we get no solution. To address this problem, we can generate a list of candidates for an OOV mention using its similar mentions. Let  $S(m)$  denote OOV mention  $m$ 's similar mentions, we define  $C(m) = \bigcup_{m' \in S(m)} C(m')$ . If still  $C(m) = 0$ , we remove  $m$  from  $\vec{M}$ , and report we cannot map it to any entity.

Here is an example to illustrate our framework. Suppose we have the following tweets:

- UserA: Yeaahhgg #habemusfut..  
I love monday night futbol =>  
#EnglishPremierLeague ManU vs  
Liverpool<sub>1</sub>
- UserA: Manchester United 3 - Liverpool<sub>2</sub>  
2 #EnglishPremierLeague GLORY, GLORY,  
MAN.UNITED!
- ...

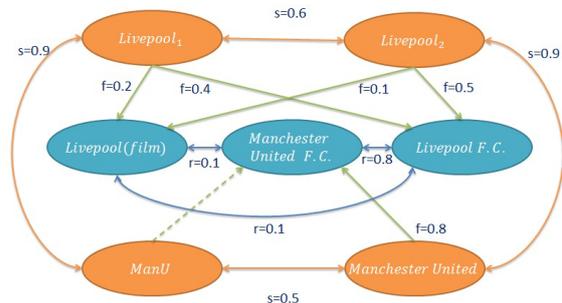

Figure 1: An illustrative example to show our framework. Ovals in orange and in blue represent mentions and entities, respectively. Each mention pair, entity pair, and mention entity pair have a similarity score represented by  $s$ ,  $r$  and  $f$ , respectively.

We need find out the best entity sequence  $\vec{E}^*$  for mentions  $\vec{M} = \{ \text{“Liverpool}_1\text{”}, \text{“Manchester United”}, \text{“ManU”}, \text{“Liverpool}_2\text{”} \}$ , from the entity sequences  $C(\vec{M}) = \{ (\text{Liverpool (film), Manchester United F.C., Manchester United F.C., Liverpool (film)}), \dots, (\text{Liverpool, F.C., Manchester United, F.C., Manchester United F.C., Liverpool (film)}) \}$ . Figure 1 illustrate our solution, where “Liverpool<sub>1</sub>” (on the left) and “Liverpool<sub>2</sub>” (on the right) are linked

to “Liverpool F.C.” (the football club), and “Manchester United” and “ManU” are linked to “Manchester United F.C.”. Notably, “ManU” is an OOV mention, but has a similar mention “Manchester United”, with which “ManU” is successfully mapped.

## 4.2 Features

We group features into three categories: local features related to mention-entity similarity ( $\vec{f}(e, m)$ ), features related to entity-entity similarity ( $r(e_i, e_j)$ ), and features related to mention-mention similarity ( $s(m_i, m_j)$ ).

### 4.2.1 Local Features

- Prior Probability:

$$f_1(m_i, e_i) = \frac{\text{count}(e_i)}{\sum_{\forall e_k \in C(m_i)} \text{count}(e_k)} \quad (2)$$

where  $\text{count}(e)$  denotes the frequency of entity  $e$  in Wikipedia’s anchor texts.

- Context Similarity:

$$f_2(m_i, e_i) = \frac{\text{cocurrence\_number}}{\text{tweet\_length}} \quad (3)$$

where: *cocurrence\_number* is the the number of the words that occur in both the tweet containing  $m_i$  and the Wikipedia page of  $e_i$ ; *tweet\_length* denotes the number of tokens of the tweet containing mention  $m_i$ .

- Edit Distance Similarity:

If  $\text{Length}(m_i) + \text{ED}(m_i, e_i) = \text{Length}(e_i)$ ,  $f_3(m_i, e_i) = 1$ , otherwise 0.  $\text{ED}(\cdot, \cdot)$  computes the character level edit distance. This feature helps to detect whether a mention is an abbreviation of its corresponding entity<sup>7</sup>.

- Mention Contains Title: If the mention contains the entity title, namely the title of the Wikipedia page introducing the entity  $e_i$ ,  $f_4(m_i, e_i) = 1$ , else 0.

- Title Contains Mention: If the entry title contains the mention,  $f_5(m_i, e_i) = 1$ , otherwise 0.

<sup>7</sup>Take “ms” and “Microsoft” for example. The length of “ms” is 2, and the edit distance between them is 7. 2 plus 7 equals to 9, which is the length of “Microsoft”.

### 4.2.2 Features Related to Entity Similarity

There are two representative definitions of entity similarity: in-link based similarity (Milne and Witten, 2008) and category based similarity (Shen et al., 2012). Considering that the Wikipedia categories are often noisy (Milne and Witten, 2008), we adopt in-link based similarity, as defined in Formula 4:

$$r(e_i, e_j) = \frac{\log|g(e_i) \cap g(e_j)| - \log \max(|g(e_i)|, |g(e_j)|)}{\log(\text{Total}) - \log \min(|g(e_i)|, |g(e_j)|)} \quad (4)$$

Where:

- *Total* is the total number of knowledge base entities;
- $g(e)$  is the number of Wikipedia definition pages that have a link to entity  $e$ .

### 4.2.3 Features Related to Mention Similarity

We define 5 features to model the similarity between two mentions  $m_i$  and  $m_j$ , as listed below, where  $t(m)$  denotes the tweet that contains mention  $m$ :

- $s_1(m_i, m_j)$ : The cosine similarity of  $t(m_i)$  and  $t(m_j)$ ; and tweets are represented as TF-IDF vectors;
- $s_2(m_i, m_j)$ : The cosine similarity of  $t(m_i)$  and  $t(m_j)$ ; and tweets are represented as topic distribution vectors;
- $s_3(m_i, m_j)$ : Whether  $t(m_i)$  and  $t(m_j)$  are published by the same account;
- $s_4(m_i, m_j)$ : Whether  $t(m_i)$  and  $t(m_j)$  contain any common hash tag;
- $s_5(m_i, m_j)$ : Edit distance related similarity between  $m_i$  and  $m_j$ , as defined in Formula 5.

$$s_5(m_i, m_j) = 1, \text{ if } \min\{\text{Length}(m_i), \text{Length}(m_j)\} + \text{ED}(m_i, m_j) = \max\{\text{Length}(m_i), \text{Length}(m_j)\},$$

$$\text{else } s_5(m_i, m_j) = 1 - \frac{\text{ED}(m_i, m_j)}{\max\{\text{Length}(m_i), \text{Length}(m_j)\}} \quad (5)$$

Note that: 1) before computing TF-IDF vectors, stop words are removed; 2) we use the Stanford Topic Modeling Toolbox<sup>8</sup> to compute the topic model, and experimentally set the number of topics to 50.

<sup>8</sup><http://nlp.stanford.edu/software/tmt/tmt-0.4/>

Finally, Formula 6 is used to integrate all the features.  $\vec{a} = (a_1, a_2, a_3, a_4, a_5)$  is the feature weight vector for mention similarity, where  $a_k \in (0, 1)$ ,  $k = 1, 2, 3, 4, 5$ , and  $\sum_{k=1}^5 a_k = 1$ .

$$s(m_i, m_j) = \sum_{k=1}^5 a_k s_k(m_i, m_j) \quad (6)$$

### 4.3 Training and Decoding

Given  $n$  mentions  $m_1, m_2, \dots, m_n$  and their corresponding entities  $e_1, e_2, \dots, e_n$ , the goal of training is to determine:  $\vec{w}^*$ , the weights of local features, and  $\vec{a}^*$ , the weights of the features related to mention similarity, according to Formula 7<sup>9</sup>.

$$(\vec{w}^*, \vec{a}^*) = \arg \min_{\vec{w}, \vec{a}} \left\{ \frac{1}{n} \sum_{i=1}^n L_1(e_i, m_i) + \alpha_1 \|\vec{w}\|^2 + \frac{\alpha_2}{2} \sum_{i,j=1}^n s(m_i, m_j) L_2(\vec{a}, e_i, e_j) \right\} \quad (7)$$

Where:

- $L_1$  is the loss function related to local compatibility, which is defined as  $\frac{1}{\vec{w} \cdot \vec{f}(e_i, m_i) + 1}$ ;
- $L_2(\vec{a}, e_i, e_j)$  is the loss function related to global coherence, which is defined as  $\frac{1}{r(e_i, e_j) \sum_{k=1}^5 a_k s_k(m_i, m_j) + 1}$ ;
- $\alpha_1$  is the weight of regularization, which is experimentally set to 1.0;
- $\alpha_2$  is the weight of  $L_2$  loss, which is experimentally set to 0.2.

Since the decoding problem defined by Formula 1 is NP hard (Kulkarni et al., 2009), we develop a greedy hill-climbing approach to tackle this challenge, as demonstrated in Algorithm 1.

In Algorithm 1,  $it$  is the number of iterations;  $Score(\vec{E}, \vec{M}) = \lambda \sum_{i=1}^n \vec{w} \cdot \vec{f}(e_i, m_i) + (1 - \lambda) \sum_{i \neq j} r(e_i, e_j) s(m_i, m_j)$ ;  $\vec{E}_{ij}$  is the vector after replacing  $e_i$  with  $e_j \in C(m_i)$  for current  $\vec{E}$ ;  $sc_{ij}$  is the score of  $\vec{E}_{ij}$ , i.e.,  $Score(\vec{E}_{ij}, \vec{M})$ . In each iteration, this rounding solution iteratively substitute entry  $e_i$  in  $\vec{E}$  to increase the total score  $cur$ . If the score cannot be further improved, it stops and returns current  $\vec{E}$ .

<sup>9</sup>This optimization problem is non-convex. We use coordinate descent to get a local optimal solution.

---

### Algorithm 1 Decoding Algorithm.

## 5 Experiments

In this section, we introduce the data set and experimental settings, and present results.

### 5.1 Data Preparation

Following most existing studies, we choose Wikipedia as our knowledge base<sup>10</sup>. We index the Wikipedia definition pages, and prepare all required prior knowledge, such as  $count(e)$ ,  $g(e)$ , and entity variation lists. We also build an inverted index with about 60 million entries for the entity variation lists.

For tweets, we use the data set shared by Meij et al. (2012)<sup>11</sup>. This data set is annotated manually by two volunteers. We get 502 annotated tweets from this data set. We keep 55 of them for

<sup>10</sup>We download the December 2012 version of Wikipedia, which contains about four million articles.

<sup>11</sup><http://ilps.science.uva.nl/resources/wsdm2012-adding-semantics-to-microblog-posts/>.

development, and the remaining for 5 fold cross-validation.

## 5.2 Settings

We consider following settings to evaluate our method.

- Comparing our method with two baselines, i.e., Wikify! (Mihalcea and Csomai, 2007) and the system proposed by Meij et al. (2012)<sup>12</sup>;
- Using only local features;
- Using various mention similarity features;
- Experiments on OOV mentions.

## 5.3 Results

Table 1 reports the comparison results. Our method outperforms both systems in terms of all metrics. Since the main difference between our method and the baselines is that our method considers not only local features, but also global features related to entity similarity and mention similarity, these results indicate the effectiveness of collective inference and global features. For example, we find two baselines incorrectly link “Nickelodeon” in the tweet “BOH will make a special appearance on Nickelodeon’s ‘Yo Gabba Gabba’ tomorrow” to the theater instead of a TV channel. In contrast, our method notices that “Yo Gabba Gabba” in the same tweet can be linked to “Yo Gabba Gabba (TV show)”, and thus it correctly maps “Nickelodeon” to “Nickelodeon (TV channel)”.

System	Pre.	Rec.	F1
Wikify!	0.375	0.421	0.396
Meij’s Method	0.734	0.632	0.679
Our Method	0.752	0.675	0.711

Table 1: Comparison with Baselines.

Table 2 shows the results when local features are incrementally added. It can be seen that: 1) using only Prior Probability feature already yields a reasonable F1; and 2) Context Similarity and Edit Distance Similarity feature have little contribution to the F1, while Mention and Entity Title Similarity feature greatly boosts the F1.

<sup>12</sup>We re-implement Wikify! since we use a new evaluation data set.

Local Feature	Pre.	Rec.	F1
P.P.	0.700	0.599	0.646
+C.S.	0.694	0.597	0.642
+E.D.S.	0.696	0.598	0.643
+M.E.T.S.	0.735	0.632	0.680

Table 2: Local Feature Analysis. P.P., C.S., E.D.S., and M.E.T.S. denote Prior Probability, Context Similarity, Edit Distance Similarity, and Mention and Entity Title Similarity, respectively.

The performance of our method with various mention similarity features is reported in Table 3. First, we can see that with this kind of features, the F1 can be significantly improved from 0.680 to 0.704. Second, we notice that TF-IDF ( $s_1$ ) and Topic Model ( $s_2$ ) features perform equally well, and combining all mention similarity features yields the best performance.

Global Feature	Pre.	Rec.	F1
$s_3+s_4+s_5$	0.744	0.653	0.700
$s_3+s_4+s_5+s_1$	0.759	0.652	0.702
$s_3+s_4+s_5+s_2$	0.760	0.653	0.703
$s_3+s_4+s_5+s_1+s_2$	0.764	0.653	0.704

Table 3: Mention Similarity Feature Analysis.

For any OOV mention, we use the strategy of guessing its possible entity candidates using similar mentions, as discussed in Section 4.1. Table 4 shows the performance of our system for OOV mentions. It can be seen that with our OOV strategy, the recall is improved from 0.653 to 0.675 (with  $p < 0.05$ ) while the Precision is slightly dropped and the overall F1 still gets better. A further study reveals that among all the 125 OOV mentions, there are 48 for which our method cannot find any entity; and nearly half of these 48 OOV mentions do have corresponding entities<sup>13</sup>. This suggests that we may need enlarge the size of variation lists or develop some mention normalization techniques.

OOV Method	Precision	Recall	F1
Ignore OOV Mention	0.764	0.653	0.704
+ OOV Method	0.752	0.675	0.711

Table 4: Performance for OOV Mentions.

<sup>13</sup>“NATO-ukraine cooperations” is such an example. It is mapped to NULL but actually has a corresponding entity “Ukraine-NATO relations”

## 6 Conclusions and Future work

We have presented a collective inference method that jointly links a set of tweet mentions to their corresponding entities. One distinguished characteristic of our method is that it integrates mention-entity similarity, entity-entity similarity, and mention-mention similarity, to address the information lack in a tweet and rich OOV mentions. We evaluate our method on a public data set. Experimental results show our method outperforms two baselines, and suggests the effectiveness of modeling mention-mention similarity, particularly for OOV mention linking.

In the future, we plan to explore two directions. First, we are going to enlarge the size of entity variation lists. Second, we want to integrate the entity mention normalization techniques as introduced by Liu et al. (2012).

## Acknowledgments

We thank the anonymous reviewers for their valuable comments. We also thank all the QuickView team members for the helpful discussions.

## Abstract

Speaker identification is the task of attributing utterances to characters in a literary narrative. It is challenging to automate because the speakers of the majority of utterances are not explicitly identified in novels. In this paper, we present a supervised machine learning approach for the task that incorporates several novel features. The experimental results show that our method is more accurate and general than previous approaches to the problem.

## 1 Introduction

Novels are important as social communication documents, in which novelists develop the plot by means of discourse between various characters. In spite of a frequently expressed opinion that all novels are simply variations of a certain number of basic plots (Tobias, 2012), every novel has a unique plot (or several plots) and a different set of characters. The interactions among characters, especially in the form of conversations, help the readers construct a mental model of the plot and the changing relationships between characters. Many of the complexities of interpersonal relationships, such as romantic interests, family ties, and rivalries, are conveyed by utterances.

A precondition for understanding the relationship between characters and plot development in a novel is the identification of speakers behind all utterances. However, the majority of utterances are not explicitly tagged with speaker names, as is the case in stage plays and film scripts. In most cases, authors rely instead on the readers' comprehension of the story and of the differences between characters.

Since manual annotation of novels is costly, a system for automatically determining speakers of utterances would facilitate other tasks related to

the processing of literary texts. Speaker identification could also be applied on its own, for instance in generating high quality audio books without human lecturers, where each character would be identifiable by a distinct way of speaking. In addition, research on spoken language processing for broadcast and multi-party meetings (Salamin et al., 2010; Favre et al., 2009) has demonstrated that the analysis of dialogues is useful for the study of social interactions.

In this paper, we investigate the task of speaker identification in novels. Departing from previous approaches, we develop a general system that can be trained on relatively small annotated data sets, and subsequently applied to other novels for which no annotation is available. Since every novel has its own set of characters, speaker identification cannot be formulated as a straightforward tagging problem with a universal set of fixed tags. Instead, we adopt a ranking approach, which enables our model to be applied to literary texts that are different from the ones it has been trained on.

Our approach is grounded in a variety of features that are easily generalizable across different novels. Rather than attempt to construct complete semantic models of the interactions, we exploit lexical and syntactic clues in the text itself. We propose several novel features, including the speaker alternation pattern, the presence of vocatives in utterances, and unsupervised actor-topic features that associate speakers with utterances on the basis of their content. Experimental evaluation shows that our approach not only outperforms the baseline, but also compares favorably to previous approaches in terms of accuracy and generality, even when tested on novels and authors that are different from those used for training.

The paper is organized as follows. After discussing previous work, and defining the terminology, we present our approach and the features that it is based on. Next, we describe the data, the an-

notation details, and the results of our experimental evaluation. At the end, we discuss an application to extracting a set of family relationships from a novel.

## 2 Related Work

Previous work on speaker identification includes both rule-based and machine-learning approaches. Glass and Bangay (2007) propose a rule generalization method with a scoring scheme that focuses on the speech verbs. The verbs, such as *said* and *cried*, are extracted from the communication category of WordNet (Miller, 1995). The speech-verb-actor pattern is applied to the utterance, and the speaker is chosen from the available candidates on the basis of a scoring scheme. Sarmiento and Nunes (2009) present a similar approach for extracting speech quotes from online news texts. They manually define 19 variations of frequent speaker patterns, and identify a total of 35 candidate speech verbs. The rule-based methods are typically characterized by low coverage, and are too brittle to be reliably applied to different domains and changing styles.

Elson and McKeown (2010) (henceforth referred to as EM2010) apply the supervised machine learning paradigm to a corpus of utterances extracted from novels. They construct a single feature vector for each pair of an utterance and a speaker candidate, and experiment with various WEKA classifiers and score-combination methods. To identify the speaker of a given utterance, they assume that all previous utterances are already correctly assigned to their speakers. Our approach differs in considering the utterances in a sequence, rather than independently from each other, and in removing the unrealistic assumption that the previous utterances are correctly identified.

The speaker identification task has also been investigated in other domains. Bethard et al. (2004) identify opinion holders by using semantic parsing techniques with additional linguistic features. Pouliquen et al. (2007) aim at detecting direct speech quotations in multilingual news. Krestel et al. (2008) automatically tag speech sentences in newspaper articles. Finally, Ruppenhofer et al. (2010) implement a rule-based system to enrich German cabinet protocols with automatic speaker attribution.

## 3 Definitions and Conventions

In this section, we introduce the terminology used in the remainder of the paper. Our definitions are different from those of EM2010 partly because we developed our method independently, and partly because we disagree with some of their choices. The examples are from Jane Austen’s *Pride and Prejudice*, which was the source of our development set.

An *utterance* is a connected text that can be attributed to a single speaker. Our task is to associate each utterance with a single speaker. Utterances that are attributable to more than one speaker are rare; in such cases, we accept correctly identifying one of the speakers as sufficient. In some cases, an utterance may include more than one quotation-delimited sequence of words, as in the following example.

*“Miss Bingley told me,” said Jane, “that he never speaks much.”*

In this case, the words *said Jane* are simply a speaker tag inserted into the middle of the quoted sentence. Unlike EM2010, we consider this a single utterance, rather than two separate ones.

We assume that all utterances within a paragraph can be attributed to a single speaker. This “one speaker per paragraph” property is rarely violated in novels — we identified only five such cases in *Pride & Prejudice*, usually involving one character citing another, or characters reading letters containing quotations. We consider this an acceptable simplification, much like assigning a single part of speech to each word in a corpus. We further assume that each utterance is contained within a single paragraph. Exceptions to this rule can be easily identified and resolved by detecting quotation marks and other typographical conventions.

The paragraphs without any quotations are referred to as *narratives*. The term *dialogue* denotes a series of utterances together with related narratives, which provide the context of conversations. We define a dialogue as a series of utterances and intervening narratives, with no more than three continuous narratives. The rationale here is that more than three narratives without any utterances are likely to signal the end of a particular dialogue.

We distinguish three types of utterances, which are listed with examples in Table 1: *explicit speaker* (identified by name within the paragraph),

Category	Example
Implicit speaker	“ <i>Don’t keep coughing so, Kitty, for heaven’s sake!</i> ”
Explicit speaker	“ <i>I do not cough for my own amusement,</i> ” replied <b>Kitty</b> .
Anaphoric speaker	“ <i>Kitty has no discretion in her coughs,</i> ” said <b>her father</b> .

Table 1: Three types of utterances.

*anaphoric speaker* (identified by an anaphoric expression), and *implicit speaker* (no speaker information within the paragraph). Typically, the majority of utterances belong to the implicit-speaker category. In *Pride & Prejudice* only roughly 25% of the utterances have explicit speakers, and an even smaller 15% belong to the anaphoric-speaker category. In modern fiction, the percentage of explicit attributions is even lower.

## 4 Speaker Identification

In this section, we describe our method of extracting explicit speakers, and our ranking approach, which is designed to capture the speaker alternation pattern.

### 4.1 Extracting Speakers

We extract explicit speakers by focusing on the speech verbs that appear before, after, or between quotations. The following verbs cover most cases in our development data: *say, speak, talk, ask, reply, answer, add, continue, go on, cry, sigh, and think*. If a verb from the above short list cannot be found, any verb that is preceded by a name or a personal pronoun in the vicinity of the utterance is selected as the speech verb.

In order to locate the speaker’s name or anaphoric expression, we apply a deterministic method based on syntactic rules. First, all paragraphs that include narrations are parsed with a dependency parser. For example, consider the following paragraph:

*As they went downstairs together, Charlotte said, “I shall depend on hearing from you very often, Eliza.”*

The parser identifies a number of dependency relations in the text, such as *doobj(went-3, downstairs-4)* and *advmod(went-3, together-5)*. Our method extracts the speaker’s name from the dependency relation *nsbj(said-8, Charlotte-7)*, which links a

speech verb with a noun phrase that is the syntactic subject of a clause.

Once an explicit speaker’s name or an anaphoric expression is located, we determine the corresponding gender information by referring to the character list or by following straightforward rules to handle the anaphora. For example, if the utterance is followed by the phrase *she said*, we infer that the gender of the speaker is female.

### 4.2 Ranking Model

In spite of the highly sequential nature of the chains of utterances, the speaker identification task is difficult to model as sequential prediction. The principal problem is that, unlike in many NLP problems, a general fixed tag set cannot be defined beyond the level of an individual novel. Since we aim at a system that could be applied to any novel with minimal pre-processing, sequential prediction algorithms such as Conditional Random Fields are not directly applicable.

We propose a more flexible approach that assigns scores to candidate speakers for each utterance. Although the sequential information is not directly modeled with tags, our system is able to indirectly utilize the speaker alternation pattern using the method described in the following section. We implement our approach with *SVM-rank* (Joachims, 2006).

### 4.3 Speaker Alternation Pattern

The speaker alternation pattern is often employed by authors in dialogues between two characters. After the speakers are identified explicitly at the beginning of a dialogue, the remaining odd-numbered and even-numbered utterances are attributable to the first and second speaker, respectively. If one of the speakers “misses their turn”, a clue is provided in the text to reset the pattern.

Based on the speaker alternation pattern, we make the following two observations:

1. The speakers of consecutive utterances are usually different.
2. The speaker of the  $n$ -th utterance in a dialogue is likely to be the same as the speaker of the  $(n - 2)$ -th utterance.

Our ranking model incorporates the speaker alternation pattern by utilizing a feature expansion scheme. For each utterance  $n$ , we first generate its own features (described in Section 5), and

Features	Novelty
Distance to Utterance	No
Speaker Appearance Count	No
Speaker Name in Utterance	No
Unsupervised Actor-Topic Model	Yes
Vocative Speaker Name	Yes
Neighboring Utterances	Yes
Gender Matching	Yes
Presence Matching	Yes

Table 2: Principal feature sets.

subsequently we add three more feature sets that represent the following neighboring utterances:  $n - 2$ ,  $n - 1$  and  $n + 1$ . Informally, the features of the utterances  $n - 1$  and  $n + 1$  encode the first observation, while the features representing the utterance  $n - 2$  encode the second observation. In addition, we include a set of four binary features that are set for the utterances in the range  $[n - 2, n + 1]$  if the corresponding explicit speaker matches the candidate speaker of the current utterance.

## 5 Features

In this section, we describe the set of features used in our ranking approach. The principal feature sets are listed in Table 2, together with an indication whether they are novel or have been used in previous work.

### 5.1 Basic Features

A subset of our features correspond to the features that were proposed by EM2010. These are mostly features related to speaker names. For example, since names of speakers are often mentioned in the vicinity of their utterances, we count the number of words separating the utterance and a name mention. However, unlike EM2010, we consider only the two nearest characters in each direction, to reflect the observation that speakers tend to be mentioned by name immediately before or after their corresponding utterances. Another feature is used to represent the number of appearances for speaker candidates. This feature reflects the relative importance of a given character in the novel. Finally, we use a feature to indicate the presence or absence of a candidate speaker’s name within the utterance. The intuition is that speakers are unlikely to mention their own name.

Feature	Example
start of utterance	“ <i>Kitty</i> ...
before period	... <i>Jane</i> .
between commas	..., <i>Elizabeth</i> , ...
between comma & period	..., <i>Mrs. Hurst</i> .
before exclamation mark	... <i>Mrs. Bennet!</i>
before question mark	... <i>Lizzy?</i> ...
vocative phrase	<i>Dear</i> ...
after vocative phrase	<i>Oh! Lydia</i> ...
2nd person pronoun	... <i>you</i> ...

Table 3: Features for the vocative identification.

### 5.2 Vocatives

We propose a novel vocative feature, which encodes the character that is explicitly addressed in an utterance. For example, consider the following utterance:

“*I hope Mr. Bingley will like it, Lizzy.*”

Intuitively, the speaker of the utterance is neither *Mr. Bingley* nor *Lizzy*; however, the speaker of the next utterance is likely to be *Lizzy*. We aim at capturing this intuition by identifying the addressee of the utterance.

We manually annotated vocatives in about 900 utterances from the training set. About 25% of the names within utterance were tagged as vocatives. A Logistic Regression classifier (Agresti, 2006) was trained to identify the vocatives. The classifier features are shown in Table 3. The features are designed to capture punctuation context, as well as the presence of typical phrases that accompany vocatives. We also incorporate interjections like “oh!” and fixed phrases like “my dear”, which are strong indicators of vocatives. Under 10-fold cross validation, the model achieved an F-measure of 93.5% on the training set.

We incorporate vocatives in our speaker identification system by means of three binary features that correspond to the utterances  $n - 1$ ,  $n - 2$ , and  $n - 3$ . The features are set if the detected vocative matches the candidate speaker of the current utterance  $n$ .

### 5.3 Matching Features

We incorporate two binary features for indicating the gender and the presence of a candidate speaker. The gender matching feature encodes the gender agreement between a speaker candidate and the speaker of the current utterance. The gender information extraction is applied to two utterance

groups: the anaphoric-speaker utterances, and the explicit-speaker utterances. We use the technique described in Section 4.1 to determine the gender of a speaker of the current utterance. In contrast with EM2010, this is not a hard constraint.

The presence matching feature indicates whether a speaker candidate is a likely participant in a dialogue. Each dialogue consists of continuous utterance paragraphs together with neighboring narration paragraphs as defined in Section 3. The feature is set for a given character if its name or alias appears within the dialogue.

#### 5.4 Unsupervised Actor-Topic Features

The final set of features is generated by the unsupervised actor-topic model (ACTM) (Celikyilmaz et al., 2010), which requires no annotated training data. The ACTM, as shown in Figure 1, extends the work of author-topic model in (Rosen-Zvi et al., 2010). It can model dialogues in a literary text, which take place between two or more speakers conversing on different topics, as distributions over topics, which are also mixtures of the term distributions associated with multiple speakers. This follows the linguistic intuition that rich contextual information can be useful in understanding dialogues.

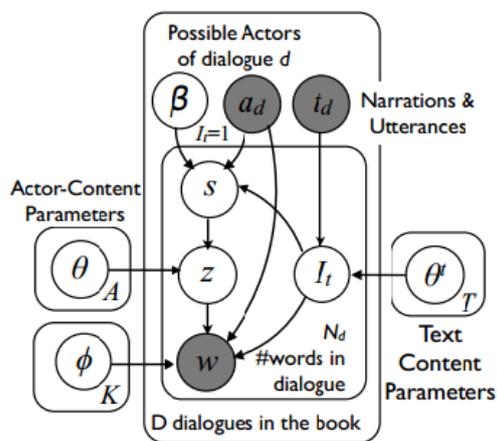

Figure 1: Graphical Representation of ACTM.

The ACTM predicts the most likely speakers of a given utterance by considering the content of an utterance and its surrounding contexts. The Actor-Topic-Term probabilities are calculated by using both the relationship of utterances and the surrounding textual clues. In our system, we utilize four binary features that correspond to the four top ranking positions from the ACTM model.

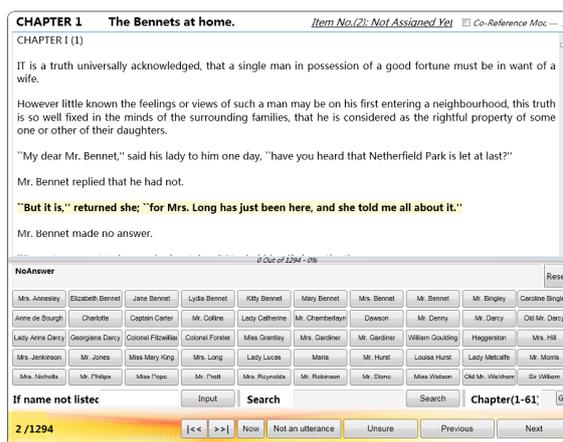

Figure 2: Annotation Tool GUI.

## 6 Data

Our principal data set is derived from the text of *Pride and Prejudice*, with chapters 19–26 as the test set, chapters 27–33 as the development set, and the remaining 46 chapters as the training set. In order to ensure high-quality speaker annotations, we developed a graphical interface (Figure 2), which displays the current utterance in context, and a list of characters in the novel. After the speaker is selected by clicking a button, the text is scrolled automatically, with the next utterance highlighted in yellow. The complete novel was annotated by a student of English literature. The annotations are publicly available<sup>1</sup>.

For the purpose of a generalization experiment, we also utilize a corpus of utterances from the 19th and 20th century English novels compiled by EM2010. The corpus differs from our data set in three aspects. First, as discussed in Section 3, we treat all quoted text within a single paragraph as a single utterance, which reduces the total number of utterances, and results in a more realistic reporting of accuracy. Second, our data set includes annotations for all utterances in the novel, as opposed to only a subset of utterances from several novels, which are not necessarily contiguous. Lastly, our annotations come from a single expert, while the annotations in the EM2010 corpus were collected through Amazon’s Mechanical Turk, and filtered by voting. For example, out of 308 utterances from *The Steppe*, 244 are in fact annotated, which raises the question whether the discarded utterances tend to be more difficult to annotate.

Table 4 shows the number of utterances in all

<sup>1</sup>[www.cs.ualberta.ca/~kondrak/austen](http://www.cs.ualberta.ca/~kondrak/austen)

	IS	AS	ES	Total
<i>Pride &amp; P.</i> (all)	663	292	305	1260
<i>Pride &amp; P.</i> (test)	65	29	32	126
<i>Emma</i>	236	55	106	397
<i>The Steppe</i>	93	39	112	244

Table 4: The number of utterances in various data sets by the type (IS - Implicit Speaker; AS - Anaphoric Speaker; ES - Explicit Speaker).

data sets. We selected Jane Austen’s *Emma* as a different novel by the same author, and Anton Chekhov’s *The Steppe* as a novel by a different author for our generalization experiments.

Since our goal is to match utterances to characters rather than to name mentions, a preprocessing step is performed to produce a list of characters in the novel and their aliases. For example, *Elizabeth Bennet* may be referred to as *Liz*, *Lizzy*, *Miss Lizzy*, *Miss Bennet*, *Miss Eliza*, and *Miss Elizabeth Bennet*. We apply a name entity tagger, and then group the names into sets of character aliases, together with their gender information. The sets of aliases are typically small, except for major characters, and can be compiled with the help of web resources, such as Wikipedia, or study guides, such as CliffsNotes<sup>TM</sup>. This preprocessing step could also be performed automatically using a canonicalization method (Andrews et al., 2012); however, since our focus is on speaker identification, we decided to avoid introducing annotation errors at this stage.

Other preprocessing steps that are required for processing a new novel include standardizing the typographical conventions, and performing POS tagging, NER tagging, and dependency parsing. We utilize the Stanford tools (Toutanova et al., 2003; Finkel et al., 2005; Marneffe et al., 2006).

## 7 Evaluation

In this section, we describe experiments conducted to evaluate our speaker identification approach. We refer to our main model as NEIGHBORS, because it incorporates features from the neighboring utterances, as described in Section 4.3. In contrast, the INDIVIDUAL model relies only on features from the current utterance. In an attempt to reproduce the evaluation methodology of EM2010, we also test the ORACLE model, which has access to the gold-standard information about the speakers of eight neighboring utterances in the

	<i>Pride &amp; P.</i>	<i>Emma</i>	<i>Steppe</i>
BASELINE	42.0	44.1	66.8
INDIVIDUAL	77.8	67.3	74.2
NEIGHBORS	82.5	74.8	80.3
ORACLE	86.5	80.1	83.6

Table 5: Speaker identification accuracy (in %) on *Pride & Prejudice*, *Emma*, and *The Steppe*.

range  $[n - 4, n + 4]$ . Lastly, the BASELINE approach selects the name that is the closest in the narration, which is more accurate than the “most recent name” baseline.

### 7.1 Results

Table 5 shows the results of the models trained on annotated utterances from *Pride & Prejudice* on three test sets. As expected, the accuracy of all learning models on the test set that comes from the same novel is higher than on unseen novels. However, in both cases, the drop in accuracy for the NEIGHBORS model is less than 10%.

Surprisingly, the accuracy is higher on *The Steppe* than on *Emma*, even though the different writing style of Chekhov should make the task more difficult for models trained on Austen’s prose. The protagonists of *The Steppe* are mostly male, and the few female characters rarely speak in the novel. This renders our gender feature virtually useless, and results in lower accuracy on anaphoric speakers than on explicit speakers. On the other hand, Chekhov prefers to mention speaker names in the dialogues (46% of utterances are in the explicit-speaker category), which makes his prose slightly easier in terms of speaker identification.

The relative order of the models is the same on all three test sets, with the NEIGHBORS model consistently outperforming the INDIVIDUAL model, which indicates the importance of capturing the speaker alternation pattern. The performance of the NEIGHBORS model is actually closer to the ORACLE model than to the INDIVIDUAL model.

Table 6 shows the results on *Emma* broken down according to the type of the utterance. Unsurprisingly, the explicit speaker is the easiest category, with nearly perfect accuracy. Both the INDIVIDUAL and the NEIGHBORS models do better on anaphoric speakers than on implicit speakers, which is also expected. However, it is not the

	IS	AS	ES	Total
INDIVIDUAL	52.5	67.3	100.0	67.3
NEIGHBORS	63.1	76.4	100.0	74.8
ORACLE	74.2	69.1	99.1	80.1

Table 6: Speaker identification accuracy (in %) on Austen’s *Emma* by the type of utterance.

case for the ORACLE model. We conjecture that the ORACLE model relies heavily on the neighborhood features (which are rarely wrong), and consequently tends to downplay the gender information, which is the only information extracted from the anaphora. In addition, anaphoric speaker is the least frequent of the three categories.

Table 7 shows the results of an ablation study performed to investigate the relative importance of features. The INDIVIDUAL model serves as the base model from which we remove specific features. All tested features appear to contribute to the overall performance, with the distance features and the unsupervised actor-topic features having the most pronounced impact. We conclude that the incorporation of the neighboring features, which is responsible for the difference between the INDIVIDUAL and NEIGHBORS models, is similar in terms of importance to our strongest textual features.

Feature	Impact
Closest Mention	-6.3
Unsupervised ACTM	-5.6
Name within Utterance	-4.8
Vocative	-2.4

Table 7: Results of feature ablation (in % accuracy) on *Pride & Prejudice*.

## 7.2 Comparison to EM2010

In this section we analyze in more detail our results on *Emma* and *The Steppe* against the published results of the state-of-the-art EM2010 system. Recall that both novels form a part of the corpus that was created by EM2010 for the development of their system.

Direct comparison to EM2010 is difficult because they compute the accuracy separately for seven different categories of utterances. For each category, they experiment with all combinations of three different classifiers and four score combination methods, and report only the accuracy

Character		
<i>id</i>	<i>name</i>	<i>gender</i>
...		
9	Mr. Collins	m
10	Charlotte	f
11	Jane Bennet	f
12	Elizabeth Bennet	f
...		

Relation			
<i>from</i>	<i>to</i>	<i>type</i>	<i>mode</i>
...			
10	9	husband	explicit
9	10	wife	derived
10	12	friend	explicit
12	10	friend	derived
11	12	sister	explicit
...			

Figure 3: Relational database with extracted social network.

achieved by the best performing combination on that category. In addition, they utilize the ground truth speaker information of the preceding utterances. Therefore, their results are best compared against our ORACLE approach.

