Introduction

Welcome to the 2009 Conference on Empirical Methods in Natural Language Processing!

The conference is organized under the auspices of SIGDAT, the ACL Special Interest Group for linguistic data and corpus-based approaches to natural language processing. It is co-located this year with ACL-IJCNLP 2009 in Singapore.

EMNLP received 475 submissions, a new record. We were able to accept 163 papers in total (an acceptance rate of 34%). Of these, 96 (20%) were accepted for oral presentation, and 67 (14%) for poster presentation. The papers were selected by a program committee of 15 area chairs, from Asia, Europe, and North America, assisted by a panel of 389 reviewers. This year EMNLP again held an author response period. Authors were able to read and respond to the reviews of their paper before the program committee made a final decision. They were asked to correct factual errors in the reviews and answer questions raised in the reviewer comments.The intention was to help produce more accurate reviews. In some cases, reviewers changed their scores in view of the authors response and the area chairs read all responses carefully prior to making recommendations for acceptance.

First and foremost, we would like to thank the authors who submitted their work to EMNLP. The sheer number of submissions reflects how broad and active our field is. We are deeply indebted to the area chairs and the reviewers for their hard work. They enabled us to select an exciting program and to provide valuable feedback to the authors. Additional thanks to the Publications Chair, David Chiang, who put this volume together. Jason Eisner helped us immensely by compiling a web site on "How to Serve as Program Chair of a Conference."[1] Special thanks to David Yarowsky and Ken Church of SIGDAT who provided much valuable advice and assistance over the past months. We are akso grateful for the financial support from Microsoft.

We are most grateful to Haizhou Li who helped us with various logistic and organizational aspects of the conference. Rich Gerber and the START team responded to our questions quickly, and helped us manage the large number of submissions smoothly. Finally, thanks are due to our predecessors, Mirella Lapata and Hwee Tou Ng, whose experience and example we shamelessly exploited.

Philipp Koehn
Rada Mihalcea

[1] http://www.cs.jhu.edu/jason/advice/how-to-chair-a-conference.html

Program Co-Chairs:

Philipp Koehn, University of Edinburgh
Rada Mihalcea, University of North Texas

Area Chairs:

Stephen Clark, University of Cambridge
Mona Diab, Columbia University
Jason Eisner, Johns Hopkins University
Katrin Erk, University of Texas
Eric Fosler-Lussier, Ohio State University
Iryna Gurevych, Darmstadt University
Hang Li, Microsoft
Chin-Yew Lin, Microsoft
Adam Lopez, University of Edinburgh
Vivi Năstase, EML Research
Miles Osborne, University of Edinburgh
Tim Paek, Microsoft
Marius Paşca, Google
Carlo Strapparava, FBK-irst
Theresa Wilson, University of Edinburgh

Local Arrangements Chair:

Haizhou Li, Institute for Infocomm Research

Publications Chair:

David Chiang, USC Information Sciences Institute

Table of Contents

Conference Program

Thursday, August 06, 2009

8:45–9:00 Opening remarks

9:00–10:00 Invited Talk

10:00–10:30 Coffee Break

Session 1A (Theatre): Semantic Parsing

10:30–10:55 *Unsupervised Semantic Parsing*
Hoifung Poon and Pedro Domingos

10:55–11:20 *Graph Alignment for Semi-Supervised Semantic Role Labeling*
Hagen Fürstenau and Mirella Lapata

11:20–11:45 *Semi-supervised Semantic Role Labeling Using the Latent Words Language Model*
Koen Deschacht and Marie-Francine Moens

11:45–12:10 *Semantic Dependency Parsing of NomBank and PropBank: An Efficient Integrated Approach via a Large-scale Feature Selection*
Hai Zhao, Wenliang Chen and Chunyu Kit

Session 1B (MR208): Machine Translation I

10:30–10:55 *First- and Second-Order Expectation Semirings with Applications to Minimum-Risk Training on Translation Forests*
Zhifei Li and Jason Eisner

10:55–11:20 *Feasibility of Human-in-the-loop Minimum Error Rate Training*
Omar F. Zaidan and Chris Callison-Burch

11:20–11:45 *Cube Pruning as Heuristic Search*
Mark Hopkins and Greg Langmead

11:45–12:10 *Effective Use of Linguistic and Contextual Information for Statistical Machine Translation*
Libin Shen, Jinxi Xu, Bing Zhang, Spyros Matsoukas and Ralph Weischedel

Thursday, August 06, 2009 (continued)

Session 1C (MR209): Machine Learning and Statistical Models I

10:30–10:55 *Active Learning by Labeling Features*
Gregory Druck, Burr Settles and Andrew McCallum

10:55–11:20 *Efficient Kernels for Sentence Pair Classification*
Fabio Massimo Zanzotto and Lorenzo Dell'Arciprete

11:20–11:45 *Graphical Models over Multiple Strings*
Markus Dreyer and Jason Eisner

11:45–12:10 *Reverse Engineering of Tree Kernel Feature Spaces*
Daniele Pighin and Alessandro Moschitti

Session 1D (MR203): Information Extraction

10:30–10:55 *A Rich Feature Vector for Protein-Protein Interaction Extraction from Multiple Corpora*
Makoto Miwa, Rune Sætre, Yusuke Miyao and Jun'ichi Tsujii

10:55–11:20 *Generalized Expectation Criteria for Bootstrapping Extractors using Record-Text Alignment*
Kedar Bellare and Andrew McCallum

11:20–11:45 *Nested Named Entity Recognition*
Jenny Rose Finkel and Christopher D. Manning

11:45–12:10 *A Unified Model of Phrasal and Sentential Evidence for Information Extraction*
Siddharth Patwardhan and Ellen Riloff

12:10–13:50 Lunch

Thursday, August 06, 2009 (continued)

Session 2A (Theatre): Subjectivity and Sentiment I

13:50–14:15 *Review Sentiment Scoring via a Parse-and-Paraphrase Paradigm*
Jingjing Liu and Stephanie Seneff

14:15–14:40 *Supervised and Unsupervised Methods in Employing Discourse Relations for Improving Opinion Polarity Classification*
Swapna Somasundaran, Galileo Namata, Janyce Wiebe and Lise Getoor

14:40–15:05 *Sentiment Analysis of Conditional Sentences*
Ramanathan Narayanan, Bing Liu and Alok Choudhary

15:05–15:30 *Subjectivity Word Sense Disambiguation*
Cem Akkaya, Janyce Wiebe and Rada Mihalcea

Session 2B (MR208): Machine Translation II

13:50–14:15 *Non-Projective Parsing for Statistical Machine Translation*
Xavier Carreras and Michael Collins

14:15–14:40 *Extending Statistical Machine Translation with Discriminative and Trigger-Based Lexicon Models*
Arne Mauser, Saša Hasan and Hermann Ney

14:40–15:05 *Feature-Rich Translation by Quasi-Synchronous Lattice Parsing*
Kevin Gimpel and Noah A. Smith

15:05–15:30 *Improved Word Alignment with Statistics and Linguistic Heuristics*
Ulf Hermjakob

Thursday, August 06, 2009 (continued)

Session 2C (MR209): Natural Language Processing for Web 2.0

13:50–14:15 *Entity Extraction via Ensemble Semantics*
Marco Pennacchiotti and Patrick Pantel

14:15–14:40 *Labeled LDA: A Supervised Topic Model for Credit Attribution in Multi-labeled Corpora*
Daniel Ramage, David Hall, Ramesh Nallapati and Christopher D. Manning

14:40–15:05 *Clustering to Find Exemplar Terms for Keyphrase Extraction*
Zhiyuan Liu, Peng Li, Yabin Zheng and Maosong Sun

15:05–15:30 *Geo-mining: Discovery of Road and Transport Networks Using Directional Patterns*
Dmitry Davidov and Ari Rappoport

Session 2D (MR203): Language Resources and Evaluation

13:50–14:15 *Wikipedia as Frame Information Repository*
Sara Tonelli and Claudio Giuliano

14:15–14:40 *Fast, Cheap, and Creative: Evaluating Translation Quality Using Amazon's Mechanical Turk*
Chris Callison-Burch

14:40–15:05 *How Well Does Active Learning* Actually *Work? Time-based Evaluation of Cost-reduction Strategies for Language Documentation*
Jason Baldridge and Alexis Palmer

15:05–15:30 *Automatically Evaluating Content Selection in Summarization without Human Models*
Annie Louis and Ani Nenkova

15:30–16:00 Coffee Break

Thursday, August 06, 2009 (continued)

Session 3A (Theatre): Discourse and Dialogue

16:00–16:25 *Classifier Combination for Contextual Idiom Detection Without Labelled Data*
Linlin Li and Caroline Sporleder

16:25–16:50 *Deriving Lexical and Syntactic Expectation-based Measures for Psycholinguistic Modeling via Incremental Top-down Parsing*
Brian Roark, Asaf Bachrach, Carlos Cardenas and Christophe Pallier

16:50–17:15 *It's Not You, it's Me: Detecting Flirting and its Misperception in Speed-Dates*
Rajesh Ranganath, Dan Jurafsky and Dan McFarland

17:15–17:40 *Recognizing Implicit Discourse Relations in the Penn Discourse Treebank*
Ziheng Lin, Min-Yen Kan and Hwee Tou Ng

Session 3B (MR208): Machine Translation III

16:00–16:25 *A Bayesian Model of Syntax-Directed Tree to String Grammar Induction*
Trevor Cohn and Phil Blunsom

16:25–16:50 *Better Synchronous Binarization for Machine Translation*
Tong Xiao, Mu Li, Dongdong Zhang, Jingbo Zhu and Ming Zhou

16:50–17:15 *Accuracy-Based Scoring for DOT: Towards Direct Error Minimization for Data-Oriented Translation*
Daniel Galron, Sergio Penkale, Andy Way and I. Dan Melamed

17:15–17:40 *Improved Statistical Machine Translation Using Monolingually-Derived Paraphrases*
Yuval Marton, Chris Callison-Burch and Philip Resnik

Thursday, August 06, 2009 (continued)

Session 3C (MR209): Summarization and Generation

16:00–16:25 *A Comparison of Model Free versus Model Intensive Approaches to Sentence Compression*
Tadashi Nomoto

16:25–16:50 *Natural Language Generation with Tree Conditional Random Fields*
Wei Lu, Hwee Tou Ng and Wee Sun Lee

16:50–17:15 *Perceptron Reranking for CCG Realization*
Michael White and Rajakrishnan Rajkumar

17:15–17:40 *Multi-Document Summarisation Using Generic Relation Extraction*
Ben Hachey

Session 3D (MR203): Lexical Semantics I

16:00–16:25 *Language Models Based on Semantic Composition*
Jeff Mitchell and Mirella Lapata

16:25–16:50 *Graded Word Sense Assignment*
Katrin Erk and Diana McCarthy

16:50–17:15 *Joint Learning of Preposition Senses and Semantic Roles of Prepositional Phrases*
Daniel Dahlmeier, Hwee Tou Ng and Tanja Schultz

17:15–17:40 *Projecting Parameters for Multilingual Word Sense Disambiguation*
Mitesh M. Khapra, Sapan Shah, Piyush Kedia and Pushpak Bhattacharyya

Thursday, August 06, 2009 (continued)

18:00–20:00 **Poster Session and Reception**

Gazpacho and Summer Rash: Lexical Relationships from Temporal Patterns of Web Search Queries
Enrique Alfonseca, Massimiliano Ciaramita and Keith Hall

A Compact Forest for Scalable Inference over Entailment and Paraphrase Rules
Roy Bar-Haim, Jonathan Berant and Ido Dagan

Discriminative Substring Decoding for Transliteration
Colin Cherry and Hisami Suzuki

Re-Ranking Models Based-on Small Training Data for Spoken Language Understanding
Marco Dinarelli, Alessandro Moschitti and Giuseppe Riccardi

Empirical Exploitation of Click Data for Task Specific Ranking
Anlei Dong, Yi Chang, Shihao Ji, Ciya Liao, Xin Li and Zhaohui Zheng

The Feature Subspace Method for SMT System Combination
Nan Duan, Mu Li, Tong Xiao and Ming Zhou

Lattice-based System Combination for Statistical Machine Translation
Yang Feng, Yang Liu, Haitao Mi, Qun Liu and Yajuan Lü

A Joint Language Model With Fine-grain Syntactic Tags
Denis Filimonov and Mary Harper

Bidirectional Phrase-based Statistical Machine Translation
Andrew Finch and Eiichiro Sumita

Real-time Decision Detection in Multi-party Dialogue
Matthew Frampton, Jia Huang, Trung Bui and Stanley Peters

On the Role of Lexical Features in Sequence Labeling
Yoav Goldberg and Michael Elhadad

Thursday, August 06, 2009 (continued)

18:00–20:00 **Poster Session and Reception (continued)**

Simple Coreference Resolution with Rich Syntactic and Semantic Features
Aria Haghighi and Dan Klein

Descriptive and Empirical Approaches to Capturing Underlying Dependencies among Parsing Errors
Tadayoshi Hara, Yusuke Miyao and Jun'ichi Tsujii

Large-Scale Verb Entailment Acquisition from the Web
Chikara Hashimoto, Kentaro Torisawa, Kow Kuroda, Stijn De Saeger, Masaki Murata and Jun'ichi Kazama

A Syntactified Direct Translation Model with Linear-time Decoding
Hany Hassan, Khalil Sima'an and Andy Way

Cross-lingual Semantic Relatedness Using Encyclopedic Knowledge
Samer Hassan and Rada Mihalcea

Joint Optimization for Machine Translation System Combination
Xiaodong He and Kristina Toutanova

Fully Lexicalising CCGbank with Hat Categories
Matthew Honnibal and James R. Curran

Bilingually-Constrained (Monolingual) Shift-Reduce Parsing
Liang Huang, Wenbin Jiang and Qun Liu

Accurate Semantic Class Classifier for Coreference Resolution
Zhiheng Huang, Guangping Zeng, Weiqun Xu and Asli Celikyilmaz

Real-Word Spelling Correction using Google Web 1T 3-grams
Aminul Islam and Diana Inkpen

Semi-supervised Speech Act Recognition in Emails and Forums
Minwoo Jeong, Chin-Yew Lin and Gary Geunbae Lee

Thursday, August 06, 2009 (continued)

18:00–20:00 **Poster Session and Reception (continued)**

Using Morphological and Syntactic Structures for Chinese Opinion Analysis
Lun-Wei Ku, Ting-Hao Huang and Hsin-Hsi Chen

Finding Short Definitions of Terms on Web Pages
Gerasimos Lampouras and Ion Androutsopoulos

Improving Nominal SRL in Chinese Language with Verbal SRL Information and Automatic Predicate Recognition
Junhui Li, Guodong Zhou, Hai Zhao, Qiaoming Zhu and Peide Qian

On the Use of Virtual Evidence in Conditional Random Fields
Xiao Li

Refining Grammars for Parsing with Hierarchical Semantic Knowledge
Xiaojun Lin, Yang Fan, Meng Zhang, Xihong Wu and Huisheng Chi

Bayesian Learning of Phrasal Tree-to-String Templates
Ding Liu and Daniel Gildea

Human-competitive Tagging Using Automatic Keyphrase Extraction
Olena Medelyan, Eibe Frank and Ian H. Witten

Supervised Learning of a Probabilistic Lexicon of Verb Semantic Classes
Yusuke Miyao and Jun'ichi Tsujii

A Study on the Semantic Relatedness of Query and Document Terms in Information Retrieval
Christof Müller and Iryna Gurevych

Predicting Subjectivity in Multimodal Conversations
Gabriel Murray and Giuseppe Carenini

Improved Statistical Machine Translation for Resource-Poor Languages Using Related Resource-Rich Languages
Preslav Nakov and Hwee Tou Ng

Thursday, August 06, 2009 (continued)

18:00–20:00 **Poster Session and Reception (continued)**

What's in a Name? In Some Languages, Grammatical Gender
Vivi Nastase and Marius Popescu

Convolution Kernels on Constituent, Dependency and Sequential Structures for Relation Extraction
Truc-Vien T. Nguyen, Alessandro Moschitti and Giuseppe Riccardi

Automatic Acquisition of the Argument-Predicate *Relations from a Frame-Annotated Corpus*
Ekaterina Ovchinnikova, Theodore Alexandrov and Tonio Wandmacher

Detecting Speculations and their Scopes in Scientific Text
Arzucan Özgür and Dragomir R. Radev

Cross-Cultural Analysis of Blogs and Forums with Mixed-Collection Topic Models
Michael Paul and Roxana Girju

Consensus Training for Consensus Decoding in Machine Translation
Adam Pauls, John Denero and Dan Klein

Using Word-Sense Disambiguation Methods to Classify Web Queries by Intent
Emily Pitler and Ken Church

Semi-Supervised Learning for Semantic Relation Classification using Stratified Sampling Strategy
Longhua Qian, Guodong Zhou, Fang Kong and Qiaoming Zhu

Construction of a Blog Emotion Corpus for Chinese Emotional Expression Analysis
Changqin Quan and Fuji Ren

A Probabilistic Model for Associative Anaphora Resolution
Ryohei Sasano and Sadao Kurohashi

Quantifier Scope Disambiguation Using Extracted Pragmatic Knowledge: Preliminary Results
Prakash Srinivasan and Alexander Yates

Thursday, August 06, 2009 (continued)

18:00–20:00 **Poster Session and Reception (continued)**

Chinese Semantic Role Labeling with Shallow Parsing
Weiwei Sun, Zhifang Sui, Meng Wang and Xin Wang

Discovery of Term Variation in Japanese Web Search Queries
Hisami Suzuki, Xiao Li and Jianfeng Gao

Towards Domain-Independent Argumentative Zoning: Evidence from Chemistry and Computational Linguistics
Simone Teufel, Advaith Siddharthan and Colin Batchelor

Character-level Analysis of Semi-Structured Documents for Set Expansion
Richard C. Wang and William W. Cohen

Classifying Relations for Biomedical Named Entity Disambiguation
Xinglong Wang, Jun'ichi Tsujii and Sophia Ananiadou

Domain adaptive bootstrapping for named entity recognition
Dan Wu, Wee Sun Lee, Nan Ye and Hai Leong Chieu

Phrase Dependency Parsing for Opinion Mining
Yuanbin Wu, Qi Zhang, Xuangjing Huang and Lide Wu

Polynomial to Linear: Efficient Classification with Conjunctive Features
Naoki Yoshinaga and Masaru Kitsuregawa

K-Best Combination of Syntactic Parsers
Hui Zhang, Min Zhang, Chew Lim Tan and Haizhou Li

Chinese Novelty Mining
Yi Zhang and Flora S. Tsai

Latent Document Re-Ranking
Dong Zhou and Vincent Wade

Friday, August 07, 2009

Session 4A (Theatre): Multi-word Expressions

8:45–9:10 *Multi-Word Expression Identification Using Sentence Surface Features*
Ram Boukobza and Ari Rappoport

9:10–9:35 *Acquiring Translation Equivalences of Multiword Expressions by Normalized Correlation Frequencies*
Ming-Hong Bai, Jia-Ming You, Keh-Jiann Chen and Jason S. Chang

9:35–10:00 *Collocation Extraction Using Monolingual Word Alignment Method*
Zhanyi Liu, Haifeng Wang, Hua Wu and Sheng Li

Session 4B (MR208): Machine Learning and Statistical Models II

8:45–9:10 *Multi-Class Confidence Weighted Algorithms*
Koby Crammer, Mark Dredze and Alex Kulesza

9:10–9:35 *Model Adaptation via Model Interpolation and Boosting for Web Search Ranking*
Jianfeng Gao, Qiang Wu, Chris Burges, Krysta Svore, Yi Su, Nazan Khan, Shalin Shah and Hongyan Zhou

9:35–10:00 *A Structural Support Vector Method for Extracting Contexts and Answers of Questions from Online Forums*
Wen-Yun Yang, Yunbo Cao and Chin-Yew Lin

Session 4C (MR209): Information Retrieval and Questions Answering

8:45–9:10 *Mining Search Engine Clickthrough Log for Matching N-gram Features*
Huihsin Tseng, Longbin Chen, Fan Li, Ziming Zhuang, Lei Duan and Belle Tseng

9:10–9:35 *The Role of Named Entities in Web People Search*
Javier Artiles, Enrique Amigó and Julio Gonzalo

9:35–10:00 *Investigation of Question Classifier in Question Answering*
Zhiheng Huang, Marcus Thint and Asli Celikyilmaz

Friday, August 07, 2009 (continued)

Session 4D (MR203): Syntax and Parsing I

8:45–9:10 *An Empirical Study of Semi-supervised Structured Conditional Models for Dependency Parsing*
Jun Suzuki, Hideki Isozaki, Xavier Carreras and Michael Collins

9:10–9:35 *Statistical Bistratal Dependency Parsing*
Richard Johansson

9:35–10:00 *Improving Dependency Parsing with Subtrees from Auto-Parsed Data*
Wenliang Chen, Jun'ichi Kazama, Kiyotaka Uchimoto and Kentaro Torisawa

10:00–10:30 Coffee Break

Session 5A (Theatre): Subjectivity and Sentiment II

10:30–10:55 *Topic-wise, Sentiment-wise, or Otherwise? Identifying the Hidden Dimension for Unsupervised Text Classification*
Sajib Dasgupta and Vincent Ng

10:55–11:20 *Adapting a Polarity Lexicon using Integer Linear Programming for Domain-Specific Sentiment Classification*
Yejin Choi and Claire Cardie

11:20–11:45 *Generating High-Coverage Semantic Orientation Lexicons From Overtly Marked Words and a Thesaurus*
Saif Mohammad, Cody Dunne and Bonnie Dorr

11:45–12:10 *Matching Reviews to Objects using a Language Model*
Nilesh Dalvi, Ravi Kumar, Bo Pang and Andrew Tomkins

Friday, August 07, 2009 (continued)

Session 5B (MR208): Lexical Semantics II

10:30–10:55 *EEG Responds to Conceptual Stimuli and Corpus Semantics*
Brian Murphy, Marco Baroni and Massimo Poesio

10:55–11:20 *A Comparison of Windowless and Window-Based Computational Association Measures as Predictors of Syntagmatic Human Associations*
Justin Washtell and Katja Markert

11:20–11:45 *Improving Verb Clustering with Automatically Acquired Selectional Preferences*
Lin Sun and Anna Korhonen

11:45–12:10 *Improving Web Search Relevance with Semantic Features*
Yumao Lu, Fuchun Peng, Gilad Mishne, Xing Wei and Benoit Dumoulin

Session 5C (MR209): Phonology and Morphology

10:30–10:55 *Can Chinese Phonemes Improve Machine Transliteration?: A Comparative Study of English-to-Chinese Transliteration Models*
Jong-Hoon Oh, Kiyotaka Uchimoto and Kentaro Torisawa

10:55–11:20 *Unsupervised Morphological Segmentation and Clustering with Document Boundaries*

Abstract

We present the first unsupervised approach to the problem of learning a semantic parser, using Markov logic. Our USP system transforms dependency trees into quasi-logical forms, recursively induces lambda forms from these, and clusters them to abstract away syntactic variations of the same meaning. The MAP semantic parse of a sentence is obtained by recursively assigning its parts to lambda-form clusters and composing them. We evaluate our approach by using it to extract a knowledge base from biomedical abstracts and answer questions. USP substantially outperforms TextRunner, DIRT and an informed baseline on both precision and recall on this task.

1 Introduction

Semantic parsing maps text to formal meaning representations. This contrasts with semantic role labeling (Carreras and Marquez, 2004) and other forms of shallow semantic processing, which do not aim to produce complete formal meanings. Traditionally, semantic parsers were constructed manually, but this is too costly and brittle. Recently, a number of machine learning approaches have been proposed (Zettlemoyer and Collins, 2005; Mooney, 2007). However, they are supervised, and providing the target logical form for each sentence is costly and difficult to do consistently and with high quality. Unsupervised approaches have been applied to shallow semantic tasks (e.g., paraphrasing (Lin and Pantel, 2001), information extraction (Banko et al., 2007)), but not to semantic parsing.

In this paper we develop the first unsupervised approach to semantic parsing, using Markov logic (Richardson and Domingos, 2006). Our USP system starts by clustering tokens of the same type, and then recursively clusters expressions whose subexpressions belong to the same clusters. Experiments on a biomedical corpus show that this approach is able to successfully translate syntactic variations into a logical representation of their common meaning (e.g., USP learns to map active and passive voice to the same logical form, etc.). This in turn allows it to correctly answer many more questions than systems based on TextRunner (Banko et al., 2007) and DIRT (Lin and Pantel, 2001).

We begin by reviewing the necessary background on semantic parsing and Markov logic. We then describe our Markov logic network for unsupervised semantic parsing, and the learning and inference algorithms we used. Finally, we present our experiments and results.

2 Background

2.1 Semantic Parsing

The standard language for formal meaning representation is first-order logic. A term is any expression representing an object in the domain. An atomic formula or atom is a predicate symbol applied to a tuple of terms. Formulas are recursively constructed from atomic formulas using logical connectives and quantifiers. A *lexical entry* defines the logical form for a lexical item (e.g., a word). The semantic parse of a sentence is derived by starting with logical forms in the lexical entries and recursively composing the meaning of larger fragments from their parts. In traditional approaches, the lexical entries and meaning-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 1–10,
Singapore, 6-7 August 2009.

composition rules are both manually constructed. Below are sample rules in a definite clause grammar (DCG) for parsing the sentence: "Utah borders Idaho".

$$Verb[\lambda \mathtt{y} \lambda \mathtt{x}.\mathtt{borders}(\mathtt{x},\mathtt{y})] \rightarrow borders$$
$$NP[\mathtt{Utah}] \rightarrow Utah$$
$$NP[\mathtt{Idaho}] \rightarrow Idaho$$
$$VP[\mathtt{rel}(\mathtt{obj})] \rightarrow Verb[\mathtt{rel}] \quad NP[\mathtt{obj}]$$
$$S[\mathtt{rel}(\mathtt{obj})] \rightarrow NP[\mathtt{obj}] \quad VP[\mathtt{rel}]$$

The first three lines are lexical entries. They are fired upon seeing the individual words. For example, the first rule applies to the word "borders" and generates syntactic category *Verb* with the meaning $\lambda \mathtt{y} \lambda \mathtt{x}.\mathtt{borders}(\mathtt{x},\mathtt{y})$ that represents the next-to relation. Here, we use the standard lambda-calculus notation, where $\lambda \mathtt{y} \lambda \mathtt{x}.\mathtt{borders}(\mathtt{x},\mathtt{y})$ represents a function that is true for any $(\mathtt{x},\mathtt{y})$-pair such that $\mathtt{borders}(\mathtt{x},\mathtt{y})$ holds. The last two rules compose the meanings of sub-parts into that of the larger part. For example, after the first and third rules are fired, the fourth rule fires and generates $VP[\lambda \mathtt{y} \lambda \mathtt{x}.\mathtt{borders}(\mathtt{x},\mathtt{y})(\mathtt{Idaho})]$; this meaning simplifies to $\lambda \mathtt{x}.\mathtt{borders}(\mathtt{x},\mathtt{Idaho})$ by the *λ-reduction rule*, which substitutes the argument for a variable in a functional application.

A major challenge to semantic parsing is syntactic variations of the same meaning, which abound in natural languages. For example, the aforementioned sentence can be rephrased as "Utah is next to Idaho,""Utah shares a border with Idaho," etc. Manually encoding all these variations into the grammar is tedious and error-prone. Supervised semantic parsing addresses this issue by learning to construct the grammar automatically from sample meaning annotations (Mooney, 2007). Existing approaches differ in the meaning representation languages they use and the amount of annotation required. In the approach of Zettlemoyer and Collins (2005), the training data consists of sentences paired with their meanings in lambda form. A probabilistic combinatory categorial grammar (PCCG) is learned using a log-linear model, where the probability of the final logical form L and meaning-derivation tree T conditioned on the sentence S is $P(L,T|S) = \frac{1}{Z}\exp\left(\sum_i w_i f_i(L,T,S)\right)$. Here Z is the normalization constant and f_i are the feature functions with weights w_i. Candidate lexical entries are generated by a domain-specific procedure based on the target logical forms.

The major limitation of supervised approaches is that they require meaning annotations for example sentences. Even in a restricted domain, doing this consistently and with high quality requires nontrivial effort. For unrestricted text, the complexity and subjectivity of annotation render it essentially infeasible; even pre-specifying the target predicates and objects is very difficult. Therefore, to apply semantic parsing beyond limited domains, it is crucial to develop unsupervised methods that do not rely on labeled meanings.

In the past, unsupervised approaches have been applied to some semantic tasks, but not to semantic parsing. For example, DIRT (Lin and Pantel, 2001) learns paraphrases of binary relations based on distributional similarity of their arguments; TextRunner (Banko et al., 2007) automatically extracts relational triples in open domains using a self-trained extractor; SNE applies relational clustering to generate a semantic network from TextRunner triples (Kok and Domingos, 2008). While these systems illustrate the promise of unsupervised methods, the semantic content they extract is nonetheless shallow and does not constitute the complete formal meaning that can be obtained by a semantic parser.

Another issue is that existing approaches to semantic parsing learn to parse syntax and semantics together.[1] The drawback is that the complexity in syntactic processing is coupled with semantic parsing and makes the latter even harder. For example, when applying their approach to a different domain with somewhat less rigid syntax, Zettlemoyer and Collins (2007) need to introduce new combinators and new forms of candidate lexical entries. Ideally, we should leverage the enormous progress made in syntactic parsing and generate semantic parses directly from syntactic analysis.

2.2 Markov Logic

In many NLP applications, there exist rich relations among objects, and recent work in statistical relational learning (Getoor and Taskar, 2007) and structured prediction (Bakir et al., 2007) has shown that leveraging these can greatly improve accuracy. One of the most powerful representations for this is Markov logic, which is a probabilistic extension of first-order logic (Richardson and Domingos, 2006). Markov logic makes it

[1] The only exception that we are aware of is Ge and Mooney (2009).

possible to compactly specify probability distributions over complex relational domains, and has been successfully applied to unsupervised coreference resolution (Poon and Domingos, 2008) and other tasks. A *Markov logic network (MLN)* is a set of weighted first-order clauses. Together with a set of constants, it defines a Markov network with one node per ground atom and one feature per ground clause. The weight of a feature is the weight of the first-order clause that originated it. The probability of a state x in such a network is given by the log-linear model $P(x) = \frac{1}{Z} \exp\left(\sum_i w_i n_i(x)\right)$, where Z is a normalization constant, w_i is the weight of the ith formula, and n_i is the number of satisfied groundings.

3 Unsupervised Semantic Parsing with Markov Logic

Unsupervised semantic parsing (**USP**) rests on three key ideas. First, the target predicate and object constants, which are pre-specified in supervised semantic parsing, can be viewed as clusters of syntactic variations of the same meaning, and can be learned from data. For example, `borders` represents the next-to relation, and can be viewed as the cluster of different forms for expressing this relation, such as "borders", "is next to", "share the border with"; `Utah` represents the state of Utah, and can be viewed as the cluster of "Utah", "the beehive state", etc.

Second, the identification and clustering of candidate forms are integrated with the learning for meaning composition, where forms that are used in composition with the same forms are encouraged to cluster together, and so are forms that are composed of the same sub-forms. This amounts to a novel form of relational clustering, where clustering is done not just on fixed elements in relational tuples, but on arbitrary forms that are built up recursively.

Third, while most existing approaches (manual or supervised learning) learn to parse both syntax and semantics, unsupervised semantic parsing starts directly from syntactic analyses and focuses solely on translating them to semantic content. This enables us to leverage advanced syntactic parsers and (indirectly) the available rich resources for them. More importantly, it separates the complexity in syntactic analysis from the semantic one, and makes the latter much easier to perform. In particular, meaning composition does not require domain-specific procedures for generating candidate lexicons, as is often needed by supervised methods.

The input to our USP system consists of dependency trees of training sentences. Compared to phrase-structure syntax, dependency trees are the more appropriate starting point for semantic processing, as they already exhibit much of the relation-argument structure at the lexical level.

USP first uses a deterministic procedure to convert dependency trees into quasi-logical forms (QLFs). The QLFs and their sub-formulas have natural lambda forms, as will be described later. Starting with clusters of lambda forms at the atom level, USP recursively builds up clusters of larger lambda forms. The final output is a probability distribution over lambda-form clusters and their compositions, as well as the MAP semantic parses of training sentences.

In the remainder of the section, we describe the details of USP. We first present the procedure for generating QLFs from dependency trees. We then introduce their lambda forms and clusters, and show how semantic parsing works in this setting. Finally, we present the Markov logic network (MLN) used by USP. In the next sections, we present efficient algorithms for learning and inference with this MLN.

3.1 Derivation of Quasi-Logical Forms

A *dependency tree* is a tree where nodes are words and edges are dependency labels. To derive the QLF, we convert each node to an unary atom with the predicate being the lemma plus POS tag (below, we still use the word for simplicity), and each edge to a binary atom with the predicate being the dependency label. For example, the node for Utah becomes $\texttt{Utah}(\texttt{n}_1)$ and the subject dependency becomes $\texttt{nsubj}(\texttt{n1}, \texttt{n2})$. Here, the $\texttt{n}_\texttt{i}$ are Skolem constants indexed by the nodes. The QLF for a sentence is the conjunction of the atoms for the nodes and edges, e.g., the sentence above will become $\texttt{borders}(\texttt{n}_1) \wedge \texttt{Utah}(\texttt{n}_2) \wedge \texttt{Idaho}(\texttt{n}_3) \wedge \texttt{nsubj}(\texttt{n}_1, \texttt{n}_2) \wedge \texttt{dobj}(\texttt{n}_1, \texttt{n}_3)$.

3.2 Lambda-Form Clusters and Semantic Parsing in USP

Given a QLF, a relation or an object is represented by the conjunction of a subset of the atoms. For example, the next-to relation is represented by $\texttt{borders}(\texttt{n}_1) \wedge \texttt{nsubj}(\texttt{n}_1, \texttt{n}_2) \wedge \texttt{dobj}(\texttt{n}_1, \texttt{n}_3)$, and the states of Utah and Idaho are represented

by $\texttt{Utah}(\texttt{n}_2)$ and $\texttt{Idaho}(\texttt{n}_3)$. The meaning composition of two sub-formulas is simply their conjunction. This allows the maximum flexibility in learning. In particular, lexical entries are no longer limited to be adjacent words as in Zettlemoyer and Collins (2005), but can be arbitrary fragments in a dependency tree.