Unfortunately, EM2010 do not break down their results by novel. They report the overall accuracy of 63% on both “anaphora trigram” (our *anaphoric speaker*), and “quote alone” (similar to our *implicit speaker*). If we combine the two categories, the numbers corresponding to our NEIGHBORS model are 65.6% on *Emma* and 64.4% on *The Steppe*, while ORACLE achieves 73.2% and 70.5%, respectively. Even though a direct comparison is not feasible, the numbers are remarkable considering the context of the experiment, which strongly favors the EM2010 system.

## 8 Extracting Family Relationships

In this section, we describe an application of the speaker identification system to the extraction of family relationships. Elson et al. (2010) extract unlabeled networks where the nodes represent characters and edges indicate their *proximity*, as indicated by their interactions. Our goal is to construct networks in which edges are labeled by the mutual relationships between characters in a novel. We focus on family relationships, but also include social relationships, such as *friend*

```

INSERT INTO Relation (id1, id2, t, m)
  SELECT r.to AS id1, r.from AS id2 , 'wife' AS t, 'derived' AS m
  FROM Relation r
  WHERE r.type='husband' AND r.mode='explicit' AND
        NOT EXISTS(SELECT * FROM Relation r2
                   WHERE r2.from=r.to AND r2.to=r.from AND r2.type=t)

```

Figure 4: An example inference rule.

and *attracted-to*.

Our approach to building a social network from the novel is to build an active database of relationships explicitly mentioned in the text, which is expanded by triggering the execution of queries that deduce implicit relations. This inference process is repeated for every discovered relationship until no new knowledge can be inferred.

The following example illustrates how speaker identification helps in the extraction of social relations among characters. Consider, the following conversation:

“How so? how can it affect them?”  
 “My dear Mr. Bennet,” replied *his wife*,  
 “how can you be so tiresome!”

If the speakers are correctly identified, the utterances are attributed to *Mr. Bennet* and *Mrs. Bennet*, respectively. Furthermore, the second utterance implies that its speaker is the wife of the preceding speaker. This is an example of an explicit relationship which is included in our database. Several similar extraction rules are used to extract explicit mentions indicating family and affective relations, including *mother*, *nephew*, and *fiancee*. We can also derive relationships that are not explicitly mentioned in the text; for example, that *Mr. Bennet* is the husband of *Mrs. Bennet*.

Figure 3 shows a snippet of the relational database of the network extracted from *Pride & Prejudice*. Table *Character* contains all characters in the book, each with a unique identifier and gender information, while Table *Relation* contains all relationships that are explicitly mentioned in the text or derived through reasoning.

Figure 4 shows an example of an inference rule used in our system. The rule derives a new relationship indicating that character  $c_1$  is the *wife* of character  $c_2$  if it is known (through an explicit mention in the text) that  $c_2$  is the *husband* of  $c_1$ . One condition for the rule to be applied is that the database must not already contain a record indicating the wife relationship. This inference rule

would derive the tuple in Figure 3 indicating that the wife of Mr. Collins is Charlotte.

In our experiment with *Pride & Prejudice*, a total of 55 explicitly indicated relationships were automatically identified once the utterances were attributed to the characters. From those, another 57 implicit relationships were derived through inference. A preliminary manual inspection of the set of relations extracted by this method (Makazhanov et al., 2012) indicates that all of them are correct, and include about 40% all personal relations that can be inferred by a human reader from the text of the novel.

## 9 Conclusion and Future Work

We have presented a novel approach to identifying speakers of utterances in novels. Our system incorporates a variety of novel features which utilize vocatives, unsupervised actor-topic models, and the speaker alternation pattern. The results of our evaluation experiments indicate a substantial improvement over the current state of the art.

There are several interesting directions for the future work. Although the approach introduced in this paper appears to be sufficiently general to handle novels written in a different style and period, more sophisticated statistical graphical models may achieve higher accuracy on this task. A reliable automatic generation of characters and their aliases would remove the need for the preprocessing step outlined in Section 6. The extraction of social networks in novels that we discussed in Section 8 would benefit from the introduction of additional inference rules, and could be extended to capture more subtle notions of sentiment or relationship among characters, as well as their development over time.

We have demonstrated that speaker identification can help extract family relationships, but the converse is also true. Consider the following utterance:

“Lizzy,” said her father, “I have given him my consent.”

In order to deduce the speaker of the utterance, we need to combine the three pieces of information: (a) the utterance is addressed to Lizzy (vocative prediction), (b) the utterance is produced by Lizzy’s father (pronoun resolution), and (c) Mr. Bennet is the father of Lizzy (relationship extraction). Similarly, in the task of compiling a list of characters, which involves resolving aliases such as *Caroline*, *Caroline Bingley*, and *Miss Bingley*, simultaneous extraction of family relationships would help detect the ambiguity of *Miss Bennet*, which can refer to any of several sisters. A joint approach to resolving speaker attribution, relationship extraction, co-reference resolution, and alias-to-character mapping would not only improve the accuracy on all these tasks, but also represent a step towards deeper understanding of complex plots and stories.

## Acknowledgments

We would like to thank Asli Celikyilmaz for collaboration in the early stages of this project, Susan Brown and Michelle Di Cintio for help with data annotation, and David Elson for the attempt to compute the accuracy of the EM2010 system on *Pride & Prejudice*. This research was partially supported by the Natural Sciences and Engineering Research Council of Canada.

## Abstract

Hierarchical Bayesian Models (HBMs) have been used with some success to capture empirically observed patterns of under- and overgeneralization in child language acquisition. However, as is well known, HBMs are “ideal” learning systems, assuming access to unlimited computational resources that may not be available to child language learners. Consequently, it remains crucial to carefully assess the use of HBMs along with alternative, possibly simpler, candidate models. This paper presents such an evaluation for a language acquisition domain where explicit HBMs have been proposed: the acquisition of English dative constructions. In particular, we present a detailed, empirically-grounded model-selection comparison of HBMs vs. a simpler alternative based on clustering along with maximum likelihood estimation that we call linear competition learning (LCL). Our results demonstrate that LCL can match HBM model performance without incurring on the high computational costs associated with HBMs.

## 1 Introduction

In recent years, with advances in probability and estimation theory, there has been much interest in Bayesian models (BMs) (Chater, Tenenbaum, and Yuille, 2006; Jones and Love, 2011) and their application to child language acquisition with its challenging com-

ination of structured information and incomplete knowledge, (Perfors, Tenenbaum, and Wonnacott, 2010; Hsu and Chater, 2010; Parisien, Fazly, and Stevenson, 2008; Parisien and Stevenson, 2010) as they offer several advantages in this domain. They can readily handle the evident noise and ambiguity of acquisition input, while at the same time providing efficiency via priors that mirror known pre-existing language biases. Further, hierarchical Bayesian Models (HBMs) can combine distinct abstraction levels of linguistic knowledge, from variation at the level of individual lexical items, to cross-item variation, using hyper-parameters to capture observed patterns of both under- and over-generalization as in the acquisition of e.g. dative alternations in English (Hsu and Chater, 2010; Perfors, Tenenbaum, and Wonnacott, 2010), and verb frames in a controlled artificial language (Wonnacott, Newport, and Tanenhaus, 2008).

HBMs can thus be viewed as providing a “rational” upper bound on language learnability, yielding optimal models that account for observed data while minimizing any required prior information. In addition, the clustering implicit in HBM modeling introduces additional parameters that can be tuned to specific data patterns. However, this comes at a well-known price: HBMs generally are also ideal learning systems, known to be computationally infeasible (Kwisthout, Wareham, and van Rooij, 2011). Approximations proposed to ensure computational tractability, like reducing the number of classes that need to be learned may also be linguistically and cognitively implausible. For instance, in terms of verb learning, this could

take the form of reducing the number of sub-categorization frames to the relevant subset, as in (Perfors, Tenenbaum, and Wonnacott, 2010), where only 2 frames are considered for ‘take’, when in fact it is listed in 6 frames by Levin (1993). Finally, comparison of various Bayesian models of the same task is rare (Jones and Love, 2011) and Bayesian inference generally can be demonstrated as simply one class of regularization or smoothing techniques among many others; given the problem at hand, there may well be other, equally compelling regularization methods for dealing with the bias-variance dilemma (e.g., SVMs (Shalizi, 2009)). Consequently, the relevance of HBMs for cognitively accurate accounts of human learning remains uncertain and needs to be carefully assessed.

Here we argue that the strengths of HBMs for a given task must be evaluated in light of their computational and cognitive costs, and compared to other viable alternatives. The focus should be on finding the simplest statistical models consistent with a given behavior, particularly one that aligns with known cognitive limitations. In the case of many language acquisition tasks this behavior often takes the form of overgeneralization, but with eventual convergence to some target language given exposure to more data.

In particular, in this paper we consider how children acquire English dative verb constructions, comparing HBMs to a simpler alternative, a linear competition learning (LCL) algorithm that models the behavior of a given verb as the linear competition between the evidence for that verb, and the average behavior of verbs belonging to its same class. The results show that combining simple clustering methods along with ordinary maximum likelihood estimation yields a result comparable to HBM performance, providing an alternative account of the same facts, without the computational costs incurred by HBM models that must rely, for example, on Markov Chain Monte Carlo (MCMC) methods for numerically integrating complex likelihood integrals, or on Chinese Restaurant Process (CRP) for producing partitions.

In terms of Marr’s hierarchy (Marr, 1982) learning verb alternations is an abstract com-

putational problem (Marr’s type I), solvable by many type II methods combining representations (models, viz. HBMs or LCLs) with particular algorithms. The HBM convention of adopting ideal learning amounts to invoking unbounded algorithmic resources, solvability in principle, even though in practice such methods, even approximate ones, are provably NP-hard (cf. (Kwisthout, Wareham, and van Rooij, 2011)). Assuming cognitive plausibility as a desideratum, we therefore examine whether HBMs can also be approximated by another type II method (LCLs) that does not demand such intensive computation. Any algorithm that approximates an HBM can be viewed as implementing a somewhat different underlying model; if it replicates HBM prediction performance but is simpler and less computationally complex then we assume it is preferable.

This paper is organized as follows: we start with a discussion of formalizations of language acquisition tasks, §2. We present our experimental framework for the dative acquisition task, formalizing a range of learning models from simple MLE methods to HBM techniques, §3, and a computational evaluation of each model, §4. We finish with conclusions and possibilities for future work, §5.

## 2 Evidence in Language Acquisition

A familiar problem for language acquisition is how children learn which verbs participate in so-called dative alternations, exemplified by the child-produced sentences 1 to 3, from the Brown (1973) corpus in CHILDES (MacWhinney, 1995).

1. *you took me three scrambled eggs* (a direct object dative (DOD) from Adam at age 3;6)
2. *Mommy can you fix dis for me ?* (a prepositional dative (PD) from Adam at age 4;7)
3. *\*Mommy, fix me my tiger* (from Adam at age 5;2)

Examples like these show that children generalize their use of verbs. For example, in sentence (1), the child Adam uses *take* as a DOD before any recorded occurrence of a similar use of *take* in adult speech to Adam. Such verbs *alternate* because they can also occur with a prepositional form, as in sentence (2). However, sometimes a child’s use of verbs like

these amounts to an overgeneralization – that is, their productive use of a verb in a pattern that does not occur in the adult grammar, as in sentence (3), above. Faced with these two verb frames the task for the learner is to decide for a particular verb if it is a non-alternating DOD only verb, a PD only verb, or an alternating verb that allows both forms.

This ambiguity raises an important learnability question, conventionally known as Baker’s paradox (Baker, 1979). On the assumption that children only receive positive examples of verb forms, then it is not clear how they might recover from the overgeneralization exhibited in sentence (3) above, because they will never receive positive sentences from adults like (3), using *fix* in a DOD form. As has long been noted, if negative examples were systematically available to learners, then this problem would be solved, since the child would be given evidence that the DOD form is not possible in the adult grammar. However, although parental correction could be considered to be a source of negative evidence, it is neither systematic nor generally available to all children (Marcus, 1993). Even when it does occur, all careful studies have indicated that it seems mostly concerned with semantic appropriateness rather than syntax. In the cases where it is related to syntax, it is often difficult to determine what the correction refers to in the utterance and besides children seem to be oblivious to the correction (Brown and Hanlon, 1970; Ingram, 1989).

One alternative solution to Baker’s paradox that has been widely discussed at least since Chomsky (1981) is the use of *indirect negative evidence*. On the indirect negative evidence model, if a verb is not found where it would be expected to occur, the learner may conclude it is not part of the adult grammar. Crucially, the indirect evidence model is inherently statistical. Different formalizations of indirect negative evidence have been incorporated in several computational learning models for learning e.g. grammars (Briscoe, 1997; Villavicencio, 2002; Kwiatkowski et al., 2010); dative verbs (Perfors, Tenenbaum, and Wonnacott, 2010; Hsu and Chater, 2010); and multiword verbs (Nematzadeh, Fazly, and Stevenson, 2013). Since a number of closely related

models can all implement the indirect negative evidence approach, the decision of which one to choose for a given task may not be entirely clear. In this paper we compare a range of statistical models consistent with a certain behavior: early overgeneralization, with eventual convergence to the correct target on the basis of exposure to more data.

### 3 Materials and Methods

#### 3.1 Dative Corpora

To emulate a child language acquisition environment we use naturalistic longitudinal child-directed data, from the Brown corpus in CHILDES, for one child (Adam) for a subset of 19 verbs in the DOD and PD verb frames, figure 1. This dataset was originally reported in Perfors, Tenenbaum, and Wonnacott (2010), and longitudinal and incremental aspects to acquisition are approximated by dividing the data available into 5 incremental epochs (E1 to E5 in the figures), where at the final epoch the learner has seen the full corpus.

Model comparison requires a gold standard database for acquisition, reporting which frames have been learned for which verbs at each stage, and how likely a child is of making creative uses of a particular verb in a new frame. An independent gold standard with developmental information (e.g. Gropen et al. (1989)) would clearly be ideal. Absent this, a first step is demonstrating that simpler alternative models can replicate HBM performance on their own terms. Therefore, the gold standard we use for evaluation is the classification predicted by Perfors, Tenenbaum, and Wonnacott (2010). The evaluations reported in our analysis take into account intrinsic characteristics of each model in relation to the likelihoods of the verbs, to determine the extent to which the models go beyond the data they were exposed to, discussed in section 2. Further, since it has been argued that very low frequency verbs may not yet be firmly placed in a child’s lexicon (Yang, 2010; Gropen et al., 1989), at each epoch we also impose a low-frequency threshold of 5 occurrences, considering only verbs that the learner has seen at least 5 times. This use of a low-frequency threshold for learning has extensive support in the literature for learning

of all kinds in both human and non-human animals, e.g. (Gallistel, 2002). A cut-off frequency in this range has also commonly been used in NLP tasks like POS tagging (Ratnaparkhi, 1999).

### 3.2 The learners

We selected a set of representative statistical models that are capable in principle of solving this classification task, ranging from what is perhaps the simplest possible, a simple binomial, all the way to multi-level hierarchical Bayesian approaches.

A Binomial distribution serves as the simplest model for capturing the behavior of a verb occurring in either DOD or PD frame. Representing the probability of DOD as  $\theta$ , after  $n$  occurrences of the verb the probability that  $y$  of them are DOD is:

$$p(y|\theta, n) = \binom{n}{y} \theta^y (1 - \theta)^{n-y} \quad (1)$$

Considering that  $p(y|\theta, n)$  is the likelihood in a Bayesian framework, the simplest and the most intuitive estimator of  $\theta$ , given  $y$  in  $n$  verb occurrences, is the Maximum Likelihood Estimator (MLE):

$$\theta_{MLE} = \frac{y}{n} \quad (2)$$

$\theta_{MLE}$  is viable as a learning model in the sense that its accuracy increases as the amount of evidence for a verb grows ( $n \rightarrow \infty$ ), reflecting the incremental, on-line character of language learning. However, one well known limitation of MLE is that it assigns zero probability mass to unseen events. Ruling out events on the grounds that they did not occur in a finite data set early in learning may be too strong – though it should be noted that this is simply one (overly strong) version of the indirect negative evidence position.

Again as is familiar, to overcome zero count problem, models adopt one or another method of smoothing to assign a small probability mass to unseen events. In a Bayesian formulation, this amounts to assigning non-zero probability mass to some set of priors; smoothing also captures the notion of *generalization*, making predictions about data that has never been seen by the learner. In the

context of verb learning smoothing could be based on several principles:

- an (innate) expectation as to how verbs in general should behave;
- an acquired class-based expectation of the behavior of a verb, based on its association to similar but more frequent verbs.

The former can be readily implemented in terms of prior probability estimates. As we discuss below, class-based estimates arise from one or another clustering method, and can produce more accurate estimates for less frequent verbs based on patterns already learned for more frequent verbs in the same class; see (Perfors, Tenenbaum, and Wonnacott, 2010). In this case, smoothing is a side-effect of the behavior of a class as a whole.

When learning begins, the prior probability is the only source of information for a learner and, as such, dominates the value of the posterior probability. However, in the large sample limit, it is the likelihood that dominates the posterior distribution regardless of the prior. In Hierarchical Bayesian Models both effects are naturally incorporated. The prior distribution is structured as a chain of distributions of parameters and hyper-parameters, and the data may be divided into classes that share some of the hyper-parameters, as defined below for the case of a three levels model:

$$\begin{aligned} \lambda &\sim \text{Exponential}(1) \\ \mu &\sim \text{Exponential}(1) \\ \alpha_k &\sim \text{Exponential}(\lambda) \\ \beta_k &\sim \text{Beta}(\mu, \mu) \\ \theta_{ik} &\sim \text{Beta}(\alpha_k \beta_k, \alpha_k (1 - \beta_k)) \\ y_i | n_i &\sim \text{Binomial}(\theta_{ik}) \end{aligned}$$

The indices refer to the possible hierarchies among the hyper-parameters.  $\lambda$  and  $\mu$  are in the top, and they are shared by all verbs. Then there are classes of different  $\alpha_k, \beta_k$ , and the probabilities for the DOD frame for the different verbs ( $\theta_{ik}$ ) are drawn according to the classes  $k$  assigned to them. An estimate for ( $\theta_{ik}$ ) for a given configuration of clusters is given by

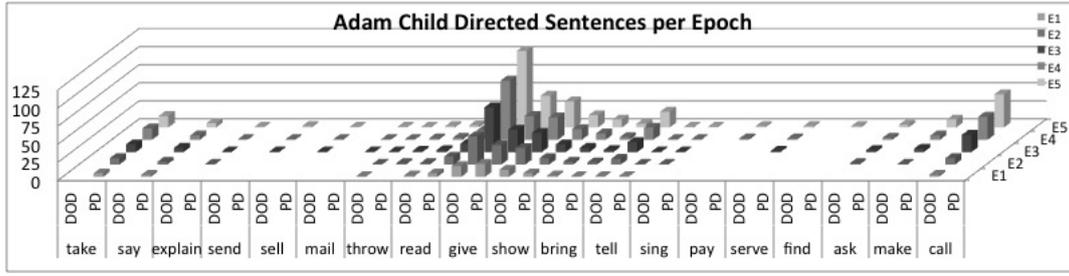

Figure 1: Verb tokens per epoch (E1 to E5)

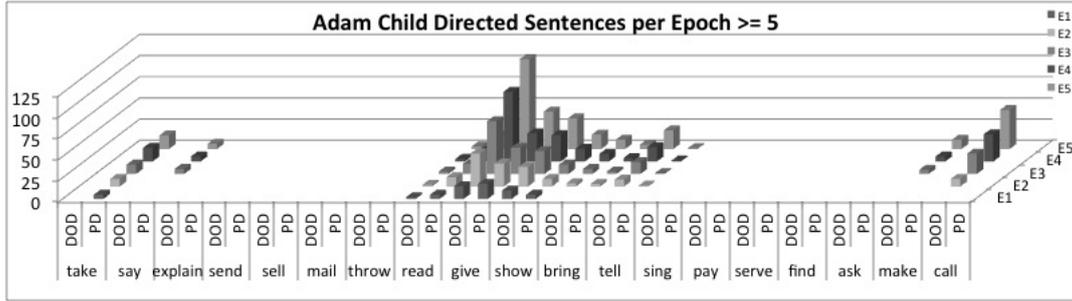

Figure 2: Verb tokens  $\geq 5$  per epoch (E1 to E5)

$$\theta_{HBM}^{ik} = \frac{1}{P(\mathbf{Y})} \int \frac{y_i + \alpha_k \beta_k}{n_i + \alpha_k} P_{L3}^*(\alpha, \beta, \lambda, \mu | \mathbf{Y}) d\alpha d\beta d\lambda d\mu$$

where  $P(\mathbf{Y})$  is the evidence of the data, the unnormalized posterior for the hyper-parameters is

$$P_{L3}^*(\alpha, \beta, \lambda, \mu | \mathbf{Y}) = \left( \prod_k P(\{y_i, n_i\}_{i \in k} | \alpha_k, \beta_k) \text{Exp}(\alpha_k | \lambda) \text{Beta}(\beta_k | \mu, \mu) \right) * \text{Exp}(\lambda | 1) \text{Exp}(\mu | 1)$$

and the likelihood for  $\alpha$  and  $\beta$  is

$$P(\{y_i, n_i\}_{i \in k} | \alpha_k, \beta_k) = \prod_{i \in k} \binom{n_i}{y_i} \frac{B(\alpha_k \beta_k + y_i, \alpha_k (1 - \beta_k) + n_i - y_i)}{B(\alpha_k \beta_k, \alpha_k (1 - \beta_k))}$$

The Hierarchical Bayesian Model prediction for  $\theta_i$  is the average of the estimate  $\theta_{HBM}^{ik}$  over all possible partitions of the verbs in the task. To simplify the notation we can write

$$\theta_{HBM} = E \left[ \frac{y + \alpha \beta}{n + \alpha} \right] \quad (3)$$

where in the expression  $E[\dots]$  are included the integrals described above and the average of all possible class partitions. Due to this complexity, in practice even small data sets require the use of MCMC methods, and statistical models for partitions, like CRP (Gelman et al., 2003; Perfors, Tenenbaum, and Wonnacott,

2010). This complexity also calls into question the cognitive fidelity of such approaches.

Eq.3 is particularly interesting because by fixing  $\alpha$  and  $\beta$  (instead of averaging over them) it is possible to deduce simpler (and classical) models: MLE corresponds to  $\alpha = 0$ ; the so called “add-one” smoothing (referred in this paper as L1) corresponds to  $\alpha = 2$  and  $\beta = 1/2$ . From Eq.3 it is also clear that if  $\alpha$  and  $\beta$  (or their distributions) are unchanged, as the evidence of a verb grows ( $n \rightarrow \infty$ ), the HBM estimate approaches MLE’s, ( $\theta_{HBM} \rightarrow \theta_{MLE}$ ). On the other hand, when  $\alpha \gg n$ ,  $\theta_{HBM} \sim \beta$ , so that  $\beta$  can be interpreted as a prior value for  $\theta$  in the low frequency limit.

Following this reasoning, we propose an alternative approach, a linear competition learner (LCL), that explicitly models the behavior of a given verb as the linear competition between the evidence for the verb, and the average behavior of verbs of the same class. As clustering is defined independently from parameter estimation, the advantages of the proposed approach are twofold. First, it is computationally much simpler, not requiring approximations by Monte Carlo methods. Second, differently from HBMs where the same attributes are used for clustering and parameter estimation (in this case the DOD and PD counts for each verb), in LCL cluster-

ing may be done using more general contexts that employ a variety of linguistic and environmental attributes.

For LCL the prior and class-based information are incorporated as:

$$\theta_{LCL} = \frac{y_i + \alpha_C \beta_C}{n_i + \alpha_C} \quad (4)$$

where  $\alpha_C$  and  $\beta_C$  are defined via justifiable heuristic expressions dependent solely on the statistics of the class attributed to each verb  $i$ .

The strength of the prior ( $\alpha_C$ ) is a monotonic function of the number of elements ( $m_C$ ) in the class  $C$ , excluding the target verb  $v_i$ . To approximate the gold standard behavior of the HBM for this task (Perfors, Tenenbaum, and Wonnacott, 2010) we chose the following function for  $\alpha_C$ :

$$\alpha_C = m_C^{3/2}(1 - m_C^{-1/5}) + 0.1 \quad (5)$$

with the strength of the prior for the LCL model depending on the number of verbs in the class, not on their frequency. Eq.5 was chosen as a good fit to HBMs, without incurring their complexity. The powers are simple fractions, not arbitrary numbers. A best fit was not attempted due to the lack of assessment of how accurate HBMs are on real data.

The prior value ( $\beta_C$ ) is a smoothed estimation of the probability of DOD in a given class, combining the evidence for all verbs in that class:

$$\beta_C = \frac{Y_C + 1/2}{N_C + 1} \quad (6)$$

in this case  $Y_C$  is the number of DOD occurrences in the class, and  $N_C$  the total number of verb occurrences in the class, in both cases excluding the target verb  $v_i$ .

The interpretation of these parameters is as follows:  $\beta_C$  is the estimate of  $\theta$  in the absence of any data for a verb; and  $\alpha_C$  controls the crossover between this estimate and MLE, with a large  $\alpha_C$  requiring a larger sample ( $n_i$ ) to overcome the bias given by  $\beta_C$ .

For comparative purposes, in this paper we examine alternative models for (a) probability estimation and (b) clustering. The models are the following:

- two models without clusters: MLE and L1;

- two models where clusters are performed independently: LCL and MLE $_{\alpha\beta}$ ; and
- the full HBM described before.

MLE $_{\alpha\beta}$  corresponds to replacing  $\alpha, \beta$  in eq.3 by their maximal likelihood values calculated from  $P(\{y_i, n_i\}_{i \in k} | \alpha, \beta)$  described before.

For models without clustering, estimation is based solely on the observed behavior of verbs. With clustering, same-cluster verbs share some parameters, influencing one another. HBMs place distributions over possible clusters, with estimation derived from averages over distributions. In HBMs, clustering and probability estimation are calculated jointly. In the other models these two estimates are calculated separately, permitting 'plug-and-play' use of external clustering methods, like X-means (Pelleg and Moore, 2000)<sup>1</sup>. However, to further assess the impact of cluster assignment on alternative model performance, we also used the clusters that maximize the evidence of the HBM for the DOD and PD counts of the target verbs, and we refer to these as Maximum Evidence (ME) clusters. In MWE clusters, verbs are separated into 3 classes: one if they have counts for both frames; another for only the DOD frame; and a final for only the PD frame.

## 4 Evaluation

The learning task consists of estimating the probability that a given verb occurs in a particular frame, using previous occurrences as the basis for this estimation. In this context, overgeneralization can be viewed as the model's predictions that a given verb seen only in one frame (say, a PD) can also occur in the other (say, a DOD) as well, and it decreases as the learner receives more data. In one extreme we have MLE, which does not overgeneralize, and in the other the L1 model, which assigns uniform probability for all unseen cases. The other 3 models fall somewhere in between, overgeneralizing beyond the observed data, using the prior and class-based smoothing to assign some (low) probability mass to an unseen verb-frame pair. The relevant models'

<sup>1</sup>Other clustering algorithms were also used; here we report X-means results as representative of these models. X-means is available from <http://www.cs.waikato.ac.nz/ml/weka/>

predictions for each of the target verbs in the DOD frame, given the full corpus, are in figure 3. In either end of the figure are the verbs that were attested in only one of the frames (PD only at the left-hand end, and DOD only at the right-hand end). For these verbs, LCL and HBM exhibit similar behavior. When the low-frequency threshold is applied,  $MLE_{\alpha\beta}$ , HBM and LCL work equally well, figure 4.

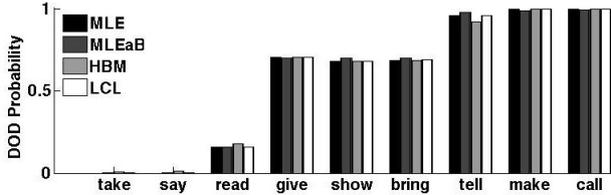

Figure 4: Probability of verbs in DOD frame, Low Frequency Threshold.

To examine how overgeneralization progresses during the course of learning as the models were exposed to increasing amounts of data, we used the corpus divided by cumulative epochs, as described in §3.1. For each epoch, verbs seen in only one of the frames were divided in 5 frequency bins, and the models were assessed as to how much overgeneralization they displayed for each of these verbs. Following Perfors, Tenenbaum, and Wonnacott (2010) overgeneralization is calculated as the absolute difference between the models predicted  $\theta$  and  $\theta_{MLE}$ , for each of the epochs, figure 5, and for comparative purposes their alternating/non-alternating classification is also adopted. For non-alternating verbs, overgeneralization reflects the degree of smoothing of each model. As expected, the more frequent a verb is, the more confident the model is in the indirect negative evidence it has for that verb, and the less it overgeneralizes, shown in the lighter bars in all epochs. In addition, the overall effect of larger amounts of data are indicated by a reduction in overgeneralization epoch by epoch. The effects of class-based smoothing can be assessed comparing L1, a model without clustering which displays a constant degree of overgeneralization regardless of the epoch, while HBM uses a distribution over clusters and the other models X-means. If a low-frequency threshold is applied, the differences between the models

decrease significantly and so does the degree of overgeneralization in the models' predictions, as shown in the 3 lighter bars in the figure.

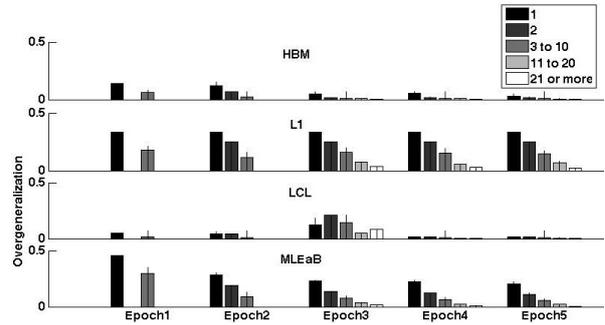

Figure 5: Overgeneralization, per epoch, per frequency bin, where 0.5 corresponds to the maximum overgeneralization.

While the models differ somewhat in their predictions, the quantitative differences need to be assessed more carefully. To compare the models and provide an overall difference measure, we use the predictions of the more complex model, HBM, as a baseline and then calculate the difference between its predictions and those of the other models. We used three different measures for comparing models, one for their standard difference; one that prioritizes agreement for high frequency verbs; and one that focuses more on low frequency verbs.

The first measure, denoted *Difference*, captures a direct comparison between two models,  $M_1$  and  $M_2$  as the average prediction difference among the verbs, and is defined as:

$$D(M_1, M_2) = \frac{1}{N_{verbs}} \sum_{i=1}^{N_{verbs}} abs(\theta_{M_1}^i - \theta_{M_2}^i)$$

This measure treats all differences uniformly, regardless of whether they relate to high or low frequency verbs in the learning sample (e.g. for *bring* with 150 counts and *serve* with only 1 have the same weight). To focus on high frequency verbs, we also define the *Weighted Difference* between two models as:

$$D_n(M_1, M_2) = \frac{1}{\sum_i n_i} \sum_{i=1}^{N_{verbs}} n_i abs(\theta_{M_1}^i - \theta_{M_2}^i)$$

Here we expect  $D_n < D$  since models tend to

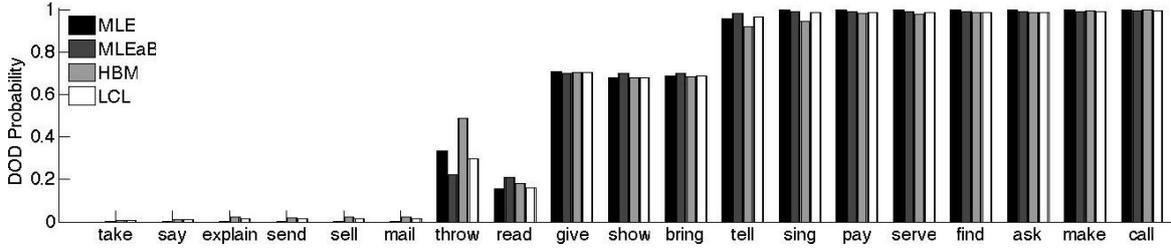

Figure 3: Probability of verbs in DOD frame.

agree as the amount of evidence for each verb increases. Conversely, our third measure, denoted *Inverted*, prioritizes the agreement between two models on low frequency verbs, defined as follows:

$$D_{1/n}(M_1, M_2) = \frac{1}{\sum_i 1/n_i} \sum_{i=1}^{N_{verbs}} \frac{1}{n_i} abs(\theta_{M_1}^i - \theta_{M_2}^i)$$

$D_{1/n}$  captures the degree of similarity in overgeneralization between two models. The results of applying these three difference measures are shown in figure 6 for the relevant models, where grey is for  $D(M_1, M_2)$ , black for  $D_n(M_1, M_2)$  and white for  $D_{1/n}(M_1, M_2)$ . Given the probabilistic nature of Monte Carlo methods, there is also a variation between different runs of the HBM model (HBM to HBM-2), and this indicates that models that perform within these bounds can be considered to be equivalent (e.g. HBMs and ME-MLE $_{\alpha\beta}$  for Weighted Difference, and the HBMs and X-MLE $_{\alpha\beta}$  for the Inverted Difference).

Comparing the prediction agreement, the strong influence of clustering is clear: the models that have HBM compatible clusters have similar performances. For instance, all the models that adopt the ME clusters for the data perform closest to HBMs. Moreover, the weighted differences tend to be smaller than 0.01 and around 0.02 for the inverted differences. The results for these measures become even closer in most cases when the low frequency threshold is adopted, figure 7, as the

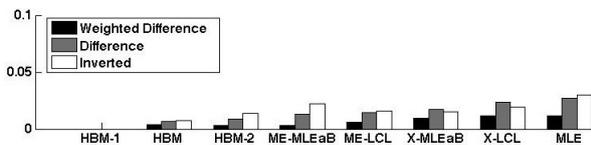

Figure 6: Model Comparisons.

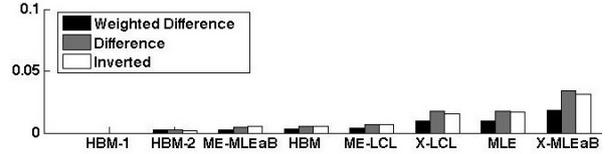

Figure 7: Model Comparison - Low Frequency Threshold.

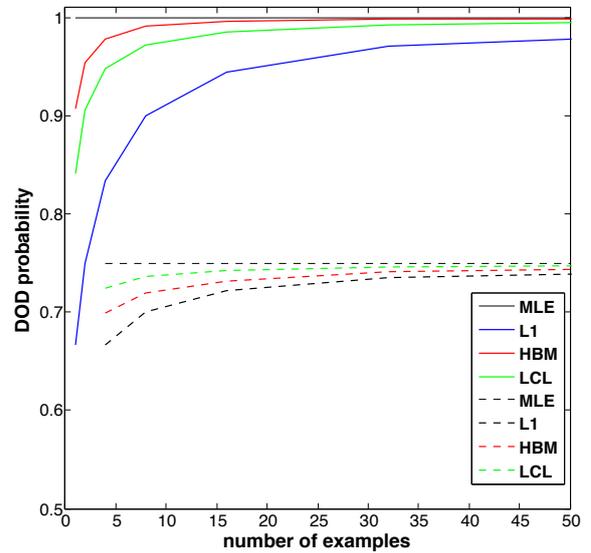

Figure 8: DOD probability evolution for models with increase in evidence

evidence reduces the influence of the prior.

To examine the decay of overgeneralization with the increase in evidence for these models, two simulated scenarios are defined for a single generic verb: one where the evidence for DOD amounts to 75% of the data (dashed lines) and in the other to 100% (solid lines), figures 9 and 8. Unsurprisingly, the performance of the models is dependent on the amount of evidence available. This is a consequence of the decrease in the influence of the priors as the sample size increases in a rate of  $1/N$ , as shown in figure 9 for the decrease in overgeneralization. Ultimately it is the ev-

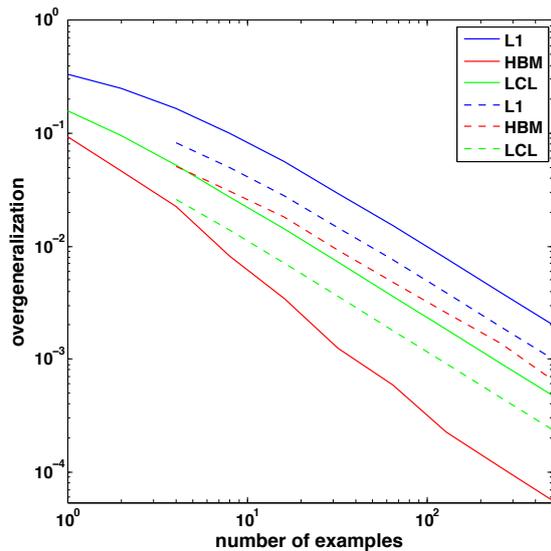

Figure 9: Overgeneralization reduction with increase in evidence

idence that dominates the posterior probability. Although the Bayesian model exhibits fast convergence, after 10 examples, the simpler model L1 is only approximately 3% below the Bayesian model in performance for scenario 1 and is still 90% accurate in scenario 2, figure 8.

These results suggest that while these models all differ slightly in the degree of overgeneralization for low frequency data and noise, these differences are small, and as evidence reaches approximately 10 examples per verb, the overall performance for all models approaches that of MLE.