For every sub-formula F, we define a corresponding lambda form that can be derived by replacing every Skolem constant $\texttt{n}_\texttt{i}$ that does not appear in any unary atom in F with a unique lambda variable $\texttt{x}_\texttt{i}$. Intuitively, such constants represent objects introduced somewhere else (by the unary atoms containing them), and correspond to the arguments of the relation represented by F. For example, the lambda form for $\texttt{borders}(\texttt{n}_1) \wedge \texttt{nsubj}(\texttt{n}_1, \texttt{n}_2) \wedge \texttt{dobj}(\texttt{n}_1, \texttt{n}_3)$ is $\lambda\texttt{x}_2\lambda\texttt{x}_3.\ \texttt{borders}(\texttt{n}_1) \wedge \texttt{nsubj}(\texttt{n}_1, \texttt{x}_2) \wedge \texttt{dobj}(\texttt{n}_1, \texttt{x}_3)$.

Conceptually, a lambda-form cluster is a set of semantically interchangeable lambda forms. For example, to express the meaning that Utah borders Idaho, we can use any form in the cluster representing the next-to relation (e.g., "borders", "shares a border with"), any form in the cluster representing the state of Utah (e.g., "the beehive state"), and any form in the cluster representing the state of Idaho (e.g., "Idaho"). Conditioned on the clusters, the choices of individual lambda forms are independent of each other.

To handle variable number of arguments, we follow Davidsonian semantics and further decompose a lambda form into the *core form*, which does not contain any lambda variable (e.g., $\texttt{borders}(\texttt{n}_1)$), and the *argument forms*, which contain a single lambda variable (e.g., $\lambda\texttt{x}_2.\texttt{nsubj}(\texttt{n}_1, \texttt{x}_2)$ and $\lambda\texttt{x}_3.\texttt{dobj}(\texttt{n}_1, \texttt{x}_3)$). Each lambda-form cluster may contain some number of *argument types*, which cluster distinct forms of the same argument in a relation. For example, in Stanford dependencies, the object of a verb uses the dependency `dobj` in the active voice, but `nsubjpass` in passive.

Lambda-form clusters abstract away syntactic variations of the same meaning. Given an instance of cluster $\texttt{T}$ with arguments of argument types $\texttt{A}_1, \cdots, \texttt{A}_\texttt{k}$, its *abstract lambda form* is given by $\lambda\texttt{x}_1 \cdots \lambda\texttt{x}_\texttt{k}.\texttt{T}(\texttt{n}) \wedge \bigwedge_{\texttt{i}=1}^{\texttt{k}} \texttt{A}_\texttt{i}(\texttt{n}, \texttt{x}_\texttt{i})$.

Given a sentence and its QLF, semantic parsing amounts to partitioning the atoms in the QLF, dividing each part into core form and argument forms, and then assigning each form to a cluster or an argument type. The final logical form is derived by composing the abstract lambda forms of the parts using the λ-reduction rule.[2]

3.3 The USP MLN

Formally, for a QLF Q, a semantic parse L partitions Q into parts $\texttt{p}_1, \texttt{p}_2, \cdots, \texttt{p}_\texttt{n}$; each part $\texttt{p}$ is assigned to some lambda-form cluster $\texttt{c}$, and is further partitioned into core form $\texttt{f}$ and argument forms $\texttt{f}_1, \cdots, \texttt{f}_\texttt{k}$; each argument form is assigned to an argument type $\texttt{a}$ in $\texttt{c}$. The USP MLN defines a joint probability distribution over Q and L by modeling the distributions over forms and arguments given the cluster or argument type.

Before presenting the predicates and formulas in our MLN, we should emphasize that they should not be confused with the atoms and formulas in the QLFs, which are represented by reified constants and variables.

To model distributions over lambda forms, we introduce the predicates $\texttt{Form}(\texttt{p}, \texttt{f}!)$ and $\texttt{ArgForm}(\texttt{p}, \texttt{i}, \texttt{f}!)$, where $\texttt{p}$ is a part, $\texttt{i}$ is the index of an argument, and $\texttt{f}$ is a QLF subformula. $\texttt{Form}(\texttt{p}, \texttt{f})$ is true iff part $\texttt{p}$ has core form $\texttt{f}$, and $\texttt{ArgForm}(\texttt{p}, \texttt{i}, \texttt{f})$ is true iff the $\texttt{i}$th argument in $\texttt{p}$ has form $\texttt{f}$.[3] The "$\texttt{f}!$" notation signifies that each part or argument can have only one form.

To model distributions over arguments, we introduce three more predicates: $\texttt{ArgType}(\texttt{p}, \texttt{i}, \texttt{a}!)$ signifies that the $\texttt{i}$th argument of $\texttt{p}$ is assigned to argument type $\texttt{a}$; $\texttt{Arg}(\texttt{p}, \texttt{i}, \texttt{p}')$ signifies that the $\texttt{i}$th argument of $\texttt{p}$ is $\texttt{p}'$; $\texttt{Number}(\texttt{p}, \texttt{a}, \texttt{n})$ signifies that there are $\texttt{n}$ arguments of $\texttt{p}$ that are assigned to type $\texttt{a}$. The truth value of $\texttt{Number}(\texttt{p}, \texttt{a}, \texttt{n})$ is determined by the `ArgType` atoms.

Unsupervised semantic parsing can be captured by four formulas:

$$\texttt{p} \in +\texttt{c} \wedge \texttt{Form}(\texttt{p}, +\texttt{f})$$
$$\texttt{ArgType}(\texttt{p}, \texttt{i}, +\texttt{a}) \wedge \texttt{ArgForm}(\texttt{p}, \texttt{i}, +\texttt{f})$$
$$\texttt{Arg}(\texttt{p}, \texttt{i}, \texttt{p}') \wedge \texttt{ArgType}(\texttt{p}, \texttt{i}, +\texttt{a}) \wedge \texttt{p}' \in +\texttt{c}'$$
$$\texttt{Number}(\texttt{p}, +\texttt{a}, +\texttt{n})$$

All free variables are implicitly universally quantified. The "+" notation signifies that the MLN contains an instance of the formula, with a separate weight, for each value combination of the

[2] Currently, we do not handle quantifier scoping or semantics for specific closed-class words such as determiners. These will be pursued in future work.

[3] There are hard constraints to guarantee that these assignments form a legal partition. We omit them for simplicity.

variables with a plus sign. The first formula models the mixture of core forms given the cluster, and the others model the mixtures of argument forms, argument types, and argument numbers, respectively, given the argument type.

To encourage clustering and avoid overfitting, we impose an exponential prior with weight α on the number of parameters.[4]

The MLN above has one problem: it often clusters expressions that are semantically opposite. For example, it clusters antonyms like "elderly/young", "mature/immature". This issue also occurs in other semantic-processing systems (e.g., DIRT). In general, this is a difficult open problem that only recently has started to receive some attention (Mohammad et al., 2008). Resolving this is not the focus of this paper, but we describe a general heuristic for fixing this problem. We observe that the problem stems from the lack of negative features for discovering meanings in contrast. In natural languages, parallel structures like conjunctions are one such feature.[5] We thus introduce an exponential prior with weight β on the number of conjunctions where the two conjunctive parts are assigned to the same cluster. To detect conjunction, we simply used the Stanford dependencies that begin with "conj". This proves very effective, fixing the majority of the errors in our experiments.

4 Inference

Given a sentence and the quasi-logical form Q derived from its dependency tree, the conditional probability for a semantic parse L is given by $Pr(L|Q) \propto \exp\left(\sum_i w_i n_i(L,Q)\right)$. The MAP semantic parse is simply $\arg\max_L \sum_i w_i n_i(L,Q)$. Enumerating all L's is intractable. It is also unnecessary, since most partitions will result in parts whose lambda forms have no cluster they can be assigned to. Instead, USP uses a greedy algorithm to search for the MAP parse. First we introduce some definitions: a partition is called *λ-reducible from* $\mathtt{p}$ if it can be obtained from the current partition by recursively λ-reducing the part containing $\mathtt{p}$ with one of its arguments; such a partition is called *feasible* if the core form of the new part is contained in some cluster. For example, consider the QLF of "Utah borders Idaho" and assume that the current partition is $\lambda \mathtt{x}_2\mathtt{x}_3.\mathtt{borders}(\mathtt{n}_1) \wedge \mathtt{nsubj}(\mathtt{n}_1,\mathtt{x}_2) \wedge \mathtt{dobj}(\mathtt{n}_1,\mathtt{x}_3)$, $\mathtt{Utah}(\mathtt{n}_2)$, $\mathtt{Idaho}(\mathtt{n}_3)$. Then the following partition is λ-reducible from the first part in the above partition: $\lambda \mathtt{x}_3.\mathtt{borders}(\mathtt{n}_1) \wedge \mathtt{nsubj}(\mathtt{n}_1,\mathtt{n}_2) \wedge \mathtt{Utah}(\mathtt{n}_2) \wedge \mathtt{dobj}(\mathtt{n}_1,\mathtt{x}_3)$, $\mathtt{Idaho}(\mathtt{n}_3)$. Whether this new partition is feasible depends on whether the core form of the new part $\lambda \mathtt{x}_3.\mathtt{borders}(\mathtt{n}_1) \wedge \mathtt{nsubj}(\mathtt{n}_1,\mathtt{n}_2) \wedge \mathtt{Utah}(\mathtt{n}_2) \wedge \mathtt{dobj}(\mathtt{n}_1,\mathtt{x}_3)$ (i.e. $\mathtt{borders}(\mathtt{n}_1) \wedge \mathtt{nsubj}(\mathtt{n}_1,\mathtt{n}_2) \wedge \mathtt{Utah}(\mathtt{n}_2)$) is contained in some lambda-form cluster.

Algorithm 1 USP-Parse(*MLN, QLF*)

```
Form parts for individual atoms in QLF and assign each to its most probable cluster
repeat
  for all parts p in the current partition do
    for all partitions that are λ-reducible from p and feasible do
      Find the most probable cluster and argument type assignments for the new part and its arguments
    end for
  end for
  Change to the new partition and assignments with the highest gain in probability
until none of these improve the probability
return current partition and assignments
```

Algorithm 1 gives pseudo-code for our algorithm. Given part $\mathtt{p}$, finding partitions that are λ-reducible from $\mathtt{p}$ and feasible can be done in time $O(ST)$, where S is the size of the clustering in the number of core forms and T is the maximum number of atoms in a core form. We omit the proof here but point out that it is related to the unordered subtree matching problem which can be solved in linear time (Kilpelainen, 1992). Inverted indexes (e.g., from $\mathtt{p}$ to eligible core forms) are used to further improve the efficiency. For a new part $\mathtt{p}$ and a cluster that contains $\mathtt{p}$'s core form, there are k^m ways of assigning $\mathtt{p}$'s m arguments to the k argument types of the cluster. For larger k and m, this is very expensive. We therefore approximate it by assigning each argument to the best type, independent of other arguments.

This algorithm is very efficient, and is used repeatedly in learning.

[4] Excluding weights of ∞ or $-\infty$, which signify hard constraints.

[5] For example, in the sentence "IL-2 inhibits X in A and induces Y in B", the conjunction between "inhibits" and "induces" suggests that they are different. If "inhibits" and "induces" are indeed synonyms, such a sentence will sound awkward and would probably be rephrased as "IL-2 inhibits X in A and Y in B".

5 Learning

The learning problem in USP is to maximize the log-likelihood of observing the QLFs obtained from the dependency trees, denoted by Q, summing out the unobserved semantic parses:

$$\begin{aligned} L_\theta(Q) &= \log P_\theta(Q) \\ &= \log \textstyle\sum_L P_\theta(Q, L) \end{aligned}$$

Here, L are the semantic parses, θ are the MLN parameters, and $P_\theta(Q, L)$ are the completion likelihoods. A serious challenge in unsupervised learning is the identifiability problem (i.e., the optimal parameters are not unique) (Liang and Klein, 2008). This problem is particularly severe for log-linear models with hard constraints, which are common in MLNs. For example, in our USP MLN, conditioned on the fact that $\mathtt{p} \in \mathtt{c}$, there is exactly one value of $\mathtt{f}$ that can satisfy the formula $\mathtt{p} \in \mathtt{c} \wedge \mathtt{Form}(\mathtt{p}, \mathtt{f})$, and if we add some constant number to the weights of $\mathtt{p} \in \mathtt{c} \wedge \mathtt{Form}(\mathtt{p}, \mathtt{f})$ for all $\mathtt{f}$, the probability distribution stays the same.[6] The learner can be easily confused by the infinitely many optima, especially in the early stages. To address this problem, we impose local normalization constraints on specific groups of formulas that are mutually exclusive and exhaustive, i.e., in each group, we require that $\sum_{i=1}^{k} e^{w_i} = 1$, where w_i are the weights of formulas in the group. Grouping is done in such a way as to encourage the intended mixture behaviors. Specifically, for the rule $\mathtt{p} \in +\mathtt{c} \wedge \mathtt{Form}(\mathtt{p}, +\mathtt{f})$, all instances given a fixed $\mathtt{c}$ form a group; for each of the remaining three rules, all instances given a fixed $\mathtt{a}$ form a group. Notice that with these constraints the completion likelihood $P(Q, L)$ can be computed in closed form for any L. In particular, each formula group contributes a term equal to the weight of the currently satisfied formula. In addition, the optimal weights that maximize the completion likelihood $P(Q, L)$ can be derived in closed form using empirical relative frequencies. E.g., the optimal weight of $\mathtt{p} \in \mathtt{c} \wedge \mathtt{Form}(\mathtt{p}, \mathtt{f})$ is $\log(n_{\mathtt{c},\mathtt{f}}/n_{\mathtt{c}})$, where $n_{\mathtt{c},\mathtt{f}}$ is the number of parts $\mathtt{p}$ that satisfy both $\mathtt{p} \in \mathtt{c}$ and $\mathtt{Form}(\mathtt{p}, \mathtt{f})$, and $n_{\mathtt{c}}$ is the number of parts $\mathtt{p}$ that satisfy $\mathtt{p} \in \mathtt{c}$.[7] We leverage this fact for efficient learning in USP.

[6] Regularizations, e.g., Gaussian priors on weights, alleviate this problem by penalizing large weights, but it remains true that weights within a short range are roughly equivalent.

[7] To see this, notice that for a given $\mathtt{c}$, the total contribution to the completion likelihood from all groundings in its formula group is $\sum_{\mathtt{f}} w_{\mathtt{c},\mathtt{f}} n_{\mathtt{c},\mathtt{f}}$. In addition, $\sum_{\mathtt{f}} n_{\mathtt{c},\mathtt{f}} = n_{\mathtt{c}}$ and there is the local normalization constraint $\sum_{\mathtt{f}} e^{w_{\mathtt{c},\mathtt{f}}} = 1$. The optimal weights $w_{\mathtt{c},\mathtt{f}}$ are easily derived by solving this constrained optimization problem.

Algorithm 2 USP-Learn(*MLN, QLFs*)

```
Create initial clusters and semantic parses
Merge clusters with the same core form
Agenda ← ∅
repeat
  for all candidate operations O do
    Score O by log-likelihood improvement
    if score is above a threshold then
      Add O to agenda
    end if
  end for
  Execute the highest scoring operation O* in the agenda
  Regenerate MAP parses for affected QLFs and update agenda and candidate operations
until agenda is empty
return the MLN with learned weights and the semantic parses
```

Another major challenge in USP learning is the summation in the likelihood, which is over all possible semantic parses for a given dependency tree. Even an efficient sampler like MC-SAT (Poon and Domingos, 2006), as used in Poon & Domingos (2008), would have a hard time generating accurate estimates within a reasonable amount of time. On the other hand, as already noted in the previous section, the lambda-form distribution is generally sparse. Large lambda-forms are rare, as they correspond to complex expressions that are often decomposable into smaller ones. Moreover, while ambiguities are present at the lexical level, they quickly diminish when more words are present. Therefore, a lambda form can usually only belong to a small number of clusters, if not a unique one. We thus simplify the problem by approximating the sum with the mode, and search instead for the L and θ that maximize $\log P_\theta(Q, L)$. Since the optimal weights and log-likelihood can be derived in closed form given the semantic parses L, we simply search over semantic parses, evaluating them using log-likelihood.

Algorithm 2 gives pseudo-code for our algorithm. The input consists of an MLN without weights and the QLFs for the training sentences. Two operators are used for updating semantic parses. The first is to merge two clusters, denoted by $\mathtt{MERGE}(\mathtt{C}_1, \mathtt{C}_2)$ for clusters $\mathtt{C}_1, \mathtt{C}_2$, which does the following:

1. Create a new cluster $\mathtt{C}$ and add all core forms in $\mathtt{C}_1, \mathtt{C}_2$ to $\mathtt{C}$;
2. Create new argument types for $\mathtt{C}$ by merging those in $\mathtt{C}_1, \mathtt{C}_2$ so as to maximize the log-likelihood;
3. Remove $\mathtt{C}_1, \mathtt{C}_2$.

Here, merging two argument types refers to pooling their argument forms to create a new argument type. Enumerating all possible ways of creating new argument types is intractable. USP approximates it by considering one type at a time and either creating a new type for it or merging it to types already considered, whichever maximizes the log-likelihood. The types are considered in decreasing order of their numbers of occurrences so that more information is available for each decision. MERGE clusters syntactically different expressions whose meanings appear to be the same according to the model.

The second operator is to create a new cluster by composing two existing ones, denoted by $\mathtt{COMPOSE}(\mathtt{C}_\mathtt{R}, \mathtt{C}_\mathtt{A})$, which does the following:

1. Create a new cluster $\mathtt{C}$;
2. Find all parts $\mathtt{r} \in \mathtt{C}_\mathtt{R}, \mathtt{a} \in \mathtt{C}_\mathtt{A}$ such that $\mathtt{a}$ is an argument of $\mathtt{r}$, compose them to $\mathtt{r}(\mathtt{a})$ by λ-reduction and add the new part to $\mathtt{C}$;
3. Create new argument types for $\mathtt{C}$ from the argument forms of $\mathtt{r}(\mathtt{a})$ so as to maximize the log-likelihood.

COMPOSE creates clusters of large lambda-forms if they tend to be composed of the same subforms (e.g., the lambda form for "is next to"). These lambda-forms may later be merged with other clusters (e.g., borders).

At learning time, USP maintains an *agenda* that contains operations that have been evaluated and are pending execution. During initialization, USP forms a part and creates a new cluster for each unary atom $\mathtt{u}(\mathtt{n})$. It also assigns binary atoms of the form $\mathtt{b}(\mathtt{n}, \mathtt{n}')$ to the part as argument forms and creates a new argument type for each. This forms the initial clustering and semantic parses. USP then merges clusters with the same core form (i.e., the same unary predicate) using MERGE.[8] At each step, USP evaluates the candidate operations and adds them to the agenda if the improvement is above a threshold.[9] The operation with the highest score is executed, and the parameters are updated with the new optimal values. The QLFs which contain an affected part are reparsed, and operations in the agenda whose score might be affected are re-evaluated. These changes are done very efficiently using inverted indexes. We omit the details here due to space limitations. USP terminates when the agenda is empty, and outputs the current MLN parameters and semantic parses.

USP learning uses the same optimization objective as hard EM, and is also guaranteed to find a local optimum since at each step it improves the log-likelihood. It differs from EM in directly optimizing the likelihood instead of a lower bound.

6 Experiments

6.1 Task

Evaluating unsupervised semantic parsers is difficult, because there is no predefined formal language or gold logical forms for the input sentences. Thus the best way to test them is by using them for the ultimate goal: answering questions based on the input corpus. In this paper, we applied USP to extracting knowledge from biomedical abstracts and evaluated its performance in answering a set of questions that simulate the information needs of biomedical researchers. We used the GENIA dataset (Kim et al., 2003) as the source for knowledge extraction. It contains 1999 PubMed abstracts and marks all mentions of biomedical entities according to the GENIA ontology, such as cell, protein, and DNA. As a first approximation to the questions a biomedical researcher might ask, we generated a set of two thousand questions on relations between entities. Sample questions are: "What regulates MIP-1alpha?", "What does anti-STAT 1 inhibit?". To simulate the real information need, we sample the relations from the 100 most frequently used verbs (excluding the auxiliary verbs *be*, *have*, and *do*), and sample the entities from those annotated in GENIA, both according to their numbers of occurrences. We evaluated USP by the number of answers it provided and the accuracy as determined by manual labeling.[10]

[8] Word-sense disambiguation can be handled by including a new kind of operator that splits a cluster into subclusters. We leave this to future work.

[9] We currently set it to 10 to favor precision and guard against errors due to inexact estimates.

[10] The labels and questions are available at http://alchemy.cs.washington.edu/papers/poon09.

6.2 Systems

Since USP is the first unsupervised semantic parser, conducting a meaningful comparison of it with other systems is not straightforward. Standard question-answering (QA) benchmarks do not provide the most appropriate comparison, because they tend to simultaneously emphasize other aspects not directly related to semantic parsing. Moreover, most state-of-the-art QA systems use supervised learning in their key components and/or require domain-specific engineering efforts. The closest available system to USP in aims and capabilities is TextRunner (Banko et al., 2007), and we compare with it. TextRunner is the state-of-the-art system for open-domain information extraction; its goal is to extract knowledge from text without using supervised labels. Given that a central challenge to semantic parsing is resolving syntactic variations of the same meaning, we also compare with RESOLVER (Yates and Etzioni, 2009), a state-of-the-art unsupervised system based on TextRunner for jointly resolving entities and relations, and DIRT (Lin and Pantel, 2001), which resolves paraphrases of binary relations. Finally, we also compared to an informed baseline based on keyword matching.

Keyword: We consider a baseline system based on keyword matching. The question substring containing the verb and the available argument is directly matched with the input text, ignoring case and morphology. We consider two ways to derive the answer given a match. The first one (**KW**) simply returns the rest of sentence on the other side of the verb. The second one (**KW-SYN**) is informed by syntax: the answer is extracted from the subject or object of the verb, depending on the question. If the verb does not contain the expected argument, the sentence is ignored.

TextRunner: TextRunner inputs text and outputs relational triples in the form (R, A_1, A_2), where R is the relation string, and A_1, A_2 the argument strings. Given a triple and a question, we first match their relation strings, and then match the strings for the argument that is present in the question. If both match, we return the other argument string in the triple as an answer. We report results when exact match is used (**TR-EXACT**), or when the triple string can contain the question one as a substring (**TR-SUB**).

RESOLVER: RESOLVER (Yates and Etzioni, 2009) inputs TextRunner triples and collectively resolves coreferent relation and argument strings. On the GENIA data, using the default parameters, RESOLVER produces only a few trivial relation clusters and no argument clusters. This is not surprising, since RESOLVER assumes high redundancy in the data, and will discard any strings with fewer than 25 extractions. For a fair comparison, we also ran RESOLVER using all extractions, and manually tuned the parameters based on eyeballing of clustering quality. The best result was obtained with 25 rounds of execution and with the entity multiple set to 200 (the default is 30). To answer questions, the only difference from TextRunner is that a question string can match any string in its cluster. As in TextRunner, we report results for both exact match (**RS-EXACT**) and substring (**RS-SUB**).

DIRT: The DIRT system inputs a path and returns a set of similar paths. To use DIRT in question answering, we queried it to obtain similar paths for the relation of the question, and used these paths while matching sentences. We first used MINIPAR (Lin, 1998) to parse input text using the same dependencies as DIRT. To determine a match, we first check if the sentence contains the question path or one of its DIRT paths. If so, and if the available argument slot in the question is contained in the one in the sentence, it is a match, and we return the other argument slot from the sentence if it is present. Ideally, a fair comparison will require running DIRT on the GENIA text, but we were not able to obtain the source code. We thus resorted to using the latest DIRT database released by the author, which contains paths extracted from a large corpus with more than 1GB of text. This puts DIRT in a very advantageous position compared with other systems. In our experiments, we used the top three similar paths, as including more results in very low precision.

USP: We built a system for knowledge extraction and question answering on top of USP. It generated Stanford dependencies (de Marneffe et al., 2006) from the input text using the Stanford parser, and then fed these to USP-Learn[11], which produced an MLN with learned weights and the MAP semantic parses of the input sentences. These MAP parses formed our knowledge base (KB). To answer questions, the system first parses the questions[12] using USP-Parse with the

[11] α and β are set to -5 and -10.

[12] The question slot is replaced by a dummy word.

Table 1: Comparison of question answering results on the GENIA dataset.

	# Total	# Correct	Accuracy
KW	150	67	45%
KW-SYN	87	67	77%
TR-EXACT	29	23	79%
TR-SUB	152	81	53%
RS-EXACT	53	24	45%
RS-SUB	196	81	41%
DIRT	159	94	59%
USP	**334**	**295**	**88%**

learned MLN, and then matches the question parse to parses in the KB by testing subsumption (i.e., a question parse matches a KB one iff the former is subsumed by the latter). When a match occurs, our system then looks for arguments of type in accordance with the question. For example, if the question is "What regulates MIP-1alpha?", it searches for the argument type of the relation that contains the argument form "nsubj" for subject. If such an argument exists for the relation part, it will be returned as the answer.

6.3 Results

Table 1 shows the results for all systems. USP extracted the highest number of answers, almost doubling that of the second highest (RS-SUB). It obtained the highest accuracy at 88%, and the number of correct answers it extracted is three times that of the second highest system. The informed baseline (KW-SYN) did surprisingly well compared to systems other than USP, in terms of accuracy and number of correct answers. TextRunner achieved good accuracy when exact match is used (TR-EXACT), but only obtained a fraction of the answers compared to USP. With substring match, its recall substantially improved, but precision dropped more than 20 points. RESOLVER improved the number of extracted answers by sanctioning more matches based on the clusters it generated. However, most of those additional answers are incorrect due to wrong clustering. DIRT obtained the second highest number of correct answers, but its precision is quite low because the similar paths contain many errors.

6.4 Qualitative Analysis

Manual inspection shows that USP is able to resolve many nontrivial syntactic variations without user supervision. It consistently resolves the syntactic difference between active and passive voices. It successfully identifies many distinct argument forms that mean the same (e.g., "X stimulates Y" $\approx$ "Y is stimulated with X", "expression of X" $\approx$ "X expression"). It also resolves many nouns correctly and forms meaningful groups of relations. Here are some sample clusters in core forms:

{investigate, examine, evaluate, analyze, study, assay}

{diminish, reduce, decrease, attenuate}

{synthesis, production, secretion, release}

{dramatically, substantially, significantly}

An example question-answer pair, together with the source sentence, is shown below:

Q: What does IL-13 enhance?

A: The 12-lipoxygenase activity of murine macrophages.

Sentence: The data presented here indicate that (1) the 12-lipoxygenase activity of murine macrophages is upregulated in vitro and in vivo by IL-4 and/or IL-13, . . .

7 Conclusion

This paper introduces the first unsupervised approach to learning semantic parsers. Our USP system is based on Markov logic, and recursively clusters expressions to abstract away syntactic variations of the same meaning. We have successfully applied USP to extracting a knowledge base from biomedical text and answering questions based on it.

Directions for future work include: better handling of antonyms, subsumption relations among expressions, quantifier scoping, more complex lambda forms, etc.; use of context and discourse to aid expression clustering and semantic parsing; more efficient learning and inference; application to larger corpora; etc.

Abstract

Unknown lexical items present a major obstacle to the development of broad-coverage semantic role labeling systems. We address this problem with a semi-supervised learning approach which acquires training instances for unseen verbs from an unlabeled corpus. Our method relies on the hypothesis that unknown lexical items will be structurally and semantically similar to known items for which annotations are available. Accordingly, we represent known and unknown sentences as graphs, formalize the search for the most similar verb as a graph alignment problem and solve the optimization using integer linear programming. Experimental results show that role labeling performance for unknown lexical items improves with training data produced automatically by our method.

1 Introduction

Semantic role labeling, the task of automatically identifying the semantic roles conveyed by sentential constituents, has recently attracted much attention in the literature. The ability to express the relations between predicates and their arguments while abstracting over surface syntactic configurations holds promise for many applications that require broad coverage semantic processing. Examples include information extraction (Surdeanu et al., 2003), question answering (Narayanan and Harabagiu, 2004), machine translation (Boas, 2005), and summarization (Melli et al., 2005).

Much progress in the area of semantic role labeling is due to the creation of resources like FrameNet (Fillmore et al., 2003), which document the surface realization of semantic roles in real world corpora. Such data is paramount for developing semantic role labelers which are usually based on supervised learning techniques and thus require training on role-annotated data. Examples of the training instances provided in FrameNet are given below:

(1) a. If [you]$_{Agent}$ [carelessly]$_{Manner}$ chance going back there, you deserve what you get.

b. Only [one winner]$_{Buyer}$ purchased [the paintings]$_{Goods}$

c. [Rachel]$_{Agent}$ injured [her friend]$_{Victim}$ [by closing the car door on his left hand]$_{Means}$.

Each verb in the example sentences evokes a *frame* which is situation-specific. For instance, *chance* evokes the *Daring* frame, *purchased* the *Commerce_buy* frame, and *injured* the *Cause_harm* frame. In addition, frames are associated with semantic roles corresponding to salient entities present in the situation evoked by the predicate. The semantic roles for the frame *Daring* are *Agent* and *Manner*, whereas for *Commerce_buy* these are *Buyer* and *Goods*. A system trained on large amounts of such *hand-annotated* sentences typically learns to identify the boundaries of the arguments of the verb predicate (argument identification) and label them with semantic roles (argument classification).

A variety of methods have been developed for semantic role labeling with reasonably good performance (F_1 measures in the low 80s on standard test collections for English; we refer the interested reader to the proceedings of the SemEval-2007 shared task (Baker et al., 2007) for an overview of the state-of-the-art). Unfortunately, the reliance on training data, which is both difficult and highly expensive to produce, presents a major obstacle to the widespread application of semantic role labeling across different languages and text genres. The English FrameNet (version 1.3) is not

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 11–20,
Singapore, 6-7 August 2009.

a small resource — it contains 502 frames covering 5,866 lexical entries and 135,000 annotated sentences. Nevertheless, by virtue of being under development it is incomplete. Lexical items (i.e., predicates evoking existing frames) are missing as well as frames and annotated sentences (their number varies greatly across lexical items). Considering how the performance of supervised systems degrades on out-of-domain data (Baker et al., 2007), not to mention unseen events, semi-supervised or unsupervised methods seem to offer the primary near-term hope for broad coverage semantic role labeling.

In this work, we develop a semi-supervised method for enhancing FrameNet with additional annotations which could then be used for classifier training. We assume that an initial set of labeled examples is available. Then, faced with an unknown predicate, i.e., a predicate that does not evoke any frame according to the FrameNet database, we must decide (a) which frames it belongs to and (b) how to automatically annotate example sentences containing the predicate. We solve both problems jointly, using a graph alignment algorithm. Specifically, we view the task of inferring annotations for new verbs as an instance of a structural matching problem and follow a graph-based formulation for pairwise global network alignment (Klau, 2009). Labeled and unlabeled sentences are represented as dependency-graphs; we formulate the search for an optimal alignment as an integer linear program where different graph alignments are scored using a function based on semantic and structural similarity. We evaluate our algorithm in two ways. We assess how accurate it is in predicting the frame for an unknown verb and also evaluate whether the annotations we produce are useful for semantic role labeling.

In the following section we provide an overview of related work. Next, we describe our graph-alignment model in more detail (Section 3) and present the resources and evaluation methodology used in our experiments (Section 4). We conclude the paper by presenting and discussing our results.

2 Related Work

Much previous work has focused on creating FrameNet-style annotations for languages other than English. A common strategy is to exploit parallel corpora and transfer annotations from English sentences onto their translations (Padó and Lapata, 2006; Johansson and Nugues, 2006). Other work attempts to automatically augment the English FrameNet in a monolingual setting either by extending its coverage or by creating additional training data.

There has been growing interest recently in determining the frame membership for unknown predicates. This is a challenging task, FrameNet currently lists 502 frames with example sentences which are simply too many (potentially related) classes to consider for a hypothetical system. Moreover, predicates may have to be assigned to multiple frames, on account of lexical ambiguity. Previous work has mainly used WordNet (Fellbaum, 1998) to extend FrameNet. For example, Burchardt et al. (2005) apply a word sense disambiguation system to annotate predicates with a WordNet sense and hyponyms of these predicates are then assumed to evoke the same frame. Johansson and Nugues (2007) treat this problem as an instance of supervised classification. Using a feature representation based also on WordNet, they learn a classifier for each frame which decides whether an unseen word belongs to the frame or not. Pennacchiotti et al. (2008) create "distributional profiles" for frames. Each frame is represented as a vector, the (weighted) centroid of the vectors representing the meaning of the predicates it evokes. Unknown predicates are then assigned to the most similar frame. They also propose a WordNet-based model that computes the similarity between the synsets representing an unknown predicate and those activated by the predicates of a frame.

All the approaches described above are type-based. They place more emphasis on extending the lexicon rather than the annotations that come with it. In our earlier work (Fürstenau and Lapata, 2009) we acquire new training instances, by projecting annotations from existing FrameNet sentences to new unseen ones. The proposed method is token-based, however, it only produces annotations for known verbs, i.e., verbs that FrameNet lists as evoking a given frame.

In this paper we generalize the proposals of Pennacchiotti et al. (2008) and Fürstenau and Lapata (2009) in a unified framework. We create training data for semantic role labeling of unknown predicates by projection of annotations from labeled onto unlabeled data. This projection is con-

ceptualized as a graph alignment problem where we seek to find a globally optimal alignment subject to semantic and structural constraints. Instead of predicting the same frame for each occurence of an unknown predicate, we consider a set of candidate frames and allow projection from any labeled predicate that can evoke one of these frames. This allows us to make instance-based decisions and thus account for predicate ambiguity.

3 Graph Alignment Method

Our approach acquires annotations for an unknown frame evoking verb by selecting sentences featuring this verb from a large unlabeled corpus (the *expansion* corpus). The choice is based upon a measure of similarity between the predicate-argument structure of the unknown verb and those of similar verbs in a manually labeled corpus (the *seed* corpus). We formulate the problem of finding the most similar verbs as the search for an optimal graph alignment (we represent labeled and unlabeled sentences as dependency graphs). Conveniently, this allows us to create labeled training instances for the unknown verb by projecting role labels from the most similar seed instance. The annotations can be subsequently used for training a semantic role labeler.