## 5 Conclusions and Future Work

HBM's have been successfully used for a number of language acquisition tasks capturing both patterns of under- and overgeneralization found in child language acquisition. Their (hyper)parameters provide robustness for dealing with low frequency events, noise, and uncertainty and a good fit to the data, but this fidelity comes at the cost of complex computation. Here we have examined HBM's against computationally simpler approaches to dative alternation acquisition, which implement the indirect negative approach. We also advanced several measures for model comparison in order to quantify their agreement to assist in the task of model selection. The results show that the proposed LCL model, in

particular, that combines class-based smoothing with maximum likelihood estimation, obtains results comparable to those of HBM's, in a much simpler framework. Moreover, when a cognitively-viable frequency threshold is adopted, differences in the performance of all models decrease, and quite rapidly approach the performance of MLE.

In this paper we used standard clustering techniques grounded solely on verb counts to enable comparison with previous work. However, a variety of additional linguistic and distributional features could be used for clustering verbs into more semantically motivated classes, using a larger number of frames and verbs. This will be examined in future work. We also plan to investigate the use of clustering methods more targeted to language tasks (Sun and Korhonen, 2009).

## Abstract

Automatic acquisition of inference rules for predicates has been commonly addressed by computing distributional similarity between vectors of argument words, operating at the word space level. A recent line of work, which addresses context sensitivity of rules, represented contexts in a latent topic space and computed similarity over topic vectors. We propose a novel two-level model, which computes similarities between word-level vectors that are biased by topic-level context representations. Evaluations on a naturally-distributed dataset show that our model significantly outperforms prior word-level and topic-level models. We also release a first context-sensitive inference rule set.

## 1 Introduction

Inference rules for predicates have been identified as an important component in semantic applications, such as Question Answering (QA) (Ravichandran and Hovy, 2002) and Information Extraction (IE) (Shinyama and Sekine, 2006). For example, the inference rule ‘ $X \text{ treat } Y \rightarrow X \text{ relieve } Y$ ’ can be useful to extract pairs of drugs and the illnesses which they relieve, or to answer a question like “Which drugs relieve headache?”. Along this vein, such inference rules constitute a crucial component in generic modeling of textual inference, under the Textual Entailment paradigm (Dagan et al., 2006; Dinu and Wang, 2009).

Motivated by these needs, substantial research was devoted to automatic learning of inference rules from corpora, mostly in an unsupervised distributional setting. This research line was mainly initiated by the highly-cited DIRT algorithm (Lin and Pantel, 2001), which learns inference for binary predicates with two argument slots (like the

rule in the example above). DIRT represents a predicate by two vectors, one for each of the argument slots, where the vector entries correspond to the argument words that occurred with the predicate in the corpus. Inference rules between pairs of predicates are then identified by measuring the similarity between their corresponding argument vectors. This general scheme was further enhanced in several directions, e.g. directional similarity (Bhagat et al., 2007; Szpektor and Dagan, 2008) and meta-classification over similarity values (Berant et al., 2011). Consequently, several knowledge resources of inference rules were released, containing the top scoring rules for each predicate (Schoenmackers et al., 2010; Berant et al., 2011; Nakashole et al., 2012).

The above mentioned methods provide a single confidence score for each rule, which is based on the obtained degree of argument-vector similarities. Thus, a system that applies an inference rule to a text may estimate the validity of the rule application based on the pre-specified rule score. However, the validity of an inference rule may depend on the context in which it is applied, such as the context specified by the given predicate’s arguments. For example, ‘ $AT\&T \text{ acquire } T\text{-Mobile} \rightarrow AT\&T \text{ purchase } T\text{-Mobile}$ ’, is a valid application of the rule ‘ $X \text{ acquire } Y \rightarrow X \text{ purchase } Y$ ’, while ‘ $Children \text{ acquire } skills \rightarrow Children \text{ purchase } skills$ ’ is not. To address this issue, a line of works emerged which computes a *context-sensitive* reliability score for each rule *application*, based on the given context.

The major trend in context-sensitive inference models utilizes latent or class-based methods for context modeling (Pantel et al., 2007; Szpektor et al., 2008; Ritter et al., 2010; Dinu and Lapata, 2010b). In particular, the more recent methods (Ritter et al., 2010; Dinu and Lapata, 2010b) modeled predicates in context as a probability distribution over topics learned by a Latent Dirichlet Allo-

cation (LDA) model. Then, similarity is measured between the two topic distribution vectors corresponding to the two sides of the rule in the given context, yielding a context-sensitive score for each particular rule application.

We notice at this point that while context-insensitive methods represent predicates by argument vectors in the original fine-grained word space, context-sensitive methods represent them as vectors at the level of latent topics. This raises the question of whether such coarse-grained topic vectors might be less informative in determining the semantic similarity between the two predicates.

To address this hypothesized caveat of prior context-sensitive rule scoring methods, we propose a novel generic scheme that integrates word-level and topic-level representations. Our scheme can be applied on top of any context-insensitive “base” similarity measure for rule learning, which operates at the word level, such as Cosine or Lin (Lin, 1998). Rather than computing a single context-insensitive rule score, we compute a distinct word-level similarity score for each topic in an LDA model. Then, when applying a rule in a given context, these different scores are weighed together based on the specific topic distribution under the given context. This way, we calculate similarity over vectors in the original word space, while biasing them towards the given context via a topic model.

In order to promote replicability and equal-term comparison with our results, we based our experiments on publicly available datasets, both for unsupervised learning of the evaluated models and for testing them over a random sample of rule applications. We apply our two-level scheme over three state-of-the-art context-insensitive similarity measures. The evaluation compares performances both with the original context-insensitive measures and with recent LDA-based context-sensitive methods, showing consistent and robust advantages of our scheme. Finally, we release a context-sensitive rule resource comprising over 2,000 frequent verbs and one million rules.

## 2 Background and Model Setting

This section presents components of prior work which are included in our model and experiments, setting the technical preliminaries for the rest of the paper. We first present context-insensitive rule

learning, based on distributional similarity at the word level, and then context-sensitive scoring for rule applications, based on topic-level similarity. Some further discussion of related work appears in Section 6.

### 2.1 Context-insensitive Rule Learning

A predicate inference rule ‘ $LHS \rightarrow RHS$ ’, such as ‘ $X \text{ acquire } Y \rightarrow X \text{ purchase } Y$ ’, specifies a directional inference relation between two predicates. Each rule side consists of a lexical predicate and (two) variable slots for its arguments.<sup>1</sup> Different representations have been used to specify predicates and their argument slots, such as word lemma sequences, regular expressions and dependency parse fragments. A rule can be *applied* when its LHS matches a predicate with a pair of arguments in a text, allowing us to infer its RHS, with the corresponding instantiations for the argument variables. For example, given the text “*AT&T acquires T-Mobile*”, the above rule infers “*AT&T purchases T-Mobile*”.

The DIRT algorithm (Lin and Pantel, 2001) follows the distributional similarity paradigm to learn predicate inference rules. For each predicate, DIRT represents each of its argument slots by an *argument vector*. We denote the two vectors of the  $X$  and  $Y$  slots of a predicate  $pred$  by  $v_{pred}^x$  and  $v_{pred}^y$ , respectively. Each entry of a vector  $v$  corresponds to a particular word (or term)  $w$  that instantiated the argument slot in a learning corpus, with a value  $v(w) = PMI(pred, w)$  (with PMI standing for point-wise mutual information).

To learn inference rules, DIRT considers (in principle) each pair of binary predicates that occurred in the corpus for a candidate rule, ‘ $LHS \rightarrow RHS$ ’. Then, DIRT computes a *reliability score* for the rule by combining the measured similarities between the corresponding argument vectors of the two rule sides. Concretely, denoting by  $l$  and  $r$  the predicates appearing in the two rule sides, DIRT’s reliability score is defined as follows:

$$\begin{aligned} \text{score}_{\text{DIRT}}(LHS \rightarrow RHS) \\ = \sqrt{\text{sim}(v_l^x, v_r^x) \cdot \text{sim}(v_l^y, v_r^y)} \end{aligned} \quad (1)$$

where  $\text{sim}(v, v')$  is a vector similarity measure. Specifically, DIRT employs the Lin similarity

<sup>1</sup>We follow most of the inference-rule learning literature, which focused on binary predicates. However, our context-sensitive scheme can be applied to any arity.

measure from (Lin, 1998), defined as follows:

$$Lin(v, v') = \frac{\sum_{w \in v \cap v'} [v(w) + v'(w)]}{\sum_{w \in v \cup v'} [v(w) + v'(w)]} \quad (2)$$

We note that the general DIRT scheme may be used while employing other “base” vector similarity measures. For example, the *Lin* measure is symmetric, and thus using it would yield the same reliability score when swapping the two sides of a rule. This issue has been addressed in a separate line of research which introduced directional similarity measures suitable for inference relations (Bhagat et al., 2007; Szpektor and Dagan, 2008; Kotlerman et al., 2010). In our experiments we apply our proposed context-sensitive similarity scheme over three different base similarity measures.

DIRT and similar context-insensitive inference methods provide a single reliability score for a learned inference rule, which aims to predict the validity of the rule’s applications. However, as exemplified in the Introduction, an inference rule may be valid in some contexts but invalid in others (e.g. *acquiring* entails *purchasing* for *goods*, but not for *skills*). Since vector similarity in DIRT is computed over the single aggregate argument vector, the obtained reliability score tends to be biased towards the dominant contexts of the involved predicates. For example, we may expect a higher score for ‘*acquire* → *purchase*’ than for ‘*acquire* → *learn*’, since the former matches a more frequent sense of *acquire* in a typical corpus. Following this observation, it is desired to obtain a *context-sensitive reliability score* for each rule application in a given context, as described next.

## 2.2 Context-sensitive Rule Applications

To assess the reliability of applying an inference rule in a given context we need some model for context representation, that should affect the rule reliability score. A major trend in past work is to represent contexts in a reduced-dimensionality latent or class-based model. A couple of earlier works utilized a cluster-based model (Pantel et al., 2007) and an LSA-based model (Szpektor et al., 2008), in a selectional-preferences style approach. Several more recent works utilize a Latent Dirichlet Allocation (LDA) (Blei et al., 2003) framework. We now present an underlying unified view of the *topic-level* models in (Ritter et al., 2010; Dinu and Lapata, 2010b), which we follow in our

own model and in comparative model evaluations. We note that a similar LDA model construction was employed also in (Séaghdha, 2010), for estimating predicate-argument likelihood.

First, an LDA model is constructed, as follows. Similar to the construction of argument vectors in the distributional model (described above in subsection 2.1), all arguments instantiating each predicate slot are extracted from a large learning corpus. Then, for each slot of each predicate, a pseudo-document is constructed containing the set of all argument words that instantiated this slot in the corpus. We denote the two documents constructed for the *X* and *Y* slots of a predicate *pred* by  $d_{pred}^x$  and  $d_{pred}^y$ , respectively. In comparison to the distributional model, these two documents correspond to the analogous argument vectors  $v_{pred}^x$  and  $v_{pred}^y$ , both containing exactly the same set of words.

Next, an LDA model is learned from the set of all pseudo-documents, extracted for all predicates.<sup>2</sup> The learning process results in the construction of *K* latent topics, where each topic *t* specifies a distribution over all words, denoted by  $p(w|t)$ , and a topic distribution for each pseudo-document *d*, denoted by  $p(t|d)$ .

Within the LDA model we can derive the a-posteriori topic distribution conditioned on a particular word within a document, denoted by  $p(t|d, w) \propto p(w|t) \cdot p(t|d)$ . In the topic-level model, *d* corresponds to a predicate slot and *w* to a particular argument word instantiating this slot. Hence,  $p(t|d, w)$  is viewed as specifying the relevance (or likelihood) of the topic *t* for the predicate slot in the context of the given argument instantiation. For example, for the predicate slot ‘*acquire Y*’ in the context of the argument ‘*IBM*’, we expect high relevance for a topic about companies, while in the context of the argument ‘*knowledge*’ we expect high relevance for a topic about abstract concepts. Accordingly, the distribution  $p(t|d, w)$  over all topics provides a topic-level representation for a predicate slot in the context of a particular argument *w*. This representation is used by the topic-level model to compute a context-sensitive score for inference rule applications, as follows.

<sup>2</sup>We note that there are variants in the type of LDA model and the way the pseudo-documents are constructed in the referenced prior work. In order to focus on the inference methods rather than on the underlying LDA model, we use the LDA framework described in this paper for all compared methods.

Consider the application of an inference rule ‘ $LHS \rightarrow RHS$ ’ in the context of a particular pair of arguments for the  $X$  and  $Y$  slots, denoted by  $w_x$  and  $w_y$ , respectively. Denoting by  $l$  and  $r$  the predicates appearing in the two rule sides, the reliability score of the topic-level model is defined as follows (we present a geometric mean formulation for consistency with DIRT):

$$\begin{aligned} \text{score}_{\text{Topic}}(LHS \rightarrow RHS, w_x, w_y) \\ = \sqrt{\text{sim}(d_l^x, d_r^x, w_x) \cdot \text{sim}(d_l^y, d_r^y, w_y)} \end{aligned} \quad (3)$$

where  $\text{sim}(d, d', w)$  is a topic-distribution similarity measure conditioned on a given context word. Specifically, Ritter et al. (2010) utilized the dot product form for their similarity measure:

$$\text{sim}_{\text{DC}}(d, d', w) = \Sigma_t[p(t|d, w) \cdot p(t|d', w)] \quad (4)$$

(the subscript DC stands for double-conditioning, as both distributions are conditioned on the argument word, unlike the measure below).

Dinu and Lapata (2010b) presented a slightly different similarity measure for topic distributions that performed better in their setting as well as in a related later paper on context-sensitive scoring of lexical similarity (Dinu and Lapata, 2010a). In this measure, the topic distribution for the right hand side of the rule is not conditioned on  $w$ :

$$\text{sim}_{\text{SC}}(d, d', w) = \Sigma_t[p(t|d, w) \cdot p(t|d')] \quad (5)$$

(the subscript SC stands for single-conditioning, as only the left distribution is conditioned on the argument word). They also experimented with a few variants for the structure of the similarity measure and assessed that best results are obtained with the dot product form. In our experiments, we employ these two similarity measures for topic distributions as baselines representing topic-level models.

Comparing the context-insensitive and context-sensitive models, we see that both of them measure similarity between vector representations of corresponding predicate slots. However, while DIRT computes  $\text{sim}(v, v')$  over vectors in the original word-level space, topic-level models compute  $\text{sim}(d, d', w)$  by measuring similarity of vectors in a reduced-dimensionality latent space. As conjectured in the introduction, such coarse-grain representation might lead to loss of information. Hence, in the next section we propose a combined two-level model, which represents predicate

slots in the original word-level space while biasing the similarity measure through topic-level context models.

### 3 Two-level Context-sensitive Inference

Our model follows the general DIRT scheme while extending it to handle context-sensitive scoring of rule applications, addressing the scenario dealt by the context-sensitive topic models. In particular, we define the context-sensitive score  $\text{score}_{\text{WT}}$ , where  $WT$  stands for the combination of the Word/Topic levels:

$$\begin{aligned} \text{score}_{\text{WT}}(LHS \rightarrow RHS, w_x, w_y) \\ = \sqrt{\text{sim}(v_l^x, v_r^x, w_x) \cdot \text{sim}(v_l^y, v_r^y, w_y)} \end{aligned} \quad (6)$$

Thus, our model computes similarity over word-level (rather than topic-level) argument vectors, while biasing it according to the specific argument words in the given rule application context. The core of our contribution is thus defining the context-sensitive word-level vector similarity measure  $\text{sim}(v, v', w)$ , as described in the remainder of this section.

Following the methods in Section 2, for each predicate  $pred$  we construct, from the learning corpus, its argument vectors  $v_{pred}^x$  and  $v_{pred}^y$  as well as its argument pseudo-documents  $d_{pred}^x$  and  $d_{pred}^y$ . For convenience, when referring to an argument vector  $v$ , we will denote the corresponding pseudo-document by  $d_v$ . Based on all pseudo-documents we learn an LDA model and obtain its associated probability distributions.

The calculation of  $\text{sim}(v, v', w)$  is composed of two steps. At learning time, we compute for each candidate rule a separate, topic-biased, similarity score per each of the topics in the LDA model. Then, at rule application time, we compute an overall reliability score for the rule by combining the per-topic similarity scores, while biasing the score combination according to the given context of  $w$ . These two steps are described in the following two subsections.

#### 3.1 Topic-biased Word-vector Similarities

Given a pair of word vectors  $v$  and  $v'$ , and any desired ‘‘base’’ vector similarity measure  $\text{sim}$  (e.g.  $\text{sim}_{\text{Lin}}$ ), we compute a *topic-biased* similarity score for each LDA topic  $t$ , denoted by  $\text{sim}_t(v, v')$ .  $\text{sim}_t(v, v')$  is computed by applying

the original similarity measure over topic-biased versions of  $v$  and  $v'$ , denoted by  $v_t$  and  $v'_t$ :

$$\text{sim}_t(v, v') = \text{sim}(v_t, v'_t)$$

where

$$v_t(w) = v(w) \cdot p(t|d_v, w)$$

That is, each value in the biased vector,  $v_t(w)$ , is obtained by weighing the original value  $v(w)$  by the relevance of the topic  $t$  to the argument word  $w$  within  $d_v$ . This way, rather than replacing altogether the word-level values  $v(w)$  by the topic probabilities  $p(t|d_v, w)$ , as done in the topic-level models, we use the latter to only bias the former while preserving fine-grained word-level representations. The notation  $\text{Lin}_t$  denotes the  $\text{sim}_t$  measure when applied using  $\text{Lin}$  as the base similarity measure  $\text{sim}$ .

This learning process results in  $K$  different topic-biased similarity scores for each candidate rule, where  $K$  is the number of LDA topics. Table 1 illustrates topic-biased similarities for the  $Y$  slot of two rules involving the predicate ‘*acquire*’. As can be seen, the topic-biased score  $\text{Lin}_t$  for ‘*acquire*  $\rightarrow$  *learn*’ for  $t_2$  is higher than the  $\text{Lin}$  score, since this topic is characterized by arguments that commonly appear with both predicates of the rule. Consequently, the two predicates are found to be distributionally similar when biased for this topic. On the other hand, the topic-biased similarity for  $t_1$  is substantially lower, since prominent words in this topic are likely to occur with ‘*acquire*’ but not with ‘*learn*’, yielding low distributional similarity. Opposite behavior is exhibited for the rule ‘*acquire*  $\rightarrow$  *purchase*’.

### 3.2 Context-sensitive Similarity

When applying an inference rule, we compute for each slot its context-sensitive similarity score  $\text{sim}_{\text{WT}}(v, v', w)$ , where  $v$  and  $v'$  are the slot’s argument vectors for the two rule sides and  $w$  is the word instantiating the slot in the given rule application. This score is computed as a weighted average of the rule’s  $K$  topic-biased similarity scores  $\text{sim}_t$ . In this average, each topic is weighed by its “relevance” for the context in which the rule is applied, which consists of the left-hand-side predicate  $v$  and the argument  $w$ . This relevance is cap-

Topic	$t_1$	$t_2$
Top 5 words	calbiochem	rights
	corel	syndrome
	networks	majority
	viacom	knowledge
	financially	skill
<i>acquire</i> $\rightarrow$ <i>learn</i>		
$\text{Lin}_t(v, v')$	0.040	0.334
$\text{Lin}(v, v')$	0.165	
<i>acquire</i> $\rightarrow$ <i>purchase</i>		
$\text{Lin}_t(v, v')$	0.427	0.241
$\text{Lin}(v, v')$	0.267	

Table 1: Two characteristic topics for the  $Y$  slot of ‘*acquire*’, along with their topic-biased  $\text{Lin}$  similarities scores  $\text{Lin}_t$ , compared with the original  $\text{Lin}$  similarity, for two rules. The relevance of each topic to different arguments of ‘*acquire*’ is illustrated by showing the top 5 words in the argument vector  $v_{\text{acquire}}^y$  for which the illustrated topic is the most likely one.

tured by  $p(t|d_v, w)$ :

$$\text{sim}_{\text{WT}}(v, v', w) = \sum_t [p(t|d_v, w) \cdot \text{sim}_t(v, v')] \quad (7)$$

This way, a rule application would obtain a high score only if the current context fits those topics for which the rule is indeed likely to be valid, as captured by a high topic-biased similarity. The notation  $\text{Lin}_{\text{WT}}$  denotes the  $\text{sim}_{\text{WT}}$  measure, when using  $\text{Lin}_t$  as the topic-biased similarity measure.

Table 2 illustrates the calculation of context-sensitive similarity scores in four rule applications, involving the  $Y$  slot of the predicate ‘*acquire*’. We observe that relative to the fixed context-insensitive  $\text{Lin}$  score, the score of ‘*acquire*  $\rightarrow$  *learn*’ is substantially promoted for the argument ‘*skill*’ while being demoted for ‘*Skype*’. The opposite behavior is observed for ‘*acquire*  $\rightarrow$  *purchase*’, altogether demonstrating how our model successfully biases the similarity score according to rule validity in context.

## 4 Experimental Settings

To evaluate our model, we compare it both to context-insensitive similarity measures as well as to prior context-sensitive methods. Furthermore, to better understand its applicability in typical NLP tasks, we focus on an evaluation setting that corresponds to a natural distribution of examples from a large corpus.

Table 2: Context-sensitive similarity scores (in bold) for the  $Y$  slots of four rule applications. The components of the score calculation are shown for the topics of Table 1. For each rule application, the table shows a couple of the topic-biased scores  $\text{Lin}_t$  of the rule (as in Table 1), along with the topic relevance for the given context  $p(t|d_v, w)$ , which weighs the topic-biased scores in the  $\text{Lin}_{WT}$  calculation. The context-insensitive  $\text{Lin}$  score is shown for comparison.

#### 4.1 Evaluated Rule Application Methods

We evaluated the following rule application methods: the original context-insensitive word model, following DIRT (Lin and Pantel, 2001), as described in Equation 1, denoted by CI; our own topic-word context-sensitive model, as described in Equation 6, denoted by WT. In addition, we evaluated two variants of the topic-level context-sensitive model, denoted DC and SC. DC follows the double conditioned contextualized similarity measure according to Equation 4, as implemented by (Ritter et al., 2010), while SC follows the single conditioned one at Equation 5, as implemented by (Dinu and Lapata, 2010b; Dinu and Lapata, 2010a).

Since our model can contextualize various distributional similarity measures, we evaluated the performance of all the above methods on several base similarity measures and their learned rule-

sets, namely Lin (Lin, 1998), BInc (Szpektor and Dagan, 2008) and vector Cosine similarity. The Lin similarity measure is described in Equation 2. Binc (Szpektor and Dagan, 2008) is a directional similarity measure between word vectors, which outperformed Lin for predicate inference (Szpektor and Dagan, 2008).

To build the rule-sets and models for the tested approaches we utilized the ReVerb corpus (Fader et al., 2011), a large scale publicly available web-based open extractions data set, containing about 15 million unique template extractions.<sup>3</sup> ReVerb template extractions/instantiations are in the form of a tuple  $(x, pred, y)$ , containing  $pred$ , a verb predicate,  $x$ , the argument instantiation of the template’s slot  $X$ , and  $y$ , the instantiation of the template’s slot  $Y$ .

ReVerb includes over 600,000 different templates that comprise a verb but may also include other words, for example ‘ $X$  can accommodate up to  $Y$ ’. Yet, many of these templates share a similar meaning, e.g. ‘ $X$  accommodate up to  $Y$ ’, ‘ $X$  can accommodate up to  $Y$ ’, ‘ $X$  will accommodate up to  $Y$ ’, etc. Following Sekine (2005), we clustered templates that share their main verb predicate in order to scale down the number of different predicates in the corpus and collect richer word co-occurrence statistics per predicate.

Next, we applied some clean-up preprocessing to the ReVerb extractions. This includes discarding stop words, rare words and non-alphabetical words instantiating either the  $X$  or the  $Y$  arguments. In addition, we discarded all predicates that co-occur with less than 100 unique argument words in each slot. The remaining corpus consists of 7 million unique extractions and 2,155 verb predicates.

Finally, we trained an LDA model, as described in Section 2, using Mallet (McCallum, 2002). Then, for each original context-insensitive similarity measure, we learned from ReVerb a rule-set comprised of the top 500 rules for every identified predicate. To complete the learning, we calculated the topic-biased similarity score for each learned rule under each LDA topic, as specified in our context-sensitive model. We release a rule set comprising the top 500 context-sensitive rules that we learned for each of the verb predicates in our learning corpus, along with our trained LDA

model.<sup>4</sup>

## 4.2 Evaluation Task

To evaluate the performance of the different methods we chose the dataset constructed by Zeichner et al. (2012).<sup>5</sup> This publicly available dataset contains about 6,500 manually annotated predicate template rule applications, each one labeled as correct or incorrect. For example, ‘*Jack agree with Jill*  $\rightarrow$  *Jack feel sorry for Jill*’ is a rule application in this dataset, labeled as incorrect, and ‘*Registration open this month*  $\rightarrow$  *Registration begin this month*’ is another rule application, labeled as correct. Rule applications were generated by randomly sampling extractions from ReVerb, such as (‘*Jack*’, ‘*agree with*’, ‘*Jill*’) and then sampling possible rules for each, such as ‘*agree with*  $\rightarrow$  *feel sorry for*’. Hence, this dataset provides naturally distributed rule inferences with respect to ReVerb.

Whenever we evaluated a distributional similarity measure (namely Lin, BInc, or Cosine), we discarded instances from Zeichner et al.’s dataset in which the assessed rule is not in the context-insensitive rule-set learned for this measure or the argument instantiation of the rule is not in the LDA lexicon. We refer to the remaining instances as the *test set* per measure, e.g. Lin’s test set. Table 3 details the size of each such test set in our experiment.

Finally, the task under which we assessed the tested models is to rank all rule applications in each test set, aiming to rank the valid rule applications above the invalid ones.

## 5 Results

We evaluated the performance of each tested method by measuring Mean Average Precision (MAP) (Manning et al., 2008) of the rule application ranking computed by this method. In order

<sup>4</sup>Our resource is available at: <http://www.cs.biu.ac.il/~nlp/downloads/wt-rules.html>

<sup>5</sup>The dataset is available at: <http://www.cs.biu.ac.il/~nlp/downloads/annotation-rule-application.htm>

Method	Lin	BInc	Cosine
CI	0.503	0.513	0.513
DC	0.451 (1200)	0.455 (1200)	0.455 (1200)
SC	0.443 (1200)	0.458 (1200)	0.452 (1200)
WT	<b>0.562</b> (100)	<b>0.584</b> (50)	<b>0.565</b> (25)

Table 4: MAP values on corresponding test set obtained by each method. Figures in parentheses indicate optimal number of LDA topics.

to compute MAP values and corresponding statistical significance, we randomly split each test set into 30 subsets. For each method we computed Average Precision on every subset and then took the average over all subsets as the MAP value.

Since all tested context-sensitive approaches are based on LDA topics, we varied for each method the number of LDA topics  $K$  that optimizes its performance, ranging from 25 to 1600 topics. We used LDA hyperparameters  $\beta = 0.01$  and  $\alpha = 0.1$  for  $K < 600$  and  $\alpha = \frac{50}{K}$  for  $K \geq 600$ .

Table 4 presents the optimal MAP performance of each tested measure. Our main result is that our model outperforms all other methods, both context-insensitive and context-sensitive, by a relative increase of more than 10% for all three similarity measures that we tested. This improvement is statistically significant at  $p < 0.01$  for BInc and Lin, and  $p < 0.015$  for Cosine, using paired t-test. This shows that our model indeed successfully leverages contextual information beyond the basic context-agnostic rule scores and is robust across measures.

Surprisingly, both baseline topic-level context-sensitive methods, namely DC and SC, underperformed compared to their context-insensitive baselines. While Dinu and Lapata (Dinu and Lapata, 2010b) did show improvement over context-insensitive DIRT, this result was obtained on the verbs of the Lexical Substitution Task in SemEval (McCarthy and Navigli, 2007), which was manually created with a bias for context-sensitive substitutions. However, our result suggests that topic-level models might not be robust enough when applied to a random sample of inferences.

An interesting indication of the differences between our word-topic model, WT, and topic-only models, DC and SC, lies in the optimal number of LDA topics required for each method. The number of topics in the range 25-100 performed almost equally well under the WT model for all base measures, with a moderate decline for higher numbers.

The need for this rather small number of topics is due to the nature of utilization of topics in WT. Specifically, topics are leveraged for high-level domain disambiguation, while fine grained word-level distributional similarity is computed for each rule under each such domain. This works best for a relatively low number of topics. However, in higher numbers, topics relate to narrower domains and then topic biased word level similarity may become less effective due to potential sparseness. On the other hand, DC and SC rely on topics as a surrogate to predicate-argument co-occurrence features, and thus require a relatively large number of them to be effective.

Delving deeper into our test-set, Zeichner et al. provided a more detailed annotation for each invalid rule application. Specifically, they annotated whether the context under which the rule is applied is valid. For example, in ‘*John bought my car*  $\rightarrow$  *John sold my car*’ the inference is invalid due to an inherently incorrect rule, but the context is valid. On the other hand in ‘*my boss raised my salary*  $\rightarrow$  *my boss constructed my salary*’ the context {‘*my boss*’, ‘*my salary*’} for applying ‘*raise*  $\rightarrow$  *construct*’ is invalid. Following, we split the test-set for the base Lin measure into two test-sets: (a) test-set<sub>vc</sub>, which includes all correct rule applications and incorrect ones only under valid contexts, and (b) test-set<sub>ivc</sub>, which includes again all correct rule applications but incorrect ones only under invalid contexts.

Table 5 presents the performance of each compared method on the two test sets. On test-set<sub>ivc</sub>, where context mismatches are abundant, our model outperformed all other baselines (statistically significant at  $p < 0.01$ ). In addition, this time DC slightly outperformed CI. This result more explicitly shows the advantages of integrating word-level and context-sensitive topic-level similarities for differentiating valid and invalid contexts for rule applications. Yet, many invalid rule applications occur under valid contexts due to inherently incorrect rules, and we want to make sure that also in this scenario our model does not fall behind the context-insensitive measure. Indeed, on test-set<sub>vc</sub>, in which context mismatches are rare, our algorithm is still better than the original measure, indicating that WT can be safely applied to distributional similarity measures without concerns of reduced performance in different context scenarios.

	test-set <sub>ivc</sub>	test-set <sub>vc</sub>
Size (valid:invalid)	432 (266:166)	645 (266:379)
CI	0.780	0.587
DC	0.796	0.498
SC	0.779	0.512
WT	<b>0.854</b>	<b>0.621</b>

## 6 Discussion and Future Work

This paper addressed the problem of computing context-sensitive reliability scores for predicate inference rules. In particular, we proposed a novel scheme that applies over any base distributional similarity measure which operates at the word level, and computes a single context-insensitive score for a rule. Based on such a measure, our scheme constructs a context-sensitive similarity measure that computes a reliability score for predicate inference rules applications in the context of given arguments.

The contextualization of the base similarity score was obtained using a topic-level LDA model, which was used in a novel way. First, it provides a topic bias for learning separate per-topic word-level similarity scores between predicates. Then, given a specific candidate rule application, the LDA model is used to infer the topic distribution relevant to the context specified by the given arguments. Finally, the context-sensitive rule application score is computed as a weighted average of the per-topic word-level similarity scores, which are weighed according to the inferred topic distribution.

While most works on context-insensitive predicate inference rules, such as DIRT (Lin and Pantel, 2001), are based on word-level similarity measures, almost all prior models addressing context-sensitive predicate inference rules are based on topic models (except for (Pantel et al., 2007), which was outperformed by later models). We therefore focused on comparing the performance of our two-level scheme with state-of-the-art prior topic-level and word-level models of distributional similarity, over a random sample of inference rule applications. Under this natural setting, the two-level scheme consistently outperformed both types of models when tested with three different base similarity measures. Notably, our model shows stable performance over a large subset of the data

where context sensitivity is rare, while topic-level models tend to underperform in such cases compared to the base context-insensitive methods.

Our work is closely related to another research line that addresses lexical similarity and substitution scenarios in context. While we focus on lexical-syntactic predicate templates and instantiations of their argument slots as context, lexical similarity methods consider various lexical units that are not necessarily predicates, with their context typically being the collection of words in a window around them.

Various approaches have been proposed to address lexical similarity. A number of works are based on a compositional semantics approach, where a prior representation of a target lexical unit is composed with the representations of words in its given context (Mitchell and Lapata, 2008; Erk and Padó, 2008; Thater et al., 2010). Other works (Erk and Padó, 2010; Reisinger and Mooney, 2010) use a rather large word window around target words and compute similarities between clusters comprising instances of word windows. In addition, (Dinu and Lapata, 2010a) adapted the predicate inference topic model from (Dinu and Lapata, 2010b) to compute lexical similarity in context.

A natural extension of our work would be to extend our two level model to accommodate context-sensitive lexical similarity. For this purpose we will need to redefine the scope of context in our model, and adapt our method to compute context-biased lexical similarities accordingly. Then we will also be able to evaluate our model on the Lexical Substitution Task (McCarthy and Navigli, 2007), which has been commonly used in recent years as a benchmark for context-sensitive lexical similarity models.

In a different NLP task, Eidelman et al. (2012) utilize a similar approach to ours for improving the performance of statistical machine translation (SMT). They learn an LDA model on the source language side of the training corpus with the purpose of identifying implicit sub-domains. Then they utilize the distribution over topics inferred for each document in their corpus to compute separate per-topic translation probability tables. Finally, they train a classifier to translate a given target word based on these tables and the inferred topic distribution of the given document in which the target word appears. A notable difference be-

tween our approach and theirs is that we use predicate pseudo-documents consisting of argument instantiations to learn our LDA model, while Eidelman et al. use the real documents in a corpus. We believe that combining these two approaches may improve performance for both textual inference and SMT and plan to experiment with this direction in future work.

## Abstract

Semantic similarity is an essential component of many Natural Language Processing applications. However, prior methods for computing semantic similarity often operate at different levels, e.g., single words or entire documents, which requires adapting the method for each data type. We present a unified approach to semantic similarity that operates at multiple levels, all the way from comparing word senses to comparing text documents. Our method leverages a common probabilistic representation over word senses in order to compare different types of linguistic data. This unified representation shows state-of-the-art performance on three tasks: semantic textual similarity, word similarity, and word sense coarsening.

## 1 Introduction

Semantic similarity is a core technique for many topics in Natural Language Processing such as Textual Entailment (Berant et al., 2012), Semantic Role Labeling (Fürstenu and Lapata, 2012), and Question Answering (Surdeanu et al., 2011). For example, textual similarity enables relevant documents to be identified for information retrieval (Hliaoutakis et al., 2006), while identifying similar words enables tasks such as paraphrasing (Glickman and Dagan, 2003), lexical substitution (McCarthy and Navigli, 2009), lexical simplification (Biran et al., 2011), and Web search result clustering (Di Marco and Navigli, 2013).

Approaches to semantic similarity have often operated at separate levels: methods for word similarity are rarely applied to documents or even single sentences (Budanitsky and Hirst, 2006; Radinsky et al., 2011; Halawi et al., 2012), while document-based similarity methods require more

linguistic features, which often makes them inapplicable at the word or microtext level (Salton et al., 1975; Maguitman et al., 2005; Elsayed et al., 2008; Turney and Pantel, 2010). Despite the potential advantages, few approaches to semantic similarity operate at the sense level due to the challenge in sense-tagging text (Navigli, 2009); for example, none of the top four systems in the recent SemEval-2012 task on textual similarity compared semantic representations that incorporated sense information (Agirre et al., 2012).

We propose a unified approach to semantic similarity across multiple representation levels from senses to documents, which offers two significant advantages. First, the method is applicable independently of the input type, which enables meaningful similarity comparisons across different scales of text or lexical levels. Second, by operating at the sense level, a unified approach is able to identify the semantic similarities that exist independently of the text's lexical forms and any semantic ambiguity therein. For example, consider the sentences:

- t1. *A manager fired the worker.*
- t2. *An employee was terminated from work by his boss.*

A surface-based approach would label the sentences as dissimilar due to the minimal lexical overlap. However, a sense-based representation enables detection of the similarity between the meanings of the words, e.g., *fire* and *terminate*. Indeed, an accurate, sense-based representation is essential for cases where different words are used to convey the same meaning.

The contributions of this paper are threefold. First, we propose a new unified representation of the meaning of an arbitrarily-sized piece of text, referred to as a **lexical item**, using a sense-based probability distribution. Second, we propose a novel alignment-based method for word sense dis-

ambiguation during semantic comparison. Third, we demonstrate that this single representation can achieve state-of-the-art performance on three similarity tasks, each operating at a different lexical level: (1) surpassing the highest scores on the SemEval-2012 task on textual similarity (Agirre et al., 2012) that compares sentences, (2) achieving a near-perfect performance on the TOEFL synonym selection task proposed by Landauer and Dumais (1997), which measures word pair similarity, and also obtaining state-of-the-art performance in terms of the correlation with human judgments on the RG-65 dataset (Rubenstein and Goodenough, 1965), and finally (3) surpassing the performance of Snow et al. (2007) in a sense-coarsening task that measures sense similarity.

## 2 A Unified Semantic Representation

We propose a representation of any lexical item as a distribution over a set of word senses, referred to as the item’s **semantic signature**. We begin with a formal description of the representation at the sense level (Section 2.1). Following this, we describe our alignment-based disambiguation algorithm which enables us to produce sense-based semantic signatures for those lexical items (e.g., words or sentences) which are not sense annotated (Section 2.2). Finally, we propose three methods for comparing these signatures (Section 2.3). As our sense inventory, we use WordNet 3.0 (Fellbaum, 1998).