Given an unknown verb, the first step is to narrow down the number of frames it could potentially evoke. FrameNet provides definitions for more than 500 frames, of which we entertain only a small number. This is done using a method similar to Pennacchiotti et al. (2008). Each frame is represented in a semantic space as the centroid of the vectors of all its known frame evoking verbs. For an unknown verb we then consider as frame candidates the k closest frames according to a measure of distributional similarity (which we compute between the unknown verb's vector and the frame centroid vector). We provide details of the semantic space we used in our experiments in Section 4.

Next, we compare each sentence featuring the unknown verb in question to labeled sentences featuring known verbs which according to FrameNet evoke any of the k candidate frames. If sufficiently similar seeds exist, the unlabeled sentence is annotated by projecting role labels from the most similar one. The similarity score of this best match is recorded as a measure of the quality (or reliability) of the new instance. After carrying out this procedure for all sentences in the expansion corpus featuring an unknown verb, we collect the highest scoring new instances and add them back to our seed corpus as new training items. In the following we discuss in more detail how the similarity of predicate-argument structures is assessed.

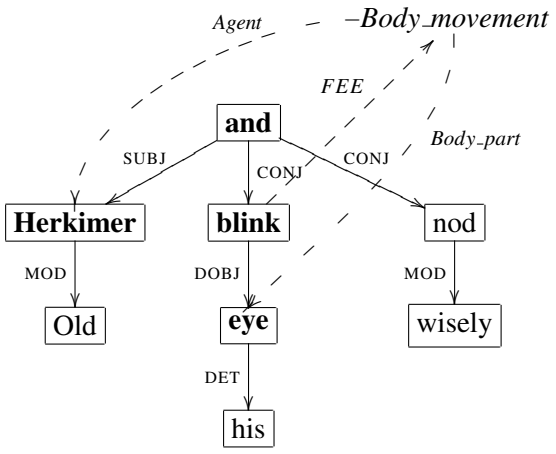

Figure 1: Annotated dependency graph for the sentence *Old Herkimer blinked his eye and nodded wisely.* The alignment domain is indicated in bold face. Labels in italics denote frame roles, whereas grammatical roles are rendered in small capitals. The verb *blink* evokes the frame *Body_Movement*.

3.1 Alignment Scoring

Let s be a semantically labeled dependency graph in which node n_{FEE} represents the frame evoking verb. Here, we use the term "labeled" to indicate that the graph contains semantic role labels in addition to grammatical role labels (e.g., subject or object). Let g be an unlabeled graph and n_{target} a verbal node in it. The "unlabeled" graph contains grammatical roles but no semantic roles. We wish to find an alignment between the predicate-argument structures of n_{FEE} and n_{target}, respectively. Such an alignment takes the form of a function σ from a set M of nodes of s (the *alignment domain*) to a set N of nodes of g (the *alignment range*). These two sets represent the relevant predicate-argument structures within the two graphs; nodes that are not members of these sets are excluded from any further computations.

If there were no mismatches between (frame) semantic arguments and syntactic arguments, we would expect all roles in s to be instantiated by syntactic dependents in n_{FEE}. This is usually the case but not always. We cannot therefore sim-

ply define M as the set of direct dependents of the predicate, but also have to consider *complex paths* between n_{FEE} and role bearing nodes. An example is given in Figure 1, where the role *Agent* is filled by a node which is not dominated by the frame evoking verb *blink*; instead, it is connected to *blink* by the complex path (CONJ^{-1}, SUBJ). For a given seed s we build a list of all such complex paths and also include all nodes of s connected to n_{FEE} by one of these paths. We thus define the alignment domain M as:

1. the predicate node n_{FEE}
2. all direct dependents of n_{FEE}, except auxiliaries
3. all nodes on complex paths originating in n_{FEE}
4. single direct dependents of any preposition or conjunction node which is in (2) or end-point of a complex path covered in (3)

The last rule ensures that the semantic heads of prepositional phrases and conjunctions are included in the alignment domain.

The alignment range N is defined in a similar way. However, we cannot extract complex paths from the unlabeled graph g, as it does not contain semantic role information. Therefore, we use the same list of complex paths extracted from s. Note that this introduces an unavoidable asymmetry into our similarity computation.

An alignment is a function $\sigma : M \rightarrow N \cup \{\varepsilon\}$ which is injective for all values except ε, i.e., $\sigma(n_1) = \sigma(n_2) \neq \varepsilon \Rightarrow n_1 = n_2$. We score the similarity of two subgraphs expressed by an alignment function σ by the following term:

$$\sum_{\substack{n \in M \\ \sigma(n) \neq \varepsilon}} \text{sem}(n, \sigma(n)) + \alpha \sum_{\substack{(n_1,n_2) \in E(M) \\ (\sigma(n_1),\sigma(n_2)) \in E(N)}} \text{syn}\left(r_{n_2}^{n_1}, r_{\sigma(n_2)}^{\sigma(n_1)}\right) \quad (2)$$

Here, sem represents a semantic similarity measure between graph nodes and syn a syntactic similarity measure between the grammatical role labels of graph edges. $E(M)$ and $E(N)$ are the sets of all graph edges between nodes of M and nodes of N, respectively, and $r_{n_2}^{n_1}$ denotes the grammatical relation between nodes n_1 and n_2.

Equation (2) expresses the similarity between two predicate-argument structures in terms of the sum of semantic similarity scores of aligned graph nodes and the sum of syntactic similarity scores of aligned graph edges. The relative weight of these two sums is determined by the parameter α. Figure 2 shows an example of an alignment between two dependency graphs. Here, the aligned node pairs *thud* and *thump*, *back* and *rest*, *against* and *against*, as well as *wall* and *front* contribute semantic similarity scores, while the three edge pairs SUBJ and SUBJ, IOBJ and IOBJ, as well as DOBJ and DOBJ contribute syntactic similarity scores.

We normalize the resulting score so that it always falls within the interval $[0, 1]$. To take into account unaligned nodes in both the alignment domain and the alignment range, we divide Equation (2) by:

$$\sqrt{|M| \cdot |N|} + \alpha \sqrt{|E(M)| \cdot |E(N)|} \quad (3)$$

A trivial alignment of a seed with itself where all semantic and syntactic scores are 1 will thus receive a score of:

$$\frac{|M| \cdot 1 + \alpha \cdot |E(M)| \cdot 1}{\sqrt{|M|^2} + \alpha \sqrt{E(M)^2}} = 1 \quad (4)$$

which is the largest possible similarity score. The lowest possible score is obviously 0, assuming that the semantic and syntactic scores cannot be negative.

Considerable latitude is available in selecting the semantic and syntactic similarity measures. With regard to semantic similarity, WordNet is a prime contender and indeed has been previously used to acquire new predicates in FrameNet (Pennacchiotti et al., 2008; Burchardt et al., 2005; Johansson and Nugues, 2007). Syntactic similarity may be operationalized in many ways, for example by taking account a hierarchy of grammatical relations (Keenan and Comrie, 1977). Our experiments employed relatively simple instantiations of these measures. We did not make use of WordNet, as we were interested in exploring the setting where WordNet is not available or has limited coverage. Therefore, we approximate the semantic similarity between two nodes via distributional similarity. We present the details of the semantic space model we used in Section 4.

If n and n' are both nouns, verbs or adjectives, we set:

$$\text{sem}(n, n') := \cos(\vec{v}_n, \vec{v}_{n'}) \quad (5)$$

where $\vec{v}_n$ and $\vec{v}_{n'}$ are the vectors representing the lemmas of n and n' respectively. If n and n'

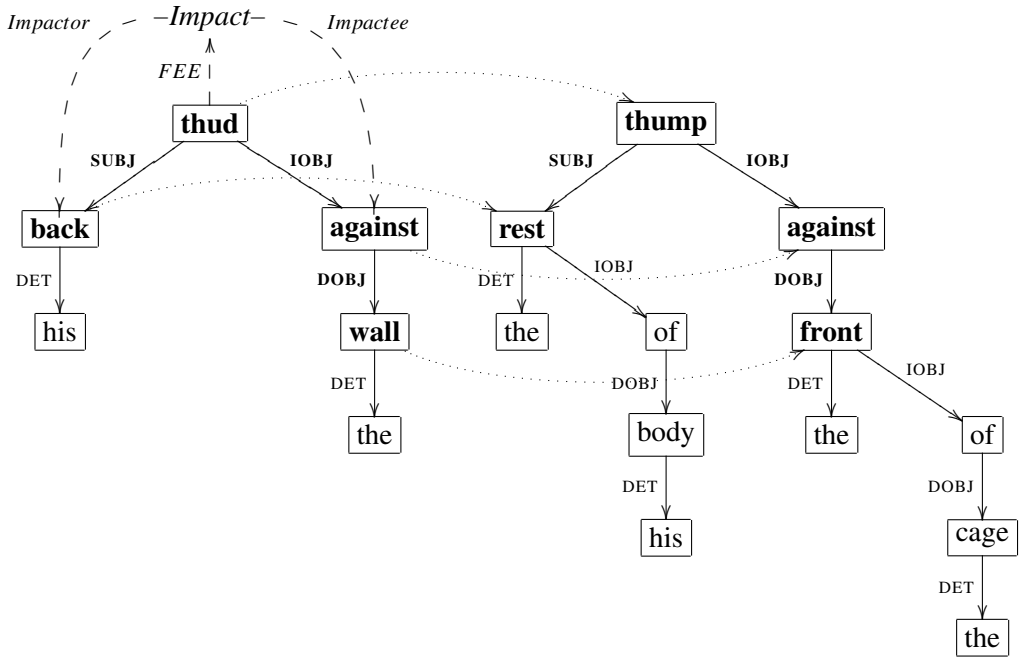

Figure 2: The dotted arrows show aligned nodes in the graphs for the two sentences *His back thudded against the wall.* and *The rest of his body thumped against the front of the cage.* (Graph edges are also aligned to each other.) The alignment domain and alignment range are indicated in bold face. The verb *thud* evokes the frame *Impact*.

are identical prepositions or conjunctions we set $\text{sem}(n,n') := 1$. In all other cases $\text{sem}(n,n') := 0$. As far as syntactic similarity is concerned, we chose the simplest metric possible and set:

$$\text{syn}\left(r,r'\right) := \begin{cases} 1 & \text{if } r = r' \\ 0 & \text{otherwise} \end{cases} \quad (6)$$

3.2 Alignment Search

The problem of finding the best alignment according to the scoring function presented in Equation (2) can be formulated as an integer linear program. Let the binary variables x_{ik} indicate whether node n_i of graph s is aligned to node n_k of graph g. Since it is not only nodes but also graph edges that must be aligned we further introduce binary variables y_{ijkl}, where $y_{ijkl} = 1$ indicates that the edge between nodes n_i and n_j of graph s is aligned to the edge between nodes n_k and n_l of graph g. This follows a general formulation of the graph alignment problem based on maximum structural matching (Klau, 2009). In order for the x_{ik} and y_{ijkl} variables to represent a valid alignment, the following constraints must hold:

1. Each node of s is aligned to at most one node of g: $\sum_k x_{ik} \leq 1$
2. Each node of g is aligned to at most one node of s: $\sum_i x_{ik} \leq 1$
3. Two edges may only be aligned if their adjacent nodes are aligned: $y_{ijkl} \leq x_{ik}$ and $y_{ijkl} \leq x_{jl}$

The scoring function then becomes:

$$\sum_{i,k} \text{sem}(n_i,n_k)x_{ik} + \alpha \cdot \sum_{i,j,k,l} \text{syn}\left(r^{n_i}_{n_j}, r^{n_k}_{n_l}\right) y_{ijkl} \quad (7)$$

We solve this optimization problem with a version of the branch-and-bound algorithm (Land and Doig, 1960). In general, this graph alignment problem is NP-hard (Klau, 2009) and usually solved approximately following a procedure similar to beam search. However, the special structure of constraints 1 to 3, originating from the required injectivity of the alignment function, allows us to solve the optimization exactly. Our implementation of the branch-and-bound algorithm does not generally run in polynomial time, however, we found that in practice we could efficiently compute optimal alignments in almost all cases (less than 0.1% of alignment pairs in our data could not be solved in reasonable time). This relatively benign behavior depends crucially on the fact that we do not have to consider alignments between

full graphs, and the number of nodes in the aligned subgraphs is limited.

4 Experimental Design

In this section we present our experimental set-up for assessing the performance of our method. We give details on the data sets we used, describe the baselines we adopted for comparison with our approach, and explain how our system output was evaluated.

Data Our experiments used annotated sentences from FrameNet as a seed corpus. These were augmented with automatically labeled sentences from the BNC which we used as our expansion corpus. FrameNet sentences were parsed with RASP (Briscoe et al., 2006). In addition to phrase structure trees, RASP delivers a dependency-based representation of the sentence which we used in our experiments. FrameNet role annotations were mapped onto those dependency graph nodes that corresponded most closely to the annotated substring (see Fürstenau (2008) for a detailed description of the mapping algorithm). BNC sentences were also parsed with RASP (Andersen et al., 2008).

We randomly split the FrameNet corpus[1] into 80% training set, 10% test set, and 10% development set. Next, all frame evoking verbs in the training set were ordered by their number of occurrence and split into two groups, *seen* and *unseen*. Every other verb from the ordered list was considered unseen. This quasi-random split covers a broad range of predicates with a varying number of annotations. Accordingly, the FrameNet sentences in the training and test sets were divided into the sets *train_seen*, *train_unseen*, *test_seen*, and *test_unseen*. As we explain below, this was necessary for evaluation purposes.

The *train_seen* dataset consisted of 24,220 sentences, with 1,238 distinct frame evoking verbs, whereas *train_unseen* contained 24,315 sentences with the same number of frame evoking verbs. Analogously, *test_seen* had 2,990 sentences and 817 unique frame evoking verbs; the number of sentences in *test_unseen* was 3,064 (with 847 unique frame evoking verbs).

Model Parameters The alignment model presented in Section 3 crucially relies on the similarity function that scores potential alignments (see Equation (2)). This function has a free parameter, the weight α for determining the relative contribution of semantic and syntactic similarity. We tuned α using leave-one-out cross-validation on the development set. For each annotated sentence in this set we found its most similar other sentence and determined the best alignment between the two dependency graphs representing them. Since the true annotations for each sentence were available, it was possible to evaluate the accuracy of our method for any α value. We did this by comparing the true annotation of a sentence to the annotation its nearest neighbor would have induced by projection. Following this procedure, we obtained best results with $\alpha = 0.2$.

The semantic similarity measure relies on a semantic space model which we built on a lemmatized version of the BNC. Our implementation followed closely the model presented in Fürstenau and Lapata (2009) as it was used in a similar task and obtained good results. Specifically, we used a context window of five words on either side of the target word, and 2,000 vector dimensions. These were the common context words in the BNC. Their values were set to the ratio of the probability of the context word given the target word to the probability of the context word overall. Semantic similarity was measured using the cosine of the angle between the vectors representing any two words. The same semantic space was used to create the distributional profile of a frame (which is the centroid of the vectors of its verbs). For each unknown verb, we consider the k most similar frame candidates (again similarity is measured via cosine). Our experiments explored different values of k ranging from 1 to 10.

Evaluation Our evaluation assessed the performance of a semantic frame and role labeler with and without the annotations produced by our method. The labeler followed closely the implementation described in Johansson and Nugues (2008). We extracted features from dependency parses corresponding to those routinely used in the semantic role labeling literature (see Baker et al. (2007) for an overview). SVM classifiers were trained[2] with the LIBLINEAR library (Fan et al., 2008) and learned to predict the frame name, role spans, and role labels. We followed

[1] Here, we consider only FrameNet example sentences featuring verbal predicates.

[2] The regularization parameter C was set to 0.1.

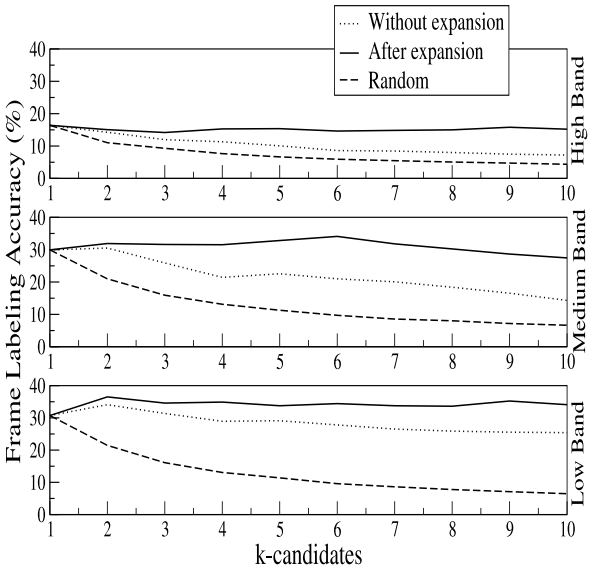

Figure 3: Frame labeling accuracy on high, medium and low frequency verbs, before and after applying our expansion method; the labeler decides among $k = 1, \ldots, 10$ candidate frames.

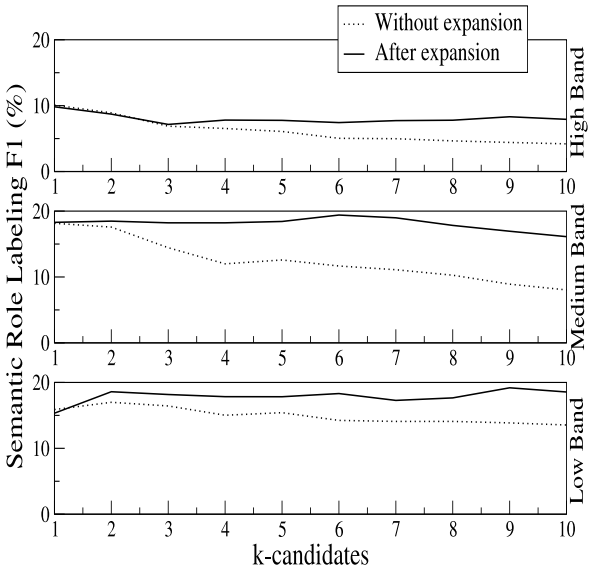

Figure 4: Role labeling F_1 for high, medium, and low frequency verbs (roles of mislabeled frames are counted as wrong); the labeler decides among $k = 1, \ldots, 10$ candidate frames.

the one-versus-one strategy for multi-class classification (Friedman, 1996).

Specifically, the labeler was trained on the *train_seen* data set without any access to training instances representative of the "unknown" verbs in *test_unseen*. We then trained the labeler on a larger set containing *train_seen* and new training examples obtained with our method. To do this, we used *train_seen* as the seed corpus and the BNC as the expansion corpus. For each "unknown" verb in *train_unseen* we obtained BNC sentences with annotations projected from their most similar seeds. The quality of these sentences as training instances varies depending on their similarity to the seed. In our experiments we added to the training set the 20 highest scoring BNC sentences per verb (adding less or more instances led to worse performance).

The average number of frames which can be evoked by a verb token in the set *test_unseen* was 1.96. About half of them (1,522 instances) can evoke only one frame, 22% can evoke two frames, and 14 instances can evoke up to 11 different frames. Finally, there are 120 instances (4%) in *test_unseen* for which the correct frame is not annotated on any sentence in *train_seen*.

5 Results

We first examine how well our method performs at frame labeling. We partitioned the frame evoking verbs in our data set into three bands (High, Medium, and Low) based on an equal division of the range of their occurrence frequency in the BNC. As frequency is strongly correlated with polysemy, the division allows us to assess how well our method is performing at different degrees of ambiguity. Figure 3 summarizes our results for High, Medium, and Low frequency verbs. The number of verbs in each band are 282, 282, and 283, respectively. We compare the frame accuracy of a labeler trained solely on the annotations available in FrameNet (Without expansion) against a labeler that also uses annotations created with our method (After expansion). Both classifiers were employed in a setting where they had to decide among k candidate frames. These were the k most similar frames to the unknown verb in question. We also show the accuracy of a simple baseline labeler, which randomly chooses one of the k candidate frames.

The graphs in Figure 3 show that for verbs in the Medium and Low frequency bands, both classifiers (with and without expansion) outperform the baseline of randomly choosing among k candidate frames. Interestingly, rather than defaulting to the most similar frame ($k = 1$), we observe that ac-

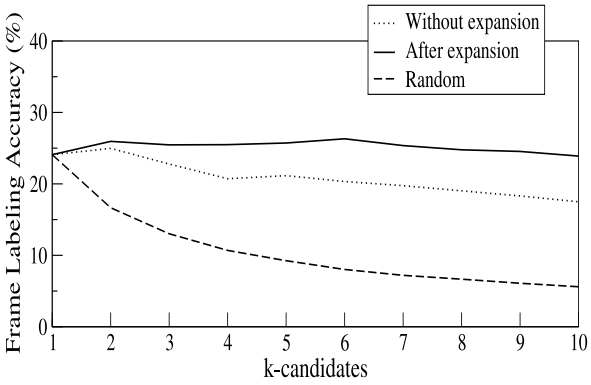

Figure 5: Hybrid frame labeling accuracy ($k = 1$ for High frequency verbs).

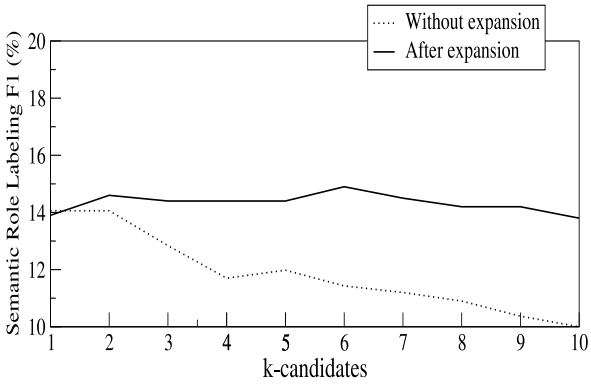

Figure 6: Hybrid role labeling F_1 ($k = 1$ for High frequency verbs).

curacy improves when frame selection is viewed as a classification task. The classifier trained on the expanded training set consistently outperforms the one trained on the original training set. While this is also true for the verbs in the High frequency band, labeling accuracy peaks at $k = 1$ and does not improve when more candidate frames are considered. This is presumably due to the skewed sense distributions of high frequency verbs, and defaulting to the most likely sense achieves relatively good performance.

Next, we evaluated our method on role labeling, again by comparing the performance of our role labeler on the expanded and original training set. Since role and frame labeling are interdependent, we count all predicted roles of an incorrectly predicted frame as wrong. This unavoidably results in low role labeling scores, but allows us to directly compare performance across different settings (e.g., different number of candidate frames, with or without expansion). Figure 4 reports labeled F_1 for verbs in the High, Medium and Low frequency bands. The results are similar to those obtained for frame labeling; the role labeler trained on the the expanded training set consistently outperforms the labeler trained on the unexpanded one. (There is no obvious baseline for role labeling, which is a complex task involving the prediction of frame labels, identification of the role bearing elements, and assignment of role labels.) Again, for High frequency verbs simply defaulting to $k = 1$ performs best.

Taken together, our results on frame and role labeling indicate that our method is not very effective for High frequency verbs (which in practice should be still annotated manually). We therefore also experimented with a hybrid approach that lets the classifier choose among k candidates for Medium and Low frequency verbs and defaults to the most similar candidate for High frequency verbs. Results for this approach are shown in Figures 5 and 6. All differences between the expanded and the unexpanded classifier when choosing between the same $k > 1$ candidates are significant according to McNemar's test ($p < .05$). The best frame labeling accuracy (26.3%) is achieved by the expanded classifier when deciding among $k = 6$ candidate frames. This is significantly better ($p < .01$) than the best performance of the unexpanded classifier (25.0%), which is achieved at $k = 2$. Role labeling results follow a similar pattern. The best expanded classifier (F_1=14.9% at $k = 6$) outperforms the best unexpanded one (F_1=14.1% at $k = 2$). The difference in performance as significant at $p < 0.05$, using stratified shuffling (Noreen, 1989).

6 Conclusions

This paper presents a novel semi-supervised approach for reducing the annotation effort involved in creating resources for semantic role labeling. Our method acquires training instances for unknown verbs (i.e., verbs that are not evoked by existing FrameNet frames) from an unlabeled corpus. A key assumption underlying our work is that verbs with similar meanings will have similar argument structures. Our task then amounts to finding the seen instances that resemble the unseen instances most, and projecting their annotations. We represent this task as a graph alignment problem, and formalize the search for an optimal alignment as an integer linear program under an

objective function that takes semantic and structural similarity into account.

Experimental results show that our method improves frame and role labeling accuracy, especially for Medium and Low frequency verbs. The overall frame labeling accuracy may seem low. There are at least two reasons for this. Firstly, the unknown verb might have a frame for which no manual annotation exists. And secondly, many errors are due to near-misses, i.e., we assign the unknown verb a wrong frame which is nevertheless very similar to the right one. In this case, accuracy will not give us any credit.

An obvious direction for future work concerns improving our scoring function. Pennacchiotti et al. (2008) show that WordNet-based similarity measures outperform their simpler distributional alternatives. An interesting question is whether the incorporation of WordNet-based similarity would lead to similar improvements in our case. Also note that currently our method assigns unknown lexical items to existing frames. A better alternative would be to decide first whether the unknown item can be classified at all (because it evokes a known frame) or whether it represents a genuinely novel frame for which manual annotation must be provided.

Acknowledgments The authors acknowledge the support of DFG (IRTG 715) and EPSRC (grant GR/T04540/01). We are grateful to Richard Johansson for his help with the re-implementation of his semantic role labeler. Special thanks to Manfred Pinkal for valuable feedback on this work.

Abstract

Semantic Role Labeling (SRL) has proved to be a valuable tool for performing automatic analysis of natural language texts. Currently however, most systems rely on a large training set, which is manually annotated, an effort that needs to be repeated whenever different languages or a different set of semantic roles is used in a certain application. A possible solution for this problem is semi-supervised learning, where a small set of training examples is automatically expanded using unlabeled texts. We present the Latent Words Language Model, which is a language model that learns word similarities from unlabeled texts. We use these similarities for different semi-supervised SRL methods as additional features or to automatically expand a small training set. We evaluate the methods on the PropBank dataset and find that for small training sizes our best performing system achieves an error reduction of 33.27% F1-measure compared to a state-of-the-art supervised baseline.

1 Introduction

Automatic analysis of natural language is still a very hard task to perform for a computer. Although some successful applications have been developed (see for instance (Chinchor, 1998)), implementing an automatic text analysis system is still a labour and time intensive task. Many applications would benefit from an intermediate representation of texts, where an automatic analysis is already performed which is sufficiently general to be useful in a wide range of applications.

Syntactic analysis of texts (such as Part-Of-Speech tagging and syntactic parsing) is an example of such a generic analysis, and has proved useful in applications ranging from machine translation (Marcu et al., 2006) to text mining in the bio-medical domain (Cohen and Hersh, 2005). A syntactic parse is however a representation that is very closely tied with the surface-form of natural language, in contrast to Semantic Role Labeling (SRL) which adds a layer of predicate-argument information that generalizes across different syntactic alternations (Palmer et al., 2005). SRL has received a lot of attention in the research community, and many systems have been developed (see section 2). Most of these systems rely on a large dataset for training that is manually annotated. In this paper we investigate whether we can develop a system that achieves state-of-the-art semantic role labeling without relying on a large number of labeled examples. We aim to do so by employing the Latent Words Language Model that learns *latent words* from a large unlabeled corpus. Latent words are words that (unlike observed words) did not occur at a particular position in a text, but given semantic and syntactic constraints from the context could have occurred at that particular position.

In section 2 we revise existing work on SRL and on semi-supervised learning. Section 3 outlines our supervised classifier for SRL and section 4 discusses the Latent Words Language Model. In section 5 we will combine the two models for semi-supervised role labeling. We will test the model on the standard PropBank dataset and compare it with state-of-the-art semi-supervised SRL systems in section 6 and finally in section 7 we draw conclusions and outline future work.

2 Related work

Gildea and Jurafsky (2002) were the first to describe a statistical system trained on the data from the FrameNet project to automatically assign semantic roles. This approach was soon followed by other researchers (Surdeanu et al., 2003; Pradhan et al., 2004; Xue and Palmer, 2004), focus-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 21–29,
Singapore, 6-7 August 2009.

ing on improved sets of features, improved machine learning methods or both, and SRL became a shared task at the CoNLL 2004, 2005 and 2008 conferences[1]. The best system (Johansson and Nugues, 2008) in CoNLL 2008 achieved an F1-measure of 81.65% on the workshop's evaluation corpus.

Semi-supervised learning has been suggested by many researchers as a solution to the annotation bottleneck (see (Chapelle et al., 2006; Zhu, 2005) for an overview), and has been applied successfully on a number of natural language processing tasks. Mann and McCallum (2007) apply Expectation Regularization to Named Entity Recognition and Part-Of-Speech tagging, achieving improved performance when compared to supervised methods, especially on small numbers of training data. Koo et al. (2008) present an algorithm for dependency parsing that uses clusters of semantically related words, which were learned in an unsupervised manner. There has been little research on semi-supervised learning for SRL. We refer to He and Gildea (2006) who tested active learning and co-training methods, but found little or no gain from semi-supervised learning, and to Swier and Stevenson (2004), who achieved good results using semi-supervised methods, but tested their methods on a small number of VerbNet roles, which have not been used by other SRL systems. To the best of our knowledge no system was able to reproduce the successful results of (Swier and Stevenson, 2004) on the PropBank roleset. Our approach most closely resembles the work of Fürstenau and Lapata (2009) who automatically expand a small training set using an automatic dependency alignment of unlabeled sentences. This method was tested on the FrameNet corpus and improved results when compared to a fully-supervised classifier. We will discuss their method in detail in section 5.

3 Semantic role labeling

Fillmore (1968) introduced semantic structures called semantic frames, describing abstract actions or common situations (frames) with common roles and themes (semantic roles). Inspired by this idea different resources were constructed, including FrameNet (Baker et al., 1998) and PropBank (Palmer et al., 2005). An alternative approach to semantic role labeling is the framework developed by Halliday (1994) and implemented by Mehay et al. (2005). PropBank has thus far received the most attention of the research community, and is used in our work.

3.1 PropBank

The goal of the PropBank project is to add semantic information to the syntactic nodes in the English Penn Treebank. The main motivation for this annotation is the preservation of semantic roles across different syntactic realizations. Take for instance the sentences

1. The window broke.
2. John broke the window.

In both sentences the constituent "the window" is broken, although it occurs at different syntactic positions. The PropBank project defines for a large collection of verbs (excluding auxiliary verbs such as "will", "can", ...) a set of senses, that reflect the different meanings and syntactic alternations of this verb. Every sense has a number of expected roles, numbered from Arg0 to Arg5. A small number of arguments are shared among all senses of all verbs, such as temporals (Arg-TMP), locatives (Arg-LOC) and directionals (Arg-DIR). Additional to the frame definitions, PropBank has annotated a large training corpus containing approximately 113.000 annotated verbs. An example of an annotated sentence is

$$[\text{John}\ _{Arg0}][\text{broke}\ _{BREAK.01}]\ [\text{the window}\ _{Arg1}].$$

Here *BREAK*.01 is the first sense of the "break" verb. Note that (1) although roles are defined for every frame separately, in reality roles with identical names are identical or very similar for all frames, a fact that is exploited to train accurate role classifiers and (2) semantic role labeling systems typically assume that a frame is fully expressed in a single sentence and thus do not try to instantiate roles across sentence boundaries. Although the original PropBank corpus assigned semantic roles to syntactic phrases (such as noun phrases), we use the CoNLL dataset, where the PropBank corpus was converted to a dependency representation, assigning semantic roles to single (head) words.

3.2 Features

In this section we discuss the features used in the semantic role labeling system. All features but the

[1] See http://www.cnts.ua.ac.be/conll/ for an overview.

Split path feature are taken from existing semantic role labeling systems, see for example (Gildea and Jurafsky, 2002; Lim et al., 2004; Thompson et al., 2006). The number in brackets denotes the number of unique features for that type.

Word We split every sentence in (unigram) word tokens, including punctuation. (37079)

Stem We reduce the word tokens to their stem, e.g. "walks" -> "walk". (28690)

POS The part-of-speech tag for every word, e.g. "NNP" (for a singular proper noun). (77)

Neighbor POS's The concatenated part-of-speech tags of the word before and the word just after the current word, e.g. "RBS_JJR". (1787)

Path This important feature describes the path through the dependency tree from the current word to the position of the predicate, e.g. "coord↑obj↑adv↑root↓dep↓nmod↓pmod", where '↑' indicates going up a constituent and '↓' going down one constituent. (829642)

Split Path Because of the nature of the path feature, an explosion of unique features is found in a given data set. We reduce this by splitting the path in different parts and using every part as a distinct feature. We split, for example, the previous path in 6 different features: "coord", "↑obj", "↑adv", "↑root", "↓dep", "↓nmod", "↓pmod". Note that the split path feature includes the POS feature, since the first component of the path is the POS tag for the current word. This feature has not been used previously for semantic role detection. (155)

For every word w_i in the training and test set we construct the feature vector $\mathbf{f}(w_i)$, where at every position in this vector 1 indicates the presence for the corresponding feature and 0 the absence of that feature.

3.3 Discriminative model

Discriminative models have been found to outperform generative models for many different tasks including SRL (Lim et al., 2004). For this reason we also employ discriminative models here. The structure of the model was inspired by a similar (although generative) model in (Thompson et al., 2006) where it was used for semantic frame classification. The model (fig. 1) assumes that the role label r_{ij} for the word w_i is conditioned on the features $\mathbf{f}_i$ and on the role label $r_{i-1\,j}$ of the previous word and that the predicate label p_j for word w_j is conditioned on the role labels $\mathbf{R}^j$ and on the features $\mathbf{f}_j$. This model can be seen as an extension of the standard Maximum Entropy Markov Model (MEMM, see (Ratnaparkhi, 1996)) with an extra dependency on the predicate label, we will henceforth refer to this model as *MEMM+pred.*

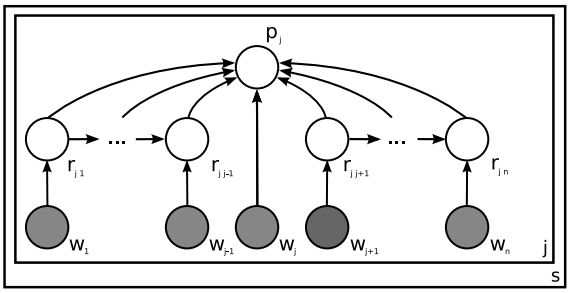

Figure 1: Discriminative model for SRL. Grey circles represent observed variables, white circles hidden variables and arrows directed dependencies. *s* ranges over all sentences in the corpus and *j* over the *n* words in the sentence.