### 2.1 Semantic Signatures

The WordNet ontology provides a rich network structure of semantic relatedness, connecting senses directly with their hypernyms, and providing information on semantically similar senses by virtue of their nearby locality in the network. Given a particular node (sense) in the network, repeated random walks beginning at that node will produce a frequency distribution over the nodes in the graph visited during the walk. To extend beyond a single sense, the random walk may be initialized and restarted from a set of senses (seed nodes), rather than just one; this multi-seed walk produces a multinomial distribution over all the senses in WordNet with higher probability assigned to senses that are frequently visited from the seeds. Prior work has demonstrated that multinomials generated from random walks over WordNet can be successfully applied to linguistic tasks such as word similarity (Hughes and Ramage,

2007; Agirre et al., 2009), paraphrase recognition, textual entailment (Ramage et al., 2009), and pseudoword generation (Pilehvar and Navigli, 2013).

Formally, we define the semantic signature of a lexical item as the multinomial distribution generated from the random walks over WordNet 3.0 where the set of seed nodes is the set of senses present in the item. This representation encompasses both when the item is itself a single sense and when the item is a sense-tagged sentence.

To construct each semantic signature, we use the iterative method for calculating topic-sensitive PageRank (Haveliwala, 2002). Let  $M$  be the adjacency matrix for the WordNet network, where edges connect senses according to the relations defined in WordNet (e.g., hypernymy and meronymy). We further enrich  $M$  by connecting a sense with all the other senses that appear in its disambiguated gloss.<sup>1</sup> Let  $\vec{v}^{(0)}$  denote the probability distribution for the starting location of the random walker in the network. Given the set of senses  $S$  in a lexical item, the probability mass of  $\vec{v}^{(0)}$  is uniformly distributed across the senses  $s_i \in S$ , with the mass for all  $s_j \notin S$  set to zero. The PageRank may then be computed using:

$$\vec{v}^{(t)} = (1 - \alpha) M \vec{v}^{(t-1)} + \alpha \vec{v}^{(0)} \quad (1)$$

where at each iteration the random walker may jump to any node  $s_i \in S$  with probability  $\alpha/|S|$ . We follow standard convention and set  $\alpha$  to 0.15. We repeat the operation in Eq. 1 for 30 iterations, which is sufficient for the distribution to converge. The resulting probability vector  $\vec{v}^{(t)}$  is the semantic signature of the lexical item, as it has aggregated its senses’ similarities over the entire graph. For our semantic signatures we used the UKB<sup>2</sup> off-the-shelf implementation of topic-sensitive PageRank.

### 2.2 Alignment-Based Disambiguation

Commonly, semantic comparisons are between word pairs or sentence pairs that do not have their lexical content sense-annotated, despite the potential utility of sense annotation in making semantic comparisons. However, traditional forms of word sense disambiguation are difficult for short texts and single words because little or no contextual information is present to perform the disambiguation task. Therefore, we propose a novel

<sup>1</sup><http://wordnet.princeton.edu>

<sup>2</sup><http://ixa2.si.ehu.es/ukb/>

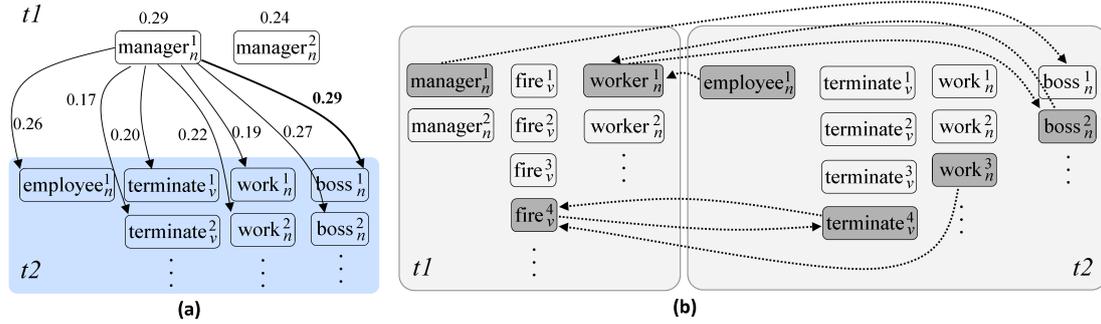

Figure 1: (a) Example alignments of the first sense of term *manager* (in sentence  $t1$ ) to the two first senses of the word types in sentence  $t2$ , along with the similarity of the two senses’ semantic signatures; (b) Alignments which maximize the similarities across words in  $t1$  and  $t2$  (the source side of an alignment is taken as the disambiguated sense of its corresponding word).

alignment-based sense disambiguation that leverages the content of the paired item in order to disambiguate each element. Leveraging the paired item enables our approach to disambiguate where traditional sense disambiguation methods can not due to insufficient context.

We view sense disambiguation as an **alignment problem**. Given two arbitrarily ordered texts, we seek the semantic alignment that maximizes the similarity of the senses of the context words in both texts. To find this maximum we use an alignment procedure which, for each word type  $w_i$  in item  $T_1$ , assigns  $w_i$  to the sense that has the maximal similarity to any sense of the word types in the compared text  $T_2$ . Algorithm 1 formalizes the alignment process, which produces a sense disambiguated representation as a result. Senses are compared in terms of their semantic signatures, denoted as function  $\mathcal{R}$ . We consider multiple definitions of  $\mathcal{R}$ , defined later in Section 2.3.

As a part of the disambiguation procedure, we leverage the one sense per discourse heuristic of Yarowsky (1995); given all the word types in two compared lexical items, each type is assigned a single sense, even if it is used multiple times. Additionally, if the same word type appears in both sentences, both will always be mapped to the same sense. Although such a sense assignment is potentially incorrect, assigning both types to the same sense results in a representation that does no worse than a surface-level comparison.

We illustrate the alignment-based disambiguation procedure using the two example sentences  $t1$  and  $t2$  given in Section 1. Figure 1(a) illustrates example alignments of the first sense of *manager* to the first two senses of the word types in sentence  $t2$  along with the similarity of the two senses’

---

### Algorithm 1 Alignment-based Sense Disambiguation

---

**Input:**  $T_1$  and  $T_2$ , the sets of word types being compared

**Output:**  $P$ , the set of disambiguated senses for  $T_1$

- 1:  $P \leftarrow \emptyset$
  - 2: **for each** token  $t_i \in T_1$
  - 3:    $max\_sim \leftarrow 0$
  - 4:    $best\_s_i \leftarrow null$
  - 5:   **for each** token  $t_j \in T_2$
  - 6:     **for each**  $s_i \in Senses(t_i), s_j \in Senses(t_j)$
  - 7:        $sim \leftarrow \mathcal{R}(s_i, s_j)$
  - 8:       **if**  $sim > max\_sim$  **then**
  - 9:          $max\_sim = sim$
  - 10:         $best\_s_i = s_i$
  - 11:    $P \leftarrow P \cup \{best\_s_i\}$
  - 12: **return**  $P$
- 

semantic signatures. For the senses of *manager*, sense  $manager_n^1$  obtains the maximal similarity value to  $boss_n^1$  among all the possible pairings of the senses for the word types in sentence  $t2$ , and as a result is selected as the sense labeling for *manager* in sentence  $t1$ .<sup>3</sup> Figure 1(b) shows the final, maximally-similar sense alignment of the word types in  $t1$  and  $t2$ . The resulting alignment produces the following sets of senses:

$$P_{t1} = \{manager_n^1, fire_v^4, worker_n^1\}$$

$$P_{t2} = \{employee_n^1, terminate_v^4, work_n^3, boss_n^2\}$$

where  $P_x$  denotes the corresponding set of senses of sentence  $x$ .

### 2.3 Semantic Signature Similarity

**Cosine Similarity.** In order to compare semantic signatures, we adopt the *Cosine* similarity measure as a baseline method. The measure is computed by treating each multinomial as a vector and then calculating the normalized dot product of the two signatures’ vectors.

<sup>3</sup>We follow Navigli (2009) and denote with  $w_p^i$  the  $i$ -th sense of  $w$  in WordNet with part of speech  $p$ .

However, a semantic signature is, in essence, a weighted ranking of the importance of WordNet senses for each lexical item. Given that the WordNet graph has a non-uniform structure, and also given that different lexical items may be of different sizes, the magnitudes of the probabilities obtained may differ significantly between the two multinomial distributions. Therefore, for computing the similarity of two signatures, we also consider two nonparametric methods that use the ranking of the senses, rather than their probability values, in the multinomial.

**Weighted Overlap.** Our first measure provides a nonparametric similarity by comparing the similarity of the rankings for intersection of the senses in both semantic signatures. However, we additionally weight the similarity such that differences in the highest ranks are penalized more than differences in lower ranks. We refer to this measure as the *Weighted Overlap*. Let  $S$  denote the intersection of all senses with non-zero probability in both signatures and  $r_i^j$  denote the rank of sense  $s_i \in S$  in signature  $j$ , where rank 1 denotes the highest rank. The sum of the two ranks  $r_i^1$  and  $r_i^2$  for a sense is then inverted, which (1) weights higher ranks more and (2) when summed, provides the maximal value when a sense has the same rank in both signatures. The unnormalized weighted overlap is then calculated as  $\sum_{i=1}^{|S|} (r_i^1 + r_i^2)^{-1}$ . Then, to bound the similarity value in  $[0, 1]$ , we normalize the sum by its maximum value,  $\sum_{i=1}^{|S|} (2i)^{-1}$ , which occurs when each sense has the same rank in both signatures.

**Top- $k$  Jaccard.** Our second measure uses the ranking to identify the top- $k$  senses in a signature, which are treated as the best representatives of the conceptual associates. We hypothesize that a specific rank ordering may be attributed to small differences in the multinomial probabilities, which can lower rank-based similarities when one of the compared orderings is perturbed due to slightly different probability values. Therefore, we consider the top- $k$  senses as an unordered set, with equal importance in the signature. To compare two signatures, we compute the Jaccard Index of the two signatures’ sets:

$$\mathcal{R}_{Jac}(U_k, V_k) = \frac{|U_k \cap V_k|}{|U_k \cup V_k|} \quad (2)$$

where  $U_k$  denotes the set of  $k$  senses with the highest probability in the semantic signature  $U$ .

Dataset	MSRvid	MSRpar	SMTeuroparl	OnWN	SMTnews
Training	750	750	734	-	-
Test	750	750	459	750	399

Table 1: Statistics of the provided datasets for the SemEval-2012 Semantic Textual Similarity task.

### 3 Experiment 1: Textual Similarity

Measuring semantic similarity of textual items has applications in a wide variety of NLP tasks. As our benchmark, we selected the recent SemEval-2012 task on Semantic Textual Similarity (STS), which was concerned with measuring the semantic similarity of sentence pairs. The task received considerable interest by facilitating a meaningful comparison between approaches.

#### 3.1 Experimental Setup

**Data.** We follow the experimental setup used in the STS task (Agirre et al., 2012), which provided five test sets, two of which had accompanying training data sets for tuning system performance. Each sentence pair in the datasets was given a score from 0 to 5 (low to high similarity) by human judges, with a high inter-annotator agreement of around 0.90 when measured using the Pearson correlation coefficient. Table 1 lists the number of sentence pairs in training and test portions of each dataset.

**Comparison Systems.** The top-ranking participating systems in the SemEval-2012 task were generally supervised systems utilizing a variety of lexical resources and similarity measurement techniques. We compare our results against the top three systems of the 88 submissions: TLsim and TLsyn, the two systems of Šarić et al. (2012), and the UKP2 system (Bär et al., 2012). UKP2 utilizes extensive resources among which are a Distributional Thesaurus computed on 10M dependency-parsed English sentences. In addition, the system utilizes techniques such as Explicit Semantic Analysis (Gabrilovich and Markovitch, 2007) and makes use of resources such as Wiktionary and Wikipedia, a lexical substitution system based on supervised word sense disambiguation (Biemann, 2013), and a statistical machine translation system. The TLsim system uses the New York Times Annotated Corpus, Wikipedia, and Google Book Ngrams. The TLsyn system also uses Google Book Ngrams, as well as dependency parsing and named entity recognition.

Ranking			System	Overall			Dataset-specific				
ALL	ALLnrm	Mean		ALL	ALLnrm	Mean	Mpar	Mvid	SMTe	OnWN	SMTn
1	1	1	ADW	<b>0.866</b>	<b>0.871</b>	<b>0.711</b>	0.694	<b>0.887</b>	<b>0.555</b>	<b>0.706</b>	<b>0.604</b>
2	3	2	UKP2	0.824	0.858	0.677	0.683	0.873	0.528	0.664	0.493
3	4	6	TLsyn	0.814	0.857	0.660	0.698	0.862	0.361	0.704	0.468
4	2	3	TLsim	0.813	0.864	0.675	<b>0.734</b>	0.880	0.477	0.679	0.398

Table 2: Performance of our system (ADW) and the 3 top-ranking participating systems (out of 88) in the SemEval-2012 Semantic Textual Similarity task. Rightmost columns report the corresponding Pearson correlation  $r$  for individual datasets, i.e., MSRpar (Mpar), MSRvid (Mvid), SMTEuoparl (SMTe), OnWN (OnWN) and SMTnews (SMTn). We also provide scores according to the three official evaluation metrics (i.e., ALL, ALLnrm, and Mean). Rankings are also presented based on the three metrics.

**System Configuration.** Here we describe the configuration of our approach, which we have called Align, Disambiguate and Walk (ADW). The STS task uses human similarity judgments on an ordinal scale from 0 to 5. Therefore, in ADW we adopted a similar approach to generating similarity values to that adopted by other participating systems, whereby a supervised system is trained to combine multiple similarity judgments to produce a final rating consistent with the human annotators. We utilized the WEKA toolkit (Hall et al., 2009) to train a Gaussian Processes regression model for each of the three training sets (cf. Table 1). The features discussed hereafter were considered in our regression model.

**Main features.** We used the scores calculated using all three of our semantic signature comparison methods as individual features. Although the *Jaccard* comparison is parameterized, we avoided tuning and instead used four features for distinct values of  $k$ : 250, 500, 1000, and 2500.

**String-based features.** Additionally, because the texts often contain named entities which are not present in WordNet, we incorporated the similarity values produced by four string-based measures, which were used by other teams in the STS task: (1) *longest common substring* which takes into account the length of the longest overlapping contiguous sequence of characters (substring) across two strings (Gusfield, 1997), (2) *longest common subsequence* which, instead, finds the longest overlapping subsequence of two strings (Allison and Dix, 1986), (3) *Greedy String Tiling* which allows reordering in strings (Wise, 1993), and (4) the character/word  $n$ -gram similarity proposed by Barrón-Cedeño et al. (2010).

We followed Šarić et al. (2012) and used the models trained on the SMTEuoparl and MSRpar datasets for testing on the SMTnews and OnWN test sets, respectively.

### 3.2 STS Results

Three evaluation metrics are provided by the organizers of the SemEval-2012 STS task, all of which are based on Pearson correlation  $r$  of human judgments with system outputs: (1) the correlation value for the concatenation of all five datasets (ALL), (2) a correlation value obtained on a concatenation of the outputs, separately normalized by least square (ALLnrm), and (3) the weighted average of Pearson correlations across datasets (Mean). Table 2 shows the scores obtained by ADW for the three evaluation metrics, as well as the Pearson correlation values obtained on each of the five test sets (rightmost columns). We also show the results obtained by the three top-ranking participating systems (i.e., UKP2, TLsim, and TLsyn). The leftmost three columns show the system rankings according to the three metrics.

As can be seen from Table 2, our system (ADW) outperforms all the 88 participating systems according to all the evaluation metrics. Our system shows a statistically significant improvement on the SMTnews dataset, with an increase in the Pearson correlation of over 0.10. MSRpar (MPar) is the only dataset in which TLsim (Šarić et al., 2012) achieves a higher correlation with human judgments. Named entity features used by the TLsim system could be the reason for its better performance on the MSRpar dataset, which contains a large number of named entities.

### 3.3 Similarity Measure Analysis

To gain more insight into the impact of our alignment-based disambiguation approach, we carried out a 10-fold cross-validation on the three training datasets (cf. Table 1) using the systems described hereafter.

**ADW-MF.** To build this system, we utilized our main features only; i.e., we did not make use of additional string-based features.

**DW.** Similarly to ADW-MF, this system utilized the main features only. In DW, however, we replaced our alignment-based disambiguation phase with a random walk-based WSD system that disambiguated the sentences separately, without performing any alignment. As our WSD system, we used UKB, a state-of-the-art knowledge-based WSD system that is based on the same topic-sensitive PageRank algorithm used by our approach. UKB initializes the algorithm from all senses of the words in the context of a word to be disambiguated. It then picks the most relevant sense of the word according to the resulting probability vector. As the lexical knowledge base of UKB, we used the same semantic network as that utilized by our approach for calculating semantic signatures.

Table 3 lists the performance values of the two above-mentioned systems on the three training sets in terms of Pearson correlation. In addition, we present in the table correlation scores for four other similarity measures reported by Bär et al. (2012):

- Pairwise Word Similarity that comprises of a set of WordNet-based similarity measures proposed by Resnik (1995), Jiang and Conrath (1997), and Lin (1998b). The aggregation strategy proposed by Corley and Mihalcea (2005) has been utilized for extending these word-to-word similarity measures for calculating text-to-text similarities.
- Explicit Semantic Analysis (Gabrilovich and Markovitch, 2007) where the high-dimensional vectors are obtained on WordNet, Wikipedia and Wiktionary.
- Distributional Thesaurus where a similarity score is computed similarly to that of Lin (1998a) using a distributional thesaurus obtained from a 10M dependency-parsed sentences of English newswire.
- Character  $n$ -grams which were also used as one of our additional features.

As can be seen from Table 3, our alignment-based disambiguation approach (ADW-MF) is better suited to the task than a conventional WSD approach (DW). Another interesting point is the high scores achieved by the Character  $n$ -grams

Similarity measure	Dataset		
	Mpar	Mvid	SMTe
DW	0.448	0.820	0.660
ADW-MF	0.485	<b>0.842</b>	<b>0.721</b>
Explicit Semantic Analysis	0.427	0.781	0.619
Pairwise Word Similarity	0.564	0.835	0.527
Distributional Thesaurus	0.494	0.481	0.365
Character $n$ -grams	<b>0.658</b>	0.771	0.554

Table 3: Performance of our main-feature system with conventional WSD (DW) and with the alignment-based disambiguation approach (ADW-MF) vs. four other similarity measures, using 10-fold cross validation on the training datasets MSRpar (Mpar), MSRvid (Mvid), and SMTeuroparl (SMTe).

measure. This confirms that string-based methods are strong baselines for semantic textual similarity. Except for the MSRpar (Mpar) dataset, our system (ADW-MF) outperforms all other similarity measures. The scores obtained by Explicit Semantic Analysis and Distributional Thesaurus are not competitive on any dataset. On the other hand, Pairwise Word Similarity achieves a high performance on MSRpar and MSRvid datasets, but performs surprisingly low on the SMTeuroparl dataset.

## 4 Experiment 2: Word Similarity

We now proceed from the sentence level to the word level. Word similarity has been a key problem for lexical semantics, with significant efforts being made by approaches in distributional semantics to accurately identify synonymous words (Turney and Pantel, 2010). Different evaluation methods exist in the literature for evaluating the performance of a word-level semantic similarity measure; we adopted two well-established benchmarks: synonym recognition and correlating word similarity judgments with those from human annotators.

For synonym recognition, we used the TOEFL dataset created by Landauer and Dumais (1997). The dataset consists of 80 multiple-choice synonym questions from the TOEFL test; a word is paired with four options, one of which is a valid synonym. Test takers with English as a second language averaged 64.5% correct. Despite multiple approaches, only recently has the test been answered perfectly (Bullinaria and Levy, 2012), underscoring the challenge of synonym recognition.

Approach	Accuracy
PPMIC (Bullinaria and Levy, 2007)	85.00%
GLSA (Matveeva et al., 2005)	86.25%
LSA (Rapp, 2003)	92.50%
ADW <sub>Jac</sub>	93.75±2.5%
ADW <sub>WO</sub>	95.00%
ADW <sub>Cos</sub>	96.25%
PR (Turney et al., 2003)	97.50%
PCCP (Bullinaria and Levy, 2012)	100.00%

Table 4: Accuracy on the 80-question TOEFL Synonym test. ADW<sub>Jac</sub>, ADW<sub>WO</sub>, and ADW<sub>Cos</sub> correspond to results with the *Jaccard*, *Weighted Overlap* and *Cosine* signature comparison measures, respectively.

For the similarity judgment evaluation, we used as benchmark the RG-65 dataset created by Rubenstein and Goodenough (1965). The dataset contains 65 word pairs judged by 51 human subjects on a scale of 0 to 4 according to their semantic similarity. Ideally, a measure’s similarity judgments are expected to be highly correlated with those of humans. To be consistent with the previous literature (Hughes and Ramage, 2007; Agirre et al., 2009), we used Spearman’s rank correlation in our experiment.

#### 4.1 Experimental Setup

Our alignment-based sense disambiguation transforms the task of comparing individual words into that of calculating the similarity of the best-matching sense pair across the two words. As there is no training data we do not optimize the  $k$  value for computing signature similarity with the *Jaccard* index; instead, we report, for the synonym recognition and the similarity judgment evaluations, the respective range of accuracies and the average correlation obtained upon using five values of  $k$  randomly selected in the range [50, 2500]: 678, 1412, 1692, 2358, 2387.

#### 4.2 Word Similarity Results: TOEFL dataset

Table 4 lists the accuracy performance of the system in comparison to the existing state of the art on the TOEFL test. ADW<sub>WO</sub>, ADW<sub>Cos</sub>, and ADW<sub>Jac</sub> correspond to our approach when *Weighted Overlap*, *Cosine*, and *Jaccard* signature comparison measures are used, respectively. Despite not being tuned for the task, our model achieves near-perfect performance, answering all but three questions correctly with the *Cosine* measure. Among the top-performing approaches, only

Word	Synonym choices (correct in bold)			
fanciful	familiar	apparent*	<b>imaginative</b> †	logical
verbal	<b>oral</b> †	overt	fitting	verbose*
resolved	<b>settled</b> *	forgotten†	publicized	examined
percentage	volume	sample	<b>proportion</b>	profit†*
figure	list	<b>solve</b> *	divide†	express
highlight	alter†	imitate	<b>accentuate</b> *	restore

Table 5: Questions answered incorrectly by our approach. Symbols † and \* correspond to the choices of our approach with the *Weighted Overlap* and *Cosine* signature comparisons respectively. We do not include the mistakes made when the *Jaccard* measure was used as they vary with the  $k$  value.

that of Rapp (2003) uses word senses, an approach that is outperformed by our method.

The errors produced by our system were largely the result of sense locality in the WordNet network. Table 5 highlights the incorrect responses. The synonym mistakes reveal cases where senses of the two words are close in WordNet, indicating some relatedness. For example, *percentage* may be interpreted colloquially as monetary value (e.g., “give me my percentage”) and elicits the synonym of *profit* in the economic domain, which ADW incorrectly selects as a synonym.

#### 4.3 Word Similarity Results: RG-65 dataset

Table 6 shows the Spearman’s  $\rho$  rank correlation coefficients with human judgments on the RG-65 dataset. As can be seen from the Table, our approach with the *Weighted Overlap* signature comparison improves over the similar approach of Hughes and Ramage (2007) which, however, does not involve the disambiguation step and considers a word as a whole unit as represented by the set of its senses.

### 5 Experiment 3: Sense Similarity

WordNet is known to be a fine-grained sense inventory with many related word senses (Palmer et al., 2007). Accordingly, multiple approaches have attempted to identify highly similar senses in order to produce a coarse-grained sense inventory. We adopt this task as a way of evaluating our similarity measure at the sense level.

#### 5.1 Coarse-graining Background

Earlier work on reducing the polysemy of sense inventories has considered WordNet-based sense relatedness measures (Mihalcea and Moldovan, 2001) and corpus-based vector representations of

Approach	Correlation
ADW <sub>Cos</sub>	0.825
Agirre et al. (2009)	0.830
Hughes and Ramage (2007)	0.838
Zesch et al. (2008)	0.840
ADW <sub>Jac</sub>	0.841
ADW <sub>WO</sub>	0.868

Table 6: Spearman’s  $\rho$  correlation coefficients with human judgments on the RG-65 dataset. ADW<sub>Jac</sub>, ADW<sub>WO</sub>, and ADW<sub>Cos</sub> correspond to results with the *Jaccard*, *Weighted Overlap* and *Cosine* signature comparison measures respectively.

word senses (Agirre and Lopez, 2003; McCarthy, 2006). Navigli (2006) proposed an automatic approach for mapping WordNet senses to the coarse-grained sense distinctions of the Oxford Dictionary of English (ODE). The approach leverages semantic similarities in gloss definitions and the hierarchical relations between senses in the ODE to cluster WordNet senses. As current state of the art, Snow et al. (2007) developed a supervised SVM classifier that utilized, as its features, several earlier sense relatedness techniques such as those implemented in the WordNet::Similarity package (Pedersen et al., 2004). The classifier also made use of resources such as topic signatures data (Agirre and de Lacalle, 2004), the WordNet domain dataset (Magnini and Cavaglia, 2000), and the mappings of WordNet senses to ODE senses produced by Navigli (2006).

## 5.2 Experimental Setup

We benchmark the accuracy of our similarity measure in grouping word senses against those of Navigli (2006) and Snow et al. (2007) on two datasets of manually-labeled sense groupings of WordNet senses: (1) sense groupings provided as a part of the Senseval-2 English Lexical Sample WSD task (Kilgarriff, 2001) which includes nouns, verbs and adjectives; (2) sense groupings included in the OntoNotes project<sup>4</sup> (Hovy et al., 2006) for nouns and verbs. Following the evaluation methodology of Snow et al. (2007), we combine the Senseval-2 and OntoNotes datasets into a third dataset.

Snow et al. (2007) considered sense grouping as a binary classification task whereby for each word every possible pairing of senses has to be classified

<sup>4</sup>Sense groupings belong to a pre-version 1.0: <http://cemantix.org/download/sense/ontonotes-sense-groups.tar.gz>

	Onto		SE-2			Onto + SE-2	
Method	Noun	Verb	Noun	Verb	Adj	Noun	Verb
$\mathcal{R}_{Cos}$	0.406	0.522	0.450	0.465	0.484	0.441	0.485
$\mathcal{R}_{WO}$	<b>0.421</b>	<b>0.544</b>	<b>0.483</b>	<b>0.482</b>	<b>0.531</b>	<b>0.470</b>	<b>0.503</b>
$\mathcal{R}_{Jac}$	0.418	0.531	0.478	0.473	0.501	0.465	0.493
SVM	0.370	0.455	NA	NA	0.473	0.423	0.432
ODE	0.218	0.396	NA	NA	0.371	0.331	0.288

Table 7: F-score sense merging evaluation on three hand-labeled datasets: OntoNotes (Onto), Senseval-2 (SE-2), and combined (Onto+SE-2). Results are reported for all three of our signature comparison measures and also for two previous works (last two rows).

as either *merged* or *not-merged*. We constructed a simple threshold-based classifier to perform the same binary classification. To this end, we calculated the semantic similarity of each sense pair and then used a threshold value  $t$  to classify the pair as merged if similarity  $\geq t$  and not-merged otherwise. We sampled out 10% of the dataset for tuning the value of  $t$ , thus adapting our classifier to the fine granularity of the dataset. We used the same held-out instances to perform a tuning of the  $k$  value used for *Jaccard* index, over the same values of  $k$  as in Experiment 1 (cf. Section 3).

## 5.3 Sense Merging Results

For a binary classification task, we can directly calculate precision, recall and F-score by constructing a contingency table. We show in Table 7 the F-score performance of our classifier as obtained by an averaged 10-fold cross-validation. Results are presented for all three of the measures of semantic signature comparison and for the three datasets: OntoNotes, Senseval-2, and the two combined. In addition, we show in Table 7 the F-score results provided by Snow et al. (2007) for their SVM-based system and for the mapping-based approach of Navigli (2006), denoted by ODE.

Table 7 shows that our methodology yields improvements over previous work on both datasets and for all parts of speech, irrespective of the semantic signature comparison method used. Among the three methods, *Weighted Overlap* achieves the best performance, which demonstrates that our transformation of semantic signatures into ordered lists of concepts and calculating similarity by rank comparison has been helpful.

## 6 Related Work

Due to the wide applicability of semantic similarity, significant efforts have been made at different lexical levels. Early work on document-level similarity was driven by information retrieval. Vector space methods provided initial successes (Salton et al., 1975), but often suffer from data sparsity when using small documents, or when documents use different word types, as in the case of paraphrases. Later efforts such as LSI (Deerwester et al., 1990), PLSA (Hofmann, 2001) and Topic Models (Blei et al., 2003; Steyvers and Griffiths, 2007) overcame these sparsity issues using dimensionality reduction techniques or modeling the document using latent variables. However, such methods were still most suitable for comparing longer texts. Complementary approaches have been developed specifically for comparing shorter texts, such as those used in the SemEval-2012 STS task (Agirre et al., 2012). Most similar to our approach are the methods of Islam and Inkpen (2008) and Corley and Mihalcea (2005), who performed a word-to-word similarity alignment; however, they did not operate at the sense level. Ramage et al. (2009) used a similar semantic representation of short texts from random walks on WordNet, which was applied to paraphrase recognition and textual entailment. However, unlike our approach, their method does not perform sense disambiguation prior to building the representation and therefore potentially suffers from ambiguity.

A significant amount of effort has also been put into measuring similarity at the word level, frequently by approaches that use distributional semantics (Turney and Pantel, 2010). These methods use contextual features to represent semantics at the word level, whereas our approach represents word semantics at the sense level. Most similar to our approach are those of Agirre et al. (2009) and Hughes and Ramage (2007), which represent word meaning as the multinomials produced from random walks on the WordNet graph. However, unlike our approach, neither of these disambiguates the two words being compared, which potentially conflates the meanings and lowers the similarity judgment.

Measures of sense relatedness have frequently leveraged the structural properties of WordNet (e.g., path lengths) to compare senses. Budanitsky and Hirst (2006) provided a survey of such WordNet-based measures. The main drawback

with these approaches lies in the WordNet structure itself, where frequently two semantically similar senses are distant in the WordNet hierarchy. Possible solutions include relying on wider-coverage networks such as WikiNet (Nastase and Strube, 2013) or multilingual ones such as BabelNet (Navigli and Ponzetto, 2012b). Fewer works have focused on measuring the similarity – as opposed to relatedness – between senses. The topic signatures method of Agirre and Lopez (2003) represents each sense as a vector over corpus-derived features in order to build comparable sense representations. However, topic signatures often produce lower quality representations due to sparsity in the local structure of WordNet, especially for rare senses. In contrast, the random walk used in our approach provides a denser, and thus more comparable, representation for all WordNet senses.

## 7 Conclusions

This paper presents a unified approach for computing semantic similarity at multiple lexical levels, from word senses to texts. Our method leverages a common probabilistic representation at the sense level for all types of linguistic data. We demonstrate that our semantic representation achieves state-of-the-art performance in three experiments using semantic similarity at different lexical levels (i.e., sense, word, and text), surpassing the performance of previous similarity measures that are often specifically targeted for each level.

In future work, we plan to explore the impact of the sense inventory-based network used in our semantic signatures. Specifically, we plan to investigate higher coverage inventories such as BabelNet (Navigli and Ponzetto, 2012a), which will handle texts with named entities and rare senses that are not in WordNet, and will also enable cross-lingual semantic similarity. Second, we plan to evaluate our method on larger units of text and formalize comparison methods between different lexical levels.

## Abstract

We create an open multilingual wordnet with large wordnets for over 26 languages and smaller ones for 57 languages. It is made by combining wordnets with open licences, data from Wiktionary and the Unicode Common Locale Data Repository. Overall there are over 2 million senses for over 100 thousand concepts, linking over 1.4 million words in hundreds of languages.

## 1 Introduction

We wish to create a lexicon covering as many languages as possible, with as much useful information as possible. Generally, language resources, to be useful, must be both **accessible** (legal to use) and **usable** (of sufficient quality, size and with a documented interface) (Ishida, 2006). We address both of these concerns in this paper.

One of the many attractions of the semantic network WordNet (Fellbaum, 1998), is that there are numerous wordnets being built for different languages. There are, in addition, many projects for groups of languages: Euro WordNet (Vossen, 1998), BalkaNet (Tufiş et al., 2004), Asian Wordnet (Charoenporn et al., 2008) and more. Although there are over 60 languages for which wordnets exist in some state of development (Fellbaum and Vossen, 2012, 316), less than half of these have released any data, and for those that have, the data is often not freely accessible (Bond and Paik, 2012). For those wordnets that are available, they are of widely varying size and quality, both in terms of accuracy and richness. Further, there is very little standardization in terms of format, what information is included, or license.

The goal of the research outlined in this paper is to make it possible for a researcher interested in working on the lexical semantics of a language or

languages to be able to access wordnets for those languages with a minimum of legal and technical barriers. In practice this means making it possible to access multiple wordnets with a common interface. We also use sources of semi-structured data that have minimal legal restrictions to automatically extend existing freely available wordnets and to create additional wordnets which can be added to our open wordnet grid.

Previous studies have leveraged multiple wordnets and Wiktionary (Wikimedia, 2013) to extend existing wordnets or create new ones (de Melo and Weikum, 2009; Hanoka and Sagot, 2012). These studies passed over the valuable sense groupings of translations within Wiktionary and merely used Wiktionary as a source of translations that were not disambiguated according to sense. The present study built and extended wordnets by directly linking Wiktionary senses to WordNet senses.

Meyer and Gurevych (2011) demonstrated the ability to automatically identify many matching senses in Wiktionary and WordNet based on the similarity of monolingual features. Our study combines monolingual features with the disambiguating power of multiple languages. In addition to differences in linking methodology, our project gives special attention to ensuring the maximum re-usability and accessibility of the data and software released.

Other large scale multilingual lexicons have been made by linking wordnet to Wikipedia (Wikipedia, 2013; de Melo and Weikum, 2010; Navigli and Ponzetto, 2012). Our approach is complementary to these: in general Wikipedia has more entities than classes, while Wiktionary has more classes.

In Section 2 we discuss linking freely available wordnets to form a single multilingual semantic network. In Section 3 we extend the wordnets with data from two sources. We show the results in Section 4 and then discuss them and outline future

work in Section 5.

## 2 Linking Multiple Wordnets

In order to make the data from existing wordnet projects more **accessible**, we have built a simple database with information from those wordnets with licenses that allow redistribution of the data. These wordnets, their licenses and recent activity are summarized in Table 1 (sizes for most of them are shown in Table 2).<sup>1</sup>

Table 1: Linked Open Wordnets

The first wordnet developed is the Princeton WordNet (PWN: Fellbaum, 1998). It is a large lexical database of English. Open class words (nouns, verbs, adjectives and adverbs) are grouped into concepts represented by sets of synonyms (synsets). Synsets are linked by semantic relations such as hyponymy and meronymy. PWN is released under an open license (allowing one to use, copy, modify and distribute it so long as you properly acknowledge the copyright).

The majority of freely available wordnets take the basic structure of the PWN and add new lemmas (words) to the existing synsets: the **extend** model (Vossen, 2005). For example,  $dog_{n:1}$  is linked to the lemmas *chien* in French, *anjing* in Malay, and so on. It is widely realized that this

<sup>1</sup>We have now added Mandarin Chinese.

model is imperfect as different languages lexicalize different concepts and link them in different ways (Fellbaum and Vossen, 2012). Nevertheless, many projects have found that the overall structure of PWN serves as a useful scaffold. The fact that, for example, a  $dog_{n:1}$  is an  $animal_{n:1}$  is language independent.

In theory, such wordnets can easily be combined into a single resource by using the PWN synsets as pivots. All languages are linked through the English wordnet. Because they are linked at the synset level, the problem of ambiguity one gets when linking bilingual dictionaries through a common language is resolved: we are linking senses to senses.

In practice, linking a new language's wordnet into the grid could be problematic for three reasons. The first problem was that the wordnets were linked to various versions of the Princeton WordNet. In order to combine them into a single multilingual structure, we had to map to a common version. The second problem was the incredible variety of formats that the wordnets are distributed in. Almost every project uses a different format. Even different versions of the same project often had slightly different formats. The final problem was legal: not all wordnets have been released under licenses that allow reuse.

The first problem can largely be overcome using the mapping scripts from Daude et al. (2003). Mapping introduces some distortions, in particular, when a synset is split, we chose to only map the translations to the most probable mapping, so some new synsets will have no translations.

The second problem we are currently solving through brute force, writing a new script for every new project we add. We make these scripts, along with the reformatted wordnets, freely available for download. Any problems or bugs found when converting the wordnets have been reported back to the original projects, with many of them fixed in newer releases. We consider this feedback to be an important part of our work: it means that other researchers and users do not have to suffer from the same problems and it encourages projects to release updates.

The third, legal, problem is being solved by an ongoing campaign to encourage projects to (re-)release their data under open licenses. Since Bond and Paik (2012) surveyed wordnet licenses in 2011, six projects have newly released data un-

der open licenses and eight projects have updated their data.

Our combined wordnet includes English (Fellbaum, 1998); Albanian (Ruci, 2008); Arabic (Black et al., 2006); Chinese (Huang et al., 2010); Danish (Pedersen et al., 2009); Finnish (Lindén and Carlson., 2010); French (Sagot and Fišer, 2008); Hebrew (Ordan and Wintner, 2007); Indonesian and Malaysian (Nurril Hirfana et al., 2011); Italian (Pianta et al., 2002); Japanese (Isahara et al., 2008); Norwegian (Bokmål and Nynorsk: Lars Nygaard 2012, p.c.); Persian (Montazery and Faili, 2010); Portuguese (de Paiva and Rademaker, 2012); Polish (Piasecki et al., 2009); Thai (Thoongsup et al., 2009) and Basque, Catalan, Galician and Spanish from the Multilingual Common Repository (Gonzalez-Agirre et al., 2012).