To estimate the parameters of the *MEMM+pred* model we turn to the successful Maximum Entropy (Berger et al., 1996) parameter estimation method. The Maximum Entropy principle states that the best model given the training data is the model such that the conditional distribution defined by the model has maximum entropy subject to the constraints represented by the training examples. There is no closed form solution to find this maximum and we thus turn to an iterative method. In this work we use Generalized Iterative Scaling[2], but other methods such as (quasi-) Newton optimization could also have been used.

4 Latent Words Language Model

4.1 Rationale

As discussed in sections 1 and 3 most SRL systems are trained today on a large set of manually annotated examples. PropBank for example contains approximately 50000 sentences. This manual annotation is both time and labour-intensive, and needs to be repeated for new languages or

[2]We use the *maxent* package available on http://maxent.sourceforge.net/

for new domains requiring a different set of roles. One approach that can help to solve this problem is semi-supervised learning, where a small set of annotated examples is used together with a large set of unlabeled examples when training a SRL model.

Manual inspection of the results of the supervised model discussed in the previous section showed that the main source of errors was incorrect labeling of a word because the word token did not occur, or occurred only a small number of times in the training set. We hypothesize that knowledge of semantic similar words could overcome this problem by associating words that occurred infrequently in the training set to similar words that occurred more frequently. Furthermore, we would like to learn these similarities automatically, to be independent of knowledge sources that might not be available for all languages or domains.

The Distributional Hypothesis, supported by theoretical linguists such as Harris (1954), states that words that occur in the same contexts tend to have similar meanings. This suggests that one can learn the similarity between two words automatically by comparing their relative contexts in a large unlabeled corpus, which was confirmed by different researchers (e.g. (Lin, 1998; McDonald and Ramscar, 2001; Grefenstette, 1994)). Different methods for computing word similarities have been proposed, differing between methods to represent the context (using dependency relationship or a window of words) and between methods that, given a set of contexts, compute the similarity between different words (ranging from cosine similarity to more complex metrics such as the Jaccard index). We refer to (Lin, 1998) for a comparison of the different similarity metrics.

In the next section we propose a novel method to learn word similarities, the Latent Words Language Model (LWLM) (Deschacht and Moens, 2009). This model learns similar words and learns the a distribution over the contexts in which certain types of words occur typically.

4.2 Definition

The LWLM introduces for a text $\mathbf{T} = w_1 ... w_N$ of length N for every observed word w_i at position i a hidden variable h_i. The model is a generative model for natural language, in which the latent variable h_i is generated by its context $C(h_i)$ and the observed word w_i is generated by the latent variable h_i. In the current model we assume that the context is $C(h_i) = \mathbf{h}_{i-2}^{i-1}\mathbf{h}_{i+1}^{i+2}$ where $\mathbf{h}_{i-2}^{i-1} = h_{i-2}h_{i-1}$ is the two previous words and $\mathbf{h}_{i+1}^{i+2} = h_{i+1}h_{i+2}$ is the two next words. The observed w_i has a value from the vocabulary V, while the hidden variable h_i is unknown, and is modeled as a probability distribution over all words of V. We will see in the next section how this distribution is estimated from a large unlabeled training corpus. The aim of this model is to estimate, at every position i, a distribution for h_i, assigning high probabilities to words that are similar to w_i, given the context of this word $C(h_i)$, and low probabilities to words that are not similar to w_i in this context.

A possible interpretation of this model states that every hidden variable h_i models the "meaning" for a particular word in a particular context. In this probabilistic model, when generating a sentence, we generate the meaning of a word (which is an unobserved representation) with a certain probability, and then we generate a certain observation by writing down one of the possible words that express this meaning.

Creating a representation that models the meaning of a word is an interesting (and controversial) topic in its own right, but in this work we make the assumption that the meaning of a particular word can be modeled using other words. Modeling the meaning of a word with other words is not an unreasonable one, since it is already employed in practice by humans (e.g. by using dictionaries and thesauri) and machines (e.g. relying on a lexical resource such as WordNet) in word sense disambiguation tasks.

4.3 Parameter estimation

As we will further see the LWLM model has three probability distributions: $P(w_i|h_i)$, the probability of the observed word w_j given the latent variable h_j, $P(h_i|\mathbf{h}_{i-2}^{i-1})$, the probability of the hidden word h_j given the previous variables h_{j-2} and h_{j-1}, and $P(h_i|\mathbf{h}_{i+1}^{i+2})$, the probability of the hidden word h_j given the next variables h_{j+1} and h_{j+2}. These distributions need to be learned from a training text $\mathbf{T}_{train} =< w_0 ... w_z >$ of length Z.

4.3.1 The Baum-Welch algorithm

The attentive reader will have noticed the similarity between the proposed model and a standard second-order Hidden Markov Model (HMM) where the hidden state is dependent on the two

previous states. However, we are not able to use the standard Baum-Welch (or forward-backward) algorithm, because the hidden variable h_i is modeled as a probability distribution over all words in the vocabulary V. The Baum-Welch algorithm would result in an execution time of $O(|V|^3 NG)$ where $|V|$ is the size of the vocabulary, N is the length of the training text and G is the number of iterations needed to converge. Since in our dataset the vocabulary size is more than $30K$ words (see section 3.2), using this algorithm is not possible. Instead we use techniques of approximate inference, i.e. Gibbs sampling.

4.3.2 Initialization

Gibbs sampling starts from a random initialization for the hidden variables and then improves the estimates in subsequent iterations. In preliminary experiments it was found that a pure random initialization results in a very long burn-in-period and a poor performance of the final model. For this reason we initially set the distributions for the hidden words equal to the distribution of words as given by a standard language model[3].

4.3.3 Gibbs sampling

We store the initial estimate of the hidden variables in $\mathbf{M}^0_{train} =< h_0 ... h_Z >$, where h_i generates w_i at every position i. Gibbs sampling is a Markov Chain Monte Carlo method that updates the estimates of the hidden variables in a number of iterations. $\mathbf{M}^{\tau}_{train}$ denotes the estimate of the hidden variables in iteration τ. In every iteration a new estimate $\mathbf{M}^{\tau+1}_{train}$ is generated from the previous estimate $\mathbf{M}^{\tau}_{train}$ by selecting a random position j and updating the value of the hidden variable at that position. The probability distributions $P^{\tau}(w_j|h_j)$, $P^{\tau}(h_j|\mathbf{h}^{j-1}_{j-2})$ and $P^{\tau}(h_j|\mathbf{h}^{j+2}_{j+1})$ are constructed by collecting the counts from all positions $i \neq j$. The hidden variable h_j is dependent on h_{j-2}, h_{j-1}, h_{j+1}, h_{j+2} and w_j and we can compute the distribution of possible values for the variable h_j as

$$P^{\tau}(h_j|w_j, \mathbf{h}^{j-1}_0, \mathbf{h}^{Z}_{j+1}) = \frac{P^{\tau}(w_j|h_j)P^{\tau}(h_j|\mathbf{h}^{j-1}_{j-2}\mathbf{h}^{j+2}_{j+1})}{\sum_{h_i} P^{\tau}(w_i|h_i)P^{\tau}(h_j|\mathbf{h}^{j-1}_{j-2}\mathbf{h}^{j+2}_{j+1})}$$

We set $P(h_j|\mathbf{h}^{j-1}_{j-2}\mathbf{h}^{j+2}_{j+1}) = P(h_j|\mathbf{h}^{j-1}_{j-2}) \cdot P(h_j|\mathbf{h}^{j+2}_{j+1})$ which can be easily computed given the above distributions. We select a new value for the hidden variable according to $P^{\tau}(h_j|w_j, \mathbf{h}^{j-1}_0, \mathbf{h}^{Z}_{j+1})$ and place it at position j in $\mathbf{M}^{\tau+1}_{train}$. The current estimate for all other unobserved words remains the same. After performing this iteration a large number of times ($|V| * 10$ in this experiment), the distribution approaches the true maximum likelihood distribution. Gibbs sampling however samples this distribution, and thus will never reach it exactly. A number of iterations ($|V| * 100$) is then performed in which Gibbs sampling oscillates around the correct distribution. We collect independent samples of this distribution every $|V| * 10$ iterations, which are then used to construct the final model.

[3] We used the interpolated Kneser-Ney model as described in (Goodman, 2001).

4.4 Evaluation of the Language Model

A first evaluation of the quality of the automatically learned latent words is by translation of this model into a sequential language model and by measuring its perplexity on previously unseen texts. In (Deschacht and Moens, 2009) we perform a number of experiments, comparing different corpora (news texts from Reuters and from Associated Press, and articles from Wikipedia) and n-gram sizes (3-gram and 4-gram). We also compared the proposed model with two state-of-the-art language models, Interpolated Kneser-Ney smoothing and *fullibmpredict* (Goodman, 2001), and found that LWLM outperformed both models on all corpora, with a perplexity reduction ranging between 12.40% and 5.87%. These results show that the estimated distributions over latent words are of a high quality and lead us to believe they could be used to improve automatic text analysis, like SRL.

5 Role labeling using latent words

The previous section discussed how the LWLM learns similar words and how these similarities improved the perplexity on an unseen text of the language model derived from this model. In this section we will see how we integrate the latent words model in two novel semi-supervised SRL models and compare these with two state-of-the-art semi-supervised models for SRL and dependency parsing.

Latent words as additional features

In a first approach we estimate the distribution of latent words for every word for both the training and test set. We then use the latent words at every

position as additional probabilistic features for the discriminative model. More specifically, we append $|V|$ extra values to the feature vector $\mathbf{f}(w_j)$, containing the probability distribution over the $|V|$ possible words for the hidden variable h_i[4]. We call this the *LWFeatures* method.

This method has the advantage that it is simple to implement and that many existing SRL systems can be easily extended by adding additional features. We also expect that this method can be employed almost effortless in other information extraction tasks, such as Named Entity Recognition or Part-Of-Speech labeling.

We compare this approach to the semi-supervised method in Koo et al. (2008) who employ clusters of related words constructed by the Brown clustering algorithm (Brown et al., 1992) for syntactic processing of texts. Interestingly, this clustering algorithm has a similar objective as LWLM since it tries to optimize a class-based language model in terms of perplexity on an unseen test text. We employ a slightly different clustering method here, the *fullibmpredict* method discussed in (Goodman, 2001). This method was shown to outperform the class based model proposed in (Brown et al., 1992) and can thus be expected to discover better clusters of words. We append the feature vector $\mathbf{f}(w_j)$ with c extra values (where c is the number of clusters), respectively set to 1 if the word w_i belongs to the corresponding cluster or to 0 otherwise. We call this method the *ClusterFeatures* method.

Automatic expansion of the training set using predicate argument alignment

We compare our approach with a method proposed by Fürstenau and Lapata (2009). This approach is more tailored to the specific case of SRL and is summarized here.

Given a set of labeled seed verbs with annotated semantic roles, for every annotated verb a number of occurrences of this verb is found in unlabeled texts where the context is similar to the context of the annotated example. The context is defined here as all words in the sentence that are direct dependents of this verb, given the syntactic dependency tree. The similarity between two occurrences of a particular verb is measured by finding all different alignments $\sigma : M_\sigma \rightarrow \{1...n\}$ $(M_\sigma \subset \{1,...,m\})$ between the m dependents of the first occurrence and the n dependents of the second occurrence. Every alignment σ is assigned a score given by

$$\sum_{i \in M_\sigma} \left(A \cdot syn(g_i, g_{\sigma(i)}) + sem(w_i, w_{\sigma(i)}) - B \right)$$

where $syn(g_i, g_{\sigma(i)})$ denotes the syntactic similarity between grammatical role[5] g_i of word w_i and grammatical role $g_{\sigma(i)}$ of word $w_{\sigma(i)}$, and $sem(w_i, w_{\sigma(i)})$ measures the semantic similarity between words w_i and $w_{\sigma(i)}$. A is a constant weighting the importance of the syntactic similarity compared to semantic similarity, and B can be interpreted as the lowest similarity value for which an alignment between two arguments is possible. The syntactic similarity $syn(g_i, g_{\sigma(i)})$ is defined as 1 if the dependency relations are identical, $0 < a < 1$ if the relations are of the same type but of a different subtype[6] and 0 otherwise. The semantic similarity $sem(w_i, w_{\sigma(i)})$ is automatically estimated as the cosine similarity between the contexts of w_i and $w_{\sigma(i)}$ in a large text corpus. For details we refer to (Fürstenau and Lapata, 2009).

For every verb in the annotated training set we find the k occurrences of that verb in the unlabeled texts where the contexts are most similar given the best alignment. We then expand the training set with these examples, automatically generating an annotation using the discovered alignments. The variable k controls the trade-off between annotation confidence and expansion size. The final model is then learned by running the supervised training method on the expanded training set. We call this method *AutomaticExpansionCOS*[7]. The values for k, a, A and B are optimized automatically in every experiment on a held-out set (disjoint from both training and test set).
We adapt this approach by employing a different method for measuring semantic similarity. Given two words w_i and $w_{\sigma(i)}$ we estimate the distribution of latent words, respectively $L(h_i)$ and

[4] Probabilities smaller than $1e10^{-4}$ were set to 0 for efficiency reasons.

[5] Note that this is a syntactic role, not a semantic role as the ones discussed in this article.

[6] Subtypes are fine-grained distinctions made by the parser such as the underlying grammatical roles in passive constructions.

[7] The only major differences with (Fürstenau and Lapata, 2009) are the dependency parser which was used (the MALT parser (Nivre et al., 2006) instead of the RASP parser (Briscoe et al., 2006)) and the corpus employed to learn semantic similarities (the Reuters corpus instead of the British National Corpus). We expect that these differences will only influence the results minimally.

	5%	20%	50%	100%
Supervised	40.49%	67.23%	74.93%	78.65%
LWFeatures	**60.29%**	**72.88%**	**76.42%**	**80.98%**
ClusterFeatures	59.51%	66.70%	70.15%	72.62%
AutomaticExpansionCOS	47.05%	53.72%	64.51%	70.52%
AutomaticExpansionLW	45.40%	53.82%	65.39%	72.66%

Table 1: Results (in F1-measure) on the CoNLL 2008 test set for the different methods, comparing the supervised method (*Supervised*) with the semi-supervised methods *LWFeatures*, *ClusterFeatures*, *AutomaticExpansionCOS* and *AutomaticExpansionLW*. See section 5 for details on the different methods. Best results are in bold.

$L(h_{\sigma(i)})$. We then compute the semantic similarity measure as the Jensen-Shannon (Lin, 1997) divergence

$$JS(L(h_i)||L(h_{\sigma(i)})) = \frac{1}{2}\left[D(L(h_i)||avg) + D\left(L(h_{\sigma(i)})||avg\right)\right]$$

where $avg = (L(h_i) + L(h_{\sigma(i)}))/2$ is the average between the two distributions and $D(L(h_i)||avg)$ is the Kullback–Leiber divergence (Cover and Thomas, 2006).

Although this change might appear only a slight deviation from the original model discussed in (Fürstenau and Lapata, 2009) it is potentially an important one, since an accurate semantic similarity measure will greatly influence the accuracy of the alignments, and thus of the accuracy of the automatic expansion. We call this method *AutomaticExpansionLW*.

6 Experiments

We perform a number of experiments where we compare the fully supervised model with the semi-supervised models proposed in the previous section. We first train the LWLM model on an unlabeled 5 million word *Reuters* corpus[8].

We perform different experiments for the supervised and the four different semi-supervised methods (see previous section). Table 1 shows the results of the different methods on the test set of the CoNLL 2008 shared task. We experimented with different sizes for the training set, ranging from 5% to 100%. When using a subset of the full training set, we run 10 different experiments with random subsets and average the results.

We see that the *LWFeatures* method performs better than the other methods across all training sizes. Furthermore, these improvements are larger for smaller training sets, showing that the approach can be applied successfully in a setting where only a small number of training examples is available.

When comparing the *LWFeatures* method with the *ClusterFeatures* method we see that, although the *ClusterFeatures* method has a similar performance for small training sizes, this performance drops for larger training sizes. A possible explanation for this result is the use of the clusters employed in the *ClusterFeatures* method. By definition the clusters merge many words into one cluster, which might lead to good generalization (more important for small training sizes) but can potentially hurt precision (more important for larger training sizes).

A third observation that can be made from table 1 is that, although both automatic expansion methods (*AutomaticExpansionCOS* and *AutomaticExpansionCOS*) outperform the supervised method for the smallest training size, for other sizes of the training set they perform relatively poorly. An informal inspection showed that for some examples in the training set, little or no correct similar occurrences were found in the unlabeled text. The algorithm described in section 5 adds the most similar k occurrences to the training set for every annotated example, also for these examples where little or no similar occurrences were found. Often the automatic alignment fails to generate correct labels for these occurrences and introduces errors in the training set. In the future we would like to perform experiments that determine dynamically (for instance based on the similarity measure between occurrences) for every annotated example how many training examples to add.

[8] See http://www.daviddlewis.com/resources

7 Conclusions and future work

We have presented the Latent Words Language Model and showed how it learns, from unlabeled texts, latent words that capture the meaning of a certain word, depending on the context. We then experimented with different methods to incorporate the latent words for Semantic Role Labeling, and tested different methods on the PropBank dataset. Our best performing method showed a significant improvement over the supervised model and over methods previously proposed in the literature. On the full training set the best method performed 2.33% better than the fully supervised model, which is a 10.91% error reduction. Using only 5% of the training data the best semi-supervised model still achieved 60.29%, compared to 40.49% by the supervised model, which is an error reduction of 33.27%. These results demonstrate that the latent words learned by the LWLM help for this complex information extraction task. Furthermore we have shown that the latent words are simple to incorporate in an existing classifier by adding additional features. We would like to perform experiments on employing this model in other information extraction tasks, such as Word Sense Disambiguation or Named Entity Recognition. The current model uses the context in a very straightforward way, i.e. the two words left and right of the current word, but in the future we would like to explore more advanced methods to improve the similarity estimates. Lin (1998) for example discusses a method where a syntactic parse of the text is performed and the context of a word is modeled using dependency triples.

The other semi-supervised methods proposed here were less successful, although all improved on the supervised model for small training sizes. In the future we would like to improve the described automatic expansion methods, since we feel that their full potential has not yet been reached. More specifically we plan to experiment with more advanced methods to decide whether some automatically generated examples should be added to the training set.

Acknowledgments

The work reported in this paper was supported by the EU-IST project CLASS (Cognitive-Level Annotation using Latent Statistical Structure, IST-027978) and the IWT-SBO project AMASS++ (IWT-SBO-060051). We thank the anonymous reviewers for their helpful comments and Dennis N. Mehay for his help on clarifying the linguistic motivation of our models.

Abstract

We present an integrated dependency-based semantic role labeling system for English from both NomBank and PropBank. By introducing assistant argument labels and considering much more feature templates, two optimal feature template sets are obtained through an effective feature selection procedure and help construct a high performance single SRL system. From the evaluations on the date set of CoNLL-2008 shared task, the performance of our system is quite close to the state of the art. As to our knowledge, this is the first integrated SRL system that achieves a competitive performance against previous pipeline systems.

1 Introduction

We investigate the possibility to construct an effective integrated system for dependency-based semantic role labeling (SRL) task. This means in this work that a single system handles all these sub-tasks, predicate identification/disambiguation and argument identification/classification, regardless of whether the predicate is verbal or nominal.

Traditionally, a SRL task, either dependency or constituent based, is implemented as two subtasks, namely, argument identification and classification. If the predicate is unknown, then a predicate identification or disambiguation subtask should be additionally considered. A pipeline framework is usually adopted to handle all these sub-tasks. The reason to divide the whole task into multiple stages is two-fold, one is each subtask asks for its favorable features, the other is at the consideration of computational efficiency. Generally speaking, a joint system is slower than a pipeline system in training. (Xue and Palmer, 2004) fount out that different features suited for different sub-tasks of SRL, i.e. argument identification and classification. The results from CoNLL shared tasks in 2005 and 2008 (Carreras and Marquez, 2005; Koomen et al., 2005; Surdeanu et al., 2008; Johansson and Nugues, 2008), further show that SRL pipeline may be one of the standard to achieve a state-of-the-art performance in practice.

In the recent years, most works on SRL, including two CoNLL shared task in 2004 and 2005, focus on verbal predicates with the availability of PropBank (Palmer et al., 2005). As a complement to PropBank, NomBank (Meyers et al., 2004) annotates nominal predicates and their corresponding semantic roles using similar semantic framework as PropBank. Though SRL for nominal predicates offers more challenge, it draws relatively little attention (Jiang and Ng, 2006).

(Pustejovsky et al., 2005) discussed the issue of merging various treebanks, including PropBank, NomBank, and others. The idea of merging these two different treebanks was implemented in the CoNLL-2008 shared task (Surdeanu et al., 2008). However, few empirical studies support the necessity of an integrated learning strategy from NomBank and PropBank. Though aiming at Chinese SRL, (Xue, 2006) reported that their experiments show that simply adding the verb data to the training set of NomBank and extracting the same features from the verb and noun instances will hurt the overall performance. From the results of CoNLL-2008 shared task, the top system by (Johansson and Nugues, 2008) also used two

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 30–39,
Singapore, 6-7 August 2009.

different subsystems to handle verbal and nominal predicates, respectively.

Despite all the above facts, an integrated SRL system still holds some sort of merits, being easier to implement, a single-stage feature selection benefiting the whole system, an all-in-one model outputting all required semantic role information and so on.

The shared tasks at the CoNLL 2008 and 2009 are devoted to the joint learning of syntactic and semantic dependencies, which show that SRL can be well performed using only dependency syntax input. Using data and evaluation settings of the CoNLL-2008 shared task, this work will only focus on semantic dependency parsing and compares the best-performing SRL system in the CoNLL-2009 shared Task (Zhao et al., 2009b) with those in the CoNLL-2008 shared task (Surdeanu et al., 2008; Hajič et al., 2009)[1].

Aiming at main drawbacks of an integrated approach, two key techniques will be applied. 1) Assistant argument labels are introduced for the further improvement of argument pruning. This helps the development of a fast and lightweight SRL system. 2) Using a greedy feature selection algorithm, a large-scale feature engineering is performed on a much larger feature template set than that in previous work. This helps us find features that may be of benefit to all SRL sub-tasks as long as possible. As two optimal feature template sets have been proven available, for the first time we report that an integrated SRL system may provide a result close to the state-of-the-art achieved by those SRL pipelines or individual systems for some specific predicates.

2 Adaptive Argument Pruning

A word-pair classification is used to formulate semantic dependency parsing as in (Zhao and Kit, 2008). As for predicate identification or disambiguation, the first word is set as a virtual root (which is virtually set before the beginning of the sentence.) and the second as a predicate candidate. As for argument identification/classification, the first word in a word pair is specified as a predicate candidate and the second as an argument candidate. In either of case, the first word is called a semantic head, and noted as p in our feature representation, the second is called a semantic dependent and noted as a.

Word pairs are collected for the classifier in such order. The first word of the pair is set to the virtual root at first, the second word is then specified as a predicate candidate. According to the result that the predicate candidate is classified or proven to be non-predicate, 1) the second word is reset to next predicate candidate if the answer is non-predicate, otherwise, 2) the first word of the pair is reset to the predicate that is just determined, and the second is set to every argument candidates one by one. The classifier will scan the input sentence from left to right to check if each word is a true predicate.

Without any constraint, all word pairs in an input sequence must be considered by the classifier, leading to poor computational efficiency and unnecessary performance loss. Thus, the training sample for SRL task needs to be pruned properly.

We use a simple strategy to prune predicate candidates, namely, only verbs and nouns are chosen in this case.

There are two paths to collect argument candidates over the sequence. One is based on an input syntactic dependency tree, the other is based on a linear path of the sentence. As for the former (hereafter it is referred to *synPth*), we continue to use a dependency version of the pruning algorithm of (Xue and Palmer, 2004). The pruning algorithm is readdressed as the following.

> Initialization: Set the given predicate as the current node;
>
> (1) The current node and all of its syntactic children are selected as argument candidates (children are traversed from left to right.).
>
> (2) Reset the current node to its syntactic head and repeat step (1) until the root is reached.

Note that this pruning algorithm is slightly different from that of (Xue and Palmer, 2004), the predicate itself is also included in the argument candidate list as the nominal predicate sometimes takes itself as its argument.

The above pruning algorithm has been shown effective. However, it is still inefficient for a SRL

[1]CoNLL-2008 is an English-only task, while CoNLL-2009 is a multilingual one. Though the English corpus in CoNLL-2009 is almost identical to the corpus in the CoNLL-2008 shared task evaluation, the latter holds more sophisticated input structure as in (Surdeanu et al., 2008). The most difference for these two tasks is that the identification of semantic predicates is required in the task of CoNLL-2008 but not in CoNLL-2009.

system that needs to tackle argument identification/classification in a single stage. Assuming that arguments trend to surround their predicate, an assistant argument label '*_NoMoreArgument*' is introduced for further pruning. If an argument candidate in the above algorithm is assigned to such a label, then the pruning algorithm will end immediately. In training, this assistant label means no more samples will be generated for the current predicate, while in test, the decoder will not search arguments any more. It will be seen that this adaptive technique more effectively prunes argument candidates without missing more true arguments.

Along the linear path (hereafter referred to *linPth*), the classifier will search all words before and after the predicate. Similar to the pruning algorithm for *synPth*, we also introduce two assistant argument labels '*_noLeft*' and '*_noRight*' to adaptively prune words too far away from the predicate.

To show how assistant argument labels actually work, we give an example for $linPth$. Suppose an input sequence with argument labels for a predicate is

$a\ \ b\ \ c\ \ d\ \ \ e\ \ \ f\ \ \ g\ \ h\ \ .$

_ _ _ A1 _ A0 _ _ _

Note that c and g are two boundary words as no more arguments appear before or after them. After two assistant argument labels are added, it will be

$a\ \ b\ \ \ \ c\ \ \ \ \ d\ \ e\ \ f\ \ \ \ \ g\ \ \ \ \ h\ \ .$

_ _ *_noLeft* A1 _ A0 *_noRight* _ _

Training samples will generated from c to g according to the above sequence.

We use a Maximum Entropy classifier with a tunable Gaussian prior as usual. Our implementation of the model adopts L-BFGS algorithm for parameter optimization.

3 Feature Templates

3.1 Elements for Feature Generation

Motivated by previous works, we carefully consider those factors from a wide range of features that can help semantic role labeling for both predicate disambiguation, argument's identification and classification as the predicate is either verbal or nominal. These works include (Gildea and Jurafsky, 2002; Carreras and Marquez, 2005; Koomen et al., 2005; Marquez et al., 2005; Dang and Palmer, 2005; Pradhan et al., 2005; Toutanova et al., 2005; Jiang and Ng, 2006; Liu and Ng, 2007; Surdeanu et al., 2007; Johansson and Nugues, 2008; Che et al., 2008). Most feature templates that we will adopt for this work will come from various combinations or integrations of the following basic elements.

Word Property. This type of elements include word form (*form* and its split form, *spForm*)[2], lemma (*lemma*,*spLemma*), and part-of-speech tag (*pos*, *spPos*), syntactic dependency label (*dprel*), and semantic dependency label (*semdprel*)[3].

Syntactic Connection. This includes syntactic head (h), left(right) farthest(nearest) child (lm, ln, rm, and rn), and high(low) support verb or noun. We explain the last item, support verb(noun). From a given word to the syntactic root along the syntactic tree, the first verb/noun/preposition that is met is called as its low support verb/noun/preposition, and the nearest one to the root is called as its high support verb/noun/preposition. The concept of support verb was broadly used (Toutanova et al., 2005; Xue, 2006; Jiang and Ng, 2006)[4], we here extend it to nouns and prepositions. In addition, we introduce a slightly modified syntactic head, $pphead$, it returns the left most sibling of a given word if the word is headed by a preposition, otherwise it returns the original head.

Path. There are two basic types of path between the predicate and the argument candidates. One is the linear path (*linePath*) in the sequence, the other is the path in the syntactic parsing tree (*dpPath*). For the latter, we further divide it into four sub-types with respect to the syntactic root, *dpPath* is the full path in the syntactic tree. Leading two paths to the root from the predicate and the argument, respectively, the common part of these two paths will be *dpPathShare*. Assume that *dpPathShare* starts from a node r', then *dpPathPred* is from the predicate to r', and *dpPathArgu* is from the argument to r'.

Family. Two types of children sets for the predicate or argument candidate are considered, the

[2]In CoNLL-2008, Treebank tokens are split at the position that a hyphen (-) or a forward slash (/) occurs. This leads to two types of feature columns, non-split and split.

[3]Lemma and pos for either training or test are from automatically pre-analyzed columns in the input files.

[4]Note that the meaning of support verb is slightly different between (Toutanova et al., 2005) and (Xue, 2006; Jiang and Ng, 2006)

first includes all syntactic children (*children*), the second also includes all but excludes the left most and the right most children (*noFarChildren*).

Concatenation of Elements. For all collected elements according to *linePath*, *children* and so on, we use three strategies to concatenate all those strings to produce the feature value. The first is *seq*, which concatenates all collected strings without doing anything. The second is *bag*, which removes all duplicated strings and sort the rest. The third is *noDup*, which removes all duplicated neighbored strings.

We address some other elements that are not included by the above description as the following.

dpTreeRelation. It returns the relationship of a and p in the input syntactic tree. The possible values for this feature include `parent`, `sibling` etc.

isCurPred. It judges if a given word is the current predicate. If the word is the predicate, then it returns the predicate itself, otherwise it returns a default value.

existCross. It judges if a forthcoming dependency relation that is between a given word pair may cause any cross with all existing dependency relations.

distance. It counts the number of words along a given path, either $dpPath$ or $linePath$.

existSemdprel. It checks if the given argument label for other predicates has been assigned to a given word.

voice. This feature returns *Active* or *Passive* for verbs, and a default value for nouns.

baseline. Two types of semantic role baseline outputs are used for features from (Carreras and Marquez, 2005)[5]. $baseline\_Ax$ tags the head of the first NP before the predicate as $A0$ and the head of the first NP after the predicate as $A1$. $baseline\_Mod$ tags the dependant of the predicate as *AM-MOD* as it is a modal verb.

We show some feature template examples derived from the above mentioned items.

a.lm.lemma The lemma of the left most child of the argument candidate.

p.h.dprel The dependant label of the syntactic head of the predicate candidate.

p$_{-1}$*.pos+p.pos pos* of the previous word of the predicate and *PoS* of the predicate itself.

a:p|dpPath.lemma.bag Collect all lemmas along the syntactic tree path from the argument to the predicate, then removed all duplicated ones and sort the rest, finally concatenate all as a feature string.

a:p.highSupportNoun|linePath.dprel.seq Collect all dependant labels along with the line path from the argument to the high support noun of the predicate, then concatenate all as a feature string.

3.2 Feature Template Selection

Based on the above mentioned elements, 781 feature templates (hereafter the set of these templates is referred to FT)[6] are initially considered. Feature templates in this initial set are constructed in a generalized way. For example, if we find that a feature template *a.lm.lemma* was once used in some existing work, then such three templates, *a.rm.lemma*, *a.rn.lemma*, *a.ln.lemma* will be also added into the set.

As an optimal feature template subset cannot be expected to be extracted from so large a set by hand, a greedy feature selection similar to that in (Jiang and Ng, 2006; Ding and Chang, 2008) is applied. The detailed algorithm is described in Algorithm 1. Assuming that the number of feature templates in a given set is n, the algorithm of (Ding and Chang, 2008) requires $O(n^2)$ times of training/test routines, it cannot handle a set that consists of hundreds of templates. As the time complexity of Algorithm 1 is only $O(n)$, it permits a large scale feature selection accomplished by paying a reasonable time cost. Though the time complexity of the algorithm given by (Jiang and Ng, 2006) is also linear, it should assume all feature templates in the initial selected set 'good' enough and handles other feature template candidates in a strict incremental way. However, these two constraints are not easily satisfied in our case, while Algorithm 1 may release these two constraints.

Choosing the first 1/10 templates in FT as the initial selected set S, the feature selection is performed for two argument candidate traverse schemes, $synPth$ and $linPth$, respectively. 4686 machine learning routines run for the former, while 6248 routines for the latter. Two feature template sets, FT_{syn} and FT_{lin}, are obtained at last. These two sets are given in Table 1-3. We see that two sets share 30 identical feature templates as in Table 1. FT_{syn} holds 51 different templates

[5]These baseline rules were developed by Erik Tjong Kim Sang, from the University of Antwerp, Belgium.

Table 1: Feature templates for both $synPth$ and $linPth$

as in Table 2 and FT_{lin} holds 57 different templates as in Table 3. In these tables, the subscripts -2(or -1) and 1(or 2) stand for the previous and next words, respectively. For example, *a.lm*$_{-1}$*.lemma* returns the lemma of the previous word of the argument's left most child.

4 Decoding

After the predicate sense is disambiguated, an optimal argument structure for each predicate is determined by the following maximal probability.

$$S_p = \text{argmax} \prod_i P(a_i|a_{i-1}, a_{i-2}, ...), \qquad (1)$$

where S_p is the argument structure, $P(a_i|a_{i-1}...)$ is the conditional probability to determine the label of the i-th argument candidate label. A beam search algorithm is used to find the optimal argument structure.

5 Evaluation Results

Our evaluation is performed on the standard training/development/test corpus of CoNLL-2008 shared task. The data is derived by merging a dependency version of the Penn Treebank with PropBank and NomBank. More details on the data are

in (Surdeanu et al., 2008). Note that CoNLL-2008 shared task is essentially a joint learning task for both syntactic and semantic dependencies, however, we will focus on semantic part of this task. The main semantic measure that we adopt is semantic labeled F_1 score (Sem-F_1). In addition, the macro labeled F_1 scores (Macro-F_1), which was used for the ranking of the participating systems of CoNLL-2008, the ratio between labeled F_1 score for semantic dependencies and the LAS for syntactic dependencies (Sem-F_1/LAS), are also given for reference.

5.1 Syntactic Dependency Parsers

We consider three types of syntactic information to feed the SRL task. One is gold-standard syntactic input, and other two are based on automatically parsing results of two parsers, the state-of-the-art syntactic parser described in (Johansson and Nugues, 2008)[7](it is referred to *Johansson*) and an integrated parser described as the following (referred to *MST*$_{ME}$).

The parser is basically based on the MSTParser[8] using all the features presented by (McDonald et al., 2006) with projective parsing. Moreover, we exploit three types of additional features to improve the parser. 1) Chen et al. (2008) used features derived from short dependency pairs based on large-scale auto-parsed data to enhance dependency parsing. Here, the same features are used, though all dependency pairs rather than short dependency pairs are extracted along with the dependency direction from training data rather than auto-parsed data. 2) Koo et al. (2008) presented new features based on word clusters obtained from large-scale unlabeled data and achieved large improvement for English and Czech. Here, the same features are also used as word clusters are generated only from the training data. 3) Nivre and McDonald (2008) presented an integrating method to provide additional information for graph-based and transition-based parsers. Here, we represent features based on dependency relations predicted by transition-based parsers for the MSTParer. For the sake of efficiency, we use a fast transition-based parser based on maximum entropy as in Zhao and Kit (2008). We still use the similar feature notations of that work.

[7]It is a 2-order maximum spanning tree parser with pseudo-projective techniques. A syntactic-semantic reranking was performed to output the final results according to (Johansson and Nugues, 2008). However, only 1-best outputs of the parser before reranking are used for our evaluation. Note that the reranking may slightly improve the syntactic performance according to (Johansson and Nugues, 2008).

[8]It's freely available at http://mstparser.sourceforge.net.

5.2 The Results

At first, we report the effectiveness of the proposed adaptive argument pruning. The numbers of argument candidates are in Table 4. The statistics is conducted on three different syntactic inputs. The coverage rate in the table means the ratio of how many true arguments are covered by the selected pruning scheme. Note that the adaptive pruning of argument candidates using assistant labels does not change this rate. This ratio only depends on which path, either $synPth$ or $linPth$, is chosen, and how good the syntactic input is (if $synPth$ is the case). From the results, we see that more than a half of argument candidates can be effectively pruned for $synPth$ and even 2/3 for $linPth$. As mentioned by (Pradhan et al., 2004), argument identification plays a bottleneck role in improving the performance of a SRL system. The effectiveness of the proposed additional pruning techniques may be seen as a significant improvement over the original algorithm of (Xue and Palmer, 2004). The results also indicate that such an assumption holds that arguments trend to close with their predicate, at either type of distance, syntactic or linear.

Based on different syntactic inputs, we obtain different results on semantic dependency parsing

as shown in Table 5. These results on different syntactic inputs also give us a chance to observe how semantic performance varies according to syntactic performance. The fact from the results is that the ratio Sem-F_1/LAS becomes relatively smaller as the syntactic input becomes better. Though not so surprised, the results do show that the argument traverse scheme $synPth$ always outperforms the other $linPth$. The result of this comparison partially shows that an integrated semantic role labeler is sensitive to the order of how argument candidates are traversed to some extent.

The performance given by $synPth$ is compared to some other systems that participated in the CoNLL-2008 shared task. They were chosen among the 20 participating systems either because they held better results (the first four participants) or because they used some joint learning techniques (Henderson et al., 2008). The results of (Titov et al., 2009) that use the similar joint learning technique as (Henderson et al., 2008) are also included[9]. Results of these evaluations on the test set are in Table 6. Top three systems of CoNLL-2008, (Johansson and Nugues, 2008; Ciaramita et al., 2008; Che et al., 2008), used SRL pipelines.

In this work, we partially use the similar techniques ($synPth$) for our participation in the shared tasks of CoNLL-2008 and 2009 (Zhao and Kit, 2008; Zhao et al., 2009b; Zhao et al., 2009a). Here we report that all SRL sub-tasks are tackled in one integrated model, while the predicate disambiguation sub-task was performed individually in both of our previous systems. Therefore, this is our first attempt at a full integrated SRL system.

(Titov et al., 2009) reported the best result by using joint learning technique up to now. The comparison indicates that our integrated system outputs a result quite close to the state-of-the-art by the pipeline system of (Johansson and Nugues, 2008) as the same syntactic structure input is adopted. It is worth noting that our system actually competes with two independent sub-systems of (Johansson and Nugues, 2008), one for verbal predicates, the other for nominal predicates. In addition, the results of our system is obtained without using additional joint learning technique like syntactic-semantic reranking. It indicates that our system is expected to obtain some further performance improvement by using such techniques.

[9]In addition, the work of (Henderson et al., 2008) and (Titov et al., 2009) jointly considered syntactic and semantic dependencies, that is significantly different from the others.

6 Conclusion

We have described a dependency-based semantic role labeling system for English from NomBank and PropBank. From the evaluations, the result of our system is quite close to the state of the art. As to our knowledge, it is the first integrated SRL system that achieves such a competitive performance against previous pipeline systems.

According to the path that the word-pair classifier traverses argument candidates, two integration schemes are presented. Argument candidate pruning and feature selection are performed on them, respectively. These two schemes are more than providing a trivial comparison. As assistant labeled are introduced to help further argument candidate pruning, and this techniques work well for both schemes, it support the assumption that arguments trend to surround their predicate. The proposed feature selection procedure also work for both schemes and output quite different two feature template sets, and either of the sets helps the system obtain a competitive performance, this fact suggests that the feature selection procedure is robust and effective, too.

Either of the presented integrated systems can provide a competitive performance. This conclusion about basic learning scheme for SRL is some different from previous literatures. However, according to our results, there does exist a 'harmony' feature template set that is helpful to both predicate and argument identification/classification, or SRL for both verbal and nominal predicates. We attribute this different conclusion to two main factors, 1) much more feature templates (for example, ten times more than those used by Xue et al.) than previous that are considered for a successful feature engineering, 2) a maximum entropy classifier makes it possible to accept so many various features in one model. Note that maximum entropy is not so sensitive to those (partially) overlapped features, while SVM and other margin-based learners are not so.

First- and Second-Order Expectation Semirings with Applications to Minimum-Risk Training on Translation Forests*

Zhifei Li and **Jason Eisner**

Johns Hopkins University, Baltimore, MD 21218, USA
zhifei.work@gmail.com, jason@cs.jhu.edu

Abstract

Many statistical translation models can be regarded as weighted logical deduction. Under this paradigm, we use weights from the expectation semiring (Eisner, 2002), to compute first-order statistics (e.g., the expected hypothesis length or feature counts) over packed forests of translations (lattices or hypergraphs). We then introduce a novel *second-order* expectation semiring, which computes second-order statistics (e.g., the variance of the hypothesis length or the gradient of entropy). This second-order semiring is essential for many interesting training paradigms such as minimum risk, deterministic annealing, active learning, and semi-supervised learning, where gradient descent optimization requires computing the gradient of entropy or risk. We use these semirings in an open-source machine translation toolkit, **Joshua**, enabling minimum-risk training for a benefit of up to 1.0 BLEU point.

1 Introduction

A hypergraph or "packed forest" (Gallo et al., 1993; Klein and Manning, 2004; Huang and Chiang, 2005) is a compact data structure that uses structure-sharing to represent exponentially many trees in polynomial space. A *weighted* hypergraph also defines a probability or other weight for each tree, and can be used to represent the hypothesis space considered (for a given input) by a monolingual parser or a tree-based translation system, e.g., tree to string (Quirk et al., 2005; Liu et al., 2006), string to tree (Galley et al., 2006), tree to tree (Eisner, 2003), or string to string with latent tree structures (Chiang, 2007).

*This research was partially supported by the Defense Advanced Research Projects Agency's GALE program via Contract No HR0011-06-2-0001. We are grateful to Sanjeev Khudanpur for early guidance and regular discussions.

Given a hypergraph, we are often interested in computing some quantities over it using dynamic programming algorithms. For example, we may want to run the Viterbi algorithm to find the most probable derivation tree in the hypergraph, or the k most probable trees. Semiring-weighted logic programming is a general framework to specify these algorithms (Pereira and Warren, 1983; Shieber et al., 1994; Goodman, 1999; Eisner et al., 2005; Lopez, 2009). Goodman (1999) describes many useful semirings (e.g., Viterbi, inside, and Viterbi-n-best). While most of these semirings are used in "testing" (i.e., decoding), we are mainly interested in the semirings that are useful for "training" (i.e., parameter estimation). The expectation semiring (Eisner, 2002), originally proposed for finite-state machines, is one such "training" semiring, and can be used to compute feature expectations for the E-step of the EM algorithm, or gradients of the likelihood function for gradient descent.

In this paper, we apply the expectation semiring (Eisner, 2002) to a hypergraph (or packed forest) rather than just a lattice. We then propose a novel *second-order* expectation semiring, nicknamed the "variance semiring."

The original first-order expectation semiring allows us to efficiently compute a vector of first-order statistics (expectations; first derivatives) on the set of paths in a lattice or the set of trees in a hypergraph. The second-order expectation semiring *additionally* computes a matrix of second-order statistics (expectations of *products*; second derivatives (Hessian); derivatives of expectations).

We present details on how to compute many interesting quantities over the hypergraph using the expectation and variance semirings. These quantities include expected hypothesis length, feature expectation, entropy, cross-entropy, Kullback-Leibler divergence, Bayes risk, variance of hypothesis length, gradient of entropy and Bayes risk, covariance and Hessian matrix, and so on. The variance semiring is essential for many interesting training paradigms such as deterministic

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 40–51,
Singapore, 6-7 August 2009.

annealing (Rose, 1998), minimum risk (Smith and Eisner, 2006), active and semi-supervised learning (Grandvalet and Bengio, 2004; Jiao et al., 2006). In these settings, we must compute the gradient of entropy or risk. The semirings can also be used for second-order gradient optimization algorithms.

We implement the expectation and variance semirings in **Joshua** (Li et al., 2009a), and demonstrate their practical benefit by using minimum-risk training to improve Hiero (Chiang, 2007).

2 Semiring Parsing on Hypergraphs

We use a specific tree-based system called Hiero (Chiang, 2007) as an example, although the discussion is general for any systems that use a hypergraph to represent the hypothesis space.

2.1 Hierarchical Machine Translation

In Hiero, a synchronous context-free grammar (SCFG) is extracted from automatically word-aligned corpora. An illustrative grammar rule for Chinese-to-English translation is

$$X \;\rightarrow\; \langle\, X_0 \text{ 的 } X_1 \,,\, X_1 \text{ of } X_0 \,\rangle\,,$$

where the Chinese word 的 means *of*, and the alignment, encoded via subscripts on the nonterminals, causes the two phrases around 的 to be reordered around *of* in the translation. Given a source sentence, Hiero uses a CKY parser to generate a hypergraph, encoding many derivation trees along with the translation strings.

2.2 Hypergraphs

Formally, a hypergraph is a pair $\langle V, E\rangle$, where V is a set of *nodes* (vertices) and E is a set of *hyperedges*, with each hyperedge connecting a *set* of *antecedent nodes* to a single *consequent node*.[1] In parsing parlance, a node corresponds to an *item* in the chart (which specifies aligned spans of input and output together with a nonterminal label). The root node corresponds to the *goal item*. A hyperedge represents an SCFG rule that has been "instantiated" at a particular position, so that the nonterminals on the right and left sides have been replaced by particular antecedent and consequent items; this corresponds to storage of backpointers in the chart.

We write $T(e)$ to denote the set of antecedent nodes of a hyperedge e. We write $I(v)$ for the set of *incoming hyperedges* of node v (i.e., hyperedges of which v is the consequent), which represent different ways of deriving v. Figure 1 shows a simple Hiero-style hypergraph. The hypergraph encodes four different derivation trees that share some of the same items. By exploiting this sharing, a hypergraph can compactly represent exponentially many trees.

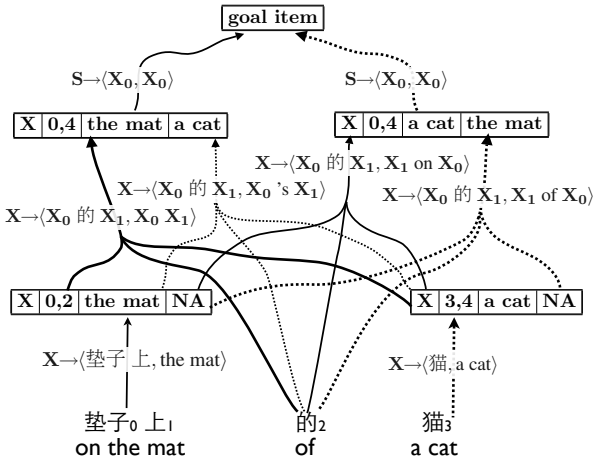

Figure 1: A toy hypergraph in Hiero. When generating the hypergraph, a trigram language model is integrated. Rectangles represent items, where each item is identified by the non-terminal symbol, source span, and left- and right-side language model states. An item has one or more incoming hyperedges. A hyperedge consists of a rule, and a pointer to an antecedent item for each non-terminal symbol in the rule.

We observe that any finite-state automaton can also be encoded as a hypergraph (in which every hyperedge is an ordinary edge that connects a *single* antecedent to a consequent). Thus, the methods of this paper apply directly to the simpler case of hypothesis lattices as well.

2.3 Semiring Parsing

We assume a hypergraph HG, which compactly encodes many derivation trees $d \in \mathrm{D}$. Given HG, we wish to extract the best derivations—or other aggregate properties of the forest of derivations. Semiring parsing (Goodman, 1999) is a general framework to describe such algorithms. To define a particular algorithm, we choose a semiring K and specify a "weight" $k_e \in K$ for each hyperedge e. The desired aggregate result then emerges as the *total weight* of all derivations in the hypergraph. For example, to simply count derivations, one can assign every hyperedge weight 1 in the semiring of *ordinary integers*; then each derivation also has weight 1, and their total weight is the number of derivations.

We write $\mathbf{K} = \langle K, \oplus, \otimes, \mathbf{0}, \mathbf{1}\rangle$ for a semiring with elements K, additive operation $\oplus$, multi-

[1] Strictly speaking, making each hyperedge designate a single consequent defines a *B-hypergraph* (Gallo et al., 1993).

plicative operation $\otimes$, additive identity $\mathbf{0}$, and multiplicative identity $\mathbf{1}$. The $\otimes$ operation is used to obtain the weight of each derivation d by *multiplying* the weights of its component hyperedges e, that is, $k_d = \bigotimes_{e \in d} k_e$. The $\oplus$ operation is used to *sum* over all derivations d in the hypergraph to obtain the *total* weight of the hypergraph HG, which is $\bigoplus_{d \in \mathrm{D}} \bigotimes_{e \in d} k_e$.[2] Figure 2 shows how to compute the total weight of an acyclic hypergraph HG.[3] In general, the total weight is a sum over exponentially many derivations d. But Figure 2 sums over these derivations in time only linear on the size of the hypergraph. Its correctness relies on axiomatic properties of the semiring: namely, $\oplus$ is associative and commutative with identity $\mathbf{0}$, $\otimes$ is associative with two-sided identity $\mathbf{1}$, and $\otimes$ distributes over $\oplus$ from both sides. The distributive property is what makes Figure 2 work. The other properties are necessary to ensure that $\bigoplus_{d \in \mathrm{D}} \bigotimes_{e \in d} k_e$ is well-defined.[4]

The algorithm in Figure 2 is general and can be applied with any semiring (e.g., Viterbi). Below, we present our novel semirings.

3 Finding Expectations on Hypergraphs

We now introduce the computational problems of this paper and the semirings we use to solve them.

3.1 Problem Definitions

We are given a function $p : \mathrm{D} \to \mathbb{R}_{\geq 0}$, which decomposes **multiplicatively** over component hyperedges e of a derivation $d \in \mathrm{D}$: that is, $p(d) \stackrel{\text{def}}{=} \prod_{e \in d} p_e$. In practice, $p(d)$ will specify a probability distribution over the derivations in the hypergraph. It is often convenient to permit this probability distribution to be unnormalized, i.e., one may have to divide it through by some Z to get a proper distribution that sums to 1.

We are also given two functions of interest $r, s : \mathrm{D} \to \mathbb{R}$, each of which decomposes **additively** over its component hyperedges e: that is, $r(d) \stackrel{\text{def}}{=} \sum_{e \in d} r_e$, and $s(d) \stackrel{\text{def}}{=} \sum_{e \in d} s_e$.

We are now interested in computing the following quantities on the hypergraph HG:

$$Z \stackrel{\text{def}}{=} \sum_{d \in \mathrm{D}} p(d) \quad (1)$$

$$\overline{r} \stackrel{\text{def}}{=} \sum_{d \in \mathrm{D}} p(d) r(d) \quad (2)$$

$$\overline{s} \stackrel{\text{def}}{=} \sum_{d \in \mathrm{D}} p(d) s(d) \quad (3)$$

$$\overline{t} \stackrel{\text{def}}{=} \sum_{d \in \mathrm{D}} p(d) r(d) s(d) \quad (4)$$

Note that $\overline{r}/Z$, $\overline{s}/Z$, and $\overline{t}/Z$ are expectations under p of $r(d)$, $s(d)$, and $r(d)s(d)$, respectively.

More formally, the probabilistic interpretation is that D is a discrete sample space (consisting

return β(root)
```

Figure 2: Inside algorithm for an acyclic hypergraph HG, which provides hyperedge weights $k_e \in \mathbf{K}$. This computes all "inside weights" $\beta(v) \in \mathbf{K}$, and returns $\beta(\text{root})$, which is total weight of the hypergraph, i.e., $\bigoplus_{d \in \mathrm{D}} \bigotimes_{e \in d} k_e$.

OUTSIDE(HG, $\mathbf{K}$)