On our server, the wordnets are all in a shared `sqlite` database using the schema produced by the Japanese WordNet project (Isahara et al., 2008). The database is based on the logical structure of the Princeton WordNet, with an additional language attribute for lemmas, examples, definitions and senses. It is a single open multilingual resource. When we redistribute the data, each project's data is made available separately, with a common format, but separate licenses.

The Scandinavian and Polish wordnets are based on the **merge** approach, where independent language specific structures are built and then some synsets linked to PWN. Typically only a small subset will be linked (due more to resource limitations than semantic incompatibility).

## 2.1 Core Concepts

Boyd-Graber et al. (2006) created a list of 5,000 **core** word senses in Princeton WordNet which represent approximately the 5,000 most frequently used word senses.<sup>2</sup> We use this list to evaluate the coverage of the wordnets: do they contain words for the most common concepts? As a very rough measure of useful coverage, we report the percentage of synsets covered from this core list. Because the list is based on English data, it is of course not a perfect measure for other languages and cultures. Note that some wordnet projects have deliberately targeted the core concepts, which of course boosts their coverage scores.

<sup>2</sup>The original list is here from <http://wordnetcode.princeton.edu/standoff-files/core-wordnet.txt>; we converted it to `wn30` synsets.

## 2.2 License Types

The licenses fall into four broad categories: **(u)** completely unrestricted, **(a)** attribution required, **(s)** share alike, and **(n)** non-commercial. The first category includes any work that is in the public domain or that the author has released without any restrictions. The second category allows anyone to use, adapt, improve, and redistribute the work as long as one attributes the work in the manner specified by the copyright holder (without suggesting an endorsement). The WordNet, MIT, and CC BY licenses are all in this category. The third category allows anyone to adapt and improve the licensed work and redistribute it, but the redistributed work must be released under the same license. The CC BY-SA, GPL, GFDL, and CeCILL-C licenses are of this type. Because derivative works can only be redistributed under the same license, works licensed under any two of these licenses cannot be combined with each other and legally redistributed. In general, a work formed from the combination of works in category **(u)** and **(a)** with a work in category **(s)** will be subject to the more restrictive terms of the the share alike license. However, the GPL, GFDL and CeCILL-C are incompatible with CC BY.<sup>3</sup> The fourth type of license further forbids the commercial use of a work. The CC BY-NC and the CC BY-NC-SA licenses are in this category, they are also incompatible with licenses in category **(s)**.

Releasing a work under the more restrictive licenses in categories **(s)** and **(n)** above substantially limit and complicate the ability to extend and combine a work into other useful forms. By maintaining a separation of databases released under incompatible licenses, we avoid any possible legal problems. Due to license incompatibilities, it is impossible to release a single database with all the wordnets, even though individually they are redistributable. We can currently combine those with licenses in groups **(u)** and **(a)** and the CC BY-SA wordnets (now everything except French and Basque).

## 3 Extending with non-wordnet data

We looked at two sources for automatically adding new entries. The Unicode Common Locale Data Repository (CLDR) has reliable information on languages, territories and dates. Wiktionary is a

<sup>3</sup><http://www.gnu.org/licenses/license-list.html#ccby>

general purpose lexicon with much more information for many words.

### 3.1 Unicode Common Locale Data Repository (CLDR)

We added information on languages, territories and dates from the Unicode Common Locale Data Repository (CLDR).<sup>4</sup> This is a collection of data maintained by the Unicode Consortium to support software internationalization and localization with locale information on formatting dates, numbers, currencies, times, and time zones, as well as help for choosing languages and countries by name. It has this data for over 194 languages. It is released under an open license that allows redistribution with proper attribution (Unicode, Inc., 2012).<sup>5</sup>

We found data for 122 languages. Most had around 550 senses (synsets and their lemmas): for example, for Portuguese: English<sub>n:1</sub> *inglês*. Some had only 40 or 50, such as Assamese, which only has the week days, month names and a few language names. The linked data was small enough to check by hand. When the original CLDR data is correct the data we generate should be correct.

The idea of using such data is not new. Quah et al. (2001) for example, use Linux locale data to extend a proprietary English-Malay lexicon. de Melo and Weikum (2009) also use this data (and data from a variety of other sources) to build an enhanced wordnet, in addition adding new synsets for concepts that are not in not wordnet. However, when they released the data as LEXVO (data about languages: CC BY-SA) and UWN (the universal multilingual wordnet: CC BY-NC-SA), they added additional license restrictions which complicate the reuse of the data and make it impossible to integrate the data back into the original wordnet project.

### 3.2 Wiktionary

Searches for a publicly-available source of Wiktionary in a preprocessed, machine-readable format did not turn up any sources that were recent and publicly-available.<sup>6</sup> Although there are sev-

eral freely-available software programs that are capable of parsing portions of the English Wiktionary, none of the programs that were evaluated appeared to extract the precise set of information desired for our task in an easy-to-use format. So the authors decided to build a custom parser capable of extracting the information needed for building open wordnets.

#### 3.2.1 Wiktionary Parser

Since each language edition of Wiktionary is formatted in a somewhat unique way, parsers must be tailored to recognize the structure and formatting of each edition on a case-by-case basis. The authors created a parser tailored to the English Wiktionary, although it can be extended to handle other language versions as well. We are releasing this code under the MIT license.<sup>7</sup>

The current version of the parser is capable of extracting headwords, parts of speech, definitions, synonyms and translations from the XML Wiktionary database dumps provided by the Wikimedia Foundation.<sup>8</sup> Within these large XML files, the main body of Wiktionary articles are stored in a Wikitext format, which is a semi-structured format. Although anyone can edit a Wiktionary page and use any style of formatting they desire, the community of users encourages adhering to established guidelines, which produces a format that is generally predictable.

Within the English Wiktionary, synonyms and translations are both grouped into sense groups that correspond with definitions in the main section. These sense groups are marked by a short text gloss (**short gloss**), which is usually an abbreviated version of one of the full definitions (**full definition**). The parser makes no attempt to match these short glosses with the full definitions. Data is simply extracted, cleaned, and then stored in a relational database or flat file.

Translations proved to be easy to extract due to the fairly consistent use of a specifically formatted translation template. These templates include a language code derived from ISO standards, the translation, and optional additional information such as gender, transliteration, script, and alternate forms. The parser extracts and retains all of this potentially valuable information.

Examples of translation templates:

<sup>7</sup>Available from the Open Multilingual Wordnet Page: <http://casta-net.jp/~kuribayashi/multi/>.

<sup>8</sup><http://dumps.wikimedia.org/>

<sup>4</sup><http://cldr.unicode.org/>

<sup>5</sup>With the extra requirement that “there is clear notice in each modified Data File or in the Software as well as in the documentation associated with the Data File(s) or Software that the data or software has been modified.”

<sup>6</sup>We later learned that McCrae et al. (2012) made a release of Wiktionary in the lemon format (<http://datahub.io/en/dataset/dbnary>). They did not, however, release the code they used to parse Wiktionary.

- Finnish:  $\{\{t+|fi|sanakirja\}\}$
- French:  $\{\{t+|fr|dictionnaire|m\}\}$

To enable later processing, it is necessary to tie synonyms and translations to their corresponding short gloss via a unique key. Most parsers simply use an automatically generated surrogate key or a key based on the ordered position of data within a Wiktionary article. Since Wiktionary is constantly changing, the side effect of this approach is that data extracted from a specific snapshot of the Wiktionary database can only be meaningfully used in connection with other data extracted by the same parser from the exact same snapshot. To overcome this, we use a unique key that can be recreated from the data itself, which we call the **defkey**. To generate this key, we concatenate the language code, headword, part of speech, and the short gloss and use the sha1 hash function (NIST, 2012) to create a unique 40-character hexadecimal string from the resulting text.

These defkeys are time and technology independent, so they allow the ability for researchers to efficiently share and compare results. Once a link is established between this defkey and a particular synset, translations added to Wiktionary at a later data can be automatically integrated into our multilingual wordnet. Conversely, if a Wiktionary contributor changes a short gloss, historical data connected to the old defkey is preserved while new data imported at a later time will not be incorrectly linked to an older definition.

Another feature of our parser is a feedback mode, which generates a report about poorly formatted data that was encountered. These automatically generated reports can be used to create a quality-enhancing feedback loop with Wiktionary.

### 3.2.2 Linking Senses

Meyer and Gurevych (2011) showed that automatic alignments between Wiktionary senses and PWN can be established with reasonable accuracy and recall by combining multiple text similarity scores to compare a bag of words based on several pieces of information linked to a WordNet sense with another bag of words obtained from a Wiktionary entry. In our study we evaluated the potential for aligning senses based on common translations in combination with monolingual similarity features.

In this study we used 20 of the wordnets de-

scribed in Section 2,<sup>9</sup> and the Wiktionary data obtained using the parser described in Section 3.2.1. Before searching for translation matches, we normalized the data to ensure the most accurate possible overlap count. First, article headwords were included as English translations of Wiktionary senses (along with synonyms). Then differences in language codes were rectified and translations containing symbolic characters or a mixture of roman and non-roman characters were marked to be ignored, save a few exceptions. This left approximately 1.4 million sense translations in 20 languages in our wordnet grid, and nearly 1.3 million Wiktionary translations in over 1,000 languages.

We then created a list of all possible alignments where at least one translation of a wordnet sense matched a translation of a Wiktionary sense. This represented a small percentage of the possible alignments, because definitions in Wiktionary that do not contain any translations were ignored in our study. Of more than 500,000 English definitions in Wiktionary, only about 130,000 presently have associated translations. The resulting graph contained over 700,000 possible sense alignments.

We calculated a number of similarity scores, the first two based on similarity in the number of lemmas, calculated using the Jaccard index:

$$\text{sim}_e(s_n, s_k) = \frac{|E(s_k) \cap E(s_n)|}{|E(s_k) \cup E(s_n)|} \quad (1)$$

$$\text{sim}_a(s_n, s_k) = \frac{|L(s_k) \cap L(s_n)|}{|L(s_k) \cup L(s_n)|} \quad (2)$$

Where  $s_k, s_n$  are concepts in Wiktionary and wordnet respectively,<sup>10</sup>  $E(s)$  is the set of English lemmas for sense  $s$  and  $L(s)$  is the set of lemmas in all languages.

As an initial pruning, we kept only matches where either:  $\text{sim}_a \geq 0.7$  **or** ( $\text{sim}_e \geq 0.5$  **and**  $\text{sim}_a \geq 0.5$ ) **or**, if  $(|L(s_k) \cap L(s_n)| > 5)$  then ( $\text{sim}_e \geq 0.5$  **and**  $\text{sim}_a \geq 0.45$ ). After applying these filters, approximately 220,000 alignment candidates remained.

We reviewed a random sample of 551 alignment candidates. Of these 136 were deemed correctly aligned. Another 48 we considered possibly close enough to produce valid translations for wordnet. All others were marked as incorrect alignments.

<sup>9</sup>We didn't use Chinese or Polish, as the wordnets were added after we had started the evaluation.

<sup>10</sup>Precisely, synsets in wordnet and senses in Wiktionary.

This development dataset was used to tune refined similarity scores.

$$\text{sim}_t(s_n, s_k) = \frac{|L(s_k) \cap L(s_n)|}{\sqrt{\alpha |L(s_k) \cup L(s_n)|}} \quad (3)$$

$$\text{sim}_d(s_n, s_k) = \frac{\text{BoW}(\text{wndef}) \cdot \text{BoW}(\text{wkdef})}{\|\text{BoW}(\text{wndef})\| \|\text{BoW}(\text{wkdef})\|} \quad (4)$$

$$\text{sim}_c(s_n, s_k) = \text{sim}_t + \beta \text{sim}_d \quad (5)$$

$\text{sim}_t$  gives higher weight to concepts that link through more lemmas, not just a higher proportion of lemmas.

$\text{sim}_d$  measures the similarity of the definitions in the two resources, using a cosine similarity score. We initially used the WordNet gloss and example sentence(s) for `wndef` and the short gloss from Wiktionary for `wkdef`. This improved the accuracy of the combined ranking score ( $\text{sim}_c$ ), but since many of the short glosses are only one or two words, the sparse input often produced a  $\text{sim}_d$  score of zero even when the candidate alignment was correct. To improve the accuracy of the  $\text{sim}_d$  component, we also added in the long definitions.

Short glosses were aligned with long definitions using a similar approach to McCrae et al. (2012). First we search for a match where the short gloss was a substring of the full definition. If that failed to produce a single possible alignment, we aligned the short gloss with the full definition that produced the greatest cosine similarity score. Finally, where the short definition was blank and only a long definition was present, we aligned the two. The results of this alignment were less than 90% accurate, so to offset the effects of this noise we included both the full definition and the short gloss in `wkdef`. For `wndef` we used the WordNet gloss, example sentence(s), and synonyms. Even though the linking of definitions within Wiktionary left much to be desired, the increased amount of text improved the accuracy of the definition based similarity component of our ranking score.

Our combined ranking score ( $\text{sim}_c$ ), based on both overlapping translations and a monolingual lexical similarity score, was able to outperform ranking based on either component in isolation. We expect that an improved alignment of short glosses to full definitions together with more accurate measures of lexical similarity such as described by Meyer and Gurevych (2011) would further improve the accuracy of a combined ranking score. We employed our combined ranking score first as a filter, where  $\text{sim}_c \geq \tau_c$ . The ranking score

is then used to select the best match among competing alignments. Alignments are based on the belief that a definition within Wiktionary should only map to a single WordNet synset (if any at all). In theory, each WordNet synset should represent a meaning distinguishable from all other synsets. Because Wiktionary is organized according to lemma first, and sense second, multiple definitions in separate articles often map to the same synset. For example *mortal* “A human; someone susceptible to death”, *individual* “A person considered alone ...”, and *person* “A single human being; an individual” all align with `someonen:1` (00007846-n). However, two distinct definitions within the same Wiktionary entry should not map to the same WordNet sense. When there are multiple possible alignments where only one can be valid,  $\text{sim}_c$  is used to determine the best match.

In addition to using the combined ranking score as a filter, we found that we could obtain a small additional increase in accuracy without reducing recall by also requiring  $\text{sim}_t \geq \tau_t$  or  $\text{sim}_d \geq \tau_d$ .

To determine ideal values for the weights and thresholds, we performed several grid searches. The parameters are interdependent and can produce reasonable results at a variety of points. Ideal values also depend on whether we wish to maximize accuracy or recall.  $\alpha$  is set at 3.2 in order to achieve an ideal target threshold of  $\tau_t = 1$ . We finally chose values of  $\beta = 0.7$  and  $\tau_c = 0.71$  which gave a reasonable balance between accuracy and recall.

## 4 Results and Evaluation

We give the data for the 26 wordnets with more than 10,000 synsets in Table 2. There are a further 57 with more than 1,000; 133 with more than 100, 200 with more than 10 and 645 with more than 1 (although most of the very small languages appear to be simple errors in the language code entered into Wiktionary). Individual totals are shown for synsets and senses from the original wordnets, the data extracted from Wiktionary, and the merged data of the wordnets, Wiktionary and CLDR. We do not show the CLDR data in the table as it is so small, generally 500-600 synsets for the top languages. Overall there are 2,040,805 senses for 117,659 concepts, using over 1,400,000 words in over 1,000 languages.

The smaller wordnets are not of much practical use, but can still serve as the core of new

**Core** shows the percentage coverage of the 5,000 core concepts.

Table 2: Merged Wordnets (with more than 10,000 entries)

projects. The bigger wordnets show the data from Wiktionary (and to a lesser extent CLDR) having only a small increase in the number of senses. The biggest change is for the medium size projects, such as Persian or Arabic, which end up with much better coverage of the most frequent core concepts. Major languages such as German or Russian, which currently do not have open wordnets get good coverage as well.

The size of the mapping table is the same as the number of English senses linked (49,951 senses). We evaluated a random sample of 160 alignments and found the accuracy to be 90% (Wiktionary sense maps to the best possible wordnet sense).

We then evaluated samples of the wordnet created from Wiktionary for several languages. For each language we choose 100 random senses, then checked them against existing wordnets.<sup>11</sup> For all unmatched entries, we then had them checked by native speakers. The results are given in Table 3. The sense accuracy is higher than the mapping accuracy: in general, entries with more translations are linked more accurately, thus raising the average precision. During the extraction and eval-

Language	% Matched	% Good

\* Not used to build the mapping from wordnet to Wiktionary.  
 \*\* We allow terms used in either Serbian or Croatian.

uation, we noticed several language specific features: for example, Serbo-Croatian had a mixture of Cyrillic and Latin entries. For languages where one script was clearly dominant, we kept only that, but really these decisions should be done for each language by a native speaker.

We make the data available in two ways. The first is a set of downloads. Each language has up to three files: the data from the wordnet project (if it exists), the data from the CLDR and the data from Wiktionary. They are kept separate in order

<sup>11</sup>For Chinese we use the wordnet from Xu et al. (2008), which is free for research but cannot be redistributed. For German we used Euro WordNet (Vossen, 1998).

to keep the licenses as free as possible. The second is as two on-line searches: one using only the data from the projects, and one with all the data combined. The combination is done by simple union.<sup>12</sup> We maintain this separation as we cannot guarantee the quality of the automatically extracted data. Because the raw data is there it is possible to combine them in other ways. The simple structure is easy to manipulate, and there is code to use this style of data with the popular tool kit NLTK (Bird et al., 2010).

## 5 Discussion and Future Work

We have created a large open wordnet of high quality (85%–99% measured on senses). Twenty six languages have more than 10,000 concepts covered, with 42–100% coverage of the most common core concepts. The data is easily downloadable with minimal restrictions. The overall accuracy is estimated at over 94%, as most of the original wordnets are hand verified (and so should be 100% accurate). The high accuracy is largely thanks to the disambiguating power of the multiple translations, made possible by the many open wordnets we have access to.

Because we link senses between wordnet and Wiktionary and then use the translations of the sense, manually validating this mapping will improve the entries in multiple languages simultaneously. As the Wiktionary-wordnet alignment mapping is linked to persistent keys it will remain useful even as the resources change. Further, it can be used to identify and add missing senses to wordnet: unmapped Wiktionary entries are candidates for new concepts.

The Universal Wordnet (UWN: de Melo and Weikum, 2009) brings in data from even more resources, and combines them to make a larger resource, choosing parameters with slightly lower precision (just under 90%). It is further linked to Wikipedia, adding many named entities. We expect that our work is complementary. Because we use a different approach, it would be possible to merge the two if the licenses allowed us to. However, since the CC BY-SA and CC-BY-NC-SA licenses are mutually exclusive, the two works cannot be combined and rereleased unless relevant parties can relicense the works. There is no easy way to improve UWN beyond checking each and every entry, which is expensive. An ad-

vantage of our approach, noted above, is that we can validate the sense matches for English and the accuracy percolates down to all the languages.

Integrating data from the most recent version of Wiktionary can be done simply and takes a few hours. It is therefore feasible to update the downloadable data regularly. Improvements in either the wordnet projects or Wiktionary (or both) can also result in improved mappings. We further hope to take advantage of ongoing initiatives in the global wordnet grid to add new concepts not in the Princeton WordNet, so that we can expand beyond an English-centered world view.

By making the data from multiple sources easily available with minimal restrictions, we hope that it will be easier to do research that exploits lexical semantics. In particular, we make the data easily accessible to the original wordnet projects, some of whom have already started to merge it into their own resources. We cannot check the accuracy of data in all languages, nor, for example, check that synsets have the most appropriate lemmas associated with them. Many languages have their own orthographic issues (for example a choice of scripts, or the choice to include vowels or not). Our automatic extraction does not deal with these issues at all. This kind of language specific quality control is best done by the individual wordnet projects.

We also consider it important to keep feeding data back to the individual wordnet projects, as much of the innovative research comes from them: the class/instance distinction from PWN; the distinction between rigid and non-rigid synsets from the Kyoto Project; domain mappings from the MultiWordNet (Pianta et al., 2002); representing orthographic variation from the Japanese Wordnet (Kuroda et al., 2011); combining close languages from the Wordnet Bahasa (Nurril Hirfana et al., 2011); and so on. For all of these reasons, we do not consider automatic extraction from/linking to Wiktionary a substitute for building languages specific wordnets.

Further work that this data should allow us to do include: automatically producing a list of bad data found in Wiktionary that can be used by Wiktionary editors to correct errors; and finding gaps in wordnet by identifying senses in Wiktionary that have a large number of translations, but fail to have any significant alignment with existing wordnet synsets.

<sup>12</sup><http://casta-net.jp/~kuribayashi/multi/>

We currently only link through the English Wiktionary and its translations. It should be possible to expand the multilingual wordnet in the same way using Wiktionaries in other languages, which we would expect to improve coverage.

Finally, Wiktionary contains a lot of useful information we are not currently using (information on gender, transliterations, pronunciations, alternative spellings and so forth). We can also think of the aligned definitions as a paraphrase corpus for English.

We have devoted more space than is usual for a computational linguistics paper to issues of licensing and sustainability. This is deliberate: we feel papers about lexical resources should be clear about licensing, and that it should be considered early on when creating new resources. There are strong arguments that open data leads to better science (Pederson, 2008), and it has been shown that open resources are cited more (Bond and Paik, 2012). In addition, how to maintain resources over time is a major unsolved problem. We consider it important that our wordnet is not just large and accurate but also maintainable and as accessible as possible.

## 6 Conclusions

We have created an open multilingual wordnet with over 26 languages. It is made by combining wordnets with open licences, data from the Unicode Common Locale Data Repository and Wiktionary. Overall there are over 2 million senses for 117,659 concepts, using over 1.4 million words in hundreds of languages.

## Acknowledgments

We would like to thank the following for their help with the evaluation: Le Tuan Anh, František Kratochvíl, Kyonghee Paik, Zina Pozen, Melanie Siegel, Stefanie Stadler, Bilyana Shuman, Liling Tan and Muhammad Zulhelmy bin Mohd Rosman.

## Abstract

We present a new bilingual FrameNet lexicon for English and German. It is created through a simple, but powerful approach to construct a FrameNet in any language using Wiktionary as an interlingual representation. Our approach is based on a sense alignment of FrameNet and Wiktionary, and subsequent translation disambiguation into the target language. We perform a detailed evaluation of the created resource and a discussion of Wiktionary as an interlingual connection for the cross-language transfer of lexical-semantic resources. The created resource is publicly available at <http://www.ukp.tu-darmstadt.de/fnwkde/>.

## 1 Introduction

FrameNet is a valuable resource for natural language processing (NLP): semantic role labeling (SRL) systems based on FrameNet provide semantic analysis for NLP applications, such as question answering (Narayanan and Harabagiu, 2004; Shi and Mihalcea, 2005) and information extraction (Mohit and Narayanan, 2003). However, their wide deployment has been prohibited by the poor coverage and limited availability of a similar resource in many languages.

Expert-built lexical-semantic resources are expensive to create. Previous cross-lingual transfer of FrameNet used corpus-based approaches, or resource alignment with multilingual expert-built resources, such as EuroWordNet. The latter indirectly also suffers from the high cost and constrained coverage of expert-built resources.

Recently, collaboratively created resources have been investigated for the multilingual extension of resources in NLP, beginning with Wikipedia (Navigli and Ponzetto, 2010). They rely on the so-called “Wisdom of the Crowds”, contributions by

a large number of volunteers, which results in a continuously updated high-quality resource available in hundreds of languages. Due to the encyclopedic nature of Wikipedia, previous work focused on encyclopedic information for Wikipedia entries, i.e., almost exclusively on nouns.

This is not enough for resources like FrameNet. Such resources need *lexical-semantic information* on *various POS*. For FrameNet, information on the predicates associated with a semantic frame – mostly verbs, nouns, and adjectives – is crucial, for instance gloss or syntactic subcategorization.

A solution for the problem of multilingual extension of lexical semantic resources is to use Wiktionary, a collaboratively created dictionary, as connection between languages. It provides high-quality lexical information on all POS, for instance glosses, sense relations, syntactic subcategorization, etc. Like Wikipedia, it is continuously extended and contains translations to hundreds of languages, including low-resource ones. To our knowledge, Wiktionary has not been evaluated as an interlingual index for the cross-lingual extension of lexical-semantic resources.

In this paper, we present a novel method for the creation of bilingual FrameNet lexicons based on an alignment to Wiktionary. We demonstrate our method on the language pair English-German and present the resulting resources, a lemma-based multilingual and a sense-disambiguated German-English FrameNet lexicon.

The understanding of lexical-semantic resources and their combinations, e.g., how alignment algorithms can be adapted to individual resource pairs and different POS, is essential for their effective use in NLP and a prerequisite for later in-task evaluation and application. To enhance this understanding for the presented resource pair, we perform a detailed analysis of the created resource and compare it to existing FrameNet resources for German.

The contributions of our work are the following: (1) We create a novel sense alignment between FrameNet and the English Wiktionary. It results in a multilingual FrameNet FNWKxx, which links FrameNet senses to lemmas in 280 languages. (2) We create a sense-disambiguated English-German FrameNet lexicon FNWKde based on FNWKxx and translation disambiguation on the German Wiktionary.<sup>1</sup> (3) We analyze the two resources and outline further steps for creating a multilingual FrameNet.

This is a major step towards the vision of this paper: a simple, but powerful approach to partially construct a FrameNet in any language using Wiktionary as an interlingual representation.

## 2 Resource Overview

**FrameNet** (Baker et al., 1998) is an expert-built lexical-semantic resource incorporating the theory of frame-semantics (Fillmore, 1976). It groups word senses in frames that represent particular situations. Thus, the verb *complete* and the noun *completion* belong to the *Activity finish* frame. The participants of these situations, typically realized as syntactic arguments, are the *semantic roles* of the frame, for instance the *Agent* performing an activity, or the *Activity* itself. FrameNet release 1.5 contains 1,015 frames, and 11,942 word senses. Corpus texts annotated with frames and their roles have been used to train automatic SRL systems.

**Wiktionary** is a collaboratively created dictionary available in over 500 language editions. It is continuously extended and revised by a community of volunteer editors. The English language edition contains over 500,000 word senses.<sup>2</sup>

Wiktionary is organized like a traditional dictionary in lexical entries and word senses. For the word senses, definitions and example sentences, as well as other lexical information, such as register (e.g., *colloquial*), phonetic transcription, inflection may be available, including language-specific types of information. Senses also provide translations to other languages. These are connected to lexical entries in the respective language editions via hyperlinks. This allows us to use Wiktionary as an interlingual connection between multiple languages.

<sup>1</sup>The xx in FNWKxx stands for all the languages in the resource. After translation disambiguation in a specific language, xx is replaced by the corresponding language code.

<sup>2</sup>as of May 2013, see <http://en.wiktionary.org/wiki/Wiktionary:Statistics>.

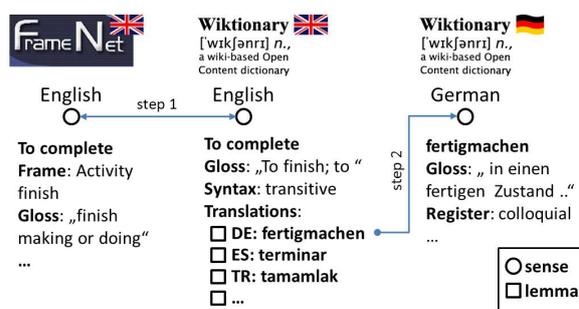

Figure 1: Method overview.

The quality of Wiktionary has been confirmed by Meyer and Gurevych (2012b) who also give an overview on the usage of Wiktionary in NLP applications such as speech synthesis.

## 3 Method Overview

Our method consists of two steps visualized in Fig. 1. In the first step, we create a novel sense alignment between FrameNet and the English Wiktionary following Niemann and Gurevych (2011). Thus, the FrameNet sense of *to complete* with frame *Activity finish* is assigned to the sense of *to complete* in Wiktionary meaning *to finish*.

This step establishes Wiktionary as an interlingual index between FrameNet senses and lemmas in many languages, and builds the foundation for the bilingual FrameNet extension.

It results in a basic multilingual FrameNet lexicon FNWKxx with translations to lemmas in 283 languages. An example: by aligning the FrameNet sense of the verb *complete* with gloss *to finish* with the corresponding English Wiktionary sense, we collect 39 translations to 22 languages, e.g., the German *fertigmachen* and the Spanish *terminar*.

The second step is the disambiguation of the translated lemmas with respect to the target language Wiktionary in order to retrieve the linguistic information of the corresponding word sense in the target language Wiktionary (Meyer and Gurevych, 2012a). We evaluate this step for English and German and create the bilingual FrameNet lexicon FNWKde. For the example sense of *complete*, we extract lexical information for the word sense of its German translation *fertigmachen*, for instance a German gloss, an example sentence, register information (*colloquial*), and synonyms, e.g., *beenden*. As a side-benefit of our method, we also extend the English FrameNet by the linguistic information in Wiktionary.

## 4 Related Work

### 4.1 Creating FrameNets in New Languages

There are two main lines of research in bootstrapping a FrameNet for languages other than English.

The first, corpus-based approach is to automatically extract word senses in the target language based on parallel corpora and frame annotations in the source language. In this vein, Padó and Lapata (2005) propose a cross-lingual FrameNet extension to German and French; Johansson and Nugues (2005) and Johansson and Nugues (2006) do this for Spanish and Swedish, and Basili et al. (2009) for Italian.

Padó and Lapata (2005) observe that their approach suffers from polysemy errors, because lemmas in the source language need to be disambiguated with respect to all the frames they evoke. To alleviate this problem, they use a disambiguation approach based on the most frequent frame; Basili et al. (2009) use distributional methods for frame disambiguation. Our approach is based on sense alignments and therefore explicitly aims to avoid such errors.

The second line of work is resource-based: FrameNet is aligned to multilingual resources in order to extract senses in the target language. Using monolingual resources, this approach has also been employed to extend FrameNet coverage for English (Shi and Mihalcea, 2005; Johansson and Nugues, 2007; Ferrandez et al., 2010).

De Cao et al. (2008) map FrameNet frames to WordNet synsets based on the embedding of FrameNet lemmas in WordNet. They use MultiWordNet, an English-Italian wordnet, to induce an Italian FrameNet lexicon with 15,000 entries.

To create *MapNet*, Tonelli and Pianta (2009) align FrameNet senses with WordNet synsets by exploiting the textual similarity of their glosses. The similarity measure is based on stem overlap of the candidates' glosses expanded by WordNet domains, the WordNet synset, and the set of senses for a FrameNet frame. In Tonelli and Pighin (2009), they use these features to train an SVM-classifier to identify valid alignments and report an  $F_1$ -score of 0.66 on a manually annotated gold standard. They report 4,265 new English senses and 6,429 new Italian senses, which were derived via MultiWordNet.

*ExtendedWordFramenet* (Laparra and Rigau, 2009; Laparra and Rigau, 2010) is also based on the alignment of FrameNet senses to Word-

Net synsets. The goal is the multilingual coverage extension of FrameNet, which is achieved by linking WordNet to wordnets in other languages (Spanish, Italian, Basque, and Catalan) in the Multilingual Central Repository. For each language, they add more than 10,000 senses to FrameNet. They rely on a knowledge-based word sense disambiguation algorithm to establish the alignment and report  $F_1=0.75$  on a gold standard based on Tonelli and Pighin (2009).

Tonelli and Giuliano (2009) align FrameNet senses to Wikipedia entries with the goal to extract word senses and example sentences in Italian. Based on Wikipedia, this alignment is restricted to nouns. Subsequent work on Wikipedia and FrameNet follows a different path and tries to enhance the modeling of selectional preferences for FrameNet predicates (Tonelli et al., 2012).

Finally, there have been suggestions to combine the corpus-based and the resource-based approaches: Borin et al. (2012) do this for Finnish and Swedish. They prove the feasibility of their approach by creating a preliminary Finnish FrameNet with 2,694 senses.

Mouton et al. (2010) directly exploit the translations in the English and French Wiktionary editions to extend the French FrameNet. They match the FrameNet senses to Wiktionary lexical entries, thus encountering the problem of polysemy in the target language. To solve this, they define a set of filters that control how target lemmas are distributed over frames, increasing precision at the expense of recall ( $P=0.74$ ,  $R=0.3$ ,  $F_1=0.42$ ). While their approach is in theory applicable to other languages, our approach goes beyond this by laying the ground for simultaneous FrameNet extension in multiple languages via FNWKxx.

### 4.2 Wiktionary Sense Alignments

Collaboratively created resources have become popular for sense alignments for NLP, starting with the alignment between WordNet and Wikipedia (Ruiz-Casado et al., 2005; Ponzetto and Navigli, 2009). Wiktionary has been subject to few alignment efforts: de Melo and Weikum (2009) integrate information from Wiktionary into Universal WordNet. Meyer and Gurevych (2011) map WordNet synsets to Wiktionary senses and show their complementary domain coverage.

## 5 FrameNet – Wiktionary Alignment

### 5.1 Alignment Technique

We follow the state-of-the-art sense alignment technique introduced by Niemann and Gurevych (2011). They align senses in WordNet to Wikipedia entries in a supervised setting using semantic similarity measures.

One reason to use their method was that it allows zero alignments or one-to-many alignments. This is crucial for obtaining a high-quality alignment of heterogeneous resources, such as the presented one, because their sense granularity and coverage can diverge a lot.

The alignment algorithm consists of two steps. In the *candidate extraction* step, we iterate over all FrameNet senses and match them with all senses from Wiktionary which have the same lemma and thus are likely to describe the same sense.

This step yields a set of candidate sense pairs  $C_{all}$ . In the *classification* step, a similarity score between the textual information associated with the senses in a candidate pair (e.g., their gloss) is computed and a threshold-based classifier decides for each pair on valid alignments.

Niemann and Gurevych (2011) combine two different types of similarity (i) cosine similarity on bag-of-words vectors (COS) and (ii) a personalized PageRank-based similarity measure (PPR). The PPR measure (Agirre and Soroa, 2009) maps the glosses of the two senses to a semantic vector space spanned up by WordNet synsets and then compares them using the chi-square measure.

The semantic vectors  $\mathbf{ppr}$  are computed using the personalized PageRank algorithm on the WordNet graph. They determine the important nodes in the graph as the nodes that a random walker following the edges visits most frequently:

$$\mathbf{ppr} = cM\mathbf{ppr} + (1 - c)\mathbf{v}_{\mathbf{ppr}}, \quad (1)$$

where  $M$  is a transition probability matrix between the  $n$  WordNet synsets,  $c$  is a damping factor, and  $\mathbf{v}_{\mathbf{ppr}}$  is a vector of size  $n$  representing the probability of jumping to the node  $i$  associated with each  $\mathbf{v}_i$ . For personalized PageRank,  $\mathbf{v}_{\mathbf{ppr}}$  is initialized in a particular way: the initial weight is distributed equally over the  $m$  vector components (i.e., synsets) associated with a word in the sense gloss, other components receive a 0 value.

For each similarity measure, Niemann and Gurevych (2011) determine a threshold ( $t_{ppr}$  and

$t_{cos}$ ) independently on a manually annotated gold standard. The final alignment decision is the conjunction of two decision functions:

$$a(s_s, s_t) = \text{PPR}(s_s, s_t) > t_{ppr} \& \text{COS}(s_s, s_t) > t_{cos}. \quad (2)$$

We differ from Niemann and Gurevych (2011) in that we use a joint training setup which determines  $t_{ppr}$  and  $t_{cos}$  to optimize classification performance directly (as proposed in Gurevych et al. (2012)):

$$(t_{ppr}, t_{cos}) = \text{argmax}_{(t_{ppr}, t_{cos})} F_1(a), \quad (3)$$

where  $F_1$  is the maximized evaluation score and  $a$  is the decision function in equation (2).

### 5.2 Candidate Extraction

To compile the candidate set, we paired senses from both resources with identical lemma-POS combinations. FrameNet senses are defined by a lemma, a gloss, and a frame. Wiktionary senses are defined by a lemma and a gloss. For the FrameNet sense *Activity finish* of the verb *complete*, we find two candidate senses in Wiktionary (*to finish* and *to make whole*). There are on average 3.7 candidates per FrameNet sense. The full candidate set  $C_{all}$  contains over 44,000 sense pairs and covers 97% of the 11,942 FrameNet senses.

### 5.3 Gold Standard Creation

For the gold standard, we sampled 2,900 candidate pairs from  $C_{all}$ . The properties of the gold standard mirror the properties of  $C_{all}$ : the sampling preserved the distribution of POS in  $C_{all}$  (around 40% verbs and nouns, and 12% adjectives) and the average numbers of candidates per FrameNet sense. This ensures that highly polysemous words as well as words with few senses are selected.

Two human raters annotated the sense pairs based on their glosses. The annotation task consisted in a two-class annotation: *Do the presented senses have same meaning - (YES/NO)*. The raters received detailed guidelines and were trained on around 100 sense pairs drawn from the sample.

We computed Cohen's  $\kappa$  to measure the inter-rater agreement between the two raters. It is  $\kappa=0.72$  on the full set, which is considered acceptable according to Artstein and Poesio (2008). An additional expert annotator disambiguated ties.

For comparison: Meyer and Gurevych (2011) report  $\kappa=0.74$  for their WordNet – Wiktionary gold standard, and Niemann and Gurevych (2011)

	adj	noun	verb	all
$\kappa$	<b>.8</b>	<b>.77</b>	<b>.65</b>	<b>.72</b>

Table 1: Inter-rater agreement.

$\kappa=0.87$  for their WordNet – Wikipedia gold standard. These gold standards only consist of nouns, which appear to be an easier annotation task than verb senses. This is supported by our analysis of the agreement by POS (see Table 1): the agreement on nouns and adjectives lies between the two agreement scores previously reported on nouns. Thus our annotation is of similar quality. Only the agreement on verbs is slightly below the acceptability threshold of 0.67 (Artstein and Poesio, 2008). The verb senses are very fine-grained and thus present a difficult alignment task. Therefore, we had an expert annotator correct the verbal part of the gold standard set. After removing the training set for the raters, the final gold standard contains 2,789 sense pairs. 28% of these are aligned.

#### 5.4 Alignment Experiments

We determined the best setting for the alignment of FrameNet and Wiktionary in a ten-fold cross-validation on the gold standard.

Besides the parameters for the computation of the PPR vectors (we used the publicly available UKB tool by Agirre and Soroa (2009)), the main parameter in the experiments is the textual information that is used to represent the senses. For FrameNet senses, we used the *lemma-pos*, *sense gloss*, *example sentences*, *frame name* and *frame definition* as textual features; for Wiktionary senses, we considered *lemma-pos*, *sense gloss*, *example sentences*, *hyponyms* and *synonyms*.

We computed the similarity scores on tokenized, lemmatized and stop-word-filtered texts.

First, we evaluated models for COS and PPR independently based on various combinations of the textual features listed above. We then used the parameter setting of the best-performing single models to train the model that jointly optimizes the thresholds for PPR and COS (see eqn. (5)). In Table 2, we report on the results of the best single models and the best joint model.

For the evaluation, we compute precision P, recall R and  $F_1$  on the positive class (aligned=true), e.g., precision P is the number of pairs correctly aligned divided by all aligned pairs.

We achieved the highest precision and  $F_1$ -score

	Evaluation	verb	noun	adj	all
P	Random-1 BL	0.503	0.559	0.661	0.557
	WKT-1 BL	0.620	0.664	0.725	0.66
	BEST COS	0.639	<b>0.778</b>	0.706	0.703
	BEST PPR	0.66	0.754	0.729	0.713
	BEST JOINT	<b>0.677</b>	0.766	<b>0.742</b>	<b>0.728</b>
R	Random-1 BL	0.471	0.546	0.683	0.540
	WKT-1 BL	0.581	0.65	0.75	0.64
	BEST COS	0.658	0.758	0.754	0.715
	BEST PPR	0.666	0.724	0.754	0.699
	BEST JOINT	<b>0.683</b>	<b>0.783</b>	<b>0.83</b>	<b>0.75</b>
$F_1$	Random-1 BL	0.487	0.552	0.672	0.549
	WKT-1 BL	0.60	0.657	0.737	0.65
	BEST COS	0.648	0.768	0.729	0.709
	BEST PPR	0.663	0.739	0.741	0.706
	BEST JOINT	<b>0.68</b>	<b>0.775</b>	<b>0.784</b>	<b>0.739</b>
	UBound	0.735	0.834	0.864	0.797

Table 2: Alignment performance by POS.

for COS using all available features, but excluding FrameNet *example sentences* because they introduce too much noise. Adding the *frame name* and *frame definition* to the often short glosses provides a richer sense representation for the COS measure.

The best-performing PPR configuration uses *sense gloss* and *lemma-pos*. For the joint model, we employed the best single PPR configuration, and a COS configuration that uses *sense gloss* extended by Wiktionary *hyponyms*, *synonyms* and FrameNet *frame name* and *frame definition*, to achieve the highest score, an  $F_1$ -score of 0.739.

#### 5.5 Gold Standard Evaluation

We compared the performance of our alignment on the gold standard to a baseline which randomly selects one target sense from the candidate set of each source sense (Random-1). We also consider the more competitive Wiktionary first sense baseline (WKT-1). It is guided by the heuristic that more frequent senses are listed first in Wiktionary (Meyer and Gurevych, 2010). It is a stronger baseline with an  $F_1$ -score of 0.65 (see Table 2).

To derive the upper bound for the alignment performance (UBound), we computed the  $F_1$  score from the average pairwise  $F_1$ -score of the annotators according to Hripcsak and Rothschild (2005).

As the evaluation set mirrors the POS distribution in FrameNet and is sufficiently large, unlike earlier alignments, we can analyze the performance by POS. The BEST JOINT model performs well on nouns, slightly better on adjectives, and worse on verbs, see Table 2. For the baselines and the UBound the same applies, with the difference that adjectives receive even better results

in comparison. This fits in with the perceived degree of difficulty according to the observed polysemy for the POS: for verbs we have many candidate sets with two or more candidates, i.e., we observe higher polysemy, while for nouns and even stronger for adjectives, many small candidate sets occur, which stand for an easier alignment decision. This is in line with the reported higher complexity of lexical resources with respect to verbs and greater difficulty in alignments and word sense disambiguation (Laparra and Rigau, 2010).

The performance of BEST JOINT on all POS is  $F_1=0.73$ , which is significantly higher than the WKT-1 baseline ( $p<0.05$  according to McNemar’s test). The performance on nouns ( $F_1=0.775$ ) is on par with the results reported by Niemann and Gurevych (2011) for nouns ( $F_1=0.78$ ).

## 5.6 Error Analysis

The confusion matrix from the evaluation of BEST JOINT on the gold standard shows 214 false positives and 191 false negatives. The false negatives suffer from low overlap between the glosses, which are often quite short (*contend - assert*), sometimes circular (*sinful - relating to sin*). Aligning senses with such glosses is difficult for a system based on semantic similarity. In about 50% of the analyzed pairs, highly similar words are used in the gloss, that we should be able to detect with second-order representations, for instance by expanding short definitions with the definitions of the contained words, or via derivational similarity.

A number of false positives occur because the gold standard was developed in a very fine-grained manner: distinctions such as causative vs. inchoative (*enlarge: become large vs. enlarge: make large*) were explicitly stressed in the definitions and thus annotated as different senses by the annotators. This was motivated by the fact that this distinction is relevant for many frames in FrameNet. The first meaning of *enlarge* belongs to the frame *Expansion*, the second to *Cause expansion*. Our similarity based approach cannot capture such differences well.

## 6 Intermediate Resource FNWKxx

### 6.1 Statistics

We applied the best system setup to the full candidate set of over 44,000 candidates to create the intermediate resource FNWKxx. The alignment consists of 12,094 sense pairs. It covers 82% of

	fine-grained P			coarse-grained P		
All POS	0.67			0.78		
By POS	verb	noun	adj	verb	noun	adj
	0.53	0.73	0.80	0.73	0.82	0.85

Table 3: Post-hoc evaluation (precision P).

the senses in FrameNet and 86% of the frames. It connects more than 9,800 unique FrameNet senses with more than 10,000 unique Wiktionary senses, which shows that both non-alignments and multiple alignments occur for some source senses.

## 6.2 Post-hoc Evaluation

Our cross-validation approach entails the danger of over-fitting. In order to verify the quality of the alignment, we performed a detailed post-hoc analysis on a sample of 270 aligned sense pairs randomly drawn from the set of aligned senses.

Because sense granularity was an issue in the error analysis, we considered two alignment decisions: (a) fine-grained alignment: the two glosses describe the same sense; (b) coarse-grained alignment. The causative/inchoative distinction is, among others, ignored.

The evaluation results are listed in Table 3. The precision for the fine-grained (a) is lower than the all-over precision on the gold standard. The evaluation by POS shows that the result for nouns and adjectives is equal or superior to the evaluation result on the gold standard, while it is worse for verbs. This shows that over-fitting, if at all, is only a risk for the verb senses.

The all-over precision for (b) exceeds the precision on the gold standard. Particularly verbs receive much better results. This shows that a coarse-grained alignment may suffice for the FrameNet extension.

This evaluation confirms the quality of the sense alignment, in particular with respect to the FrameNet extension. But it also elicits the question whether a coarse-grained alignment would suffice. We will discuss this question below.

## 6.3 Resource Analysis

For each of the aligned senses in the 12,094 aligned sense pairs, we extracted **glosses** from Wiktionary. Because FrameNet glosses are often very brief, the additional glosses will benefit algorithms such as frame detection for SRL. We also added 4,352 new **example sentences** from Wik-

tionary to FrameNet.

We can extract 2,151 new **lemma-POS** for FrameNet frames from the synonyms of the aligned senses in Wiktionary. We also extract other related lemma-POS, for instance 487 antonyms, 126 hyponyms, and 19 hypernyms.

This step establishes Wiktionary as an interlingual connection between FrameNet and a large number of languages, including low-resource ones: via Wiktionary, we connect FrameNet senses to **translations** in 283 languages, e.g., we translate the sense of the verb *complete* associated with the frame *Activity Finish* to the German colloquial *fertigmachen*, the Spanish *terminar*, the Turkish *tamamlamak*, and 19 other languages.

For 36 languages, we can extract more than 1,000 translations each, among them low-resource languages such as Telugu, Swahili, or Kurdish. The languages with most translations are: Finnish (9,333), Russian (7,790), and German (6,871). The number of Finnish translations is more than three times larger than the preliminary Finnish FrameNet by Borin et al. (2012). Likewise, we get three times the number of German lemma-POS than provided by the SALSA corpus.

## 7 Translation Disambiguation

### 7.1 Disambiguation Method

FNWKxx initially does not provide lexical-semantic information for the German translations: the translations link to a lemma in the German Wiktionary, not a target sense. In order to integrate the information attached to a German Wiktionary sense, e.g., the gloss, into our resource, the lemmas need to be disambiguated.

We use the sense-disambiguated Wiktionary resulting from a recently published approach for the disambiguation of relations and translations in Wiktionary (Meyer and Gurevych, 2012a) to create our new bilingual (German-English) FrameNet lexicon FNWKde.

Their approach combines information on the source sense and all potential target senses in order to determine the best target sense in a rule-based disambiguation strategy. The information is encoded as binary features, which are ordered in a back-off hierarchy: if the first feature applies, the target sense is selected, otherwise the second feature is considered, and so forth.

The most important features are: definition overlap between source and automatically trans-

	SALSA2	P&L05	FNWKde
Type	Corpus	Corpus	Lexicon
Creation	Manual	Automatic	Automatic
Frames(+p)	266(907)	468	755
Senses	1,813	9,851	5,897
Examples	24,184	1,672,551	6,933
Glosses	-	-	5,897

Table 4: Frame-semantic resources for German.

lated target definition; occurrence of the source lemma in the target definition; shared linguistic information (e.g., same register); inverse translation relations (i.e., the source lemma occurs on the translation list of the target sense); relation overlap; Lesk measure between original and translated glosses in source and target language; and finally, backing off to the first target sense.

For the gold standard evaluation of the approach we refer to Meyer and Gurevych (2012a): their system obtained an  $F_1$ -score of 0.67 for the task of disambiguating translations from English to German, and an  $F_1$ -score of 0.79 for the disambiguation of English sense relations. We use the latter to identify target senses of synonyms in FNWKxx.

## 8 Resource FNWKde

### 8.1 Statistics

Table 4 gives an overview of FNWKde. It contains 5,897 pairs of German Wiktionary senses and FrameNet senses, i.e., 86% of the translations could be disambiguated. Each sense has a gloss, and there are 6,933 example sentences.

Based on the relation disambiguation and inference of new relations by Meyer and Gurevych (2012a), we can also disambiguate synonyms in the English Wiktionary. This leads to a further extension of the English FrameNet summarized in Table 5. The number of Wiktionary senses aligned to FrameNet senses is increased by 50%.

We also provide results for other sense relations, e.g., antonyms. We will discuss whether and how they can be integrated as FrameNet senses in our resource below.

### 8.2 Post-hoc Evaluation

Because the errors of two subsequently applied automatic methods can multiply, we provide a post-hoc evaluation of the results.

To evaluate the quality of the German FrameNet lexicon, we collected the FrameNet senses for a list of 15 frames that were sampled by Padó and

Relation	# English senses per FrameNet sense	# English senses per frame
SYNONYM	17,713	13,288
HYPONYM	4,818	3,347
HYPERNYM	6,369	3,961
ANTONYM	9,626	6,737

Table 5: Statistics after relation disambiguation.

Lapata (2005) according to three frequency bands on a large corpus. There are 115 senses associated with these frames in our resource. In a manual evaluation of these 115 senses, we find that 67% were assigned correctly to their frames. This is higher than expected, considering the errors from the applied methods add up.

Further analysis revealed that both resource creation steps contribute equally to the 39 errors. For 17 of the evaluated sense pairs, redundancy confirms their quality: they were obtained independently by two or three alignment-and-translation paths and do not contain alignment errors.

### 8.3 Comparison

We compare FNWKde to two German frame-semantic resources, the manually annotated SALSA corpus (Burchardt et al., 2006) and a resource from Padó and Lapata (2005), henceforth P&L05. Note that both resources are frame-annotated corpora, while FNWKde is a FrameNet-like *lexicon* and contains information complementary to the corpora. The different properties of the resources are contrasted in Table 4.

The automatically developed resources, including FNWKde, provide a larger number of senses than SALSA. The annotated corpora contain a large number of examples, but they do not provide any glosses, which are useful for frame detection in SRL, nor do they contain any other lexical-semantic information.

FNWKde covers a larger number of FrameNet frames than the other two resources. 266 of the 907 frames in SALSA are connected to original FrameNet frames, the others are newly-developed proto-frames *p* (shown in parentheses in Table 4).

Table 6 describes the proportion of the overlapping frames and senses<sup>3</sup> to the respective resources. The numbers on frame overlap show that our resource covers the frames in the other

<sup>3</sup>Note that the senses in SALSA and P&L05 are defined by frame, lemma, and POS. In Table 6, FNWKde senses with identical frame, lemma, and POS, but different gloss are therefore conflated to one sense.

	Resource r	% of r	% of FNWKde
Frame	SALSA 2	89%	31%
	P&L05	90%	55%
Sense	SALSA 2	15%	5%
	P&L05	10%	19%

Table 6: Overlap of FNWKde with resource r.

resources well (89% and 90% coverage respectively), and that it adds frames not covered in the other resources: P&L05 only covers 55% of the frames in FNWKde. The sense overlap shows that the resources have senses in common, which confirms the quality of the automatically developed resources, but they also complement each other. FNWKde, for instance, adds 3,041 senses to P&L05.

## 9 Discussion: a Multilingual FrameNet

FNWKxx builds an excellent starting point to create FrameNet lexicons in various languages: the translation counts, for instance 6,871 for German, compare favorably to FrameNet 1.5, which contains 9,700 English lemma-POS.

To create those FrameNet lexicons, the translation disambiguation approach used for FNWKde (step 2 in Fig. 1) needs to be adapted to other languages. The approach is in theory applicable to any language, but there are some obstacles: first, it relies on the availability of the target sense in the target language Wiktionary. For many of the top 30 languages in FNWKxx, the Wiktionary editions seem sufficiently large to provide targets for translation disambiguation,<sup>4</sup> and they are continuously extended. Second, our approach requires access to the target language Wiktionary, but the data format across Wiktionary language editions is not standardized. Third, the approach requires machine translation into the target language. For languages, where such a tool is not available, we could default to the first-sense-heuristic, or encourage the Wiktionary community to link the translations to their target Wiktionary senses inspired by Sajous et al. (2010).

Another issue that applies to all automatic (and also manual) approaches of cross-lingual FrameNet extension is the restricted cross-language applicability of frames. Boas (2005) reports that, while many frames are largely

<sup>4</sup>see overview table at <http://www.ukp.tu-darmstadt.de/fnwkde/>.

language-independent, other frames receive culture-specific or language-specific interpretations, for example calendars or holidays. Also, fine-grained sense and frame distinctions may be more relevant in one language than in another language. Such granularity differences also led to the addition of proto-frames in SALSA 2 (Rehbein et al., 2012). Therefore, manual correction or extension of a multilingual FrameNet based on FNWKde may be desired for specific applications. In this case, the automatically created FrameNets in other languages are good starting points that can be quickly and efficiently compiled.

The quality of the multilingual FNWKxx depends on i) the translations in the interlingual connection Wiktionary, which are manually created, controlled by the community, and therefore reliable, and ii) on the FrameNet–Wiktionary alignment. Therefore, we evaluated our sense alignment method in detail. The alignment reaches state-of-the-art results, and the analysis shows that the method is particularly fit for a coarse-grained alignment. We however find lower performance for verbs in a fine-grained setting. We argue that an improved alignment algorithm, for instance taking subcategorization information into account, can identify the fine-grained distinctions.

The post-hoc analysis raised the question of FrameNet frame granularity. Do separate frames exist for causative/inchoative alternations (as *Being dry* and *Cause to be dry* for *to dry*), or do they belong to the same frame (*Make noise* for *to creak* and *to creak something*)? For the coarse-grained frames, fine-grained decisions can be merged in a second classification step. Alternatively, we could map Wiktionary senses directly to frames, and include features that cover the granularity distinctions, e.g., whether the existing senses of a frame show the semantic alternation.

We could use the same approach to assign senses to a frame which are derived via sense relations other than synonymy, i.e., for linking antonyms or hyponyms to a frame. Some frames do cover antonymous predicates, others do not.

Based on Wiktionary, our approach suffers less from the disadvantages of previous resource-based work, i.e., the constraints of expert-built resources and the lack of lexical information in Wikipedia. Unlike corpus-based approaches for cross-lingual FrameNet extension, our approach does not provide frame-semantic annotations for the example

sentences. Our advantage is that we create a FrameNet *lexicon* with lexical-semantic information in the target language. Example annotations can be additionally obtained via cross-lingual annotation projection (Padó and Lapata, 2009), and the lexical information in FNWKde can be used to guide this process.

## 10 Conclusion

The resource-coverage bottleneck for frame-semantic resources is particularly severe for less well-resourced languages. We present a simple, but effective approach to solve this problem using the English Wiktionary as an interlingual representation and subsequent translation disambiguation in the target language. We validate our approach on the language pair English-German and discuss the options and requirements for creating FrameNets in further languages.

As part of this work, we created the first sense alignment between FrameNet and the English Wiktionary. The resulting resource FNWKxx connects FrameNet senses to over 280 languages. The bilingual English-German FrameNet lexicon FNWKde competes with manually created resources, as shown by a comparison to the SALSA corpus.

We make both resources publicly available in the standardized format UBY-LMF (Eckle-Kohler et al., 2012), which supports automatic processing of the resources via the UBY Java API, see <http://www.ukp.tu-darmstadt.de/fnwkde/>.

We also extended FrameNet by several thousand new English senses from Wiktionary which are provided as part of FNWKde. In our future work, we will evaluate the benefits of the extracted information to SRL.

## Acknowledgments

This work has been supported by the Volkswagen Foundation as part of the Lichtenberg-Professorship Program under grant No. I/82806 and by the German Research Foundation under grant No. GU 798/3-1 and grant No. GU 798/9-1.

We thank Christian Meyer and Judith-Eckle Kohler for insightful discussions and comments, and Christian Wirth for contributions in the early stage of this project. We also thank the anonymous reviewers for their helpful remarks.

## Abstract

Parallel text is the fuel that drives modern machine translation systems. The Web is a comprehensive source of preexisting parallel text, but crawling the entire web is impossible for all but the largest companies. We bring web-scale parallel text to the masses by mining the Common Crawl, a public Web crawl hosted on Amazon's Elastic Cloud. Starting from nothing more than a set of common two-letter language codes, our open-source extension of the STRAND algorithm mined 32 terabytes of the crawl in just under a day, at a cost of about \$500. Our large-scale experiment uncovers large amounts of parallel text in dozens of language pairs across a variety of domains and genres, some previously unavailable in curated datasets. Even with minimal cleaning and filtering, the resulting data boosts translation performance across the board for five different language pairs in the news domain, and on open domain test sets we see improvements of up to 5 BLEU. We make our code and data available for other researchers seeking to mine this rich new data resource.<sup>1</sup>

## 1 Introduction

A key bottleneck in porting statistical machine translation (SMT) technology to new languages and domains is the lack of readily available parallel corpora beyond curated datasets. For a handful of language pairs, large amounts of parallel data

are readily available, ordering in the hundreds of millions of words for Chinese-English and Arabic-English, and in tens of millions of words for many European languages (Koehn, 2005). In each case, much of this data consists of government and news text. However, for most language pairs and domains there is little to no curated parallel data available. Hence discovery of parallel data is an important first step for translation between most of the world's languages.

The Web is an important source of parallel text. Many websites are available in multiple languages, and unlike other potential sources—such as multilingual news feeds (Munteanu and Marcu, 2005) or Wikipedia (Smith et al., 2010)—it is common to find document pairs that are direct translations of one another. This natural parallelism simplifies the mining task, since few resources or existing corpora are needed at the outset to bootstrap the extraction process.

Parallel text mining from the Web was originally explored by individuals or small groups of academic researchers using search engines (Nie et al., 1999; Chen and Nie, 2000; Resnik, 1999; Resnik and Smith, 2003). However, anything more sophisticated generally requires direct access to web-crawled documents themselves along with the computing power to process them. For most researchers, this is prohibitively expensive. As a consequence, web-mined parallel text has become the exclusive purview of large companies with the computational resources to crawl, store, and process the entire Web.

To put web-mined parallel text back in the hands of individual researchers, we mine parallel text from the Common Crawl, a regularly updated 81-terabyte snapshot of the public internet hosted

\*This research was conducted while Chris Callison-Burch was at Johns Hopkins University.

<sup>1</sup>[github.com/jrs026/CommonCrawlMiner](https://github.com/jrs026/CommonCrawlMiner)

on Amazon’s Elastic Cloud (EC2) service.<sup>2</sup> Using the Common Crawl completely removes the bottleneck of web crawling, and makes it possible to run algorithms on a substantial portion of the web at very low cost. Starting from nothing other than a set of language codes, our extension of the STRAND algorithm (Resnik and Smith, 2003) identifies potentially parallel documents using cues from URLs and document content (§2). We conduct an extensive empirical exploration of the web-mined data, demonstrating coverage in a wide variety of languages and domains (§3). Even without extensive pre-processing, the data improves translation performance on strong baseline news translation systems in five different language pairs (§4). On general domain and speech translation tasks where test conditions substantially differ from standard government and news training text, web-mined training data improves performance substantially, resulting in improvements of up to 1.5 BLEU on standard test sets, and 5 BLEU on test sets outside of the news domain.

## 2 Mining the Common Crawl

The Common Crawl corpus is hosted on Amazon’s Simple Storage Service (S3). It can be downloaded to a local cluster, but the transfer cost is prohibitive at roughly 10 cents per gigabyte, making the total over \$8000 for the full dataset.<sup>3</sup> However, it is unnecessary to obtain a copy of the data since it can be accessed freely from Amazon’s Elastic Compute Cloud (EC2) or Elastic MapReduce (EMR) services. In our pipeline, we perform the first step of identifying candidate document pairs using Amazon EMR, download the resulting document pairs, and perform the remaining steps on our local cluster. We chose EMR because our candidate matching strategy fit naturally into the Map-Reduce framework (Dean and Ghemawat, 2004).

Our system is based on the STRAND algorithm (Resnik and Smith, 2003):

1. *Candidate pair selection*: Retrieve candidate document pairs from the CommonCrawl corpus.
2. *Structural Filtering*:
  - (a) Convert the HTML of each document

into a sequence of start tags, end tags, and text chunks.

- (b) Align the linearized HTML of candidate document pairs.
  - (c) Decide whether to accept or reject each pair based on features of the alignment.
3. *Segmentation*: For each text chunk, perform sentence and word segmentation.
  4. *Sentence Alignment*: For each aligned pair of text chunks, perform the sentence alignment method of Gale and Church (1993).
  5. *Sentence Filtering*: Remove sentences that appear to be boilerplate.

**Candidate Pair Selection** We adopt a strategy similar to that of Resnik and Smith (2003) for finding candidate parallel documents, adapted to the parallel architecture of Map-Reduce.

The *mapper* operates on each website entry in the CommonCrawl data. It scans the URL string for some indicator of its language. Specifically, we check for:

1. Two/three letter language codes (ISO-639).
2. Language names in English and in the language of origin.

If either is present in a URL and surrounded by non-alphanumeric characters, the URL is identified as a potential match and the mapper outputs a key value pair in which the key is the original URL with the matching string replaced by \*, and the value is the original URL, language name, and full HTML of the page. For example, if we encounter the URL `www.website.com/fr/`, we output the following.

- Key: `www.website.com/*/`
- Value: `www.website.com/fr/`, French, (full website entry)

The *reducer* then receives all websites mapped to the same “language independent” URL. If two or more websites are associated with the same key, the reducer will output all associated values, as long as they are not in the same language, as determined by the language identifier in the URL.

This URL-based matching is a simple and inexpensive solution to the problem of finding candidate document pairs. The mapper will discard

<sup>2</sup>[commoncrawl.org](http://commoncrawl.org)

<sup>3</sup><http://aws.amazon.com/s3/pricing/>

most, and neither the mapper nor the reducer do anything with the HTML of the documents aside from reading and writing them. This approach is very simple and likely misses many good potential candidates, but has the advantage that it requires no information other than a set of language codes, and runs in time roughly linear in the size of the dataset.

**Structural Filtering** A major component of the STRAND system is the alignment of HTML documents. This alignment is used to determine which document pairs are actually parallel, and if they are, to align pairs of text blocks within the documents.

The first step of structural filtering is to linearize the HTML. This means converting its DOM tree into a sequence of start tags, end tags, and chunks of text. Some tags (those usually found within text, such as “font” and “a”) are ignored during this step. Next, the tag/chunk sequences are aligned using dynamic programming. The objective of the alignment is to maximize the number of matching items.

Given this alignment, Resnik and Smith (2003) define a small set of features which indicate the alignment quality. They annotated a set of document pairs as parallel or non-parallel, and trained a classifier on this data. We also annotated 101 Spanish-English document pairs in this way and trained a maximum entropy classifier. However, even when using the best performing subset of features, the classifier only performed as well as a naive classifier which labeled every document pair as parallel, in both accuracy and F1. For this reason, we excluded the classifier from our pipeline. The strong performance of the naive baseline was likely due to the unbalanced nature of the annotated data— 80% of the document pairs that we annotated were parallel.

**Segmentation** The text chunks from the previous step may contain several sentences, so before the sentence alignment step we must perform sentence segmentation. We use the Punkt sentence splitter from NLTK (Loper and Bird, 2002) to perform both sentence and word segmentation on each text chunk.

**Sentence Alignment** For each aligned text chunk pair, we perform sentence alignment using the algorithm of Gale and Church (1993).

**Sentence Filtering** Since we do not perform any boilerplate removal in earlier steps, there are many sentence pairs produced by the pipeline which contain menu items or other bits of text which are not useful to an SMT system. We avoid performing any complex boilerplate removal and only remove segment pairs where either the source and target text are identical, or where the source or target segments appear more than once in the extracted corpus.

### 3 Analysis of the Common Crawl Data

We ran our algorithm on the 2009-2010 version of the crawl, consisting of 32.3 terabytes of data. Since the full dataset is hosted on EC2, the only cost to us is CPU time charged by Amazon, which came to a total of about \$400, and data storage/transfer costs for our output, which came to roughly \$100. For practical reasons we split the run into seven subsets, on which the full algorithm was run independently. This is different from running a single Map-Reduce job over the entire dataset, since websites in different subsets of the data cannot be matched. However, since the data is stored as it is crawled, it is likely that matching websites will be found in the same split of the data. Table 1 shows the amount of raw parallel data obtained for a large selection of language pairs.

As far as we know, ours is the first system built to mine parallel text from the Common Crawl. Since the resource is new, we wanted to understand the quantity, quality, and type of data that we are likely to obtain from it. To this end, we conducted a number of experiments to measure these features. Since our mining heuristics are very simple, these results can be construed as a lower bound on what is actually possible.

#### 3.1 Recall Estimates

Our first question is about recall: of all the possible parallel text that is actually available on the Web, how much does our algorithm actually find in the Common Crawl? Although this question is difficult to answer precisely, we can estimate an answer by comparing our mined URLs against a large collection of previously mined URLs that were found using targeted techniques: those in the French-English Gigaword corpus (Callison-Burch et al., 2011).

We found that 45% of the URL pairs would

	<b>French</b>	<b>German</b>	<b>Spanish</b>	<b>Russian</b>	<b>Japanese</b>	<b>Chinese</b>
Segments	10.2M	7.50M	5.67M	3.58M	1.70M	1.42M
Source Tokens	128M	79.9M	71.5M	34.7M	9.91M	8.14M
Target Tokens	118M	87.5M	67.6M	36.7M	19.1M	14.8M
	<b>Arabic</b>	<b>Bulgarian</b>	<b>Czech</b>	<b>Korean</b>	<b>Tamil</b>	<b>Urdu</b>
Segments	1.21M	909K	848K	756K	116K	52.1K
Source Tokens	13.1M	8.48M	7.42M	6.56M	1.01M	734K
Target Tokens	13.5M	8.61M	8.20M	7.58M	996K	685K
	<b>Bengali</b>	<b>Farsi</b>	<b>Telugu</b>	<b>Somali</b>	<b>Kannada</b>	<b>Pashto</b>
Segments	59.9K	44.2K	50.6K	52.6K	34.5K	28.0K
Source Tokens	573K	477K	336K	318K	305K	208K
Target Tokens	537K	459K	358K	325K	297K	218K

Table 1: The amount of parallel data mined from CommonCrawl for each language paired with English. Source tokens are counts of the foreign language tokens, and target tokens are counts of the English language tokens.

have been discovered by our heuristics, though we actually only find 3.6% of these URLs in our output.<sup>4</sup> If we had included “f” and “e” as identifiers for French and English respectively, coverage of the URL pairs would increase to 74%. However, we chose not to include single letter identifiers in our experiments due to the high number of false positives they generated in preliminary experiments.

### 3.2 Precision Estimates

Since our algorithms rely on cues that are mostly external to the contents of the extracted data and have no knowledge of actual languages, we wanted to evaluate the precision of our algorithm: how much of the mined data actually consists of parallel sentences?

To measure this, we conducted a manual analysis of 200 randomly selected sentence pairs for each of three language pairs. The texts are heterogeneous, covering several topical domains like tourism, advertising, technical specifications, finances, e-commerce and medicine. For German-English, 78% of the extracted data represent perfect translations, 4% are paraphrases of each other (convey a similar meaning, but cannot be used for SMT training) and 18% represent misalignments. Furthermore, 22% of the true positives are potentially machine translations (judging by the quality), whereas in 13% of the cases one of the sentences contains additional content not ex-

<sup>4</sup>The difference is likely due to the coverage of the CommonCrawl corpus.

pressed in the other. As for the false positives, 13.5% of them have either the source or target sentence in the wrong language, and the remaining ones representing failures in the alignment process. Across three languages, our inspection revealed that around 80% of randomly sampled data appeared to contain good translations (Table 2). Although this analysis suggests that language identification and SMT output detection (Venugopal et al., 2011) may be useful additions to the pipeline, we regard this as reasonably high precision for our simple algorithm.

Language	Precision
Spanish	82%
French	81%
German	78%

Table 2: Manual evaluation of precision (by sentence pair) on the extracted parallel data for Spanish, French, and German (paired with English).

In addition to the manual evaluation of precision, we applied language identification to our extracted parallel data for several additional languages. We used the “langid.py” tool (Lui and Baldwin, 2012) at the segment level, and report the percentage of sentence pairs where both sentences were recognized as the correct language. Table 3 shows our results. Comparing against our manual evaluation from Table 2, it appears that many sentence pairs are being incorrectly judged as non-parallel. This is likely because language identification tends to perform poorly on short segments.

French	German	Spanish	Arabic
63%	61%	58%	51%
Chinese	Japanese	Korean	Czech
50%	48%	48%	47%
Russian	Urdu	Bengali	Tamil
44%	31%	14%	12%
Kannada	Telugu	Kurdish	
12%	6.3%	2.9%	

Table 3: Automatic evaluation of precision through language identification for several languages paired with English.

### 3.3 Domain Name and Topic Analysis

Although the above measures tell us something about how well our algorithms perform in aggregate for specific language pairs, we also wondered about the actual contents of the data. A major difficulty in applying SMT even on languages for which we have significant quantities of parallel text is that most of that parallel text is in the news and government domains. When applied to other genres, such systems are notoriously brittle. What kind of genres are represented in the Common Crawl data?

We first looked at the domain names which contributed the most data. Table 4 gives the top five domains by the number of tokens. The top two domain names are related to travel, and they account for about 10% of the total data.

We also applied Latent Dirichlet Allocation (LDA; Blei et al., 2003) to learn a distribution over latent topics in the extracted data, as this is a popular exploratory data analysis method. In LDA a topic is a unigram distribution over words, and each document is modeled as a distribution over topics. To create a set of documents from the extracted CommonCrawl data, we took the English side of the extracted parallel segments for each URL in the Spanish-English portion of the data. This gave us a total of 444,022 documents. In our first experiment, we used the MALLET toolkit (McCallum, 2002) to generate 20 topics, which are shown in Table 5.

Some of the topics that LDA finds correspond closely with specific domains, such as topics 1 (`blingee.com`) and 2 (`opensubtitles.org`). Several of the topics correspond to the travel domain. Foreign stop words appear in a few of the topics. Since our sys-

tem does not include any language identification, this is not surprising.<sup>5</sup> However it does suggest an avenue for possible improvement.

In our second LDA experiment, we compared our extracted CommonCrawl data with Europarl. We created a set of documents from both CommonCrawl and Europarl, and again used MALLET to generate 100 topics for this data.<sup>6</sup> We then labeled each document by its most likely topic (as determined by that topic’s mixture weights), and counted the number of documents from Europarl and CommonCrawl for which each topic was most prominent. While this is very rough, it gives some idea of where each topic is coming from. Table 6 shows a sample of these topics.

In addition to exploring topics in the datasets, we also performed additional intrinsic evaluation at the domain level, choosing top domains for three language pairs. We specifically classified sentence pairs as useful or boilerplate (Table 7). Among our observations, we find that commercial websites tend to contain less boilerplate material than encyclopedic websites, and that the ratios tend to be similar across languages in the same domain.

	FR	ES	DE
<code>www.booking.com</code>	52%	71%	52%
<code>www.hotel.info</code>	34%	44%	-
<code>memory-alpha.org</code>	34%	25%	55%

Table 7: Percentage of useful (non-boilerplate) sentences found by domain and language pair. `hotel.info` was not found in our German-English data.

## 4 Machine Translation Experiments

For our SMT experiments, we use the Moses toolkit (Koehn et al., 2007). In these experiments, a baseline system is trained on an existing parallel corpus, and the experimental system is trained on the baseline corpus plus the mined parallel data. In all experiments we include the target side of the mined parallel data in the language model, in order to distinguish whether results are due to influences from parallel or monolingual data.

<sup>5</sup>We used MALLET’s stop word removal, but that is only for English.

<sup>6</sup>Documents were created from Europarl by taking “SPEAKER” tags as document boundaries, giving us 208,431 documents total.

Genre	Domain	Pages	Segments	Source Tokens	Target Tokens
	<i>Total</i>	444K	5.67M	71.5M	67.5M
travel	www.booking.com	13.4K	424K	5.23M	5.14M
travel	www.hotel.info	9.05K	156K	1.93M	2.13M
government	www.fao.org	2.47K	60.4K	1.07M	896K
religious	scriptures.lds.org	7.04K	47.2K	889K	960K
political	www.amnesty.org	4.83K	38.1K	641K	548K

Table 4: The top five domains from the Spanish-English portion of the data. The domains are ranked by the combined number of source and target tokens.

Table 5: A list of 20 topics generated using the MALLET toolkit (McCallum, 2002) and their most likely tokens.

#### 4.1 News Domain Translation

Our first set of experiments are based on systems built for the 2012 Workshop on Statistical Machine Translation (WMT) (Callison-Burch et al., 2012) using all available parallel and monolingual data for that task, aside from the French-English Gigaword. In these experiments, we use 5-gram language models when the target language is English or German, and 4-gram language models for French and Spanish. We tune model weights using minimum error rate training (MERT; Och, 2003) on the WMT 2008 test data. The results are given in Table 8. For all language pairs and both test sets (WMT 2011 and WMT 2012), we show an improvement of around 0.5 BLEU.

We also included the French-English Gigaword in separate experiments given in Table 9, and Table 10 compares the sizes of the datasets used. These results show that even on top of a different, larger parallel corpus mined from the web, adding CommonCrawl data still yields an improvement.

#### 4.2 Open Domain Translation

A substantial appeal of web-mined parallel data is that it might be suitable to translation of domains other than news, and our topic modeling analysis (§3.3) suggested that this might indeed be the case. We therefore performed an additional set of experiments for Spanish-English, but we include test sets from outside the news domain.

Europarl	CommonCrawl	Most Likely Tokens
9	2975	hair body skin products water massage treatment natural oil weight acid plant

Table 9: BLEU scores for French-English and English-French before and after adding the mined parallel data to systems trained on data from WMT data including the French-English Gigaword (Callison-Burch et al., 2011).

For these experiments, we also include training data mined from Wikipedia using a simplified version of the sentence aligner described by Smith et al. (2010), in order to determine how the effect of such data compares with the effect of web-mined data. The baseline system was trained using only the Europarl corpus (Koehn, 2005) as parallel data, and all experiments use the same language model trained on the target sides of Europarl, the English side of all linked Spanish-English Wikipedia articles, and the English side of the mined CommonCrawl data. We use a 5-gram language model and tune using MERT (Och,

Corpus	EN-FR	EN-ES	EN-DE
<b>News Commentary</b>	2.99M	3.43M	3.39M
<b>Europarl</b>	50.3M	49.2M	47.9M

Table 10: The size (in English tokens) of the training corpora used in the SMT experiments from Tables 8 and 9 for each language pair.

2003) on the WMT 2009 test set.

Unfortunately, it is difficult to obtain meaningful results on some open domain test sets such as the Wikipedia dataset used by Smith et al. (2010). Wikipedia copied across the public internet, and we did not have a simple way to filter such data from our mined datasets.