```
for v in HG
    α(v) ← 0
α(root) ← 1
for v in reverse topological order on HG
    for e ∈ I(v)                                ▷ each incoming hyperedge
        for u ∈ T(e)                            ▷ each antecedent node
            α(u) ← α(u) ⊕ (α(v) ⊗ k_e ⊗
                           ⊗_{w∈T(e),w≠u} β(w))
```

Figure 3: Computes the "outside weights" $\alpha(v)$. Can only be run after INSIDE(HG) of Figure 2 has already computed the inside weights $\beta(v)$.

[2] Eisner (2002) uses *closed semirings* that are also equipped with a Kleene closure operator *. For example, in the real semiring $\langle \mathbb{R}, +, \times, 0, 1 \rangle$, we define $p^* = (1-p)^{-1}$ $(= 1 + p + p^2 + \ldots)$ for $|p| < 1$ and is undefined otherwise. The closure operator enables exact summation over the *infinitely* many paths in a cyclic FSM, or trees in a hypergraph with non-branching cycles, without the need to iterate around cycles to numerical convergence. For completeness, we specify the closure operator for our semirings, satisfying the axioms $k^* = 1 \oplus k \otimes k^* = 1 \oplus k^* \otimes k$, but we do not use it in our experiments since our hypergraphs are acyclic.

[3] We assume that HG has *already* been built by deductive inference (Shieber et al., 1994). But in practice, the nodes' inside weights $\beta(v)$ are usually accumulated *as the hypergraph is being built*, so that pruning heuristics can consult them.

[4] Actually, the notation $\bigotimes_{e \in d} k_e$ assumes that $\otimes$ is commutative as well, as does the notation "for $u \in T(e)$" in our algorithms; neither specifies a loop order. One could however use a non-commutative semiring by ordering each hyperedge's antecedents and specifying that a derivation's weight is the product of the weights of its hyperedges *when visited in prefix order*. Tables 1–2 will not assume any commutativity.

INSIDE-OUTSIDE(HG, $\mathbf{K}$, X)

1 ▷ Run inside and outside on HG with only k_e weights
2 $\hat{k} \leftarrow$ INSIDE(HG, $\mathbf{K}$) ▷ see Figure 2
3 OUTSIDE(HG, $\mathbf{K}$) ▷ see Figure 3
4 ▷ Do a single linear combination to get $\hat{x}$
5 $\hat{x} \leftarrow \mathbf{0}$
6 **for** v **in** HG ▷ each node
7 **for** $e \in I(v)$ ▷ each incoming hyperedge
8 $\overline{k_e} \leftarrow \alpha(v)$
9 **for** $u \in T(e)$ ▷ each antecedent node
10 $\overline{k_e} \leftarrow \overline{k_e}\,\beta(u)$
11 $\hat{x} \leftarrow \hat{x} + (\overline{k_e}\, x_e)$
12 **return** $\langle \hat{k}, \hat{x} \rangle$

Figure 4: If every hyperedge specifies a weight $\langle k_e, x_e \rangle$ in some expectation semiring $\mathbb{E}_{\mathbf{K},X}$, then this inside-outside algorithm is a more efficient alternative to Figure 2 for computing the total weight $\langle \hat{k}, \hat{x} \rangle$ of the hypergraph, especially if the x_e are vectors. First, at lines 2–3, the inside and outside algorithms are run using only the k_e weights, obtaining only $\hat{k}$ (without $\hat{x}$) but also obtaining all inside and outside weights $\beta, \alpha \in \mathbf{K}$ as a side effect. Then the second component $\hat{x}$ of the total weight is accumulated in lines 5–11 as a linear combination of all the x_e values, namely $\hat{x} = \sum_e \overline{k_e} x_e$, where $\overline{k_e}$ is computed at lines 8–10 using α and β weights. The linear coefficient $\overline{k_e}$ is the "exclusive weight" for hyperedge e, meaning that the *product* $\overline{k_e} k_e$ is the total weight in $\mathbf{K}$ of all derivations $d \in$ D that include e.

of all derivations in the hypergraph), p is a measure over this space, and $r, s : \mathrm{D} \rightarrow \mathbb{R}$ are random variables. Then $\overline{r}/Z$ and $\overline{s}/Z$ give the expectations of these random variables, and $\overline{t}/Z$ gives the expectation of their product $t = rs$, so that $\overline{t}/Z - (\overline{r}/Z)(\overline{s}/Z)$ gives their covariance.

Example 1: $r(d)$ is the length of the translation corresponding to derivation d (arranged by setting r_e to the number of target-side terminal words in the SCFG rule associated with e). Then $\overline{r}/Z$ is the expected hypothesis length. ***Example 2:*** $r(d)$ evaluates the loss of d compared to a reference translation, using some additively decomposable loss function. Then $\overline{r}/Z$ is the risk (expected loss), which is useful in minimum-risk training. ***Example 3:*** $r(d)$ is the number of times that a certain feature fires on d. Then $\overline{r}/Z$ is the expected feature count, which is useful in maximum-likelihood training. We will generalize later in Section 4 to allow $r(d)$ to be a vector of features. ***Example 4:*** Suppose $r(d)$ and $s(d)$ are identical and both compute hypothesis length. Then the second-order statistic $\overline{t}/Z$ is the second moment of the length distribution, so the variance of hypothesis length can be found as $\overline{t}/Z - (\overline{r}/Z)^2$.

3.2 Computing the Quantities

We will use the semiring parsing framework to compute the quantities (1)–(4). Although each is a sum over exponentially many derivations, we will compute it in $O(|\mathrm{HG}|)$ time using Figure 2.

In the simplest case, let $\mathbf{K} = \langle \mathbb{R}, +, \times, 0, 1 \rangle$, and define $k_e = p_e$ for each hyperedge e. Then the algorithm of Figure 2 reduces to the classical inside algorithm (Baker, 1979) and computes Z.

Next suppose $\mathbf{K}$ is the expectation semiring (Eisner, 2002), shown in Table 1. Define $k_e = \langle p_e, p_e r_e \rangle$. Then Figure 2 will return $\langle Z, \overline{r} \rangle$.

Finally, suppose $\mathbf{K}$ is our novel *second-order* expectation semiring, which we introduce in Table 2. Define $k_e = \langle p_e, p_e r_e, p_e s_e, p_e r_e s_e \rangle$. Then the algorithm of Figure 2 returns $\langle Z, \overline{r}, \overline{s}, \overline{t} \rangle$. Note that, to compute $\overline{t}$, one cannot simply construct a *first-order* expectation semiring by defining $t(d) \stackrel{\text{def}}{=} r(d)s(d)$ because $t(d)$, unlike $r(d)$ and $s(d)$, is not additively decomposable over the hyperedges in d.[5] Also, when $r(d)$ and $s(d)$ are identical, the second-order expectation semiring allows us to compute variance as $\overline{t}/Z - (\overline{r}/Z)^2$, which is why we may call our second-order expectation semiring the **variance semiring**.

3.3 Correctness of the Algorithms

To prove our claim about the first-order expectation semiring, we first observe that the definitions in Table 1 satisfy the semiring axioms. The reader can easily check these axioms (as well as the closure axioms in footnote 2). With a valid semiring, we then simply observe that Figure 2 returns the total weight $\bigoplus_{d \in \mathrm{D}} \bigotimes_{e \in d} k_e = \bigoplus_{d \in \mathrm{D}} \langle p(d), p(d)r(d) \rangle = \langle Z, \overline{r} \rangle$. It is easy to verify the second equality from the definitions of $\oplus$, Z, and $\overline{r}$. The first equality requires proving that $\bigotimes_{e \in d} k_e = \langle p(d), p(d)r(d) \rangle$ from the definitions of $\otimes, k_e$, $p(d)$, and $r(d)$. The main intuition is that $\otimes$ can be used to build up $\langle p(d), p(d)r(d) \rangle$ inductively from the k_e: if d decomposes into two disjoint subderivations d_1, d_2, then $\langle p(d), p(d)r(d) \rangle = \langle p(d_1)p(d_2), p(d_1)p(d_2)(r(d_1) + r(d_2)) \rangle = \langle p(d_1), p(d_1)r(d_1) \rangle \otimes \langle p(d_2), p(d_2)r(d_2) \rangle$. The base cases are where d is a single hyperedge e, in which case $\langle p(d), p(d)r(d) \rangle = k_e$ (thanks to our choice of k_e), and where d is empty, in which case

[5] However, in a more tricky way, the second-order expectation semiring can be constructed using the first-order expectation semiring, as will be seen in Section 4.3.

Element	$\langle p, r \rangle$
$\langle p_1, r_1 \rangle \otimes \langle p_2, r_2 \rangle$	$\langle p_1 p_2,\ p_1 r_2 + p_2 r_1 \rangle$
$\langle p_1, r_1 \rangle \oplus \langle p_2, r_2 \rangle$	$\langle p_1 + p_2,\ r_1 + r_2 \rangle$
$\langle p, r \rangle^*$	$\langle p^*, p^* p^* r \rangle$
$\mathbf{0}$	$\langle 0, 0 \rangle$
$\mathbf{1}$	$\langle 1, 0 \rangle$

Table 1: **Expectation semiring**: Each element in the semiring is a **pair** $\langle p, r \rangle$. The second and third rows define the operations between two elements $\langle p_1, r_1 \rangle$ and $\langle p_2, r_2 \rangle$, and the last two rows define the identities. Note that the multiplicative identity $\mathbf{1}$ has an r component of 0.

s_a	s_b	$a + b$		$a \cdot b$	
		s_{a+b}	ℓ_{a+b}	$s_{a \cdot b}$	$\ell_{a \cdot b}$
+	+	+	$\ell_a + \log(1 + e^{\ell_b - \ell_a})$	+	$\ell_a + \ell_b$
+	-	+	$\ell_a + \log(1 - e^{\ell_b - \ell_a})$	-	$\ell_a + \ell_b$
-	+	-	$\ell_a + \log(1 - e^{\ell_b - \ell_a})$	-	$\ell_a + \ell_b$
-	-	-	$\ell_a + \log(1 + e^{\ell_b - \ell_a})$	+	$\ell_a + \ell_b$

Table 3: **Storing signed values in log domain**: each value a $(= s_a e^{\ell_a})$ is stored as a **pair** $\langle s_a, \ell_a \rangle$ where s_a and ℓ_a are the **sign bit** of a and **natural logarithm** of $|a|$, respectively. This table shows the operations between two values $a = s_a 2^{\ell_a}$ and $b = s_b 2^{\ell_b}$, assuming $\ell_a \geq \ell_b$. *Note:* $\log(1 + x)$ (where $|x| < 1$) should be computed by the Mercator series $x - x^2/2 + x^3/3 - \cdots$, e.g., using the math library function log1p.

$\langle p(d), p(d) r(d) \rangle = \mathbf{1}$. It follows by induction that $\langle p(d), p(d) r(d) \rangle = \bigotimes_{e \in d} k_e$.

The proof for the second-order expectation semiring is similar. In particular, one mainly needs to show that $\bigotimes_{e \in d} k_e = \langle p(d), p(d) r(d), p(d) s(d), p(d) r(d) s(d) \rangle$.

3.4 Preventing Underflow/Overflow

In Tables 1–2, we do not discuss how to store p, r, s, and t. If p is a probability, it often suffers from the underflow problem. r, s, and t may suffer from both underflow and overflow problems, depending on their scales.

To address these, we could represent p in the log domain as usual. However, r, s, and t can be positive or negative, and we cannot directly take the log of a negative number. Therefore, we represent real numbers as ordered pairs. Specifically, to represent $a = s_a e^{\ell_a}$, we store $\langle s_a, \ell_a \rangle$, where the $s_a \in \{+, -\}$ is the **sign bit** of a and the floating-point number ℓ_a is the **natural logarithm** of $|a|$.[6] Table 3 shows the "$\cdot$" and "$+$"operations.

[6] An alternative that avoids log and exp is to store $a = f_a 2^{e_a}$ as $\langle f_a, e_a \rangle$, where f_a is a *floating-point number* and e_a is a sufficiently wide *integer*. E.g., combining a 32-bit f_a with a 32-bit e_a will in effect extend f_a's 8-bit internal exponent to 32 bits by adding e_a to it. This gives much more dynamic range than the 11-bit exponent of a 64-bit double-precision floating-point number, if vastly less than in Table 3.

4 Generalizations and Speedups

In this section, we generalize beyond the above case where p, r, s are $\mathbb{R}$-valued. In general, p may be an element of some other semiring, and r and s may be **vectors** or other algebraic objects.

When r and s are vectors, especially high-dimensional vectors, the basic "inside algorithm" of Figure 2 will be slow. We will show how to speed it up with an "inside-outside algorithm."

4.1 Allowing Feature Vectors and More

In general, for P, R, S, T, we can define the first-order expectation semiring $\mathbb{E}_{P,R} = \langle P \times R, \oplus, \otimes, \mathbf{0}, \mathbf{1} \rangle$ and the second-order expectation semiring $\mathbb{E}_{P,R,S,T} = \langle P \times R \times S \times T, \oplus, \otimes, \mathbf{0}, \mathbf{1} \rangle$, using the definitions from Tables 1–2. But do those definitions remain meaningful, and do they continue to satisfy the semiring axioms?

Indeed they do when $P = \mathbb{R}, R = \mathbb{R}^n, S = \mathbb{R}^m, T = \mathbb{R}^{n \times m}$, with rs defined as the outer product $rs^{\mathbf{T}}$ (a matrix) where $s^{\mathbf{T}}$ is the transpose of s. In this way, the second-order semiring $\mathbb{E}_{P,R,S,T}$ lets us take expectations of vectors and outer products of vectors. So we can find *means* and *covariances* of any number of linearly decomposable quantities (e.g., feature counts) defined on the hypergraph.

We will consider some other choices in Sections 4.3–4.4 below. Thus, for generality, we conclude this section by stating the precise technical conditions needed to construct $\mathbb{E}_{P,R}$ and $\mathbb{E}_{P,R,S,T}$:

- P is a semiring
- R is a P-module (e.g, a vector space), meaning that it comes equipped with an associative and commutative addition operation with an identity element 0, and also a multiplication operation $P \times R \to R$, such that $p(r_1 + r_2) = pr_1 + pr_2$, $(p_1 + p_2)r = p_1 r + p_2 r$, $p_1(p_2 r) = (p_1 p_2)r$
- S and T are also P-modules
- there is a multiplication operation $R \times S \to T$ that is bilinear, i.e., $(r_1 + r_2)s = r_1 s + r_2 s$, $r(s_1 + s_2) = rs_1 + rs_2$, $(pr)s = p(rs)$, $r(ps) = p(rs)$

As a matter of notation, note that above and in Tables 1–2, we overload "+" to denote any of the addition operations within P, R, S, T; overload "0" to denote their respective additive identities; and overload concatenation to denote any of the multiplication operations within or between

Element	$\langle p, r, s, t \rangle$
$\langle p_1, r_1, s_1, t_1 \rangle \otimes \langle p_2, r_2, s_2, t_2 \rangle$	$\langle p_1 p_2,\ p_1 r_2 + p_2 r_1,\ p_1 s_2 + p_2 s_1,$ $p_1 t_2 + p_2 t_1 + r_1 s_2 + r_2 s_1 \rangle$
$\langle p_1, r_1, s_1, t_1 \rangle \oplus \langle p_2, r_2, s_2, t_2 \rangle$	$\langle p_1 + p_2,\ r_1 + r_2,\ s_1 + s_2,\ t_1 + t_2 \rangle$
$\langle p, r, s, t \rangle^*$	$\langle p^*,\ p^* p^* r,\ p^* p^* s,\ p^* p^* (p^* r s + p^* r s + t) \rangle$
$\mathbf{0}$	$\langle 0, 0, 0, 0 \rangle$
$\mathbf{1}$	$\langle 1, 0, 0, 0 \rangle$

Table 2: **Second-order expectation semiring** (variance semiring): Each element in the semiring is a **4-tuple** $\langle p, r, s, t \rangle$. The second and third rows define the operations between two elements $\langle p_1, r_1, s_1, t_1 \rangle$ and $\langle p_2, r_2, s_2, t_2 \rangle$, while the last two rows define the identities. Note that the multiplicative identity $\mathbf{1}$ has r,s and t components of 0.

P, R, S, T. "1" refers to the multiplicative identity of P. We continue to use distinguished symbols $\oplus, \otimes, \mathbf{0}, \mathbf{1}$ for the operations and identities in our "main semiring of interest," $\mathbb{E}_{P,R}$ or $\mathbb{E}_{P,R,S,T}$.

To compute equations (1)–(4) in this more general setting, we must still require multiplicative or additive decomposability, defining $p(d) \stackrel{\text{def}}{=} \prod_{e \in d} p_e$, $r(d) \stackrel{\text{def}}{=} \sum_{e \in d} r_e$, $s(d) \stackrel{\text{def}}{=} \sum_{e \in d} s_e$ as before. But the $\prod$ and $\sum$ operators here now denote appropriate operations within P, R, and S respectively (rather than the usual operations within $\mathbb{R}$).

4.2 Inside-Outside Speedup for First-Order Expectation Semirings

Under the first-order expectation semiring $\mathbb{E}_{\mathbb{R},\mathbb{R}^n}$, the inside algorithm of Figure 2 will return $\langle Z, \overline{r} \rangle$ where $\overline{r}$ is a vector of n feature expectations.

However, Eisner (2002, section 5) observes that this is inefficient when n is large. Why? The inside algorithm takes the trouble to compute an inside weight $\beta(v) \in \mathbb{R} \times \mathbb{R}^n$ for *each* node v in the hypergraph (or lattice). The second component of $\beta(v)$ is a presumably *dense* vector of all features that fire in all subderivations rooted at node v. Moreover, as $\beta(v)$ is computed in lines 3–8, that vector is built up (via the $\otimes$ and $\oplus$ operations of Table 1) as a linear combination of other dense vectors (the second components of the various $\beta(u)$). These vector operations can be slow.

A much more efficient approach (usually) is the traditional inside-outside algorithm (Baker, 1979).[7] Figure 4 generalizes the inside-outside algorithm to work with any expectation semiring $\mathbb{E}_{\mathbf{K},X}$.[8] We are given a hypergraph HG whose edges have weights $\langle k_e, x_e \rangle$ in this semiring (so now $k_e \in \mathbf{K}$ denotes only *part* of the edge weight, not all of it). INSIDE-OUTSIDE$(\text{HG}, \mathbf{K}, X)$ finds $\bigoplus_{d \in \text{D}} \bigotimes_{e \in d} \langle k_e, x_e \rangle$, which has the form $\langle \hat{k}, \hat{x} \rangle$.

But, INSIDE$(\text{HG}, \mathbb{E}_{\mathbf{K},X})$ could accomplish the same thing. So what makes the inside-outside algorithm more efficient? It turns out that $\hat{x}$ can be found quickly as a *single* linear combination $\sum_e \overline{k_e} x_e$ of just the feature vectors x_e that appear on *individual* hyperedges—typically a sum of very sparse vectors! And the linear coefficients $\overline{k_e}$, as well as $\hat{k}$, are computed entirely within the cheap semiring $\mathbf{K}$. They are based on β and α values obtained by first running INSIDE$(\text{HG}, \mathbf{K})$ and OUTSIDE$(\text{HG}, \mathbf{K})$, which use *only* the k_e part of the weights and ignore the more expensive x_e.

It is noteworthy that the expectation semiring is not used at all by Figure 4. Although the return value $\langle \hat{k}, \hat{x} \rangle$ is in the expectation semiring, it is built up not by $\oplus$ and $\otimes$ but rather by computing $\hat{k}$ and $\hat{x}$ separately. One might therefore wonder why the expectation semiring and its operations are still needed. One reason is that the input to Figure 4 consists of hyperedge weights $\langle k_e, x_e \rangle$ in the expectation semiring—and these weights may well have been constructed using $\otimes$ and $\oplus$. For example, Eisner (2002) uses finite-state operations such as composition, which do combine weights entirely within the expectation semiring before their result is passed to the forward-backward algorithm. A second reason is that when we work with a *second-order* expectation semiring in Section 4.4 below, the $\hat{k}, \beta$, and α values in Figure 4 will turn out to be elements of a first-order expectation semiring, and *they* must still be constructed by first-order $\otimes$ and $\oplus$, via calls to Figures 2–3.

Why does inside-outside work? Whereas the inside algorithm computes $\bigoplus_{d \in \text{D}} \bigotimes_{e \in d}$ in any semiring, the inside-outside algorithm exploits the special structure of an expectation semiring. By that semiring's definitions of $\oplus$ and $\otimes$ (Table 1), $\bigoplus_{d \in \text{D}} \bigotimes_{e \in d} \langle k_e, x_e \rangle$ can be found as

[7] Note, however, that the expectation semiring requires *only* the forward/inside pass to compute expectations, and thus it is more efficient than the traditional inside-outside algorithm (which requires two passes) if we are interested in computing only a small number of quantities.

[8] This follows Eisner (2002), who similarly generalized the forward-backward algorithm.

$\langle \sum_{d \in \mathrm{D}} \prod_{e \in d} k_e, \sum_{d \in \mathrm{D}} \sum_{e \in d} (\prod_{e' \in d, e' \neq e} k_{e'}) x_e \rangle$. The first component (giving $\hat{k}$) is found by calling the inside algorithm on just the k_e part of the weights. The second component (giving $\hat{x}$) can be rearranged into $\sum_e \sum_{d:\, e \in d} (\prod_{e' \in d, e' \neq e} k_{e'}) x_e = \sum_e \overline{k_e} x_e$, where $\overline{k_e} \stackrel{\text{def}}{=} \sum_{d:\, e \in d} (\prod_{e' \in d, e' \neq e} k_{e'})$ is found from β, α.

The application described at the start of this subsection is the classical inside-outside algorithm. Here $\langle k_e, x_e \rangle \stackrel{\text{def}}{=} \langle p_e, p_e r_e \rangle$, and the algorithm returns $\langle \hat{k}, \hat{x} \rangle = \langle Z, \overline{r} \rangle$. In fact, that $\hat{x} = \overline{r}$ can be seen directly: $\overline{r} = \sum_d p(d) r(d) = \sum_d p(d) (\sum_{e \in d} r_e) = \sum_e \sum_{d:\, e \in d} p(d) r_e = \sum_e (\overline{k_e} k_e) r_e = \sum_e \overline{k_e} x_e = \hat{x}$. This uses the fact that $\overline{k_e} k_e = \sum_{d:\, e \in d} p(d)$.

4.3 Lifting Trick for Second-Order Semirings

We now observe that the second-order expectation semiring $\mathbb{E}_{P,R,S,T}$ can be obtained indirectly by nesting one first-order expectation semiring inside another! First "lift" P to obtain the first-order expectation semiring $\mathbf{K} \stackrel{\text{def}}{=} \mathbb{E}_{P,R}$. Then lift this a second time to obtain the "nested" first-order expectation semiring $\mathbb{E}_{\mathbf{K},X} = \mathbb{E}_{(\mathbb{E}_{P,R}),(S \times T)}$, where we equip $X \stackrel{\text{def}}{=} S \times T$ with the operations $\langle s_1, t_1 \rangle + \langle s_2, t_2 \rangle \stackrel{\text{def}}{=} \langle s_1 + s_2, t_1 + t_2 \rangle$ and $\langle p, r \rangle \langle s, t \rangle \stackrel{\text{def}}{=} \langle ps, pt + rs \rangle$. The resulting first-order expectation semiring has elements of the form $\langle \langle p, r \rangle, \langle s, t \rangle \rangle$. Table 4 shows that it is indeed isomorphic to $\mathbb{E}_{P,R,S,T}$, with corresponding elements $\langle p, r, s, t \rangle$.

This construction of the second-order semiring as a first-order semiring is a useful bit of abstract algebra, because it means that known properties of first-order semirings will also apply to second-order ones. First of all, we are immediately guaranteed that the second-order semiring satisfies the semiring axioms. Second, we can directly apply the inside-outside algorithm there, as we now see.

4.4 Inside-Outside Speedup for Second-Order Expectation Semirings

Given a hypergraph weighted by a *second-order* expectation semiring $\mathbb{E}_{P,R,S,T}$. By recasting this as the *first-order* expectation semiring $\mathbb{E}_{\mathbf{K},X}$ where $\mathbf{K} = \mathbb{E}_{P,R}$ and $X = (S \times T)$, we can again apply INSIDE-OUTSIDE$(\mathrm{HG}, \mathbf{K}, X)$ to find the total weight of all derivations.

For example, to speed up Section 3.2, we may define $\langle k_e, x_e \rangle = \langle \langle p_e, p_e r_e \rangle, \langle p_e s_e, p_e r_e s_e \rangle \rangle$ for each hyperedge e. Then the inside-outside algorithm of Figure 4 will compute $\langle \hat{k}, \hat{x} \rangle = \langle \langle Z, \overline{r} \rangle, \langle \overline{s}, \overline{t} \rangle \rangle$, more quickly than the inside algorithm of Figure 2 computed $\langle Z, \overline{r}, \overline{s}, \overline{t} \rangle$.

Figure 4 in this case will run the inside and outside algorithms *in the semiring* $\mathbb{E}_{P,R}$, so that $k_e, \hat{k}, \alpha, \beta$, and $\overline{k_e}$ will now be elements of $P \times R$ (not just elements of P as in the first-order case). Finally it finds $\hat{x} = \sum_e \overline{k_e} x_e$, where $x_e \in S \times T$.[9]

This is a particularly effective speedup over the inside algorithm when R consists of scalars (or small vectors) whereas S, T are sparse high-dimensional vectors. We will see exactly this case in our experiments, where our weights $\langle p, r, s, t \rangle$ denote (probability, risk, gradient of probability, gradient of risk), or (probability, entropy, gradient of probability, gradient of entropy).

5 Finding Gradients on Hypergraphs

In Sections 3.2 and 4.1, we saw how our semirings helped find the sum Z of all $p(d)$, and compute *expectations* $\overline{r}, \overline{s}, \overline{t}$ of $r(d)$, $s(d)$, and $r(d)s(d)$.

It turns out that these semirings can *also* compute first- and second-order *partial derivatives* of all the above results, with respect to a parameter vector $\theta \in \mathbb{R}^m$. That is, we ask how they are affected when θ changes slightly from its current value. The elementary values p_e, r_e, s_e are now assumed to implicitly be functions of θ.

Case 1: Recall that $Z \stackrel{\text{def}}{=} \sum_d p(d)$ is computed by INSIDE$(\mathrm{HG}, \mathbb{R})$ if each hyperedge e has weight p_e. "Lift" this weight to $\langle p_e, \nabla p_e \rangle$, where $\nabla p_e \in \mathbb{R}^m$ is a gradient vector. Now $\langle Z, \nabla Z \rangle$ will be returned by INSIDE$(\mathrm{HG}, \mathbb{E}_{\mathbb{R}, \mathbb{R}^m})$— or, more efficiently, by INSIDE-OUTSIDE$(\mathrm{HG}, \mathbb{R}, \mathbb{R}^m)$.

Case 2: To differentiate a second time, "lift" the above weights again to obtain $\langle \langle p_e, \nabla p_e \rangle, \nabla \langle p_e, \nabla p_e \rangle \rangle = \langle \langle p_e, \nabla p_e \rangle, \langle \nabla p_e, \nabla^2 p_e \rangle \rangle$, where $\nabla^2 p_e \in \mathbb{R}^{m \times m}$ is the Hessian matrix of second-order mixed partial derivatives. These weights are in a second-order expectation semiring.[10] Now

[9] Figure 4 was already proved generally correct in Section 4.2. To understand more specifically how $\langle \overline{s}, \overline{t} \rangle$ gets computed, observe in analogy to the end of Section 4.2 that

$$\begin{aligned}
\langle \overline{s}, \overline{t} \rangle &= \textstyle\sum_d \langle p(d) s(d), p(d) r(d) s(d) \rangle \\
&= \textstyle\sum_d \langle p(d), p(d) r(d) \rangle \langle s(d), 0 \rangle \\
&= \textstyle\sum_d \langle p(d), p(d) r(d) \rangle \sum_{e \in d} \langle s_e, 0 \rangle \\
&= \textstyle\sum_e \sum_{d:\, e \in d} \langle p(d), p(d) r(d) \rangle \langle s_e, 0 \rangle \\
&= \textstyle\sum_e (\overline{k_e} k_e) \langle s_e, 0 \rangle = \sum_e \overline{k_e} \langle p_e, p_e r_e \rangle \langle s_e, 0 \rangle \\
&= \textstyle\sum_e \overline{k_e} \langle p_e s_e, p_e r_e s_e \rangle = \sum_e \overline{k_e} x_e = \hat{x}.
\end{aligned}$$

[10] Modulo the trivial isomorphism from $\langle \langle p, r \rangle, \langle s, t \rangle \rangle$ to $\langle p, r, s, t \rangle$ (see Section 4.3), the intended semiring both here and in Case 3 is the one that was defined at the start of Section 4.1, in which r, s are vectors and their product is defined

$$\begin{aligned}
\langle\langle p_1, r_1\rangle, \langle s_1, t_1\rangle\rangle \oplus \langle\langle p_2, r_2\rangle, \langle s_2, t_2\rangle\rangle &= \langle\langle p_1, r_1\rangle + \langle p_2, r_2\rangle,\ \langle s_1, t_1\rangle + \langle s_2, t_2\rangle\rangle \\
&= \langle\langle p_1 + p_2,\ r_1 + r_2\rangle,\ \langle s_1 + s_2,\ t_1 + t_2\rangle\rangle \\
\langle\langle p_1, r_1\rangle, \langle s_1, t_1\rangle\rangle \otimes \langle\langle p_2, r_2\rangle, \langle s_2, t_2\rangle\rangle &= \langle\langle p_1, r_1\rangle\langle p_2, r_2\rangle,\ \langle p_1, r_1\rangle\langle s_2, t_2\rangle + \langle p_2, r_2\rangle\langle s_1, t_1\rangle\rangle \\
&= \langle\langle p_1 p_2,\ p_1 r_2 + p_2 r_1\rangle,\ \langle p_1 s_2 + p_2 s_1,\ p_1 t_2 + p_2 t_1 + r_1 s_2 + r_2 s_1\rangle\rangle
\end{aligned}$$

Table 4: **Constructing second-order expectation semiring as first-order**. Here we show that the operations in $\mathbb{E}_{\mathbf{K},X}$ are isomorphic to Table 2's operations in $\mathbb{E}_{P,R,S,T}$, provided that $\mathbf{K} \stackrel{\text{def}}{=} \mathbb{E}_{P,R}$ and $X \stackrel{\text{def}}{=} S \times T$ is a $\mathbf{K}$-module, in which addition is defined by $\langle s_1, t_1\rangle + \langle s_2, t_2\rangle \stackrel{\text{def}}{=} \langle s_1 + s_2, t_1 + t_2\rangle$, and left-multiplication by $\mathbf{K}$ is defined by $\langle p, r\rangle\langle s, t\rangle \stackrel{\text{def}}{=} \langle ps, pt + rs\rangle$.

$\langle Z, \nabla Z, \nabla Z, \nabla^2 Z\rangle$ will be returned by INSIDE$(\text{HG}, \mathbb{E}_{\mathbb{R},\mathbb{R}^m,\mathbb{R}^m,\mathbb{R}^{m\times m}})$, or more efficiently by INSIDE-OUTSIDE$(\text{HG}, \mathbb{E}_{\mathbb{R},\mathbb{R}^m}, \mathbb{R}^m \times \mathbb{R}^{m\times m})$.

Case 3: Our experiments will need to find expectations and their partial derivatives. Recall that $\langle Z, \overline{r}\rangle$ is computed by INSIDE$(\text{HG}, \mathbb{E}_{\mathbb{R},\mathbb{R}^n})$ when the edge weights are $\langle p_e, p_e r_e\rangle$ with $r_e \in \mathbb{R}^n$. Lift these weights to $\langle\langle p_e, p_e r_e\rangle, \nabla\langle p_e, p_e r_e\rangle\rangle = \langle\langle p_e, p_e r_e\rangle, \langle \nabla p_e, (\nabla p_e) r_e + p_e(\nabla r_e)\rangle\rangle$. Now $\langle Z, \overline{r}, \nabla Z, \nabla\overline{r}\rangle$ will be returned by INSIDE$(\text{HG}, \mathbb{E}_{\mathbb{R},\mathbb{R}^n,\mathbb{R}^m,\mathbb{R}^{n\times m}})$ or by INSIDE-OUTSIDE$(\text{HG}, \mathbb{E}_{\mathbb{R},\mathbb{R}^n}, \mathbb{R}^m \times \mathbb{R}^{n\times m})$.[11]

5.1 What Connects Gradients to Expectations?

In ***Case 1***, we claimed that the *same* algorithm will compute either gradients $\langle Z, \nabla Z\rangle$ or expectations $\langle Z, \overline{r}\rangle$, if the hyperedge weights are set to $\langle p_e, \nabla p_e\rangle$ or $\langle p_e, p_e r_e\rangle$ respectively.[12] This may seem wonderful and mysterious. We now show in two distinct ways why this follows from our setup of Section 3.1. At the end, we derive as a special case the well-known relationship between gradients and expectations in log-linear models.

From Expectations to Gradients One perspective is that our semiring fundamentally finds expectations. Thus, we must be finding ∇Z by formulating it as a certain expectation $\overline{r}$. Specifically, $\nabla Z = \nabla \sum_d p(d) = \sum_d \nabla p(d) = \sum_d p(d) r(d) = \overline{r}$, provided that $r(d) = (\nabla p(d))/p(d)$. That can be arranged by defining $r_e \stackrel{\text{def}}{=} (\nabla p_e)/p_e$.[13] So that is why the input weights $\langle p_e, p_e r_e\rangle$ take the form $\langle p_e, \nabla p_e\rangle$.

From Gradients to Expectations An alternative perspective is that our semiring fundamentally finds gradients. Indeed, pairs like $\langle p, \nabla p\rangle$ have long been used for this purpose (Clifford, 1873) under the name "dual numbers." Operations on dual numbers, including those in Table 1, compute a result in $\mathbb{R}$ *along with* its gradient. For example, our $\otimes$ multiplies dual numbers, since $\langle p_1, \nabla p_1\rangle \otimes \langle p_2, \nabla p_2\rangle = \langle p_1 p_2, p_1(\nabla p_2) + (\nabla p_1) p_2\rangle = \langle p_1 p_2, \nabla(p_1 p_2)\rangle$. The inside algorithm thus computes both Z and ∇Z in a single "forward" or "inside" pass—known as automatic differentiation in the forward mode. The inside-outside algorithm instead uses the reverse mode (a.k.a. back-propagation), where a separate "backward" or "outside" pass is used to compute ∇Z.

How can we modify this machinery to produce expectations $\overline{r}$ given some *arbitrary* r_e of interest? Automatic differentiation may be used on any function (e.g., a neural net), but for our simple sum-of-products function Z, it happens that $\nabla Z = \nabla(\sum_d \prod_e p_e) = \sum_d \sum_{e\in d}(\prod_{e'\in d, e'\neq e} p_{e'})\nabla p_e$. Our trick is to surreptitiously *replace* the ∇p_e in the input weights $\langle p_e, \nabla p_e\rangle$ with $p_e r_e$. Then the output changes similarly: the algorithms will *instead* find $\sum_d \sum_{e\in d}(\prod_{e'\in d, e'\neq e} p_{e'}) p_e r_e$, which reduces to $\sum_d \sum_{e\in d} p(d) r_e = \sum_d p(d) \sum_{e\in d} r_e = \sum_d p(d) r(d) = \overline{r}$.

Log-linear Models as a Special Case Replacing ∇p_e with $p_e r_e$ is unnecessary if ∇p_e already equals $p_e r_e$. That is the case in log-linear models, where $p_e \stackrel{\text{def}}{=} \exp(r_e \cdot \theta)$ for some feature vector r_e associated with e. So there, ∇Z already equals $\overline{r}$—yielding a key useful property of log-linear

to be $rs^{\mathbf{T}}$, a matrix. However, when using this semiring to compute second derivatives (Case 2) or covariances, one may exploit the invariant that $r = s$, e.g., to avoid storing s and to compute $r_1 s_2 + s_1 r_2$ in multiplication simply as $2 \cdot r_1 r_2$.

[11] Or, if $n > m$, it is faster to instead use INSIDE-OUTSIDE$(\text{HG}, \mathbb{E}_{\mathbb{R},\mathbb{R}^m}, \mathbb{R}^n \times \mathbb{R}^{m\times n})$, swapping the second and third components of the 4-tuple and transposing the matrix in the fourth component. Algebraically, this changes nothing because $\mathbb{E}_{\mathbb{R},\mathbb{R}^n,\mathbb{R}^{m\times n\times m}}$ and $\mathbb{E}_{\mathbb{R},\mathbb{R}^m,\mathbb{R}^{n\times m\times n}}$ are isomorphic, thanks to symmetries in Table 2. This method computes the expectation of the gradient rather than the gradient of the expectation—they are equal.

[12] ***Cases 2–3*** relied on the fact that this relationship still holds even when the scalars $Z, p_e \in \mathbb{R}$ are replaced by more complex objects that we wish to differentiate. Our discussion below sticks to the scalar case for simplicity, but would generalize fairly straightforwardly. Pearlmutter and Siskind (2007) give the relevant generalizations of dual numbers.

[13] Proof: $r(d) = \sum_{e\in d} r_e = \sum_{e\in d}(\nabla p_e)/p_e = \sum_{e\in d} \nabla \log p_e = \nabla \sum_{e\in d} \log p_e = \nabla \log \prod_{e\in d} p_e = \nabla \log p(d) = (\nabla p(d))/p(d)$.

models, that $\nabla \log Z = (\nabla Z)/Z = \bar{r}/Z$, the vector of feature expectations (Lau et al., 1993).

6 Practical Applications

Given a hypergraph HG whose hyperedges e are annotated with values p_e. Recall from Section 3.1 that this defines a probability distribution over all derivations d in the hypergraph, namely $p(d)/Z$ where $p(d) \stackrel{\text{def}}{=} \prod_{e \in d} p_e$.

6.1 First-Order Expectation Semiring $\mathbb{E}_{\mathbb{R},\mathbb{R}}$

In Section 3, we show how to compute the **expected hypothesis length** or **expected feature counts**, using the algorithm of Figure 2 with a first-order expectation semiring $\mathbb{E}_{\mathbb{R},\mathbb{R}}$. In general, given hyperedge weights $\langle p_e, p_e r_e \rangle$, the algorithm computes $\langle Z, \bar{r} \rangle$ and thus $\bar{r}/Z$, the expectation of $r(d) \stackrel{\text{def}}{=} \sum_{e \in d} r_e$. We now show how to compute a few other quantities by choosing r_e appropriately.

Entropy on a Hypergraph The entropy of the distribution of *derivations* in a hypergraph[14] is

$$\begin{aligned} \mathrm{H}(p) &= -\sum_{d \in \mathrm{D}} (p(d)/Z) \log(p(d)/Z) \qquad (5) \\ &= \log Z - \frac{1}{Z} \sum_{d \in \mathrm{D}} p(d) \log p(d) \\ &= \log Z - \frac{1}{Z} \sum_{d \in \mathrm{D}} p(d) r(d) = \log Z - \frac{\bar{r}}{Z} \end{aligned}$$

provided that we define $r_e \stackrel{\text{def}}{=} \log p_e$ (so that $r(d) = \sum_{e \in d} r_e = \log p(d)$). Of course, we can compute $\langle Z, \bar{r} \rangle$ as explained in Section 3.2.

Cross-Entropy and KL Divergence We may be interested in computing the cross-entropy or KL divergence between two distributions p and q. For example, in variational decoding for machine translation (Li et al., 2009b), p is a distribution represented by a hypergraph, while q, represented by a finite state automaton, is an approximation to p. The cross entropy between p and q is defined as

$$\begin{aligned} \mathrm{H}(p,q) &= -\sum_{d \in \mathrm{D}} (p(d)/Z_p) \log(q(d)/Z_q) \qquad (6) \\ &= \log Z_q - \frac{1}{Z_p} \sum_{d \in \mathrm{D}} p(d) \log q(d) \\ &= \log Z_q - \frac{1}{Z_p} \sum_{d \in \mathrm{D}} p(d) r(d) = \log Z_q - \frac{\bar{r}}{Z_p} \end{aligned}$$

where the first term Z_q can be computed using the inside algorithm with hyperedge weights q_e, and the numerator and denominator of the second term using an expectation semiring with hyperedge weights $\langle p_e, p_e r_e \rangle$ with $r_e \stackrel{\text{def}}{=} \log q_e$.

The KL divergence to p from q can be computed as $\mathrm{KL}(p \,\|\, q) = \mathrm{H}(p,q) - \mathrm{H}(p)$.

Expected Loss (Risk) Given a reference sentence y^*, the expected loss (i.e., Bayes risk) of the hypotheses in the hypergraph is defined as,

$$\mathrm{R}(p) = \sum_{d \in \mathrm{D}} (p(d)/Z) L(\mathrm{Y}(d), y^*) \qquad (7)$$

where $\mathrm{Y}(d)$ is the target yield of d and $L(y, y^*)$ is the **loss** of the hypothesis y with respect to the reference y^*. The popular machine translation metric, BLEU (Papineni et al., 2001), is not **additively** decomposable, and thus we are not able to compute the expected loss for it. Tromble et al. (2008) develop the following loss function, of which a linear approximation to BLEU is a special case,

$$L(y, y^*) = -(\theta_0 |y| + \sum_{w \in N} \theta_w \#_w(y) \delta_w(y*)) \qquad (8)$$

where w is an n-gram type, N is a set of n-gram types with $n \in [1,4]$, $\#_w(y)$ is the number of occurrence of the n-gram w in y, $\delta_w(y^*)$ is an indicator to check if y^* contains at least one occurrence of w, and θ_n is the weight indicating the relative importance of an n-gram match. If the hypergraph is *already* annotated with n-gram ($n \geq 4$) language model states, this loss function is **additively** decomposable. Using $r_e \stackrel{\text{def}}{=} L_e$ where L_e is the *loss* for a hyperedge e, we compute the expected loss,

$$\mathrm{R}(p) = \frac{\sum_{d \in \mathrm{D}} p(d) L(\mathrm{Y}(d), y^*)}{Z} = \frac{\bar{r}}{Z} \qquad (9)$$

6.2 Second-Order Expectation Semirings

With second-order expectation semirings, we can compute from a hypergraph the expectation and variance of hypothesis length; the feature expectation vector and covariance matrix; the Hessian (matrix of second derivatives) of Z; and the gradients of entropy and expected loss. The computations should be clear from earlier discussion. Below we compute gradient of entropy or Bayes risk.

Gradient of Entropy or Risk It is easy to see that the gradient of entropy (5) is

$$\nabla \mathrm{H}(p) = \frac{\nabla Z}{Z} - \frac{Z \nabla \bar{r} - \bar{r} \nabla Z}{Z^2} \qquad (10)$$

[14] Unfortunately, it is intractable to compute the entropy of the distribution over *strings* (each string's probability is a sum over several derivations). But Li et al. (2009b, section 5.4) do estimate the gap between derivational and string entropies.

We may compute $\langle Z, \overline{r}, \nabla Z, \nabla \overline{r} \rangle$ as explained in ***Case 3*** of Section 5 by using $k_e \stackrel{\text{def}}{=} \langle p_e, p_e r_e, \nabla p_e, (\nabla p_e) r_e + p_e \nabla r_e \rangle \stackrel{\text{def}}{=} \langle p_e, p_e \log p_e, \nabla p_e, (1 + \log p_e) \nabla p_e \rangle$, where ∇p_e depends on the particular parameterization of the model (see Section 7.1 for an example).

Similarly, the gradient of risk of (9) is

$$\nabla \mathrm{R}(p) = \frac{Z \nabla \overline{r} - \overline{r} \nabla Z}{Z^2} \tag{11}$$

We may compute $\langle Z, \overline{r}, \nabla Z, \nabla \overline{r} \rangle$ using $k_e \stackrel{\text{def}}{=} \langle p_e, p_e L_e, \nabla p_e, L_e \nabla p_e \rangle$.

7 Minimum-Risk Training for MT

We now show how we improve the training of a Hiero MT model by optimizing an objective function that includes entropy and risk. Our objective function could be computed with a first-order expectation semiring, but computing it *along with its gradient* requires a second-order one.

7.1 The Model p

We assume a **globally normalized linear model** for its simplicity. Each derivation d is scored by

$$\text{score}(d) \stackrel{\text{def}}{=} \Phi(d) \cdot \theta = \sum_i \Phi_i(d)\, \theta_i \tag{12}$$

where $\Phi(d) \in \mathbb{R}^m$ is a vector of features of d. We then define the unnormalized distribution $p(d)$ as

$$p(d) = \exp(\gamma \cdot \text{score}(d)) \tag{13}$$

where the scale factor γ adjusts how sharply the distribution favors the highest-scoring hypotheses.

7.2 Minimum-Risk Training

Adjusting θ or γ changes the distribution p. Minimum error rate training (MERT) (Och, 2003) tries to tune θ to minimize the BLEU loss of a decoder that chooses the most probable output according to p. (γ has no effect.) MERT's specialized line-search addresses the problem that this objective function is piecewise constant, but it does not scale to a large number of parameters.

Smith and Eisner (2006) instead propose a *differentiable* objective that can be optimized by gradient descent: the Bayes risk $\mathrm{R}(p)$ of (7). This is the *expected* loss if one were (hypothetically) to use a *randomized* decoder, which chooses a hypothesis d in proportion to its probability $p(d)$. If entropy $\mathrm{H}(p)$ is large (e.g., small γ), the Bayes risk is smooth and has few local minima. Thus, Smith and Eisner (2006) try to avoid local minima by starting with large $\mathrm{H}(p)$ and decreasing it gradually during optimization. This is called **deterministic annealing** (Rose, 1998). As $\mathrm{H}(p) \to 0$ (e.g., large γ), the Bayes risk does approach the MERT objective (i.e. minimizing 1-best error).The objective is

$$\text{minimize } \mathrm{R}(p) - T \cdot \mathrm{H}(p) \tag{14}$$

where the "temperature" T starts high and is explicitly decreased as optimization proceeds.

7.3 Gradient Descent Optimization

Solving (14) for a given T requires computing the entropy $\mathrm{H}(p)$ and risk $\mathrm{R}(p)$ and their gradients with respect to θ and γ. Smith and Eisner (2006) followed MERT in constraining their decoder to only an n-best list, so for them, computing these quantities did not involve dynamic programming. We compare those methods to *training on a hypergraph containing exponentially many hypotheses*. In this condition, we need our new second-order semiring methods and must also approximate BLEU (during training only) by an additively decomposable loss (Tromble et al., 2008).[15]

Our algorithms require that $p(d)$ of (13) is **multiplicatively** decomposable. It suffices to define $\Phi(d) \stackrel{\text{def}}{=} \sum_{e \in d} \Phi_e$, so that all features are *local* to individual hyperedges; the vector Φ_e indicates which features fire on hyperedge e. Then $\text{score}(d)$ of (12) is **additively** decomposable:

$$\text{score}(d) = \sum_{e \in d} \text{score}_e = \sum_{e \in d} \Phi_e \cdot \theta \tag{15}$$

We can then set $p_e = \exp(\gamma \cdot \text{score}_e)$, and $\nabla p_e = \gamma p_e \Phi(e)$, and use the algorithms described in Section 6 to compute $\mathrm{H}(p)$ and $\mathrm{R}(p)$ and their gradients with respect to θ and γ.[16]

[15] Pauls et al. (2009) concurrently developed a method to maximize the *expected* n-gram counts on a *hypergraph* using gradient descent. Their objective is similar to the minimum risk objective (though without annealing), and their gradient descent optimization involves in algorithms in computing expected feature/n-gram counts as well as expected *products* of features and n-gram counts, which can be viewed as instances of our general algorithms with first- and second-order semirings. They focused on tuning only a small number (i.e. *nine*) of features as in a regular MERT setting, while our experiments involve both a small and a large number of features.

[16] It is easy to verify that the gradient of a function f (e.g. entropy or risk) with respect to γ can be written as a weighted sum of gradients with respect to the feature weights θ_i, i.e.

$$\frac{\partial f}{\partial \gamma} = \frac{1}{\gamma} \sum_i \theta_i \times \frac{\partial f}{\partial \theta_i} \tag{16}$$

7.4 Experimental Results

7.4.1 Experimental Setup

We built a translation model on a corpus for IWSLT 2005 Chinese-to-English translation task (Eck and Hori, 2005), which consists of 40k pairs of sentences. We used a *5-gram* language model with modified Kneser-Ney smoothing, trained on the bitext's English using SRILM (Stolcke, 2002).

7.4.2 Tuning a Small Number of Features

We first investigate how minimum-risk training (MR), with and without deterministic annealing (DA), performs compared to regular MERT. MR without DA just fixes $T = 0$ and $\gamma = 1$ in (14). All MR or MR+DA uses an approximated BLEU (Tromble et al., 2008) (for training only), while MERT uses the exact corpus BLEU in training.

The first five rows in Table 5 present the results by tuning the weights of *five* features ($\theta \in \mathbb{R}^5$). We observe that MR or MR+DA performs worse than MERT *on the dev set*. This may be mainly because MR or MR+DA uses an approximated BLEU while MERT doesn't. *On the test set*, MR or MR+DA on an n-best list is comparable to MERT. But our new approach, MR or MR+DA *on a hypergraph*, does consistently better (statistically significant) than MERT, despite approximating BLEU.[17]

Did DA help? For both n-best and hypergraph, MR+DA did obtain a better BLEU score than plain MR on the dev set.[18] This shows that DA helps with the local minimum problem, as hoped. However, DA's improvement on the dev set did not transfer to the test set.

7.4.3 Tuning a Large Number of Features

MR (with or without DA) is scalable to tune a large number of features, while MERT is not. To achieve competitive performance, we adopt a *forest reranking* approach (Li and Khudanpur, 2009; Huang, 2008). Specifically, our training has two stages. In the *first* stage, we train a baseline system as usual. We also find the optimal feature weights for the five features mentioned before, using the method of MR+DA operating on a hypergraph. In the *second* stage, we generate a hypergraph for each sentence in the training data (which consists of about 40k sentence pairs), using the baseline system. In this stage, we add 21k additional unigram and bigram target-side language model features (cf. Li and Khudanpur (2008)). For example, a specific bigram "the cat" can be a feature. Note that the total score by the baseline system is also a feature in the second-stage model. With these features and the 40k hypergraphs, we run the MR training to obtain the optimal weights.

	Training scheme	dev	test
	MERT (Nbest, small)	42.6	47.7
	MR (Nbest, small)	40.8	47.7
	MR+DA (Nbest, small)	41.6	47.8
NEW!	MR (hypergraph, small)	41.3	48.4
NEW!	MR+DA (hypergraph, small)	41.9	48.3
NEW!	MR (hypergraph, large)	42.3	**48.7**

Table 5: BLEU scores on the Dev and test sets under different training scenarios. In the "small" model, five features (i.e., one for the language model, three for the translation model, and one for word penalty) are tuned. In the "large" model, 21k additional unigram and bigram features are used.

During test time, a similar procedure is followed. For a given test sentence, the baseline system first generates a hypergraph, and then the hypergraph is reranked by the second-stage model. The last row in Table 5 reports the BLEU scores. Clearly, adding more features improves (statistically significant) the case with only five features. We plan to incorporate more informative features described by Chiang et al. (2009).[19]

8 Conclusions

We presented first-order expectation semirings and inside-outside computation in more detail than (Eisner, 2002), and developed extensions to higher-order expectation semirings. This enables efficient computation of many interesting quantities over the exponentially many derivations encoded in a hypergraph: second derivatives (Hessians), expectations of products (covariances), and expectations such as risk and entropy along with their derivatives. To our knowledge, algorithms for these problems have not been presented before.

Our approach is theoretically elegant, like other work in this vein (Goodman, 1999; Lopez, 2009; Gimpel and Smith, 2009). We used it practically to enable a new form of minimum-risk training that improved Chinese-English MT by 1.0 BLEU point. Our implementation will be released within the open-source MT toolkit **Joshua** (Li et al., 2009a).

[17] Pauls et al. (2009) concurrently observed a similar pattern (i.e., MR performs worse than MERT on the dev set, but performs better on a test set).

[18] We also verified that MR+DA found a better objective value (i.e., expected loss on the dev set) than MR.

[19] Their MIRA training tries to favor a specific oracle translation—indeed a specific tree—from the (pruned) hypergraph. MR does not commit to such an arbitrary choice.

Abstract

Minimum error rate training (MERT) involves choosing parameter values for a machine translation (MT) system that maximize performance on a tuning set as measured by an automatic evaluation metric, such as BLEU. The method is best when the system will eventually be evaluated using the same metric, but in reality, most MT evaluations have a human-based component. Although performing MERT with a human-based metric seems like a daunting task, we describe a new metric, RYPT, which takes human judgments into account, but only requires human input to build a database that can be reused over and over again, hence eliminating the need for human input at tuning time. In this investigative study, we analyze the diversity (or lack thereof) of the candidates produced during MERT, we describe how this redundancy can be used to our advantage, and show that RYPT is a better predictor of translation quality than BLEU.

1 Introduction

Many state-of-the-art machine translation (MT) systems over the past few years (Och and Ney, 2002; Koehn et al., 2003; Chiang, 2007; Koehn et al., 2007; Li et al., 2009) rely on several models to evaluate the "goodness" of a given candidate translation in the target language. The MT system proceeds by searching for the highest-scoring candidate translation, as scored by the different model components, and returns that candidate as the hypothesis translation. Each of these models need not be a probabilistic model, and instead corresponds to a feature that is a function of a (candidate translation,foreign sentence) pair.

Treated as a log-linear model, we need to assign a weight for each of the features. Och (2003) shows that setting those weights should take into account the evaluation metric by which the MT system will eventually be judged. This is achieved by choosing the weights so as to maximize the performance of the MT system on a development set, as measured by that evaluation metric. The other insight of Och's work is that there exists an efficient algorithm to find such weights. This process has come to be known as the MERT phase (for **M**inimum **E**rror **R**ate **T**raining) in training pipelines of MT systems.

A problem arises if the performance of the system is not judged by an automatic evaluation metric such as BLEU or TER, but instead through an evaluation process involving a human. The GALE evaluation, for instance, judges the quality of systems as measured by human-targeted TER (HTER), which computes the edit distance between the system's output and a version of the output post-edited by a human. The IWSLT and WMT workshops also have a manual evaluation component, as does the NIST Evaluation, in the form of adequacy and fluency (LDC, 2005).

In theory, one could imagine trying to optimize a metric like HTER during the MERT phase, but that would require the availability of an HTER automatic scorer, which, by definition, does not exist. If done manually, the scoring of thousands of candidates produced during MERT would literally take weeks, and cost a large sum of money. For these reasons, researchers resort to optimizing an automatic metric (almost always BLEU) as a proxy for human judgment.

As daunting as such a task seems for any human-based metric, we describe a new metric, RYPT, that takes human judgment into accout when scoring candidates, but takes advantage of the redundancy in the candidates produced during MERT. In this investigative study, we describe how this redundancy can be used to our advantage to eliminate the need to involve a human at any

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 52–61,
Singapore, 6-7 August 2009.

time except when building a database of reusable judgments, and furthermore show that RYPT is a better predictor of translation quality than BLEU, making it an excellent candidate for MERT tuning.

The paper is organized as follows. We start by describing the core idea of MERT before introducing our new metric, RYPT, and describing the data collection effort we undertook to collect the needed human judgments. We analyze a MERT run optimizing BLEU to quantify the level of redundancy in the candidate set, and also provide an extensive analysis of the collected judgments, before describing a set of experiments showing RYPT is a better predictor of translation quality than BLEU. Following a discussion of our findings, we briefly review related work, before pointing out future directions and summarizing.

2 Och's Line Search Method

A common approach to translating a source sentence f in a foreign language is to select the candidate translation e that maximizes the posterior probability:

$$Pr(e \mid f) \stackrel{\text{def}}{=} \frac{\exp(s_\Lambda(e,f))}{\sum_{e'} \exp(s_\Lambda(e',f))}.$$

This defines $Pr(e \mid f)$ using a *log-linear model* that associates a sentence pair (e, f) with a feature vector $\Phi(e,f) = \{\phi_1(e,f), ..., \phi_M(e,f)\}$, and assigns a score

$$s_\Lambda(e,f) \stackrel{\text{def}}{=} \Lambda \cdot \Phi(e,f) = \sum_{m=1}^{M} \lambda_m \phi_m(e,f)$$

for that sentence pair, with the feature weights $\Lambda = \{\lambda_1, ..., \lambda_M\}$ being the parameters of the model. Therefore, the system selects the translation $\hat{e}$:

$$\hat{e} = \operatorname*{argmax}_e Pr(e \mid f) = \operatorname*{argmax}_e s_\Lambda(e,f). \quad (1)$$

Och (2003) provides evidence that Λ should be chosen by optimizing an objective function basd on the evaluation metric of interest, rather than likelihood. Since the error surface is not smooth, and a grid search is too expensive, Och suggests an alternative, efficient, line optimization approach.

Assume we are performing a line optimization along the d^{th} dimension. Consider a foreign sentence f, and let the candidate set for f be $\{e_1, ..., e_K\}$. Recall from (1) that the 1-best candidate at a given Λ is the one with maximum $\sum_{m=1}^{M} \lambda_m \phi_m(e_k, f)$. We can rewrite the sum as $\lambda_d \phi_d(e_k, f) + \sum_{m \neq d} \lambda_m \phi_m(e_k, f)$. The second term is constant with respect to λ_d, and so is $\phi_d(e_k, f)$. Renaming those two quantities $\texttt{offest}_\Lambda(e_k)$ and $\texttt{slope}(e_k)$, we get

$$s_\Lambda(e_k, f) = \texttt{slope}(e_k)\lambda_d + \texttt{offset}_\Lambda(e_k).$$

Therefore, if we plot the score for a candidate translation vs. λ_d, that candidate will be represented by a line. If we plot the lines for all candidates (Figure 1), then the upper envelope of these lines indicates the best candidate at any value for λ_d.

Therefore, the objective function is piece-wise linear across any of the M dimensions[1], meaning we only need to evaluate it at the "critical" points corresponding to line intersection points. Furthermore, we only need to calculate the sufficient statistics once, at the smallest critical point, and then simply adjust the sufficient statistics to reflect changes in the set of 1-best candidates.

2.1 The BLEU Metric

The metric most often used with MERT is BLEU (Papineni et al., 2002), where the score of a candidate c against a reference translation r is:

$$BLEU = BP(len(c), len(r)) \cdot \exp(\sum_{n=1}^{4} \frac{1}{4} \log p_n),$$

where p_n is the n-gram precision[2] and BP is a brevity penalty meant to penalize short outputs, to discourage improving precision at the expense of recall.

There are several compelling reasons to optimize to BLEU. It is the most widely reported metric in MT research, and has been shown to correlate well with human judgment (Papineni et al., 2002; Coughlin, 2003). But BLEU is also particularly suitable for MERT, because it can be computed quite efficiently, and its sufficient statistics are decomposable, as required by MERT.[3,4]

[1] Or, in fact, along any linear combination of the M dimensions.

[2] *Modifed* precision, to be precise, based on clipped n-gram counts.

[3] Note that for the sufficient statistics to be decomposable, the metric itself need not be – this is in fact the case with BLEU.

[4] Strictly speaking, the sufficient statistics need not be de-

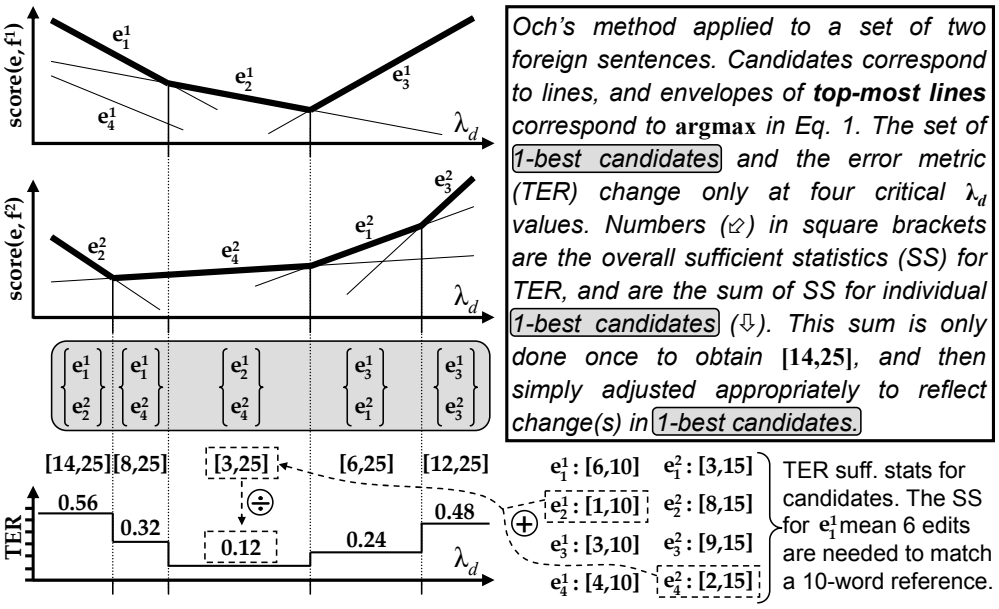

Figure 1: Och's method applied to a set of two foreign sentences. This figure is essentially a visualization of equation (1). We show here sufficient statistics for TER for simplicity, since there are only 2 of them, but the metric optimized in MERT is usually BLEU.

In spite of these advantages, recent work has pointed out a number of problematic aspects of BLEU that should cause one to pause and reconsider the reliance on it. Chiang et al. (2008) investigate several weaknesses in BLEU and show there are realistic scenraios where the BLEU score should not be trusted, and in fact behaves in a counter-intuitive manner. Furthermore, Callison-Burch et al. (2006) point out that it is not always appropriate to use BLEU to compare systems to each other. In particular, the quality of rule-based systems is usually underestimated by BLEU.

All this raises doubts regarding BLEU's adequacy as a proxy for human judgment, which is a particularly important issue in the context of setting parameters during the MERT phase. But what is the alternative?

2.2 (Non-)Applicability of Och's Method to Human Metrics

In principle, MERT is applicable to any evaluation metric, including HTER, as long as its sufficient statistics are decomposable.[4] In practice, of course, the method requires the evaluation of thousands of candidate translations. Whereas this is not a problem with a metric like BLEU, for which automatic (and fast) scorers are available, such an evaluation with a human metric would require a large amount of effort and money, meaning that a single MERT run would take weeks to complete, and would cost thousands of dollars. Assume a single candidate string takes 10 seconds to post-edit, at a cost of $0.10. Even with such an (overly) optimistic estimate, scoring 100 candidates for each of 1000 sentences would take 35 8-hour work days and cost $10,000. The cost would further grow linearly with the number of MERT iterations and the n-best list size. On the other hand, optimizing for BLEU takes on the order of minutes per iteration, and costs nothing.

[4] composable in MERT, as they can be recalculated at each critical point. However, this would slow down the optimization process quite a bit, since one cannot traverse the dimension by simply adjusting the sufficient statistics to reflect changes in 1-best candidates.

2.3 The RYPT Metric

We suggest here a new metric that combines the best of both worlds, in that it is based on human judgment, but that is a viable metric to be used in the MERT phase. The key to the feasiblity is the reliance on a *database* of human judgment rather than immendiate feedback for each candidate, and so human feedback is only needed once, and the collected human judgments can be reused over and over again by an automatic scorer.

The basic idea is to reward syntactic constituents in the source sentence that get aligned to "acceptable" translations in the candidate sen-

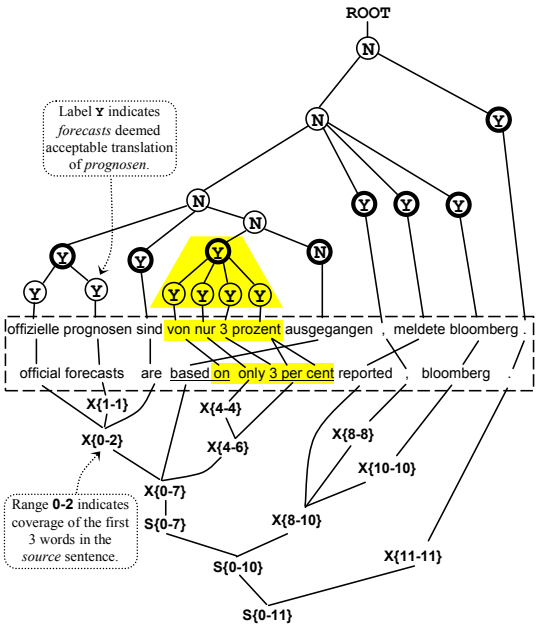

Figure 2: The source parse tree (top) and the candidate derivation tree (bottom). Nodes in the parse tree with a thick border correspond to the frontier node set with maxLen $= 4$. The human annotator only sees the portion surrounded by the dashed rectangle, including the highlighting (though excluding the word alignment links).

tence, and penalize constituents that do not. For instance, consider the source-candidate sentence pair of Figure 2. To evaluate the candidate translation, the source parse tree is first obtained (Dubey, 2005), and each subtree is matched with a substring in the candidate string. If the source substring covered by this subtree is translated into an acceptable substring in the candidate, that node gets a YES label. Otherwise, the node gets a NO label.

The metric we propose is taken to be the ratio of YES nodes in the parse tree (or RYPT). The candidate in Figure 2, for instance, would get a RYPT score of $13/18 = 0.72$.

To justify its use as a proxy for HTER-like metrics, we need to demonstrate that this metric correlates well with human judgment. But it is also important to show that we can obtain the YES/NO label assignments in an efficient and affordable manner. At first glance, this seems to require a human to provide judgments for each candidate, much like with HTER. But we describe in the next section strategies that minimize the number of judgments we need to actually collect.

3 Collecting Human Judgments

The first assumption we make to minimize the number of human judgments, is that once we have a judgment for a source-candidate substring pair, that same judgment can be used across all candidates for this source sentence. In other words, we build a database for each source sentence, which consists of <source substring,target substring,judgment> entries. For a given source substring, multiple entries exist, each with a different target candidate substring. The judgment field is one of YES, NO, and NOT SURE.

Note that the entries do not store the full candidate string, since we reuse a judgment across all the candidates of that source sentence. For instance, if we collect the judgment:

<der patient,the patient,YES>

from the sentence pair:

der patient wurde isoliert .
the patient was isolated .

then this would apply to any candidate translation of this source sentence. And so all of the following substrings are labeled YES as well:

the patient isolated .
the patient was in isolation .
the patient has been isolated .

Similarly, if we collect the judgment:

<der patient,of the patient,NO>

from the sentence pair:

der patient wurde isoliert .
of the patient was isolated .

then this would apply to any candidate translation of the source, and the following substrings are labeled NO as well:

of the patient isolated .
of the patient was in isolation .
of the patient has been isolated .

The strategy of using judgments across candidates reduces the amount of labels we need to collect, but evaluating a candidate translation for the source sentence of Figure 2 would still require obtaining 18 labels, one for each node in the parse tree. Instead of querying a human for each one

of those nodes, it is quite reasonable to percolate existing labels up and down the parse tree: if a node is labeled NO, this likely means that all its ancestors would also be labeled NO, and if a node is labeled YES, this likely means that all its descendents whould also be labeled YES.

While those two strategies (using judgments across candidates, and percolating labels up and down the tree) are only approximations for the true labels, employing them considerably reduces the amount of data we need to collect.

3.1 Obtaining Source-to-Candidate Alignments

How do we determine which segment of the candidate sentence aligns to a given source segment? Given a word alignment between the source and the candidate, we take the target substring to contain any word aligned with at least one word in the source segment. One could run an aligner (e.g. GIZA++) on the two sentences to obtain the word alignment, but we take a different approach.

We use Joshua (Li et al., 2009), in our experiments. Joshua is a hierarchical parsing-based MT system, and it can be instructed to produce derivation trees instead of the candidate sentence string itself. Furthermore, each node in the derivation tree is associated with the two indices in the source sentence that indicate the segment corresponding to this derivation subtree (the numbers indicated in curly brackets in Figure 2).

Using this information, we are able to recover most of the phrasal alignments. There are other phrasal alignments that can be deduced from the structure of the tree indirectly, by systematically discarding source words that are part of another phrasal alignment. For instance, in Figure 2, one can observe the alignment (offizielle,prognosen,sind)–(official,forecasts,are) and the alignment (prognosen)–(forecasts) to deduce (offizielle,sind)–(official,are).

Although some of the phrasal alignment are one-to-one mappings, many of them are many-to-many. By construction, any deduced many-to-many mapping has occurred in the training parallel corpus at least once. And so we recover the individual word alignments by consulting the parallel corpus from which the grammar rules were extracted (which requires maintaining the word alignments obtained prior to rule extraction).[5]

We emphasize here that our recovery of word alignment from phrasal alignment is independent from the hierarchical and parsing-based nature of the Joshua system. And so the alignment approach we suggest here can be applied to a different MT system as well, as long as that system provides phrasal alignment along with the output. In particular, a phrase-based system such as Moses can be modified in a straightforward manner to provide phrasal alignments, and then apply our method.

4 Data Collection

We chose the WMT08 German-English news dataset to work with, and since this is an investigative study of a novel approach, we collected judgments for a subset of 250 source sentences from the development set for the set of candidate sentences produced in the last iteration of a MERT run optimizing BLEU on the full 2051-sentence development set. The MT system we used is Joshua (Li et al., 2009), a software package that comes complete with a grammar extraction module and a MERT module, in addition to the decoder itself.

What segments of the source should be chosen to be judged? We already indicated that we limit ourselves, by definition of RYPT, to segments that are covered exactly by a subtree in the source parse tree. This has a couple of nice advantages: it allows us to present an annotator with a high number of alternatives judged simulataneously (since the annotator is shown a source segment and several candidates, not just one), and this probably also makes judging them easier – it is reasonable to assume that strings corresponding to syntactic constituents are easier to process by a human.

Our query selection strategy attempts to maximize the amount of YES/NO percolation that would take place. We therefore ensure that for any 2 queries, the corresponding source segments do not overlap: such overlap indicates that one subtree is completely contained within the other. Having both queries (in the same batch) might be redundant if we use the above percolation procedure.

The idea is to select source segments so that they fully cover the entire source sentence, but have no overlap amongst them. In one extreme, each query would correspond to an entire parse tree. This is not ideal since the overwhelming majority of the judgments will most likely be NO,

[5] We incorporated our implementation of the source-candidate aligner into the Joshua software as a new `aligner` package.

which does not help identify where the problem is. In the other extreme, each query would correspond to a subtree rooted at a preterminal. This is also not ideal, since it would place too much emphasis on translations of unigrams.

So we need a middle ground. We select a maximum-source-length `maxLen` to indicate how long we're willing to let source segments be. Then we start at the root of the parse tree, and propagate a "frontier" node set down the parse tree, to end up with a set of nodes that fully cover the source sentence, have no overlap amongst them, and with each covering no more than `maxLen` source words. For instance, with `maxLen` set to 4, the frontier set of Figure 2 are the nodes with a thick border. An algorithmic description is provided in Algorithm 1.

Algorithm 1 Constructing the frontier node set for a parse tree.

Input: A source parse tree T rooted at `ROOT`, and a maximum source length `maxLen`.
Return: A nonempty set `frontierSet`, containing a subset of the nodes in T.

1. Initialize `frontierSet` to the empty set.
2. Initialize `currNodes` to $\{$`ROOT`$\}$.
3. **while** `currNodes` is not empty **do**
4. Initialize `newNodes` to the empty set.
5. **for** each node N in `currNodes` **do**
6. **if** N covers $\leq$ `maxLen` source words **then**
7. Add N to `frontierSet`.
8. **else**
9. Add children of N to `newNodes`.
10. **end if**
11. **end for**
12. Set `currNodes` = `newNodes`
13. **end while**
14. Return `frontierSet`.

This would ensure that our queries cover between 1 and `maxLen` source words, and ensures they do not overlap, which would allow us to take full advantage of the downward-`YES` and upward-`NO` percolation. We set `maxLen` $= 4$ based on a pilot study of 10 source sentences and their candidates, having observed that longer segments tend to always be labeled as `NO`, and shorter segments tend to be so deep down the parse tree.

4.1 Amazon Mechanical Turk

We use the infrastructure of Amazon's Mechanical Turk (AMT)[6] to collect the labels. AMT is a virtual marketplace that allows "requesters" to create and post tasks to be completed by "workers" around the world. To create the tasks (called *Human Intelligence Tasks*, or HITs), a requester supplies an HTML template along with a comma-separated-values database, and AMT automatically creates the HITs and makes them available to workers. The queries are displayed as an HTML page (based on the provided HTML template), with the user indicating the label (`YES`, `NO`, or `NOT SURE`) by selecting the appropriate radio button. The instructions read, in part:[7]

> You are shown a "source" German sentence with a highlighted segment, followed by several candidate translations with corresponding highlighted segments. Your task is to decide if each highlighted English segment is an acceptable translation of the highlighted German segment.

In each HIT, the worker is shown up to 10 alternative translations of a highlighted source segment, with each itself highlighted within a full candidate string in which it appears. To aid the worker in the task, they are also shown the reference translation, with a highlighted portion that corresponds to the source segment, deduced using word alignments obtained with GIZA++.[8]

4.2 Cost of Data Collection

The total number of HITs created was 3873, with the reward for completing a HIT depending on how many alternative translations are being judged. On average, each HIT cost 2.1 cents and involved judging 3.39 alternatives. 115 distinct workers put in a total of 30.82 hours over a period of about 4 days. On average, a label required 8.4 seconds to determine (i.e. at a rate of 426 labels per hour). The total cost was $81.44: $21.43 for Amazon's commission, $53.47 for wages, and

[6] AMT's website: `http://www.mturk.com`.

[7] Template and full instructions can be viewed at `http://cs.jhu.edu/~ozaidan/hmert`.

[8] These alignments are not always precise, and we do note that fact in the instructions. We also deliberately highlight the reference substring in a different color to make it clear that workers should judge a candidate substring primarily based on the source substring, not the reference substring.

$6.54 for bonuses[9], for a cost per label of 0.62 cents (i.e. at a rate of 161.32 labels per dollar). Excluding Amazon's commission, the effective hourly 'wage' was $1.95.

5 Experimental Results and Analysis

By limiting our queries to source segments corresponding to frontier nodes with `maxLen` $= 4$, we obtain a total of 3601 subtrees across the 250 sentences, for an average of 14.4 per sentence. On average, each subtree has 3.65 alternative translations. Only about 4.8% of the judgments were returned as `NOT SURE` (or, occasionally, blank), with the rest split into 35.1% `YES` judgments and 60.1% `NO` judgments.

The coverage we get before percolating labels up and down the trees is 39.4% of the nodes, increasing to a coverage of 72.9% after percolation. This is quite good, considering we only do a single data collection pass, and considering that about 10% of the subtrees do not align to candidate substrings to begin with (e.g. single source words that lack a word alignment into the candidate string).

The main question, of course, is whether or not those labels allow us to calculate a RYPT score that is reliably correlated with human judgment. We designed an experiment to compare the predictive power of RYPT vs. BLEU. Given the candidate set of a source sentence, we rerank the candidate set according to RYPT and extract the top-1 candidate, and we rerank the candidate set according to BLEU, and extract the top-1 candidate. We then present the two candidates to human judges, and ask them to choose the one that is a more adequate translation. For reliability, we collect 3 judgments per sentence pair comparison, instead of just 1.

The results show that RYPT significantly outperforms BLEU when it comes to predicting human preference, with its choice prevailing in 46.1% of judgments vs. 36.0% for BLEU, with 17.9% judged to be of equal quality (left half of Table 1). This advantage is especially true when the judgments are grouped by sentence, and we examine cases of strong agreement among the three annotators (Table 2): whereas BLEU's candidate is strongly preferred in 32 of the candidate pairs (bottom 2 rows), RYPT's candidate is strongly preferred in about double that number: 60 candidate pairs (top 2 rows).

This is quite a remarkable result, given that BLEU, by definition, selects a candidate that has significant overlap with the reference shown to the annotators to aid in their decision-making. This means that BLEU has an inherent advantage in comparisons where both candidates are more or less of equal quality, since annotators are encouraged (in the instructions) to make a choice even if the two candidates seem of be of equal quality at first glance. Pressed to make such a choice, the annotator is likely to select the candidate that superficially 'looks' more like the reference to be the 'better' of the two candidates. That candidate will most likely be the BLEU-selected one.