We therefore considered two tests that were less likely to be problematic. The Tatoeba corpus (Tiedemann, 2009) is a collection of example sentences translated into many languages by volunteers. The front page of [tatoeba.org](http://tatoeba.org) was discovered by our URL matching heuristics, but we excluded any sentence pairs that were found in the CommonCrawl data from this test set.

The second dataset is a set of crowdsourced translation of Spanish speech transcriptions from the Spanish Fisher corpus.<sup>7</sup> As part of a research effort on cross-lingual speech applications, we obtained English translations of the data using Amazon Mechanical Turk, following a protocol similar to one described by Zaidan and Callison-Burch (2011): we provided clear instructions, employed several quality control measures, and obtained redundant translations of the complete dataset (Lopez et al., 2013). The advantage of this data for our open domain translation test is twofold. First, the Fisher dataset consists of conversations in various Spanish dialects on a wide variety of prompted topics. Second, because we obtained the translations ourselves, we could be absolutely assured that they did not appear in some form anywhere on the Web, making it an ideal blind test.

	<b>WMT10</b>	<b>Tatoeba</b>	<b>Fisher</b>
<b>Europarl</b>	89/72/46/20	94/75/45/18	87/69/39/13
<b>+Wiki</b>	92/78/52/24	96/80/50/21	91/75/44/15
<b>+Web</b>	96/82/56/27	99/88/58/26	96/83/51/19
<b>+Both</b>	96/84/58/29	99/89/60/27	96/83/52/20

Table 11:  $n$ -gram coverage percentages (up to 4-grams) of the source side of our test sets given our different parallel training corpora computed at the type level.

	<b>WMT10</b>	<b>Tatoeba</b>	<b>Fisher</b>
<b>Europarl</b>	27.21	36.13	46.32
<b>+Wiki</b>	28.03	37.82	49.34
<b>+Web</b>	28.50	41.07	51.13
<b>+Both</b>	28.74	41.12	52.23

Table 12: BLEU scores for Spanish-English before and after adding the mined parallel data to a baseline Europarl system.

We used 1000 sentences from each of the Tatoeba and Fisher datasets as test. For comparison, we also test on the WMT 2010 test set (Callison-Burch et al., 2010). Following Munteanu and Marcu (2005), we show the  $n$ -gram coverage of each corpus (percentage of  $n$ -grams from the test corpus which are also found in the training corpora) in Table 11. Table 12 gives end-to-end results, which show a strong improvement on the WMT test set (1.5 BLEU), and larger

<sup>7</sup>Linguistic Data Consortium LDC2010T04.

improvements on Tatoeba and Fisher (almost 5 BLEU).

## 5 Discussion

Web-mined parallel texts have been an exclusive resource of large companies for several years. However, when web-mined parallel text is available to everyone at little or no cost, there will be much greater potential for groundbreaking research to come from all corners. With the advent of public services such as Amazon Web Services and the Common Crawl, this may soon be a reality. As we have shown, it is possible to obtain parallel text for many language pairs in a variety of domains very cheaply and quickly, and in sufficient quantity and quality to improve statistical machine translation systems. However, our effort has merely scratched the surface of what is possible with this resource. We will make our code and data available so that others can build on these results.

Because our system is so simple, we believe that our results represent lower bounds on the gains that should be expected in performance of systems previously trained only on curated datasets. There are many possible means through which the system could be improved, including more sophisticated techniques for identifying matching URLs, better alignment, better language identification, better filtering of data, and better exploitation of resulting cross-domain datasets. Many of the components of our pipeline were basic, leaving considerable room for improvement. For example, the URL matching strategy could easily be improved for a given language pair by spending a little time crafting regular expressions tailored to some major websites. Callison-Burch et al. (2011) gathered almost 1 trillion tokens of French-English parallel data this way. Another strategy for mining parallel webpage pairs is to scan the HTML for links to the same page in another language (Nie et al., 1999).

Other, more sophisticated techniques may also be possible. Uszkoreit et al. (2010), for example, translated all non-English webpages into English using an existing translation system and used near-duplicate detection methods to find candidate parallel document pairs. Ture and Lin (2012) had a similar approach for finding parallel Wikipedia documents by using near-duplicate detection, though they did not need to apply a full translation system to all non-English documents.

Instead, they represented documents in bag-of-words vector space, and projected non-English document vectors into the English vector space using the translation probabilities of a word alignment model. By comparison, one appeal of our simple approach is that it requires only a table of language codes. However, with this system in place, we could obtain enough parallel data to bootstrap these more sophisticated approaches.

It is also compelling to consider ways in which web-mined data obtained from scratch could be used to bootstrap other mining approaches. For example, Smith et al. (2010) mine parallel sentences from *comparable* documents in Wikipedia, demonstrating substantial gains on open domain translation. However, their approach required seed parallel data to learn models used in a classifier. We imagine a two-step process, first obtaining parallel data from the web, followed by comparable data from sources such as Wikipedia using models bootstrapped from the web-mined data. Such a process could be used to build translation systems for new language pairs in a very short period of time, hence fulfilling one of the original promises of SMT.

## Abstract

We consider the problem of using sentence compression techniques to facilitate query-focused multi-document summarization. We present a sentence-compression-based framework for the task, and design a series of learning-based compression models built on parse trees. An innovative beam search decoder is proposed to efficiently find highly probable compressions. Under this framework, we show how to integrate various indicative metrics such as linguistic motivation and query relevance into the compression process by deriving a novel formulation of a compression scoring function. Our best model achieves statistically significant improvement over the state-of-the-art systems on several metrics (e.g. 8.0% and 5.4% improvements in ROUGE-2 respectively) for the DUC 2006 and 2007 summarization task.

## 1 Introduction

The explosion of the Internet clearly warrants the development of techniques for organizing and presenting information to users in an effective way. Query-focused multi-document summarization (MDS) methods have been proposed as one such technique and have attracted significant attention in recent years. The goal of query-focused MDS is to synthesize a brief (often fixed-length) and well-organized summary from a set of topic-related documents that answer a complex question or address a topic statement. The resulting summaries, in turn, can support a number of information analysis applications including open-ended question answering, recommender systems, and summarization of search engine results. As further evidence of its importance, the Document Understanding Conference (DUC) has used query-focused MDS as its main task since 2004 to foster

new research on automatic summarization in the context of users' needs.

To date, most top-performing systems for multi-document summarization—whether query-specific or not—remain largely *extractive*: their summaries are comprised exclusively of sentences selected directly from the documents to be summarized (Erkan and Radev, 2004; Haghighi and Vanderwende, 2009; Celikyilmaz and Hakkani-Tür, 2011). Despite their simplicity, extractive approaches have some disadvantages. First, lengthy sentences that are partly relevant are either excluded from the summary or (if selected) can block the selection of other important sentences, due to summary length constraints. In addition, when people write summaries, they tend to abstract the content and seldom use entire sentences taken verbatim from the original documents. In news articles, for example, most sentences are lengthy and contain both potentially useful information for a summary as well as unnecessary details that are better omitted. Consider the following DUC query as input for a MDS system:<sup>1</sup> “*In what ways have stolen artworks been recovered? How often are suspects arrested or prosecuted for the thefts?*” One manually generated summary includes the following sentence but removes the bracketed words in gray:

A man suspected of stealing a million-dollar collection of [hundreds of ancient] Nepalese and Tibetan art objects in New York [11 years ago] was arrested [Thursday at his South Los Angeles home, where he had been hiding the antiquities, police said].

In this example, the compressed sentence is rela-

<sup>1</sup>From DUC 2005, query for topic d422g.

tively more succinct and readable than the original (e.g. in terms of Flesch-Kincaid Reading Ease Score (Kincaid et al., 1975)). Likewise, removing information irrelevant to the query (e.g. “11 years ago”, “police said”) is crucial for query-focused MDS.

Sentence compression techniques (Knight and Marcu, 2000; Clarke and Lapata, 2008) are the standard for producing a compact and grammatical version of a sentence while preserving relevance, and prior research (e.g. Lin (2003)) has demonstrated their potential usefulness for generic document summarization. Similarly, strides have been made to incorporate sentence compression into query-focused MDS systems (Zajic et al., 2006). Most attempts, however, fail to produce better results than those of the best systems built on pure extraction-based approaches that use no sentence compression.

In this paper we investigate the role of sentence compression techniques for query-focused MDS. We extend existing work in the area first by investigating the role of *learning-based* sentence compression techniques. In addition, we design three types of approaches to sentence-compression—*rule-based*, *sequence-based* and *tree-based*—and examine them within our compression-based framework for query-specific MDS. Our top-performing sentence compression algorithm incorporates measures of query relevance, content importance, redundancy and language quality, among others. Our tree-based methods rely on a scoring function that allows for easy and flexible tailoring of sentence compression to the summarization task, ultimately resulting in significant improvements for MDS, while at the same time remaining competitive with existing methods in terms of sentence compression, as discussed next.

We evaluate the summarization models on the standard Document Understanding Conference (DUC) 2006 and 2007 corpora<sup>2</sup> for query-focused MDS and find that all of our compression-based summarization models achieve statistically significantly better performance than the best DUC 2006 systems. Our best-performing system yields an 11.02 ROUGE-2 score (Lin and Hovy, 2003), a 8.0% improvement over the best reported score (10.2 (Davis et al., 2012)) on the

<sup>2</sup>We believe that we can easily adapt our system for tasks (e.g. TAC-08’s opinion summarization or TAC-09’s update summarization) or domains (e.g. web pages or wikipedia pages). We reserve that for future work.

DUC 2006 dataset, and an 13.49 ROUGE-2, a 5.4% improvement over the best score in DUC 2007 (12.8 (Davis et al., 2012)). We also observe substantial improvements over previous systems w.r.t. the manual Pyramid (Nenkova and Passonneau, 2004) evaluation measure (26.4 vs. 22.9 (Jagarlamudi et al., 2006)); human annotators furthermore rate our system-generated summaries as having less redundancy and comparable quality w.r.t. other linguistic quality metrics. With these results we believe we are the first to successfully show that sentence compression can provide statistically significant improvements over pure extraction-based approaches for query-focused MDS.

## 2 Related Work

Existing research on query-focused multi-document summarization (MDS) largely relies on extractive approaches, where systems usually take as input a set of documents and select the top relevant sentences for inclusion in the final summary. A wide range of methods have been employed for this task. For unsupervised methods, sentence importance can be estimated by calculating topic signature words (Lin and Hovy, 2000; Conroy et al., 2006), combining query similarity and document centrality within a graph-based model (Otterbacher et al., 2005), or using a Bayesian model with sophisticated inference (Daumé and Marcu, 2006). Davis et al. (2012) first learn the term weights by Latent Semantic Analysis, and then greedily select sentences that cover the maximum combined weights. Supervised approaches have mainly focused on applying discriminative learning for ranking sentences (Fuentes et al., 2007). Lin and Bilmes (2011) use a class of carefully designed submodular functions to reward the diversity of the summaries and select sentences greedily.

Our work is more related to the less studied area of sentence compression as applied to (single) document summarization. Zajic et al. (2006) tackle the query-focused MDS problem using a compress-first strategy: they develop heuristics to generate multiple alternative compressions of all sentences in the original document; these then become the candidates for extraction. This approach, however, does not outperform some extraction-based approaches. A similar idea has been studied for MDS (Lin, 2003; Gillick and Favre, 2009),

but limited improvement is observed over extractive baselines with simple compression rules. Finally, although learning-based compression methods are promising (Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011), it is unclear how well they handle issues of redundancy.

Our research is also inspired by probabilistic sentence-compression approaches, such as the noisy-channel model (Knight and Marcu, 2000; Turner and Charniak, 2005), and its extension via synchronous context-free grammars (SCFG) (Aho and Ullman, 1969; Lewis and Stearns, 1968) for robust probability estimation (Galley and McKeown, 2007). Rather than attempt to derive a new parse tree like Knight and Marcu (2000) and Galley and McKeown (2007), we learn to safely remove a set of constituents in our parse tree-based compression model while preserving grammatical structure and essential content. Sentence-level compression has also been examined via a discriminative model McDonald (2006), and Clarke and Lapata (2008) also incorporate discourse information by using integer linear programming.

### 3 The Framework

We now present our query-focused MDS framework consisting of three steps: Sentence Ranking, Sentence Compression and Post-processing. First, sentence ranking determines the importance of each sentence given the query. Then, a sentence compressor iteratively generates the most likely succinct versions of the ranked sentences, which are cumulatively added to the summary, until a length limit is reached. Finally, the post-processing stage applies coreference resolution and sentence reordering to build the summary.

**Sentence Ranking.** This stage aims to rank sentences in order of relevance to the query. Unsurprisingly, ranking algorithms have been successfully applied to this task. We experimented with two of them – Support Vector Regression (SVR) (Mozer et al., 1997) and LambdaMART (Burges et al., 2007). The former has been used previously for MDS (Ouyang et al., 2011). LambdaMart on the other hand has shown considerable success in information retrieval tasks (Burges, 2010); we are the first to apply it to summarization. For training, we use 40 topics (i.e. queries) from the DUC 2005 corpus (Dang, 2005) along with their manually generated abstracts. As in previous work (Shen and Li,

Basic Features
relative/absolute position
is among the first 1/3/5 sentences?
number of words (with/without stopwords)
number of words more than 5/10 (with/without stopwords)
Query-Relevant Features
unigram/bigram/skip bigram (at most four words apart) overlap
unigram/bigram TF/TF-IDF similarity
mention overlap
subject/object/indirect object overlap
semantic role overlap
relation overlap
Query-Independent Features
average/total unigram/bigram IDF/TF-IDF
unigram/bigram TF/TF-IDF similarity with the centroid of the cluster
average/sum of sumBasic/SumFocus (Toutanova et al., 2007)
average/sum of mutual information
average/sum of number of topic signature words (Lin and Hovy, 2000)
basic/improved sentence scorers from Conroy et al. (2006)
Content Features
contains verb/web link/phone number?
contains/portion of words between parentheses

Table 1: Sentence-level features for sentence ranking.

2011; Ouyang et al., 2011), we use the ROUGE-2 score, which measures bigram overlap between a sentence and the abstracts, as the objective for regression.

While space limitations preclude a longer discussion of the full feature set (ref. Table 1), we describe next the query-relevant features used for sentence ranking as these are the most important for our summarization setting. The goal of this feature subset is to determine the similarity between the query and each candidate sentence. When computing similarity, we remove stopwords as well as the words “discuss, describe, specify, explain, identify, include, involve, note” that are adopted and extended from Conroy et al. (2006). Then we conduct simple query expansion based on the title of the topic and cross-document coreference resolution. Specifically, we first add the words from the topic title to the query. And for each mention in the query, we add other mentions within the set of documents that corefer with this mention. Finally, we compute two versions of the features—one based on the original query and another on the expanded one. We also derive the semantic role overlap and relation instance overlap between the query and each sentence. Cross-document coreference resolution, semantic role labeling and relation extraction are accomplished via the methods described in Section 5.

**Sentence Compression.** As the main focus of this paper, we propose three types of compression methods, described in detail in Section 4 below.

**Post-processing.** Post-processing performs *coreference resolution* and *sentence ordering*.

Basic Features	Syntactic Tree Features
first 1/3/5 tokens (toks)? last 1/3/5 toks? first letter/all letters capitalized? is negation? is stopword? <b>Dependency Tree Features</b> dependency relation (dep rel) parent/grandparent dep rel is the root? has a depth larger than 3/5?	POS tag parent/grandparent label leftmost child of parent? second leftmost child of parent? is headword? in NP/VP/ADVP/ADJP chunk? <b>Semantic Features</b> is a predicate? semantic role label
Rule-Based Features	
For each rule in Table 2, we construct a corresponding feature to indicate whether the token is identified by the rule.	

Table 3: Token-level features for sequence-based compression.

We replace each pronoun with its referent unless they appear in the same sentence. For sentence ordering, each compressed sentence is assigned to the most similar (tf-idf) query sentence. Then a Chronological Ordering algorithm (Barzilay et al., 2002) sorts the sentences for each query based first on the time stamp, and then the position in the source document.

## 4 Sentence Compression

Sentence compression is typically formulated as the problem of removing secondary information from a sentence while maintaining its grammaticality and semantic structure (Knight and Marcu, 2000; McDonald, 2006; Galley and McKeown, 2007; Clarke and Lapata, 2008). We leave other rewrite operations, such as paraphrasing and re-ordering, for future work. Below we describe the sentence compression approaches developed in this research: RULE-BASED COMPRESSION, SEQUENCE-BASED COMPRESSION, and TREE-BASED COMPRESSION.

### 4.1 Rule-based Compression

Turner and Charniak (2005) have shown that applying hand-crafted rules for trimming sentences can improve both content and linguistic quality. Our rule-based approach extends existing work (Conroy et al., 2006; Toutanova et al., 2007) to create the linguistically-motivated compression rules of Table 2. To avoid ill-formed output, we disallow compressions of more than 10 words by each rule.

### 4.2 Sequence-based Compression

As in McDonald (2006) and Clarke and Lapata (2008), our sequence-based compression model makes a binary “keep-or-delete” decision for each word in the sentence. In contrast, however, we

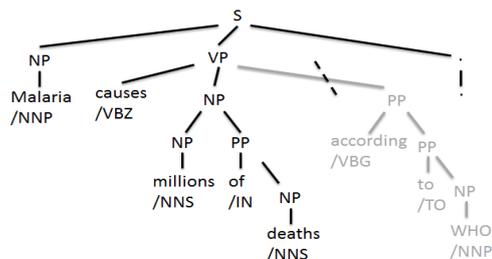

Figure 1: Diagram of tree-based compression. The nodes to be dropped are grayed out. In this example, the root of the gray subtree (a “PP”) would be labeled REMOVE. Its siblings and parent are labeled RETAIN and PARTIAL, respectively. The trimmed tree is realized as “Malaria causes millions of deaths.”

view compression as a sequential tagging problem and make use of linear-chain Conditional Random Fields (CRFs) (Lafferty et al., 2001) to select the most likely compression. We represent each sentence as a sequence of tokens,  $X = x_0x_1 \dots x_n$ , and generate a sequence of labels,  $Y = y_0y_1 \dots y_n$ , that encode which tokens are kept, using a BIO label format: {B-RETAIN denotes the beginning of a retained sequence, I-RETAIN indicates tokens “inside” the retained sequence, O marks tokens to be removed}.

The CRF model is built using the features shown in Table 3. “Dependency Tree Features” encode the grammatical relations in which each word is involved as a dependent. For the “Syntactic Tree”, “Dependency Tree” and “Rule-Based” features, we also include features for the two words that precede and the two that follow the current word. Detailed descriptions of the training data and experimental setup are in Section 5.

During inference, we find the maximally likely sequence  $Y$  according to a CRF with parameter  $\theta$  ( $Y = \arg \max_{Y'} P(Y'|X; \theta)$ ), while simultaneously enforcing the rules of Table 2 to reduce the hypothesis space and encourage grammatical compression. To do this, we encode these rules as features for each token, and whenever these feature functions fire, we restrict the possible label for that token to “O”.

### 4.3 Tree-based Compression

Our tree-based compression methods are in line with syntax-driven approaches (Galley and McKeown, 2007), where operations are carried out on parse tree constituents. Unlike previous work (Knight and Marcu, 2000; Galley and McKeown, 2007), we do not produce a new parse tree,

Rule	Example
Header	[MOSCOW , October 19 ( Xinhua ) –] Russian federal troops Tuesday continued...
Relative dates	...Centers for Disease Control confirmed [Tuesday] that there was...
Intra-sentential attribution	...fueling the La Nina weather phenomenon, [the U.N. weather agency said].
Lead adverbials	[Interestingly], while the Democrats tend to talk about...
Noun appositives	Wayne County Prosecutor [John O’Hara] wanted to send a message...
Nonrestrictive relative clause	Putin, [who was born on October 7, 1952 in Leningrad], was elected in the presidential election...
Adverbial clausal modifiers (Lead sentence)	[Starting in 1998], California will require 2 per cent of a manufacturer... [Given the short time], car makers see electric vehicles as...
Within Parentheses	...to Christian home schoolers in the early 1990s [(www.homecomputermarket.com)].

Table 2: Linguistically-motivated rules for sentence compression. The grayed-out words in brackets are removed.

but focus on learning to identify the proper set of constituents to be removed. In particular, when a node is dropped from the tree, all words it subsumes will be deleted from the sentence.

Formally, given a parse tree  $T$  of the sentence to be compressed and a tree traversal algorithm,  $T$  can be presented as a list of ordered constituent nodes,  $T = t_0 t_1 \dots t_m$ . Our objective is to find a set of labels,  $L = l_0 l_1 \dots l_m$ , where  $l_i \in \{\text{RETAIN, REMOVE, PARTIAL}\}$ . RETAIN (RET) and REMOVE (REM) denote whether the node  $t_i$  is retained or removed. PARTIAL (PAR) means  $t_i$  is partly removed, i.e. at least one child subtree of  $t_i$  is dropped.

Labels are identified, in order, according to the tree traversal algorithm. Every node label needs to be *compatible* with the labeling history: given a node  $t_i$ , and a set of labels  $l_0 \dots l_{i-1}$  predicted for nodes  $t_0 \dots t_{i-1}$ ,  $l_i = \text{RET}$  or  $l_i = \text{REM}$  is *compatible* with the history when all children of  $t_i$  are labeled as RET or REM, respectively;  $l_i = \text{PAR}$  is *compatible* when  $t_i$  has at least two descendents  $t_j$  and  $t_k$  ( $j < i$  and  $k < i$ ), one of which is RETAINED and the other, REMOVED. As such, the root of the gray subtree in Figure 1 is labeled as REM; its left siblings as RET; its parent as PAR.

As the space of possible compressions is exponential in the number of leaves in the parse tree, instead of looking for the globally optimal solution, we use beam search to find a set of highly likely compressions and employ a language model trained on a large corpus for evaluation.

**A Beam Search Decoder.** The beam search decoder (see Algorithm 1) takes as input the sentence’s parse tree  $T = t_0 t_1 \dots t_m$ , an ordering  $O$  for traversing  $T$  (e.g. postorder) as a sequence of nodes in  $T$ , the set  $L$  of possible node labels, a scoring function  $S$  for evaluating each sentence compression hypothesis, and a beam size  $N$ . Specifically,  $O$  is a permutation on the set  $\{0, 1, \dots, m\}$ —each element an

index onto  $T$ . Following  $O$ ,  $T$  is re-ordered as  $t_{O_0} t_{O_1} \dots t_{O_m}$ , and the decoder considers each ordered constituent  $t_{O_i}$  in turn. In iteration  $i$ , all existing sentence compression hypotheses are expanded by one node,  $t_{O_i}$ , labeling it with **all compatible** labels. The new hypotheses (usually sub-sentences) are ranked by the scorer  $S$  and the top  $N$  are preserved to be extended in the next iteration. See Figure 2 for an example.

```

Input : parse tree  $T$ , ordering  $O = O_0 O_1 \dots O_m$ ,
          $L = \{\text{RET, REM, PAR}\}$ , hypothesis scorer  $S$ ,
         beam size  $N$ 
Output:  $N$  best compressions

stack  $\leftarrow \Phi$  (empty set);
foreach node  $t_{O_i}$  in  $T = t_{O_0} \dots t_{O_m}$  do
  if  $i == 0$  (first node visited) then
    foreach label  $l_{O_0}$  in  $L$  do
      newHypothesis  $h' \leftarrow [l_{O_0}]$ ;
      put  $h'$  into Stack;
    end
  else
    newStack  $\leftarrow \Phi$  (empty set);
    foreach hypothesis  $h$  in stack do
      foreach label  $l_{O_i}$  in  $L$  do
        if  $l_{O_i}$  is compatible then
          newHypothesis  $h' \leftarrow h + [l_{O_i}]$ ;
          put  $h'$  into newStack;
        end
      end
    end
    stack  $\leftarrow$  newStack;
  end
Apply  $S$  to sort hypotheses in stack in descending order;
Keep the  $N$  best hypotheses in stack;
end

```

Algorithm 1: Beam search decoder.

Our **BASIC Tree-based Compression** instantiates the beam search decoder with postorder traversal and a hypothesis scorer that takes a possible sentence compression—a sequence of nodes (e.g.  $t_{O_0} \dots t_{O_k}$ ) and their labels (e.g.  $l_{O_0} \dots l_{O_k}$ )—and returns  $\sum_{j=1}^k \log P(l_{O_j} | t_{O_j})$  (denoted later as  $Score_{Basic}$ ). The probability is estimated by a Maximum Entropy classifier (Berger et al.,

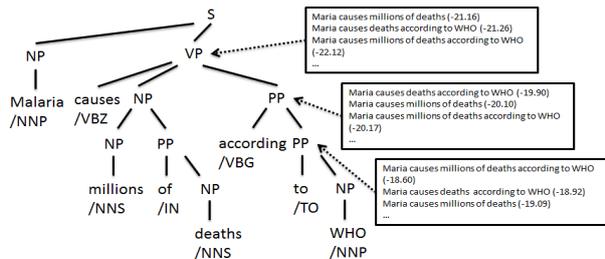

Figure 2: Example of beam search decoding. For postorder traversal, the three nodes are visited in a bottom-up order. The associated compression hypotheses (boxed) are ranked based on the scores in parentheses. Beam scores for other nodes are omitted.

Basic Features	Syntactic Tree Features

semantic roles of head node	has a depth larger than 3/5?†
<b>Rule-Based Features</b>	
For each rule in Table 2, we construct a corresponding feature to indicate whether the token is identified by the rule.	

Table 4: Constituent-level features for tree-based compression. \* or † denote features that are concatenated with every Syntactic Tree feature to compose a new one.

1996) trained at the constituent level using the features in Table 4. We also apply the rules of Table 2 during the decoding process. Concretely, if the words subsumed by a node are identified by any rule, we only consider REM as the node's label.

Given the  $N$ -best compressions from the decoder, we evaluate the yield of the trimmed trees using a language model trained on the Gigaword (Graff, 2003) corpus and return the compression with the highest probability. Thus, the decoder is quite flexible — its learned scoring function allows us to incorporate features salient for sentence compression while its language model guarantees the linguistic quality of the compressed string. In the sections below we consider additional improvements.

### 4.3.1 Improving Beam Search

**CONTEXT-aware search** is based on the intuition that predictions on preceding context can be leveraged to facilitate the prediction of the current node. For example, parent nodes with

children that have all been removed (retained) should have a label of REM (RET). In light of this, we encode these contextual predictions as additional features of  $S$ , that is, ALL-CHILDREN-REMOVED/RETAINED, ANY-LEFTSIBLING-REMOVED/RETAINED/PARTLY\_REMOVED, LABEL-OF-LEFT-SIBLING/HEAD-NODE.

**HEAD-driven search** modifies the BASIC postorder tree traversal by visiting the head node first at each level, leaving other orders unchanged. In a nutshell, if the head node is dropped, then its modifiers need not be preserved. We adopt the same features as CONTEXT-aware search, but remove those involving left siblings. We also add one more feature: LABEL-OF-THE-HEAD-NODE-IT-MODIFIES.

### 4.3.2 Task-Specific Sentence Compression

The current scorer  $Score_{Basic}$  is still fairly naive in that it focuses only on features of the sentence to be compressed. *However extra-sentential knowledge can also be important for query-focused MDS.* For example, information regarding relevance to the query might lead the decoder to produce compressions better suited for the summary. Towards this goal, we construct a compression scoring function—the *multi-scorer* (MULTI)—that allows the incorporation of multiple task-specific scorers. Given a hypothesis at any stage of decoding, which yields a sequence of words  $W = w_0w_1\dots w_j$ , we propose the following component scorers.

**Query Relevance.** Query information ought to guide the compressor to identify the relevant content. The query  $Q$  is expanded as described in Section 3. Let  $|W \cap Q|$  denote the number of unique overlapping words between  $W$  and  $Q$ , then  $score_q = |W \cap Q|/|W|$ .

**Importance.** A query-independent importance score is defined as the average Sum-Basic (Toutanova et al., 2007) value in  $W$ , i.e.  $score_{im} = \sum_{i=1}^j SumBasic(w_i)/|W|$ .

**Language Model.** We let  $score_{lm}$  be the probability of  $W$  computed by a language model.

**Cross-Sentence Redundancy.** To encourage diversified content, we define a redundancy score to discount replicated content:  $score_{red} = 1 - |W \cap C|/|W|$ , where  $C$  is the words already selected for the summary.

The *multi-scorer* is defined as a linear combination of the component scorers: Let  $\vec{\alpha} = (\alpha_0, \dots, \alpha_4)$ ,  $0 \leq \alpha_i \leq 1$ ,  $\overrightarrow{score} = (score_{Basic}, score_q, score_{im}, score_{lm}, score_{red})$ ,

$$S = score_{multi} = \vec{\alpha} \cdot \overrightarrow{score} \quad (1)$$

The parameters  $\vec{\alpha}$  are tuned on a held-out tuning set by grid search. We linearly normalize the score of each metric, where the minimum and maximum values are estimated from the tuning data.

## 5 Experimental Setup

We evaluate our methods on the DUC 2005, 2006 and 2007 datasets (Dang, 2005; Dang, 2006; Dang, 2007), each of which is a collection of newswire articles. 50 complex queries (topics) are provided for DUC 2005 and 2006, 35 are collected for DUC 2007 main task. Relevant documents for each query are provided along with 4 to 9 human MDS abstracts. The task is to generate a summary within 250 words to address the query. We split DUC 2005 into two parts: 40 topics to train the sentence ranking models, and 10 for ranking algorithm selection and parameter tuning for the multi-scorer. DUC 2006 and DUC 2007 are reserved as held out test sets.

*Sentence Compression.* The dataset from Clarke and Lapata (2008) is used to train the CRF and MaxEnt classifiers (Section 4). It includes 82 newswire articles with one manually produced compression aligned to each sentence.

*Preprocessing.* Documents are processed by a full NLP pipeline, including token and sentence segmentation, parsing, semantic role labeling, and an information extraction pipeline consisting of mention detection, NP coreference, cross-document resolution, and relation detection (Florin et al., 2004; Luo et al., 2004; Luo and Zitouni, 2005).

*Learning for Sentence Ranking and Compression.* We use Weka (Hall et al., 2009) to train a support vector regressor and experiment with various rankers in RankLib (Dang, 2011)<sup>3</sup>. As LambdaMART has an edge over other rankers on the held-out dataset, we selected it to produce ranked sentences for further processing. For sequence-based compression using CRFs, we employ Mallet (McCallum, 2002) and integrate the Table 2 rules during inference. NLTK (Bird et al., 2009)

<sup>3</sup>Default parameters are used. If an algorithm needs a validation set, we use 10 out of 40 topics.

MaxEnt classifiers are used for tree-based compression. Beam size is fixed at 2000.<sup>4</sup> Sentence compressions are evaluated by a 5-gram language model trained on Gigaword (Graff, 2003) by SRILM (Stolcke, 2002).

## 6 Results

The results in Table 5 use the official ROUGE software with standard options<sup>5</sup> and report ROUGE-2 (R-2) (measures bigram overlap) and ROUGE-SU4 (R-SU4) (measures unigram and skip-bigram separated by up to four words). We compare our sentence-compression-based methods to the best performing systems based on ROUGE in DUC 2006 and 2007 (Jagarlamudi et al., 2006; Pingali et al., 2007), system by Davis et al. (2012) that report the best R-2 score on DUC 2006 and 2007 thus far, and to the purely extractive methods of SVR and LambdaMART.

Our sentence-compression-based systems (marked with †) show statistically significant improvements over pure extractive summarization for both R-2 and R-SU4 (paired *t*-test,  $p < 0.01$ ). This means our systems can effectively remove redundancy within the summary through compression. Furthermore, our HEAD-driven beam search method with MULTI-scorer beats all systems on DUC 2006<sup>6</sup> and all systems on DUC 2007 except the best system in terms of R-2 ( $p < 0.01$ ). Its R-SU4 score is also significantly ( $p < 0.01$ ) better than extractive methods, rule-based and sequence-based compression methods on both DUC 2006 and 2007. Moreover, our systems with learning-based compression have considerable compression rates, indicating their capability to remove superfluous words as well as improve summary quality.

**Human Evaluation.** The Pyramid (Nenkova and Passonneau, 2004) evaluation was developed to manually assess how many relevant facts or Summarization Content Units (SCUs) are captured by system summaries. We ask a professional annotator (who is not one of the authors, is highly experienced in annotating for various NLP tasks, and is fluent in English) to carry out a Pyramid evaluation on 10 randomly selected topics from

<sup>4</sup>We looked at various beam sizes on the heldout data, and observed that the performance peaks around this value.

Table 6: Human evaluation on our multi-scorer based system, Jagarlamudi et al. (2006) (Best DUC system (ROUGE)), and Lacatusu et al. (2006) (Best DUC system (LQ)). Our system can synthesize more relevant content according to Pyramid ( $\times 100$ ). We also examine linguistic quality (LQ) in Grammaticality (Gra), Non-redundancy (Non-Red), Referential clarity (Ref), Focus (Foc), and Structure and Coherence (Coh) like Dang (2006), each rated from 1 (very poor) to 5 (very good). Our system has better non-redundancy than Jagarlamudi et al. (2006) and is comparable to Jagarlamudi et al. (2006) and Lacatusu et al. (2006) in other metrics except grammaticality.

the DUC 2006 task with gold-standard SCU annotation in abstracts. The Pyramid score (see Table 6) is re-calculated for the system with best ROUGE scores in DUC 2006 (Jagarlamudi et al., 2006) along with our system by the same annotator to make a meaningful comparison.

We further evaluate the linguistic quality (LQ) of the summaries for the same 10 topics in accordance with the measurement in Dang (2006). Four native speakers who are undergraduate students in computer science (none are authors) performed the task. We compare our system based on HEAD-driven beam search with MULTI-scorer to the best systems in DUC 2006 achieving top ROUGE scores (Jagarlamudi et al., 2006) (Best DUC system (ROUGE)) and top linguistic quality scores (Lacatusu et al., 2006) (Best DUC system (LQ))<sup>7</sup>. The average score and standard deviation for each metric is displayed in Table 6. Our system achieves a higher Pyramid score, an indication that it captures more of the salient facts. We also

attain better non-redundancy than Jagarlamudi et al. (2006), meaning that human raters perceive less replicative content in our summaries. Scores for other metrics are comparable to Jagarlamudi et al. (2006) and Lacatusu et al. (2006), which either uses minimal non-learning-based compression rules or is a pure extractive system. However, our compression system sometimes generates less grammatical sentences, and those are mostly due to parsing errors. For example, parsing a clause starting with a past tense verb as an adverbial clausal modifier can lead to an ill-formed compression. Those issues can be addressed by analyzing  $k$ -best parse trees and we leave it in the future work. A sample summary from our multi-scorer based system is in Figure 3.

**Sentence Compression Evaluation.** We also evaluate sentence compression separately on (Clarke and Lapata, 2008), adopting the same partitions as (Martins and Smith, 2009), i.e. 1, 188 sentences for training and 441 for testing. Our compression models are compared with Hedge Trimmer (Dorr et al., 2003), a discriminative model proposed by McDonald (2006) and a

<sup>7</sup>Lacatusu et al. (2006) obtain the best scores in three linguistic quality metrics (i.e. grammaticality, focus, structure and coherence), and overall responsiveness on DUC 2006.

System	C Rate	Uni-Prec	Uni-Rec	Uni-F1	Rel-F1
HedgeTrimmer	57.64%	0.72	0.65	0.64	0.50
McDonald (2006)	70.95%	0.77	0.78	<i>0.77</i>	0.55
Martins and Smith (2009)	71.35%	0.77	0.78	<i>0.77</i>	0.56
Rule-based	87.65%	0.74	0.91	0.80	0.63
Sequence	70.79%	0.77	0.80	<i>0.76</i>	0.58
Tree (BASIC)	69.65%	0.77	0.79	0.75	0.56
Tree (CONTEXT)	67.01%	<b>0.79</b>	0.78	<i>0.76</i>	0.57
Tree (HEAD)	68.06%	<b>0.79</b>	0.80	<i>0.77</i>	<b>0.59</b>

Table 7: Sentence compression comparison. The true c rate is 69.06% for the test set. Tree-based approaches all use single-scorer. Our context-aware and head-driven tree-based approaches outperform all the other systems significantly ( $p < 0.01$ ) in precision (**Uni-Prec**) without sacrificing the recalls (i.e. there is no statistically significant difference between our models and McDonald (2006) / M & S (2009) with  $p > 0.05$ ). *Italicized* numbers for unigram F1 (**Uni-F1**) are statistically indistinguishable ( $p > 0.05$ ). Our head-driven tree-based approach also produces significantly better grammatical relations F1 scores (**Rel-F1**) than all the other systems except the rule-based method ( $p < 0.01$ ).

Topic <i>D0626H</i> : How were the bombings of the US embassies in Kenya and Tanzania conducted? What terrorist groups and individuals were responsible? How and where were the attacks planned?
WASHINGTON, August 13 (Xinhua) – President Bill Clinton Thursday condemned terrorist bomb attacks at U.S. embassies in Kenya and Tanzania and vowed to find the bombers and bring them to justice. Clinton met with his top aides Wednesday in the White House to assess the situation following the twin bombings at U.S. embassies in Kenya and Tanzania, which have killed more than 250 people and injured over 5,000, most of them Kenyans and Tanzanians. Local sources said the plan to bomb U.S. embassies in Kenya and Tanzania took three months to complete and bombers destined for Kenya were dispatched through Somali and Rwanda. FBI Director Louis Freeh, Attorney General Janet Reno and other senior U.S. government officials will hold a news conference at 1 p.m. EDT (1700GMT) at FBI headquarters in Washington “to announce developments in the investigation of the bombings of the U.S. embassies in Kenya and Tanzania,” the FBI said in a statement. ...

Figure 3: Part of the summary generated by the multi-scorer based summarizer for topic *D0626H* (DUC 2006). Grayed out words are removed. Query-irrelevant phrases, such as temporal information or source of the news, have been removed.

dependency-tree based compressor (Martins and Smith, 2009)<sup>8</sup>. We adopt the metrics in Martins and Smith (2009) to measure the unigram-level macro precision, recall, and F1-measure with respect to human annotated compression. In addition, we also compute the F1 scores of grammatical relations which are annotated by RASP (Briscoe and Carroll, 2002) according to Clarke and Lapata (2008).

In Table 7, our context-aware and head-driven tree-based compression systems show statistically significantly ( $p < 0.01$ ) higher precisions (**Uni-**

**Prec**) than all the other systems, without decreasing the recalls (**Uni-Rec**) significantly ( $p > 0.05$ ) based on a paired *t*-test. Unigram F1 scores (**Uni-F1**) in italics indicate that the corresponding systems are not statistically distinguishable ( $p > 0.05$ ). For grammatical relation evaluation, our head-driven tree-based system obtains statistically significantly ( $p < 0.01$ ) better F1 score (**Rel-F1**) than all the other systems except the rule-based system).

## 7 Conclusion

We have presented a framework for query-focused multi-document summarization based on sentence compression. We propose three types of compression approaches. Our tree-based compression method can easily incorporate measures of query relevance, content importance, redundancy and language quality into the compression process. By testing on a standard dataset using the automatic metric ROUGE, our models show substantial improvement over pure extraction-based methods and state-of-the-art systems. Our best system also yields better results for human evaluation based on Pyramid and achieves comparable linguistic quality scores.

## Acknowledgments

## Abstract

We address the challenge of generating natural language abstractive summaries for spoken meetings in a domain-independent fashion. We apply *Multiple-Sequence Alignment* to induce abstract generation templates that can be used for different domains. An *Overgenerate-and-Rank* strategy is utilized to produce and rank candidate abstracts. Experiments using in-domain and out-of-domain training on disparate corpora show that our system uniformly outperforms state-of-the-art supervised extract-based approaches. In addition, human judges rate our system summaries significantly higher than compared systems in fluency and overall quality.

## 1 Introduction

Meetings are a common way to collaborate, share information and exchange opinions. Consequently, automatically generated meeting summaries could be of great value to people and businesses alike by providing quick access to the essential content of past meetings. *Focused meeting summaries* have been proposed as particularly useful; in contrast to summaries of a meeting as a whole, they refer to summaries of a specific aspect of a meeting, such as the DECISIONS reached, PROBLEMS discussed, PROGRESS made or ACTION ITEMS that emerged (Carenini et al., 2011). Our goal is to provide an automatic summarization system that can generate abstract-style focused meeting summaries to help users digest the vast amount of meeting content in an easy manner.

Existing meeting summarization systems remain largely *extractive*: their summaries are comprised exclusively of patchworks of utterances selected directly from the meetings to be summarized (Riedhammer et al., 2010; Bui et al., 2009; Xie et al., 2008). Although relatively easy to construct, extractive approaches fall short of producing concise and readable summaries, largely due

C: Looking at what we've got, we we want an LCD display with a spinning wheel.  
B: You have to have some push-buttons, don't you?  
C: Just spinning and not scrolling, I would say.  
B: I think the spinning wheel is definitely very now.  
A: but since LCDs seems to be uh a definite yes,  
C: We're having push-buttons on the outside  
C: and then on the inside an LCD with spinning wheel,

### Decision Abstract (Summary):

The remote will have push buttons outside, and an LCD and spinning wheel inside.

A: and um I'm not sure about the buttons being in the shape of fruit though.

D: Maybe make it like fruity colours or something.

C: The power button could be like a big apple or something.

D: Um like I'm just thinking bright colours.

### Problem Abstract (Summary):

How to incorporate a fruit and vegetable theme into the remote.

Figure 1: Clips from the AMI meeting corpus (McCowan et al., 2005). A, B, C and D refer to distinct speakers. Also shown is the gold-standard (manual) abstract (summary) for the decision and the problem.

to the noisy, fragmented, ungrammatical and unstructured text of meeting transcripts (Murray et al., 2010b; Liu and Liu, 2009).

In contrast, human-written meeting summaries are typically in the form of *abstracts* — distillations of the original conversation written in new language. A user study from Murray et al. (2010b) showed that people demonstrate a strong preference for abstractive summaries over extracts when the text to be summarized is conversational. Consider, for example, the two types of focused summary along with their associated dialogue snippets in Figure 1. We can see that extracts are likely to include unnecessary and noisy information from the meeting transcripts. On the contrary, the manually composed summaries (abstracts) are more compact and readable, and are written in a distinctly non-conversational style.

To address the limitations of extract-based summaries, we propose a complete and fully automatic domain-independent abstract generation framework for focused meeting summarization. Following existing language generation research (Angeli et al., 2010; Konstas and Lapata, 2012), we first perform *content selection*: given the dialogue acts relevant to one element of the meeting (e.g. a single decision or problem), we train a classifier to identify summary-worthy phrases. Next, we develop an “overgenerate-and-rank” strategy (Walker et al., 2001; Heilman and Smith, 2010) for *surface realization*, which generates and ranks candidate sentences for the abstract. After redundancy reduction, the full meeting abstract can thus comprise the focused summary for each meeting element. As described in subsequent sections, the generation framework allows us to identify and reformulate the important information for the focused summary. Our contributions are as follows:

- To the best of our knowledge, our system is the first fully automatic system to generate natural language abstracts for spoken meetings.
- We present a novel template extraction algorithm, based on Multiple Sequence Alignment (MSA) (Durbin et al., 1998), to induce domain-independent templates that guide abstract generation. MSA is commonly used in bioinformatics to identify equivalent fragments of DNAs (Durbin et al., 1998) and has also been employed for learning paraphrases (Barzilay and Lee, 2003).
- Although our framework requires labeled training data for each type of focused summary (decisions, problems, etc.), we also make initial tries for domain adaptation so that our summarization method does not need human-written abstracts for each new meeting domain (e.g. faculty meetings, theater group meetings, project group meetings).

We instantiate the abstract generation framework on two corpora from disparate domains — the AMI Meeting Corpus (Mccowan et al., 2005) and ICSI Meeting Corpus (Janin et al., 2003) — and produce systems to generate focused summaries with regard to four types of

meeting elements: DECISIONS, PROBLEMS, ACTION ITEMS, and PROGRESS. Automatic evaluation (using ROUGE (Lin and Hovy, 2003) and BLEU (Papineni et al., 2002)) against manually generated focused summaries shows that our summarizers uniformly and statistically significantly outperform two baseline systems as well as a state-of-the-art supervised extraction-based system. Human evaluation also indicates that the abstractive summaries produced by our systems are more linguistically appealing than those of the utterance-level extraction-based system, preferring them over summaries from the extraction-based system of comparable semantic correctness (62.3% vs. 37.7%).

Finally, we examine the generality of our model across domains for two types of focused summarization — decisions and problems — by training the summarizer on out-of-domain data (i.e. the AMI corpus for use on the ICSI meeting data, and vice versa). The resulting systems yield results comparable to those from the same system trained on in-domain data, and statistically significantly outperform supervised extractive summarization approaches trained on in-domain data.

## 2 Related Work

Most research on spoken dialogue summarization attempts to generate summaries for full dialogues (Carenini et al., 2011). Only recently has the task of focused summarization been studied. Supervised methods are investigated to identify key phrases or utterances for inclusion in the decision summary (Fernández et al., 2008; Bui et al., 2009). Based on Fernández et al. (2008), a relation representation is proposed by Wang and Cardie (2012) to form structured summaries; we adopt this representation here for content selection.

Our research is also in line with generating abstractive summaries for conversations. Extractive approaches (Murray et al., 2005; Xie et al., 2008; Galley, 2006) have been investigated extensively in conversation summarization. Murray et al. (2010a) present an abstraction system consisting of interpretation and transformation steps. Utterances are mapped to a simple conversation ontology in the interpretation step according to their type, such as a decision or problem. Then an integer linear programming approach is employed to select the utterances that cover more entities as

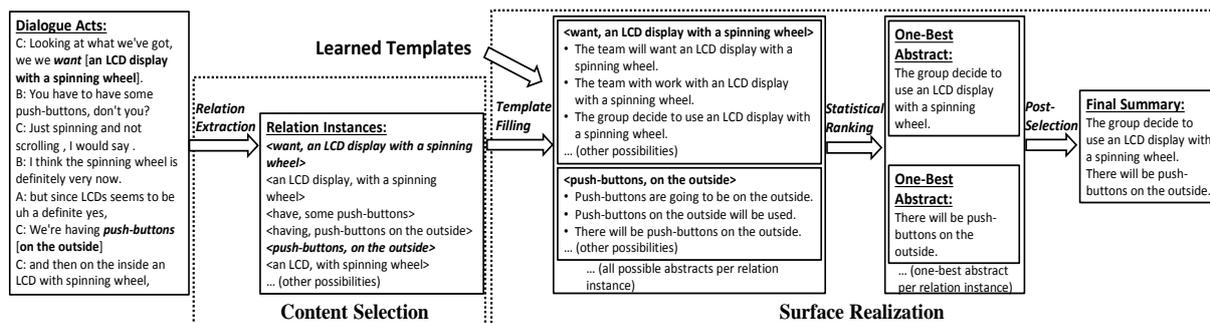

Figure 2: The abstract generation framework. It takes as input a cluster of meeting-item-specific dialogue acts, from which one focused summary is constructed. Sample relation instances are denoted in **bold** (The indicators are further *italicized* and the arguments are in [brackets]). Summary-worthy relation instances are identified by content selection module (see Section 4) and then filled into the learned templates individually. A statistical ranker subsequently selects one best abstract per relation instance (see Section 5.2). The post-selection component reduces the redundancy and outputs the final summary (see Section 5.3).

determined by an external ontology. Liu and Liu (2009) apply sentence compression on extracted summary utterances. Though some of the unnecessary words are dropped, the resulting compressions can still be ungrammatical and unstructured.

This work is also broadly related to expert system-based language generation (Reiter and Dale, 2000) and concept-to-text generation tasks (Angeli et al., 2010; Konstas and Lapata, 2012), where the generation process is decomposed into content selection (or text planning) and surface realization. For instance, Angeli et al. (2010) learn from structured database records and parallel textual descriptions. They generate texts based on a series of decisions made to select the records, fields, and proper templates for rendering. Those techniques that are tailored to specific domains (e.g. weather forecasts or sportcastings) cannot be directly applied to the conversational data, as their input is well-structured and the templates learned are domain-specific.

### 3 Framework

Our domain-independent abstract generation framework produces a summarizer that generates a grammatical abstract from a cluster of *meeting-element-related dialogue acts (DAs)* — all utterances associated with a single decision, problem, action item or progress step of interest. Note that identifying these DA clusters is a difficult task in itself (Bui et al., 2009). Accordingly, our experiments evaluate two conditions — one in which we assume that they are perfectly identified, and one in which we identify the clusters automatically.

The summarizer consists of two major components and is depicted in Figure 2. Given the DA cluster to be summarized, the *Content Selection* module identifies a set of summary-worthy *relation instances* represented as indicator-argument pairs (i.e. these constitute a finer-grained representation than DAs). The *Surface Realization* component then generates a short summary in three steps. In the first step, each relation instance is filled into templates with disparate structures that are learned automatically from the training set (*Template Filling*). A statistical ranker then selects one best abstract per relation instance (*Statistical Ranking*). Finally, selected abstracts are processed for redundancy removal in *Post-Selection*. Detailed descriptions for each individual step are provided in Sections 4 and 5.

### 4 Content Selection

Phrase-based content selection approaches have been shown to support better meeting summaries (Fernández et al., 2008). Therefore, we chose a content selection representation of a finer granularity than an utterance: we identify *relation instances* that can both effectively detect the crucial content and incorporate enough syntactic information to facilitate the downstream surface realization.

More specifically, our relation instances are based on information extraction methods that identify a lexical *indicator* (or *trigger*) that evokes a relation of interest and then employ syntactic information, often in conjunction with semantic constraints, to find the *argument constituent* (or *target phrase*) to be extracted. Rela-

tion instances, then, are represented by **indicator-argument** pairs (Chen et al., 2011). For example, in the DA cluster of Figure 2, *⟨want, an LCD display with a spinning wheel⟩* and *⟨push-buttons, on the outside⟩* are two relation instances.

**Relation Instance Extraction** We adopt and extend the syntactic constraints from Wang and Cardie (2012) to identify all relation instances in the input utterances; the summary-worthy ones will be selected by a discriminative classifier. Constituent and dependency parses are obtained by the Stanford parser (Klein and Manning, 2003). Both the indicator and argument take the form of constituents in the parse tree. We restrict the eligible indicator to be a noun or verb; the eligible arguments is a noun phrase (NP), prepositional phrase (PP) or adjectival phrase (ADJP). A valid indicator-argument pair should have at least one content word and satisfy one of the following constraints:

- When the indicator is a noun, the argument has to be a modifier or complement of the indicator.
- When the indicator is a verb, the argument has to be the subject or the object if it is an NP, or a modifier or complement of the indicator if it is a PP/ADJP.

We view relation extraction as a binary classification problem rather than a clustering task (Chen et al., 2011). All relation instances can be categorized as summary-worthy or not, but only the summary-worthy ones are used for abstract generation. A discriminative classifier is trained for this purpose based on Support Vector Machines (SVMs) (Joachims, 1998) with an RBF kernel. For training data construction, we consider a relation instance to be a positive example if it shares any content word with its corresponding abstracts, and a negative example otherwise. The features used are shown in Table 1.

## 5 Surface Realization

In this section, we describe surface realization, which renders the relation instances into natural language abstracts. This process begins with template extraction (Section 5.1). Once the templates are learned, the relation instances from Section 4 are filled into the templates to generate an abstract (see Section 5.2). Redundancy handling is discussed in Section 5.3.

<b>Basic Features</b>
number of words/content words
portion of content words/stopwords
number of content words in indicator/argument
number of content words that are also in previous DA
indicator/argument only contains stopword?
number of new nouns
<b>Content Features</b>
has capitalized word?
has proper noun?
TF/IDF/TFIDF min/max/average
<b>Discourse Features</b>
main speaker or not?
is in an adjacency pair (AP)?
is in the source/target of the AP?
number of source/target DA in the AP
is the target of the AP a positive/negative/neutral response?
is the source of the AP a question?
<b>Syntax Features</b>
indicator/argument constituent tag
dependency relation of indicator and argument

Table 1: Features for content selection. Most are adapted from previous work (Galley, 2006; Xie et al., 2008; Wang and Cardie, 2012). Every basic or content feature is concatenated with the constituent tags of indicator and argument to compose a new one. Main speakers include the most talkative speaker (who has said the most words) and other speakers whose word count is more than 20% of the most talkative one (Xie et al., 2008). Adjacency pair (AP) (Galley, 2006) is an important conversational analysis concept; each AP consists of a source utterance and a target utterance produced by different speakers.

### 5.1 Template Extraction

**Sentence Clustering.** Template extraction starts with clustering the sentences that constitute the manually generated abstracts in the training data according to their lexical and structural similarity. From each cluster, multiple-sequence alignment techniques are employed to capture the recurring patterns.

Intuitively, desirable templates are those that can be applied in different domains to generate the same type of focused summary (e.g. decision or problem summaries). We do not want sentences to be clustered only because they describe the same domain-specific details (e.g. they are all about “data collection”), which will lead to fragmented templates that are not reusable for new domains. We therefore replace all appearances of dates, numbers, and proper names with generic labels. We also replace words that appear in both the abstract and supporting dialogue acts by a label indicating its phrase type. For any noun phrase with its head word abstracted, the whole phrase is also replaced with “NP”.

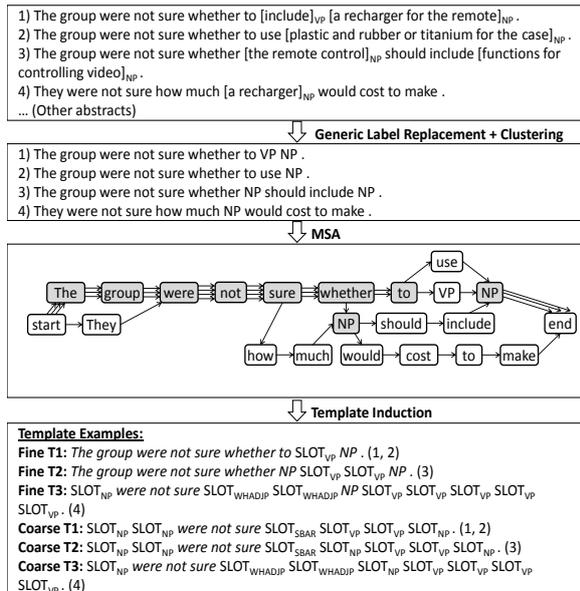

Figure 3: Example of template extraction by Multiple-Sequence Alignment for problem abstracts from AMI. Backbone nodes shared by at least 50% sentences are shaded. The grammatical errors exist in the original abstracts.

Following Barzilay and Lee (2003), we approach the sentence clustering task by hierarchical complete-link clustering with a similarity metric based on word n-gram overlap ( $n = 1, 2, 3$ ). Clusters with fewer than three abstracts are removed<sup>1</sup>.

**Learning the Templates via MSA.** For learning the structural patterns among the abstracts, *Multiple-Sequence Alignment (MSA)* is first computed for each cluster. MSA takes as input multiple sentences and one scoring function to measure the similarity between any two words. For insertions or deletions, a gap cost is also added. MSA can thus find the best way to align the sequences with insertions or deletions in accordance with the scorer. However, computing an optimal MSA is NP-complete (Wang and Jiang, 1994), thus we implement an approximate algorithm (Needleman and Wunsch, 1970) that iteratively aligns two sequences each time and treats the resulting alignment as a new sequence<sup>2</sup>. Figure 3 demonstrates an MSA computed from a sample cluster of ab-

<sup>1</sup>Clustering stops when the similarity between any pairwise clusters is below 5. This is applied to every type of summarization. We tune the parameter on a small held-out development set by manually evaluating the induced templates. No significant change is observed within a small range.

<sup>2</sup>We adopt the scoring function for MSA from Barzilay and Lee (2003), where aligning two identical words scores 1, inserting a gap scores  $-0.01$ , and aligning two different words scores  $-0.5$ .

stracts. The MSA is represented in the form of word lattice, from which we can detect the structural similarities shared by the sentences.

To transform the resulting MSAs into templates, we need to decide whether a word in the sentence should be retained to comprise the template or abstracted. The *backbone* nodes in an MSA are identified as the ones shared by more than 50%<sup>3</sup> of the cluster’s sentences (shaded in gray in Figure 3). We then create a FINE template for each sentence by abstracting the non-backbone words, i.e. replacing each of those words with a generic token (last step in Figure 3). We also create a COARSE template that only preserves the nodes shared by all of the cluster’s sentences. By using the operations above, domain-independent patterns are thus identified and domain-specific details are removed.

Note that we do not explicitly evaluate the quality of the learned templates, which would require a significant amount of manual evaluation. Instead, they are evaluated extrinsically. We encode the templates as features (Angeli et al., 2010) that could be selected or ignored in the succeeding abstract ranking model.

## 5.2 Template Filling

**An Overgenerate-and-Rank Approach.** Since filling the relation instances into templates of distinct structures may result in abstracts of varying quality, we rank the abstracts based on the features of the template, the transformation conducted, and the generated abstract. This is realized by the *Overgenerate-and-Rank* strategy (Walker et al., 2001; Heilman and Smith, 2010). It takes as input a set of relation instances (from the same cluster)  $R = \{\langle ind_i, arg_i \rangle\}_{i=1}^N$  that are produced by content selection component, a set of templates  $T = \{t_j\}_{j=1}^M$  that are represented as parsing trees, a transformation function  $F$  (described below), and a statistical ranker  $S$  for ranking the generated abstracts, for which we defer description later in this Section.

For each  $\langle ind_i, arg_i \rangle$ , the overgenerate-and-rank approach fills it into each template in  $T$  by applying  $F$  to generate all possible abstracts. Then the ranker  $S$  selects the best abstract  $abs_i$ . Post-selection is conducted on the abstracts  $\{abs_i\}_{i=1}^N$  to form the final summary.

<sup>3</sup>See Barzilay and Lee (2003) for a detailed discussion about the choice of 50% according to pigeonhole principle.

The transformation function  $F$  models the *constituent-level* transformations of relation instances and their mappings to the parse trees of templates. With the intuition that people will reuse the relation instances from the transcripts albeit not necessarily in their original form to write the abstracts, we consider three major types of mapping operations for the indicator or argument in the source pair, namely, *Full-Constituent Mapping*, *Sub-Constituent Mapping*, and *Removal*. *Full-Constituent Mapping* denotes that a source constituent is mapped directly to a target constituent of the template parse tree with the same tag. *Sub-Constituent Mapping* encodes more complex and flexible transformations in that a sub-constituent of the source is mapped to a target constituent with the same tag. This operation applies when the source has a tag of PP or ADJP, in which case its sub-constituent, if any, with a tag of NP, VP or ADJP can be mapped to the target constituent with the same tag. For instance, an argument “with a spinning wheel” (PP) can be mapped to an NP in a template because it has a sub-constituent “a spinning wheel” (NP). *Removal* means a source is not mapped to any constituent in the template.

Formally,  $F$  is defined as:

$$F(\langle ind^{src}, arg^{src} \rangle, t) = \{\langle ind_k^{tran}, arg_k^{tran}, ind_k^{tar}, arg_k^{tar} \rangle\}_{k=1}^K$$

where  $\langle ind^{src}, arg^{src} \rangle \in R$  is a relation instance (*source pair*);  $t \in T$  is a template;  $ind_k^{tran}$  and  $arg_k^{tran}$  is the *transformed pair* of  $ind^{src}$  and  $arg^{src}$ ;  $ind_k^{tar}$  and  $arg_k^{tar}$  are constituents in  $t$ , and they compose one *target pair* for  $\langle ind^{src}, arg^{src} \rangle$ . We require that  $ind^{src}$  and  $arg^{src}$  are not removed at the same time. Moreover, for valid  $ind_k^{tar}$  and  $arg_k^{tar}$ , the words subsumed by them should be all abstracted in the template, and they do not overlap in the parse tree.

To obtain the realized abstract, we traverse the parse tree of the filled template in pre-order. The words subsumed by the leaf nodes are thus collected sequentially.

**Learning a Statistical Ranker.** We utilize a discriminative ranker based on Support Vector Regression (SVR) (Smola and Schölkopf, 2004) to rank the generated abstracts. Given the training data that includes clusters of gold-standard summary-worthy relation instances, associated abstracts they support, and the parallel templates for each abstract, training samples for the ranker are

<p><b>Basic Features</b>            number of words in <math>ind^{src}/arg^{src}</math>            number of new nouns in <math>ind^{src}/arg^{src}</math>  <math>ind_k^{tran}/arg_k^{tran}</math> only has stopword?            number of new nouns in <math>ind_k^{tran}/arg_k^{tran}</math></p>

<p><b>Template Features</b>            template type (fine/coarse)            realized template (e.g. “the group decided to”)            number of words in template            the template has verb?</p>
<p><b>Realization Features</b>            realization has verb?            realization starts with verb?            realization has adjacent verbs/NPs?  <math>ind^{src}</math> precedes/succeeds <math>arg^{src}</math>?  <math>ind^{tar}</math> precedes/succeeds <math>arg^{tar}</math>?            above 2 features have same value?</p>
<p><b>Language Model Features</b>  <math>\log p_{LM}</math>(first word in <math>ind_k^{tran}</math>   previous 1/2 words)  <math>\log p_{LM}</math>(realization)  <math>\log p_{LM}</math>(first word in <math>arg_k^{tran}</math>   previous 1/2 words)  <math>\log p_{LM}</math>(realization)/length  <math>\log p_{LM}</math>(next word   last 1/2 words in <math>ind_k^{tran}</math>)  <math>\log p_{LM}</math>(next word   last 1/2 words in <math>arg_k^{tran}</math>)</p>

Table 2: Features for abstracts ranking. The language model features are based on a 5-gram language model trained on Gigaword (Graff, 2003) by SRILM (Stolcke, 2002).

constructed according to the transformation function  $F$  mentioned above. Each sample is represented as:

$$(\langle ind^{src}, arg^{src} \rangle, \langle ind_k^{tran}, arg_k^{tran}, ind_k^{tar}, arg_k^{tar} \rangle, t, a)$$

where  $\langle ind^{src}, arg^{src} \rangle$  is the source pair,  $\langle ind_k^{tran}, arg_k^{tran} \rangle$  is the transformed pair,  $\langle ind_k^{tar}, arg_k^{tar} \rangle$  is the target pair in template  $t$ , and  $a$  is the abstract parallel to  $t$ .

We first find  $\langle ind_k^{tar,abs}, arg_k^{tar,abs} \rangle$ , which is the corresponding constituent pair of  $\langle ind_k^{tar}, arg_k^{tar} \rangle$  in  $a$ . Then we identify the summary-worthy words subsumed by  $\langle ind_k^{tran}, arg_k^{tran} \rangle$  that also appear in  $a$ . If those words are all subsumed by  $\langle ind_k^{tar,abs}, arg_k^{tar,abs} \rangle$ , then it is considered to be a positive sample, and a negative sample otherwise. Table 2 displays the features used in abstract ranking.

### 5.3 Post-Selection: Redundancy Handling.

Post-selection aims to maximize the information coverage and minimize the redundancy of the summary. Given the generated abstracts  $A =$

**Input** : relation instances  $R = \{\langle ind_i, arg_i \rangle\}_{i=1}^N$ ,  
generated abstracts  $A = \{abs_i\}_{i=1}^N$ , objective  
function  $f$ , cost function  $C$

**Output**: final abstract  $G$

$G \leftarrow \Phi$  (empty set);  
 $U \leftarrow A$ ;  
**while**  $U \neq \Phi$  **do**  
     $abs \leftarrow \arg \max_{abs_i \in U} \frac{f(A, G \cup abs_i) - f(A, G)}{C(abs_i)}$ ;  
    **if**  $f(A, G \cup abs) - f(A, G) \geq 0$  **then**  
         $G \leftarrow G \cup abs$ ;  
    **end**  
     $U \leftarrow U \setminus abs$ ;  
**end**

**Algorithm 1:** Greedy algorithm for post-selection to generate the final summary.

$\{abs_i\}_{i=1}^N$ , we use a greedy algorithm (Lin and Bilmes, 2010) to select a subset  $A'$ , where  $A' \subseteq A$ , to form the final summary. We define  $w_{ij}$  as the unigram similarity between abstracts  $abs_i$  and  $abs_j$ ,  $C(abs_i)$  as the number of words in  $abs_i$ . We employ the following objective function:

$$f(A, G) = \sum_{abs_i \in A \setminus G} \sum_{abs_j \in G} w_{i,j}, G \subseteq A$$

Algorithm 1 sequentially finds an abstract with the greatest ratio of objective function gain to length, and add it to the summary if the gain is non-negative.

## 6 Experimental Setup

**Corpora.** Two disparate corpora are used for evaluation. The AMI meeting corpus (Mccowan et al., 2005) contains 139 scenario-driven meetings, where groups of four people participate in a series of four meetings for a fictitious project of designing remote control. The ICSI meeting corpus (Janin et al., 2003) consists of 75 naturally occurring meetings, each of them has 4 to 10 participants. Compared to the fabricated topics in AMI, the conversations in ICSI tend to be specialized and technical, e.g. discussion about speech and language technology. We use 57 meetings in ICSI and 139 meetings in AMI that include a short (usually one-sentence), manually constructed abstract summarizing each important output for every meeting. Decision and problem summaries are annotated for both corpora. AMI has extra action item summaries, and ICSI has progress summaries. The set of dialogue acts that support each abstract are annotated as such.

**System Inputs.** We consider two system input settings. In the **True Clusterings** setting, we use the annotations to create perfect partitions of the DAs for input to the system; in the **System**

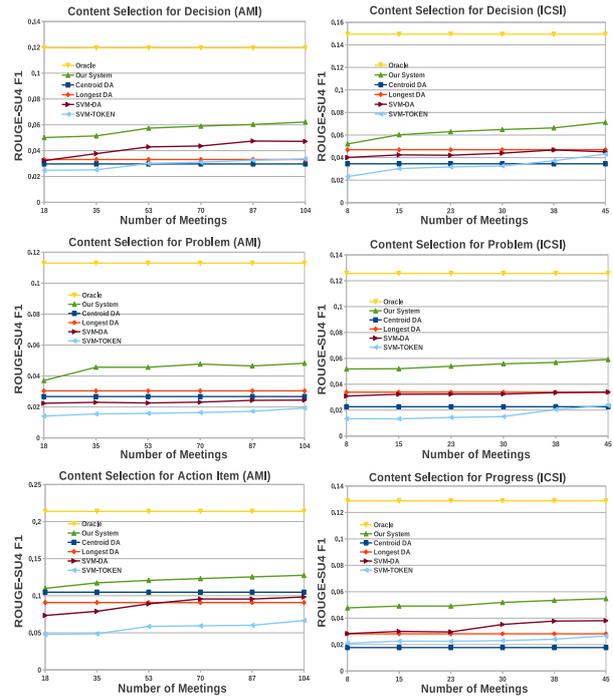

Figure 4: Content selection evaluation by using ROUGE-SU4 (multiplied by 100). SVM-DA and SVM-TOKEN denotes for supervised extract-based methods with SVMs on utterance- and token-level. Summaries for decision, problem, action item, and progress are generated and evaluated for AMI and ICSI (with names in parentheses). X-axis shows the number of meetings used for training.

**Clusterings** setting, we employ a hierarchical agglomerative clustering algorithm used for this task in (Wang and Cardie, 2011). DAs are grouped according to a classifier trained beforehand.

**Baselines and Comparisons.** We compare our system with (1) two unsupervised baselines, (2) two supervised extractive approaches, and (3) an oracle derived from the gold standard abstracts.

**Baselines.** As in Riedhammer et al. (2010), the LONGEST DA in each cluster is selected as the summary. The second baseline picks the cluster prototype (i.e. the DA with the largest TF-IDF similarity with the cluster centroid) as the summary according to Wang and Cardie (2011). Although it is possible that important content is spread over multiple DAs, both baselines allow us to determine summary quality when summaries are restricted to a single utterance.

**Supervised Learning.** We also compare our approach to two supervised extractive summarization methods — Support Vector Machines (Joachims, 1998) trained with the same fea-

tures as our system (see Table 1) to identify the important **DAs** (no syntax features) (Xie et al., 2008; Sandu et al., 2010) or **tokens** (Fernández et al., 2008) to include into the summary<sup>4</sup>.

*Oracle.* We compute an oracle consisting of the words from the DA cluster that also appear in the associated abstract to reflect the gap between the best possible extracts and the human abstracts.

## 7 Results

**Content Selection Evaluation.** We first employ ROUGE (Lin and Hovy, 2003) to evaluate the content selection component with respect to the human written abstracts. ROUGE computes the ngram overlapping between the system summaries with the reference summaries, and has been used for both text and speech summarization (Dang, 2005; Xie et al., 2008). We report ROUGE-2 (R-2) and ROUGE-SU4 (R-SU4) that are shown to correlate with human evaluation reasonably well.

In AMI, four meetings of different functions are carried out in each group<sup>5</sup>. 35 meetings for “conceptual design” are randomly selected for testing. For ICSI, we reserve 12 meetings for testing.

The R-SU4 scores for each system are displayed in Figure 4 and show that our system uniformly outperforms the baselines and supervised systems. The learning curve of our system is relatively flat, which means not many training meetings are required to reach a usable performance level.

Note that the ROUGE scores are relative low when the reference summaries are human abstracts, even for evaluation among abstracts produced by different annotators (Dang, 2005). The intrinsic difference of styles between dialogue and human abstract further lowers the scores. But the trend is still respected among the systems.

**Abstract Generation Evaluation.** To evaluate the full abstract generation system, the BLEU score (Papineni et al., 2002) (the precision of unigrams and bigrams with a brevity penalty) is computed with human abstracts as reference. BLEU has a fairly good agreement with human judgement and has been used to evaluate a variety of language generation systems (Angeli et al., 2010; Konstas and Lapata, 2012).

<sup>4</sup>We use  $SVM^{light}$  (Joachims, 1999) with RBF kernel by default parameters for SVM-based classifiers and regressor.

<sup>5</sup>The four types of meetings in AMI are: project kick-off (35 meetings), functional design (35 meetings), conceptual design (35 meetings), and detailed design (34 meetings).

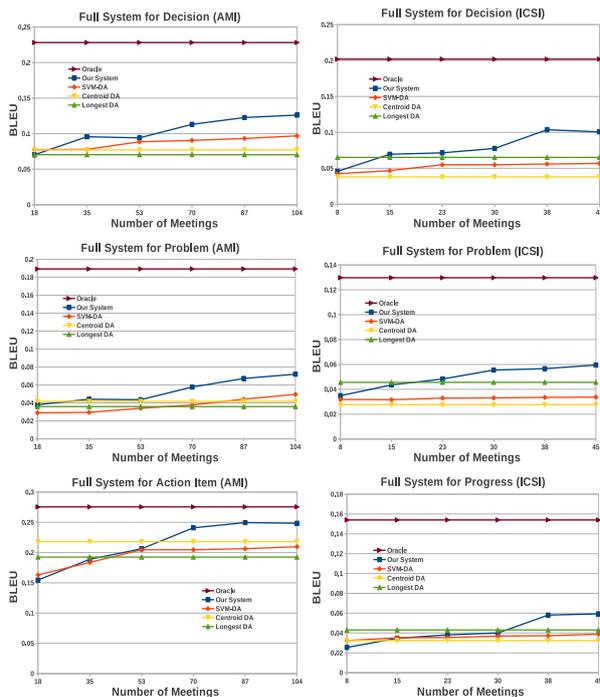

Figure 5: Full abstract generation system evaluation by using BLEU (multiplied by 100). SVM-DA denotes for supervised extractive methods with SVMs on utterance-level.

We are not aware of any existing work generating abstractive summaries for conversations. Therefore, we compare our full system against a supervised utterance-level extractive method based on SVMs along with the baselines. The BLEU scores in Figure 5 show that our system improves the scores consistently over the baselines and the SVM-based approach.

**Domain Adaptation Evaluation.** We further examine our system in domain adaptation scenarios for decision and problem summarization, where we train the system on AMI for use on ICSI, and vice versa. Table 3 indicates that, with both true clusterings and system clusterings, our system trained on out-of-domain data achieves comparable performance with the same system trained on in-domain data. In most experiments, it also significantly outperforms the baselines and the extract-based approaches ( $p < 0.05$ ).

**Human Evaluation.** We randomly select 15 decision and 15 problem DA clusters (true clusterings). We evaluate **fluency** (is the text grammatical?) and **semantic correctness** (does the summary convey the gist of the DAs in the cluster?) for OUR SYSTEM trained on IN-domain data

and OUT-of-domain data, and for the utterance-level extraction system (SVM-DA) trained on in-domain data. Each cluster of DAs along with three randomly ordered summaries are presented to the judges. Five native speaking Ph.D. students (none are authors) performed the task.

We carry out an one-way Analysis of Variance which shows significant differences in score as a function of system ( $p < 0.05$ , paired  $t$ -test). Results in Table 4 demonstrate that our system summaries are significantly more compact and fluent than the extract-based method ( $p < 0.05$ ) while semantic correctness is comparable.

The judges also **rank** the three summaries in terms of the overall quality in content, conciseness and grammaticality. An inter-rater agreement of Fleiss’s  $\kappa = 0.45$  (moderate agreement (Landis and Koch, 1977)) was computed. Judges selected our system as the best system in 62.3% scenarios (IN-DOMAIN: 35.6%, OUT-OF-DOMAIN: 26.7%). Sample summaries are exhibited in Figure 6.

## 8 Conclusion

We presented a domain-independent abstract generation framework for focused meeting summarization. Experimental results on two disparate meeting corpora show that our system can uni-

Decision Summary:
<b>Human:</b> The remote will have push buttons outside, and an LCD and spinning wheel inside.
<b>Our System (In):</b> The group decide to use an LCD display with a spinning wheel. There will be push-buttons on the outside.
<b>Our System (Out):</b> LCD display is going to be with a spinning wheel. It is necessary having push-buttons on the outside.
<b>SVM-DA:</b> Looking at what we’ve got, we we want an LCD display with a spinning wheel. Just spinning and not scrolling, I would say. I think the spinning wheel is definitely very now. We’re having push-buttons on the outside
Problem Summary:
<b>Human:</b> How to incorporate a fruit and vegetable theme into the remote.
<b>Our System (In):</b> Whether to include the shape of fruit. The team had to thinking bright colors.
<b>Our System (Out):</b> It is unclear that the buttons being in the shape of fruit.
<b>SVM-DA:</b> and um Im not sure about the buttons being in the shape of fruit though.

Figure 6: Sample decision and problem summaries generated by various systems for examples in Figure 1.

formly outperform the state-of-the-art supervised extraction-based systems in both automatic and manual evaluation. Our system also exhibits an ability to train on out-of-domain data to generate abstracts for a new target domain.

## 9 Acknowledgments

This work was supported in part by National Science Foundation Grant IIS-0968450 and a gift from Boeing. We thank Moontae Lee, Myle Ott, Yiye Ruan, Chenhao Tan, and the ACL reviewers for valuable suggestions and advice on various aspects of this work.