To test this hypothesis, we repeated the experiment *without showing the annotators the reference translations*, and limited data collection to workers living in Germany, making judgments based only on the source sentences. (We only collected one judgment per source sentence, since German workers on AMT are in short supply.)

As expected, the difference is even more pronounced: human judges prefer the RYPT-selected candidate 45.2% of the time, while BLEU's candidate is preferred only 29.2% of the time, with 25.6% judged to be of equal quality (right half of Table 1). Our hypothesis is further supported by the fact that most of the gain of the "equal-quality" category comes from BLEU, which loses 6.8 percentage points, whereas RYPT's share remains largely intact, losing less than a single percentage point.

5.1 Analysis of Data Collection

Recall that we minimize data collection by performing label percolation and by employing a frontier node set selection strategy. While the results just presented indicate those strategies provide a good approximation of some 'true' RYPT score, label percolation was a strategy based primarily on intuition, and choosing `maxLen` $= 4$ for frontier set construction was based on examining a limited amount of preliminary data.

Therefore, and in addition to encouraging empricial results, we felt a more rigorous quantitative analysis was in order, especially with future, more ambitious annotation projects on the horizon. To this end, we collected a *complete* set of judgments for 50 source sentences and their candidates. That is, we generated a query for each and every node

[9] We would review the collected labels and give a 20% reward for good workers to encourage them to come back and complete more HITs.

	References shown; unrestricted		References **not** shown; restricted to DE workers

RYPT +2	15	6.0	RYPT +any	120	48.0
RYPT +1	60	24.0			
$\pm$ 0	42	16.8	$\pm$ 0	42	16.8
BLEU +1	55	22.0			
BLEU +2	5	2.0	BLEU +any	88	35.2
BLEU +3	28	11.2			
Total	250	100.0	Total	250	100.0

Table 2: Ranking comparison results, grouped by sentence. This table corresponds to the left half of Table 1. 3 judgments were collected for each comparison, with the "aggregate" for a comparison calculated from these 3 judgments. For instance, an aggregate of "RYPT +3" means all 3 judgments favored RYPT's choice, and "RYPT +1" means one more judgment favored RYPT than did BLEU.

in the source parse tree, instead of limiting ourselves to a frontier node set. (Though we did limit the length of a source segment to be ≤ 7 words.) This would allow us to judge the validity of label percolation, and under different `maxLen` values.

Furthermore, we collected *multiple* judgments for each query in order to minimize the effet of bad/random annotations. For each of 5580 generated queries, we collected five judgments, for a total of 27,900 judgments.[10] As before, the annotator would pick one of `YES`, `NO`, and `NOT SURE`.

First, collecting multiple judgments allowed us to investigate inter-annotator agreement. In 68.9% of the queries, at least 4 of the 5 annotators chose the same label, signifying a high degree of inter-annotator agreement. This is especially encouraging considering that we identified about 15% of the HITs as being of poor quality, and blocked the respective annotators from doing further HITs.[11]

We then examine the *applicability* and *validity* of label percolation. For each of 7 different values for Algorithm 1's `maxLen`, we ignore all but labels that would be requested under that `maxLen` value, and percolate the labels up and down the tree. In Figure 3 we plot the coverage before and after percolation (middle two curves), and observe expansion in coverage across different values of `maxLen`, peaking at about +33% for `maxLen`$= 4$ and 5, with most of the benefit coming from `YES` percolation (bottom two curves).

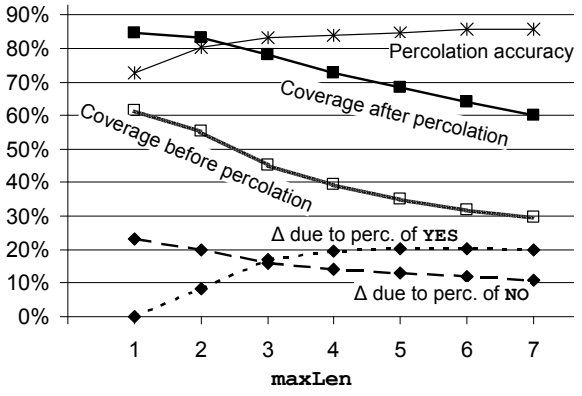

Figure 3: Label percolation under different `maxLen` values. The bottom two curves are the breakdown of the difference between the middle two. Accuracy is measured against majority votes.

[10] For a given query, the five collected judgments are from five different annotators, since AMT ensures an annotator is never shown the same HIT twice.

[11] It is especially easy to identify (and then block) such annotators when they submit a relatively large number of HITs, since inspecting some of their annotations would indicate they are answering randomly and/or inconsistently.

We also measure the accuracy of labels deduced from percolation (top curve of Figure 3). We define a percolated label to be correct if it matches the label given by a majority vote over the collected labels for that particular node. We find that accuracy at low `maxLen` values is significantly lower than at higer values (e.g. 72.6% vs. 84.1% for 1 vs. 4). This means a middle value such as 3 or 4 is optimal. Higher values could be suitable if we wish to emphasize translation fluency.

6 Related Work

Nießen et al. (2000) is an early work that also constructs a database of translations and judgments. There, a source sentence is stored along with all the translations that have already been manually judged, along with their scores. They utilize this database to carry out "semi-automatic" evaluation in a fast and convenient fashion thanks to tool they developed with a user-friendly GUI.

In their annual evaluation, the WMT workshop has effectively conducted manual evaluation of submitted systems over the past few years by distributing the work across tens of volunteers, though they relied on a self-designed online portal. On the other hand, Snow et al. (2008) illustrate how AMT can be used to collect data in a "fast and cheap" fashion, for a number of NLP tasks, such as word sense disambiguation. They go a step further and model the behavior of their annotators to reduce annotator bias. This was possible as they collect multiple judgments for each query from multiple annotators.

The question of how to design an automatic metric that best approximates human judgment has received a lot of attention lately. NIST started organizing the Metrics for Machine Translation Challenge (MetricsMATR) in 2008, with the aim of developing automatic evaluation metrics that correlate highly with human judgment of translation quality. The latest WMT workshop (Callison-Burch et al., 2009) also conducted a full assessment of how well a suite of automatic metrics correlate with human judgment.

7 Future Work

This pilot study has demonstrated the feasibility of collecting a large number of human judgments, and has shown that the RYPT metric is better than BLEU at picking out the best translation. The next step is to run a complete MERT run. This will involve collecting data for thousands of alternative translations for several hundreds source sentences. Based on our analysis, this it should be cost-effective to solicit these judgments using AMT. After training MERT using RYPT as an objective function the, the next logical step would be to compare two outputs of a system. One output would have parameters optimized to BLEU and the other to RYPT. The hope is that the RYPT-trained system would be better under the final HTER evaluation than the BLEU-trained system.

We are also investigating a probabilistic approach to percolating the labels up and down the tree, whereby the label of a node is treated as a random variable, and inference is performed based on values of the other observed nodes, as well as properties of the source/candidate segment. Cast this way, a probabilistic approach is actually quite appealing, and one could use collected data to train a prediction model (such as a Markov random field).

8 Summary

We propose a human-based metric, RYPT, that is quite feasible to optimize using MERT, relying on the redundancy in the candidate set, and collecting judgments using Amazon's Mechanical Turk infrastructure. We show this could be done in a quite cost-effective manner, and produces data of good quality. We show the effectiveness of the metric by illustrating that it is a better predictor of human judgment of translation quality than BLEU, the most commonly used metric in MT. We show this is the case even with a modest amount of data that does not cover the entirety of all parse trees, on which the metric is dependent. The collected data represents a database that can be reused over and over again, hence limiting human feedback to the initial phase only.

Abstract

Cube pruning is a fast inexact method for generating the items of a beam decoder. In this paper, we show that cube pruning is essentially equivalent to A* search on a specific search space with specific heuristics. We use this insight to develop faster and exact variants of cube pruning.

1 Introduction

In recent years, an intense research focus on machine translation (MT) has raised the quality of MT systems to the degree that they are now viable for a variety of real-world applications. Because of this, the research community has turned its attention to a major drawback of such systems: they are still quite slow. Recent years have seen a flurry of innovative techniques designed to tackle this problem. These include cube pruning (Chiang, 2007), cube growing (Huang and Chiang, 2007), early pruning (Moore and Quirk, 2007), closing spans (Roark and Hollingshead, 2008; Roark and Hollingshead, 2009), coarse-to-fine methods (Petrov et al., 2008), pervasive laziness (Pust and Knight, 2009), and many more.

This massive interest in speed is bringing rapid progress to the field, but it comes with a certain amount of baggage. Each technique brings its own terminology (from the *cubes* of (Chiang, 2007) to the *lazy lists* of (Pust and Knight, 2009)) into the mix. Often, it is not entirely clear why they work. Many apply only to specialized MT situations. Without a deeper understanding of these methods, it is difficult for the practitioner to combine them and adapt them to new use cases.

In this paper, we attempt to bring some clarity to the situation by taking a closer look at one of these existing methods. Specifically, we cast the popular technique of *cube pruning* (Chiang, 2007) in the well-understood terms of heuristic search (Pearl, 1984). We show that cube pruning is essentially equivalent to A* search on a specific search space with specific heuristics. This simple observation affords a deeper insight into how and why cube pruning works. We show how this insight enables us to easily develop faster and exact variants of cube pruning for tree-to-string transducer-based MT (Galley et al., 2004; Galley et al., 2006; DeNero et al., 2009).

2 Motivating Example

We begin by describing the problem that cube pruning addresses. Consider a synchronous context-free grammar (SCFG) that includes the following rules:

$$\mathrm{A} \rightarrow \langle \mathrm{A}_{\boxed{0}}\ \mathrm{B}_{\boxed{1}},\ \mathrm{A}_{\boxed{0}}\ \mathrm{B}_{\boxed{1}} \rangle \quad (1)$$

$$\mathrm{B} \rightarrow \langle \mathrm{A}_{\boxed{0}}\ \mathrm{B}_{\boxed{1}},\ \mathrm{B}_{\boxed{1}}\ \mathrm{A}_{\boxed{0}} \rangle \quad (2)$$

$$\mathrm{A} \rightarrow \langle \mathrm{B}_{\boxed{0}}\ \mathrm{A}_{\boxed{1}},\ \mathrm{c}\ \mathrm{B}_{\boxed{0}}\ \mathrm{b}\ \mathrm{A}_{\boxed{1}} \rangle \quad (3)$$

$$\mathrm{B} \rightarrow \langle \mathrm{B}_{\boxed{0}}\ \mathrm{A}_{\boxed{1}},\ \mathrm{B}_{\boxed{0}}\ \mathrm{A}_{\boxed{1}} \rangle \quad (4)$$

Figure 1 shows CKY decoding in progress. CKY is a bottom-up algorithm that works by building objects known as *items*, over increasingly larger *spans* of an input sentence (in the context of SCFG decoding, the items represent partial translations of the input sentence). To limit running time, it is common practice to keep only the n "best" items per span (this is known as *beam decoding*). At this point in Figure 1, every span of size 2 or less has already been filled, and now we want to fill span $[2, 5]$ with the n items of lowest cost. Cube pruning addresses the problem of how to compute the n-best items efficiently.

We can be more precise if we introduce some terminology. An SCFG *rule* has the form $\mathrm{X} \rightarrow \langle \sigma, \varphi, \sim \rangle$, where X is a nonterminal (called the *postcondition*), σ, φ are strings that may contain terminals and nonterminals, and $\sim$ is a 1-1 correspondence between equivalent nonterminals of σ and φ.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 62–71,
Singapore, 6-7 August 2009.

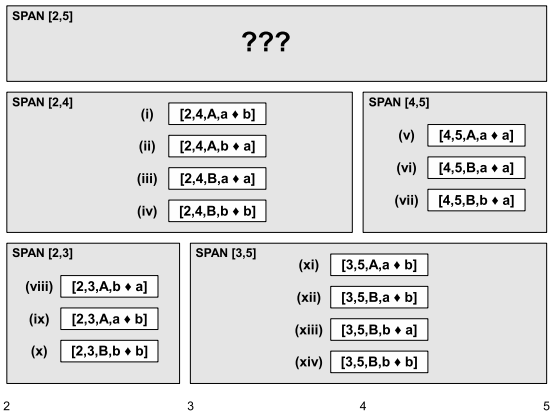

Figure 1: CKY decoding in progress. We want to fill span [2,5] with the lowest cost items.

Usually SCFG rules are represented like the example rules (1)-(4). The subscripts indicate corresponding nonterminals (according to $\sim$). Define the *preconditions* of a rule as the ordered sequence of its nonterminals. For clarity of presentation, we will henceforth restrict our focus to binary rules, i.e. rules of the form: $\mathrm{Z} \rightarrow \langle \mathrm{X}_{\boxed{0}}\ \mathrm{Y}_{\boxed{1}}, \varphi \rangle$. Observe that all the rules of our example are binary rules.

An *item* is a triple that contains a span and two strings. We refer to these strings as the *postcondition* and the *carry*, respectively. The *postcondition* tells us which rules may be applied to the item. The *carry* gives us extra information required to correctly score the item (in SCFG decoding, typically it consists of boundary words for an n-gram language model). [1] To flatten the notation, we will generally represent items as a 4-tuple, e.g. $[2, 4, \mathrm{X}, \mathrm{a} \diamond \mathrm{b}]$.

In CKY, new items are created by applying rules to existing items:

$$\frac{r : \mathrm{Z} \rightarrow \langle \mathrm{X}_{\boxed{0}}\ \mathrm{Y}_{\boxed{1}}, \varphi \rangle \quad [\alpha, \delta, \mathrm{X}, \kappa_1] \quad [\delta, \beta, \mathrm{Y}, \kappa_2]}{[\alpha, \beta, \mathrm{Z}, \mathsf{carry}(r, \kappa_1, \kappa_2)]} \tag{5}$$

In other words, we are allowed to apply a rule r to a pair of items ι_1, ι_2 if the item spans are complementary and $\mathsf{preconditions}(r) = \langle \mathsf{postcondition}(\iota_1), \mathsf{postcondition}(\iota_2) \rangle$. The new item has the same postcondition as the applied rule. We form the carry for the new item through an application-dependent function carry that combines the carries of its subitems (e.g. if the carry is n-gram boundary words, then carry computes the new boundary words). As a shorthand, we introduce the notation $\iota_1 \succcurlyeq r \preccurlyeq \iota_2$ to describe an item created by applying formula (5) to rule r and items ι_1, ι_2.

When we create a new item, it is scored using the following formula: [2]

$$\begin{aligned} \mathsf{cost}(\iota_1 \succcurlyeq r \preccurlyeq \iota_2) \triangleq\ & \mathsf{cost}(r) \\ & + \mathsf{cost}(\iota_1) \\ & + \mathsf{cost}(\iota_2) \\ & + \mathsf{interaction}(r, \kappa_1, \kappa_2) \end{aligned} \tag{6}$$

We assume that each grammar rule r has an associated cost, denoted $\mathsf{cost}(r)$. The *interaction cost*, denoted $\mathsf{interaction}(r, \kappa_1, \kappa_2)$, uses the carry information to compute cost components that cannot be incorporated offline into the rule costs (again, for our purposes, this is a language model score).

Cube pruning addresses the problem of efficiently computing the n items of lowest cost for a given span.

3 Item Generation as Heuristic Search

Refer again to the example in Figure 1. We want to fill span [2,5]. There are 26 distinct ways to apply formula (5), which result in 10 unique items. One approach to finding the lowest-cost n items: perform all 26 distinct inferences, compute the cost of the 10 unique items created, then choose the lowest n.

The 26 different ways to form the items can be structured as a search tree. See Figure 2. First we choose the subspans, then the rule preconditions, then the rule, and finally the subitems. Notice that this search space is already quite large, even for such a simple example. In a realistic situation, we are likely to have a search tree with thousands (possibly millions) of nodes, and we may only want to find the best 100 or so goal nodes. To explore this entire search space seems wasteful. Can we do better?

Why not perform heuristic search directly on this search space to find the lowest-cost n items? In order to do this, we just need to add heuristics to the internal nodes of the space.

Before doing so, it will help to elaborate on some of the details of the search tree. Let $\mathsf{rules}(\mathrm{X}, \mathrm{Y})$ be the subset of rules with preconditions $\langle \mathrm{X}, \mathrm{Y} \rangle$, sorted by increasing cost. Similarly,

[1] Note that the carry is a generic concept that can store any kind of non-local scoring information.

[2] Without loss of generality, we assume an additive cost function.

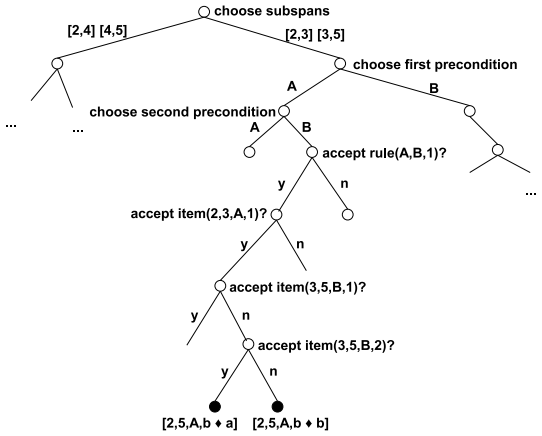

Figure 2: Item creation, structured as a search space. $\mathsf{rule}(\mathrm{X}, \mathrm{Y}, k)$ denotes the k^{th} lowest-cost rule with preconditions $\langle \mathrm{X}, \mathrm{Y} \rangle$. $\mathsf{item}(\alpha, \beta, \mathrm{X}, k)$ denotes the k^{th} lowest-cost item of span $[\alpha, \beta]$ with postcondition X.

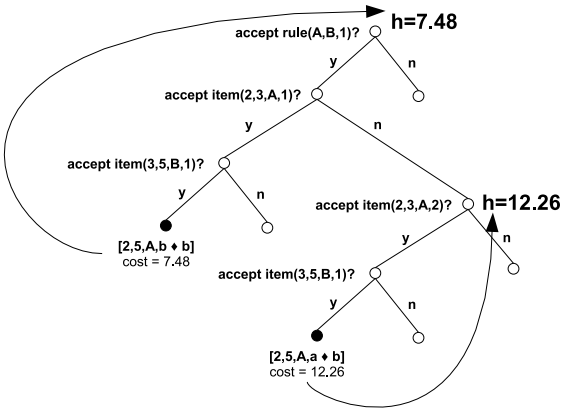

Figure 3: The lookahead heuristic. We set the heuristics for rule and item nodes by looking ahead at the cost of the greedy solution from that point in the search space.

let $\mathsf{items}(\alpha, \beta, \mathrm{X})$ be the subset of items with span $[\alpha, \beta]$ and postcondition X, also sorted by increasing cost. Finally, let $\mathsf{rule}(\mathrm{X}, \mathrm{Y}, k)$ denote the k^{th} rule of $\mathsf{rules}(\mathrm{X}, \mathrm{Y})$ and let $\mathsf{item}(\alpha, \beta, \mathrm{X}, k)$ denote the k^{th} item of $\mathsf{items}(\alpha, \beta, \mathrm{X})$.

A path through the search tree consists of the following sequence of decisions:

1. Set i, j, k to 1.
2. Choose the subspans: $[\alpha, \delta], [\delta, \beta]$.
3. Choose the first precondition X of the rule.
4. Choose the second precondition Y of the rule.
5. While rule not yet accepted and $i < |\mathsf{rules}(\mathrm{X}, \mathrm{Y})|$:
   (a) Choose to accept/reject $\mathsf{rule}(\mathrm{X}, \mathrm{Y}, i)$. If reject, then increment i.
6. While item not yet accepted for subspan $[\alpha, \delta]$ and $j < |\mathsf{items}(\alpha, \delta, \mathrm{X})|$:
   (a) Choose to accept/reject $\mathsf{item}(\alpha, \delta, \mathrm{X}, j)$. If reject, then increment j.
7. While item not yet accepted for subspan $[\delta, \beta]$ and $k < |\mathsf{items}(\delta, \beta, \mathrm{Y})|$:
   (a) Choose to accept/reject $\mathsf{item}(\delta, \beta, \mathrm{Y}, k)$. If reject, then increment k.

Figure 2 shows two complete search paths for our example, terminated by *goal nodes* (in black). Notice that the internal nodes of the search space can be classified by the type of decision they govern. To distinguish between these nodes, we will refer to them as *subspan nodes*, *precondition nodes*, *rule nodes*, and *item nodes*.

We can now proceed to attach heuristics to the nodes and run a heuristic search protocol, say A*, on this search space. For subspan and precondition nodes, we attach trivial uninformative heuristics, i.e. $h = -\infty$. For goal nodes, the heuristic is the actual cost of the item they represent. For rule and item nodes, we will use a simple type of heuristic, often referred to in the literature as a *lookahead heuristic*. Since the rule nodes and item nodes are ordered, respectively, by rule and item cost, it is possible to "look ahead" at a greedy solution from any of those nodes. See Figure 3. This greedy solution is reached by choosing to accept every decision presented until we hit a goal node.

If these heuristics were admissible (i.e. lower bounds on the cost of the best reachable goal node), this would enable us to exactly generate the n-best items without exhausting the search space (assuming the heuristics are strong enough for A* to do some pruning). Here, the lookahead heuristics are clearly not admissible, however the hope is that A* will generate n "good" items, and that the time savings will be worth sacrificing exactness for.

4 Cube Pruning as Heuristic Search

In this section, we will compare cube pruning with our A* search protocol, by tracing through their respective behaviors on the simple example of Figure 1.

4.1 Phase 1: Initialization

To fill span $[\alpha, \beta]$, cube pruning (CP) begins by constructing a *cube* for each tuple of the form:

$$\langle [\alpha, \delta], [\delta, \beta],\ \mathrm{X}\ ,\ \mathrm{Y} \rangle$$

where X and Y are nonterminals. A cube consists of three axes: $\mathsf{rules}(\mathrm{X}, \mathrm{Y})$ and $\mathsf{items}(\alpha, \delta, \mathrm{X})$ and $\mathsf{items}(\delta, \beta, \mathrm{Y})$. Figure 4(left) shows the nontrivial cubes for our example scenario.

Contrast this with A*, which begins by adding the root node of our search space to an empty heap (ordered by heuristic cost). It proceeds to repeatedly pop the lowest-cost node from the heap, then add its children to the heap (we refer to this operation as *visiting* the node). Note that before A* ever visits a rule node, it will have visited every subspan and precondition node (because they all have cost $h = -\infty$). Figure 4(right) shows the state of A* at this point in the search. We assume that we do not generate dead-end nodes (a simple matter of checking that there exist applicable rules and items for the chosen subspans and preconditions). Observe the correspondence between the cubes and the heap contents at this point in the A* search.

4.2 Phase 2: Seeding the Heap

Cube pruning proceeds by computing the "best" item of each cube $\langle [\alpha, \delta], [\delta, \beta],\ \mathrm{X}\ ,\ \mathrm{Y} \rangle$, i.e.

$$\mathsf{item}(\alpha, \delta, \mathrm{X}, 1) \gtrdot \mathsf{rule}(\mathrm{X}, \mathrm{Y}, 1) \lessdot \mathsf{item}(\delta, \beta, \mathrm{Y}, 1)$$

Because of the interaction cost, there is no guarantee that this will really be the best item of the cube, however it is likely to be a good item because the costs of the individual components are low. These items are added to a heap (to avoid confusion, we will henceforth refer to the two heaps as the *CP heap* and the *A* heap*), and prioritized by their costs.

Consider again the example. CP seeds its heap with the "best" items of the 4 cubes. There is now a direct correspondence between the CP heap and the A* heap. Moreover, the costs associated with the heap elements also correspond. See Figure 5.

4.3 Phase 3: Finding the First Item

Cube pruning now pops the lowest-cost item from the CP heap. This means that CP has decided to keep the item. After doing so, it forms the "one-off" items and pushes those onto the CP heap. See Figure 5(left). The popped item is:

$$\text{item (viii)} \gtrdot \text{rule (1)} \lessdot \text{item (xii)}$$

CP then pushes the following one-off successors onto the CP heap:

$$\text{item (viii)} \gtrdot \text{rule (2)} \lessdot \text{item (xii)}$$
$$\text{item (ix)} \gtrdot \text{rule (1)} \lessdot \text{item (xii)}$$
$$\text{item (viii)} \gtrdot \text{rule (1)} \lessdot \text{item (xiii)}$$

Contrast this with A*, which pops the lowest-cost *search node* from the A* heap. Here we need to assume that our A* protocol differs slightly from standard A*. Specifically, it will practice *node-tying*, meaning that when it visits a rule node or an item node, then it also (atomically) visits all nodes on the path to its lookahead goal node. See Figure 5(right). Observe that all of these nodes have the same heuristic cost, thus standard A* is *likely* to visit these nodes in succession without the need to enforce node-tying, but it would not be guaranteed (because the heuristics are not admissible). A* keeps the goal node it finds and adds the successors to the heap, scored with their lookahead heuristics. Again, note the direct correspondence between what CP and A* keep, and what they add to their respective heaps.

4.4 Phase 4: Finding Subsequent Items

Cube pruning and A* continue to repeat Phase 3 until k unique items have been kept. While we could continue to trace through the example, by now it should be clear: cube pruning and our A* protocol with node-tying are doing the same thing at each step. In fact, they are *exactly the same algorithm*. We do not present a formal proof here; this statement should be regarded as confident conjecture.

The node-tying turns out to be an unnecessary artifact. In our early experiments, we discovered that node-tying has no impact on speed or quality. Hence, for the remainder of the paper, we view cube pruning in very simple terms: as nothing more than standard A* search on the search space of Section 3.

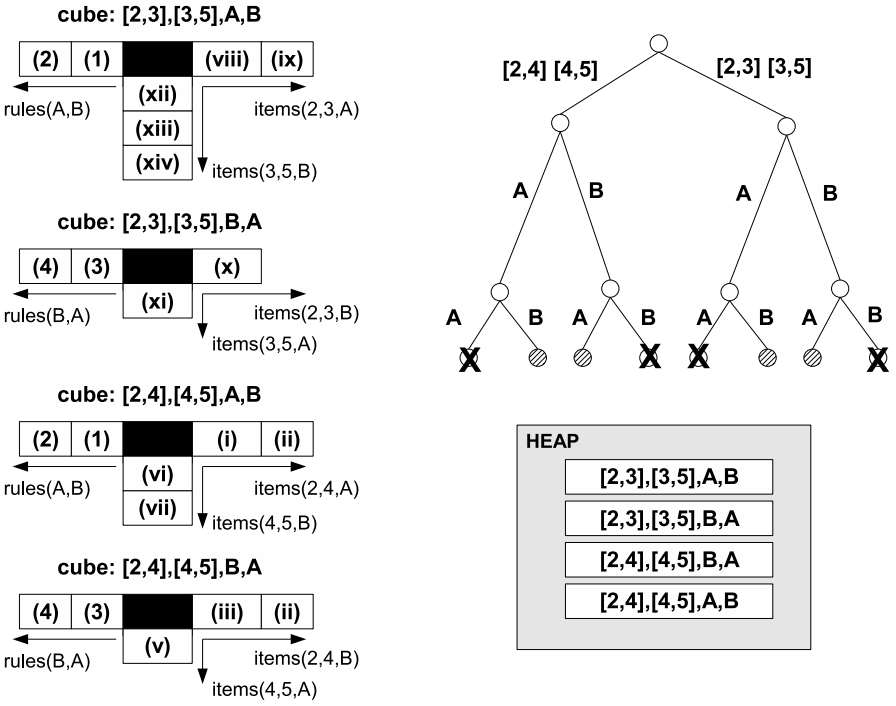

Figure 4: (left) Cube formation for our example. (right) The A* protocol, after all subspan and precondition nodes have been visited. Notice the correspondence between the cubes and the A* heap contents.

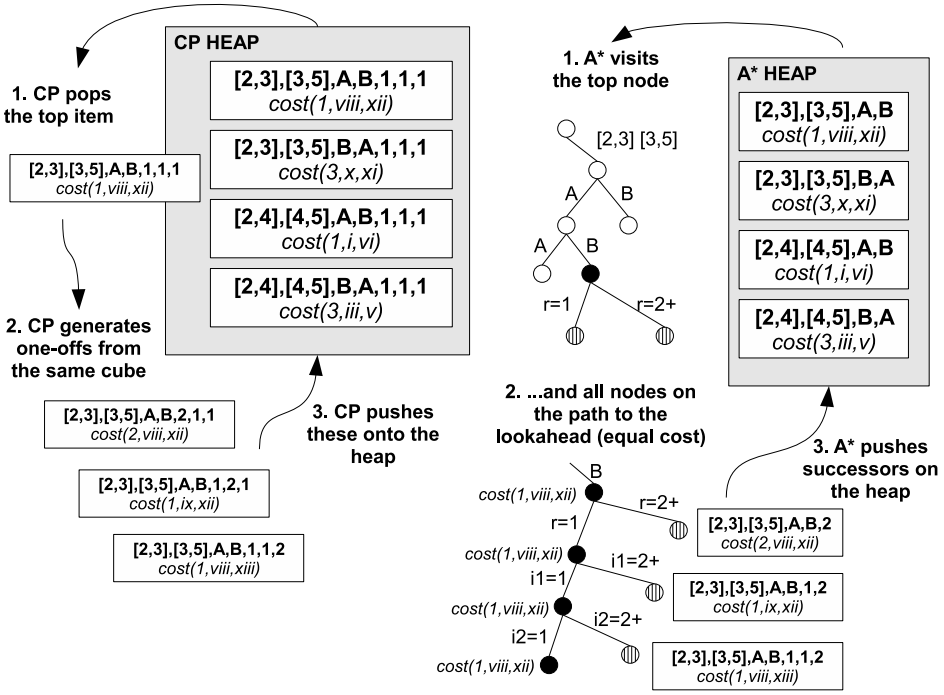

Figure 5: (left) One step of cube pruning. (right) One step of the A* protocol. In this figure, $\mathsf{cost}(r, \iota_1, \iota_2) \triangleq \mathsf{cost}(\iota_1 \succ r \prec \iota_2)$.

5 Augmented Cube Pruning

Viewed in this light, the idiosyncracies of cube pruning begin to reveal themselves. On the one hand, rule and item nodes are associated with strong but inadmissible heuristics (the short explanation for why cube pruning is an inexact algorithm). On the other hand, subspan and precondition nodes are associated with weak trivial heuristics. This should be regarded neither as a surprise nor a criticism, considering cube pruning's origins in hierarchical phrase-based MT models (Chiang, 2007), which have only a small number of distinct nonterminals.

But the situation is much different in tree-to-string transducer-based MT (Galley et al., 2004; Galley et al., 2006; DeNero et al., 2009). Transducer-based MT relies on SCFGs with large nonterminal sets. Binarizing the grammars (Zhang et al., 2006) further increases the size of these sets, due to the introduction of virtual nonterminals.

A key benefit of the heuristic search viewpoint is that it is well positioned to take advantage of such insights into the structure of a particular decoding problem. In the case of transducer-based MT, the large set of preconditions encourages us to introduce a nontrivial heuristic for the precondition nodes. The inclusion of these heuristics into the CP search will enable A* to eliminate certain preconditions from consideration, giving us a speedup. For this reason we call this strategy *augmented cube pruning*.

5.1 Heuristics on preconditions

Recall that the total cost of a goal node is given by Equation (6), which has four terms. We will form the heuristic for a precondition node by creating a separate heuristic for each of the four terms and using the sum as the overall heuristic.

To describe these heuristics, we will make intuitive use of the wildcard operator $*$ to extend our existing notation. For instance, $\mathsf{items}(\alpha, \beta, *)$ will denote the union of $\mathsf{items}(\alpha, \beta, \mathrm{X})$ over all possible X, sorted by cost.

We associate the heuristic $h(\delta, \mathrm{X}, \mathrm{Y})$ with the search node reached by choosing subspans $[\alpha, \delta]$, $[\delta, \beta]$, precondition X (for span $[\alpha, \delta]$), and precondition Y (for span $[\delta, \beta]$). The heuristic is the sum of four terms, mirroring Equation (6):

$$\begin{aligned} h(\delta, \mathrm{X}, \mathrm{Y}) &= \mathsf{cost}(\mathsf{rule}(\mathrm{X}, \mathrm{Y}, 1)) \\ &+ \mathsf{cost}(\mathsf{item}(\alpha, \delta, \mathrm{X}, 1)) \\ &+ \mathsf{cost}(\mathsf{item}(\delta, \beta, \mathrm{Y}, 1)) \\ &+ \mathsf{ih}(\delta, \mathrm{X}, \mathrm{Y}) \end{aligned}$$

The first three terms are admissible because each is simply the minimum possible cost of some choice remaining to be made. To construct the *interaction heuristic* $\mathsf{ih}(\delta, \mathrm{X}, \mathrm{Y})$, consider that in a translation model with an integrated n-gram language model, the interaction cost $\mathsf{interaction}(r, \kappa_1, \kappa_2)$ is computed by adding the language model costs of any new complete n-grams that are created by combining the carries (boundary words) with each other and with the lexical items on the rule's target side, taking into account any reordering that the rule may perform. We construct a backoff-style estimate of these new n-grams by looking at $\mathsf{item}(\alpha, \delta, \mathrm{X}, 1) = [\alpha, \delta, \mathrm{X}, \kappa_1]$, $\mathsf{item}(\delta, \beta, \mathrm{Y}, 1) = [\delta, \beta, \mathrm{Y}, \kappa_2]$, and $\mathsf{rule}(\mathrm{X}, \mathrm{Y}, 1)$. We set $\mathsf{ih}(\delta, \mathrm{X}, \mathrm{Y})$ to be a linear combination of the backoff n-grams of the carries κ_1 and κ_2, as well as any n-grams introduced by the rule. For instance, if

$$\begin{aligned} \kappa_1 &= \mathrm{a\ b} \diamond \mathrm{c\ d} \\ \kappa_2 &= \mathrm{e\ f} \diamond \mathrm{g\ h} \\ \mathsf{rule}(\mathrm{X}, \mathrm{Y}, 1) &= \mathrm{Z} \rightarrow \langle \mathrm{X}_{\boxed{0}}\ \mathrm{Y}_{\boxed{1}},\ \mathrm{X}_{\boxed{0}}\ \mathrm{g\ h\ i}\ \mathrm{Y}_{\boxed{1}} \rangle \end{aligned}$$

then

$$\begin{aligned} \mathsf{ih}(\delta, \mathrm{X}, \mathrm{Y}) &= \gamma_1 \cdot \mathsf{LM}(\mathrm{a}) + \gamma_2 \cdot \mathsf{LM}(\mathrm{a\ b}) \\ &+ \gamma_1 \cdot \mathsf{LM}(\mathrm{e}) + \gamma_2 \cdot \mathsf{LM}(\mathrm{e\ f}) \\ &+ \gamma_1 \cdot \mathsf{LM}(\mathrm{g}) + \gamma_2 \cdot \mathsf{LM}(\mathrm{g\ h}) \\ &+ \gamma_3 \cdot \mathsf{LM}(\mathrm{g\ h\ i}) \end{aligned}$$

The coefficients of the combination are free parameters that we can tune to trade off between more pruning and more admissability. Setting the coefficients to zero gives perfect admissibility but is also weak.

The heuristic for the first precondition node is computed similarly:

$$\begin{aligned} h(\delta, \mathrm{X}, *) &= \mathsf{cost}(\mathsf{rule}(\mathrm{X}, *, 1)) \\ &+ \mathsf{cost}(\mathsf{item}(\alpha, \delta, \mathrm{X}, 1)) \\ &+ \mathsf{cost}(\mathsf{item}(\delta, \beta, *, 1)) \\ &+ \mathsf{ih}(\delta, \mathrm{X}, *) \end{aligned}$$

Standard CP			Augmented CP		
nodes (k)	BLEU	time	nodes (k)	BLEU	time

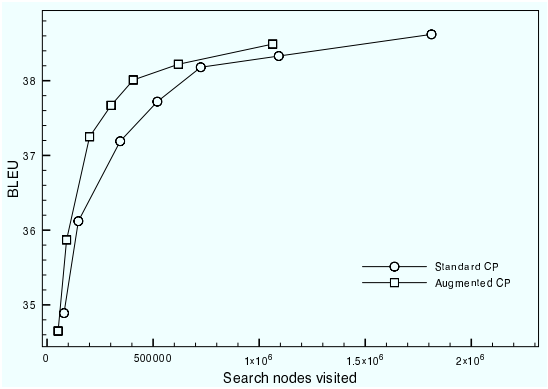

Figure 6: Nodes visited by standard and augmented cube pruning.

We also apply analogous heuristics to the subspan nodes.

5.2 Experimental setup

We evaluated all of the algorithms in this paper on a syntax-based Arabic-English translation system based on (Galley et al., 2006), with rules extracted from 200 million words of parallel data from NIST 2008 and GALE data collections, and with a 4-gram language model trained on 1 billion words of monolingual English data from the LDC Gigaword corpus. We evaluated the system's performance on the NIST 2008 test corpus, which consists of 1357 Arabic sentences from a mixture of newswire and web domains, with four English reference translations. We report BLEU scores (Papineni et al., 2002) on untokenized, recapitalized output.

5.3 Results for Augmented Cube Pruning

The results for augmented cube pruning are compared against cube pruning in Table 1. The data

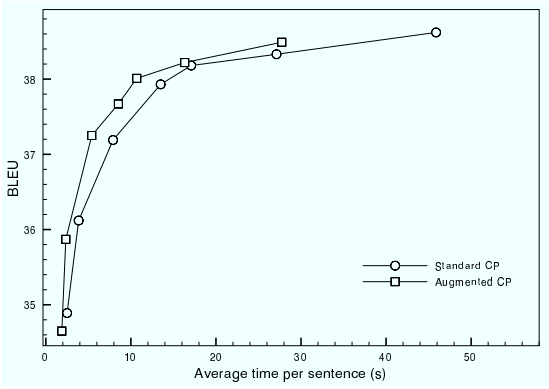

Figure 7: Time spent by standard and augmented cube pruning, average seconds per sentence.

goal	74618	74159
TOTAL	1092449	619125
BLEU	38.33	38.22

Table 2: Breakdown of visited search nodes by type (for a fixed beam size).

from that table are also plotted in Figure 6 and Figure 7. Each line gives the number of nodes visited by the heuristic search, the average time to decode one sentence, and the BLEU of the output. The number of items kept by each span (the beam) is increased in each subsequent line of the table to indicate how the two algorithms differ at various beam sizes. This also gives a more complete picture of the speed/BLEU tradeoff offered by each algorithm. Because the two algorithms make the same sorts of lookahead computations with the same implementation, they can be most directly compared by examining the number of visited nodes. Augmenting cube pruning with admissible heuristics on the precondition nodes leads to a substantial decrease in visited nodes, by 35-44%. The reduction in nodes converges to a consistent 40% as the beam increases. The BLEU with augmented cube pruning drops by an average of 0.1 compared to standard cube pruning. This is due to the additional inadmissibility of the interaction heuristic.

To see in more detail how the heuristics affect the search, we give in Table 2 the number of nodes of each type visited by both variants for one beam

size. The precondition heuristic enables A* to prune more than half the precondition nodes.

6 Exact Cube Pruning

Common wisdom is that the speed of cube pruning more than compensates for its inexactness (recall that this inexactness is due to the fact that it uses A* search with inadmissible heuristics). Especially when we move into transducer-based MT, the search space becomes so large that brute-force item generation is much too slow to be practical. Still, within the heuristic search framework we may ask the question: is it possible to apply strictly admissible heuristics to the cube pruning search space, and in so doing, create a version of cube pruning that is both fast *and* exact, one that finds the n *best* items for each span and not just n *good* items? One might not expect such a technique to outperform cube pruning in practice, but for a given use case, it would give us a relatively fast way of assessing the BLEU drop incurred by the inexactness of cube pruning.

Recall again that the total cost of a goal node is given by Equation (6), which has four terms. It is easy enough to devise strong lower bounds for the first three of these terms by extending the reasoning of Section 5. Table 3 shows these heuristics. The major challenge is to devise an effective lower bound on the fourth term of the cost function, the interaction heuristic, which in our case is the incremental language model cost.

We take advantage of the following observations:

1. *In a given span, many boundary word patterns are repeated.* In other words, for a particular span $[\alpha, \beta]$ and carry κ, we often see many items of the form $[\alpha, \beta, \mathrm{X}, \kappa]$, where the only difference is the postcondition X.

2. *Most rules do not introduce lexical items.* In other words, most of the grammar rules have the form $\mathrm{Z} \rightarrow \langle \mathrm{X}_0\ \mathrm{Y}_1,\ \mathrm{X}_0\ \mathrm{Y}_1 \rangle$ (concatenation rules) or $\mathrm{Z} \rightarrow \langle \mathrm{X}_0\ \mathrm{Y}_1,\ \mathrm{Y}_1\ \mathrm{X}_0 \rangle$ (inversion rules).

The idea is simple. We split the search into three searches: one for concatenation rules, one for inversion rules, and one for lexical rules. Each search finds the n–best items that can be created using its respective set of rules. We then take these $3n$ items and keep the best n.

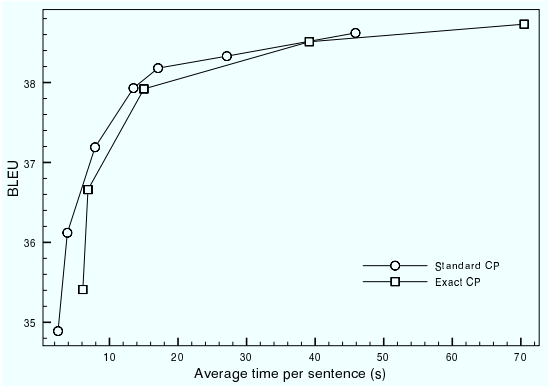

Figure 8: Time spent by standard and exact cube pruning, average seconds per sentence.

Doing this split enables us to precompute a strong and admissible heuristic on the interaction cost. Namely, for a given span $[\alpha, \beta]$, we precompute $\mathsf{ih}_{adm}(\delta, \mathrm{X}, \mathrm{Y})$, which is the best LM cost of combining carries from $\mathsf{items}(\alpha, \delta, \mathrm{X})$ and $\mathsf{items}(\delta, \beta, \mathrm{Y})$. Notice that this statistic is only straightforward to compute once we can assume that the rules are concatenation rules or inversion rules. For the lexical rules, we set $\mathsf{ih}_{adm}(\delta, \mathrm{X}, \mathrm{Y}) = 0$, an admissible but weak heuristic that we can fortunately get away with because of the small number of lexical rules.

6.1 Results for Exact Cube Pruning

Computing the $\mathsf{ih}_{adm}(\delta, \mathrm{X}, \mathrm{Y})$ heuristic is not cheap. To be fair, we first compare exact CP to standard CP in terms of overall running time, including the computational cost of this overhead. We plot this comparison in Figure 8. Surprisingly, the time/quality tradeoff of exact CP is extremely similar to standard CP, suggesting that exact cube pruning is actually a practical alternative to standard CP, and not just of theoretical value. We found that the BLEU loss of standard cube pruning at moderate beam sizes was between 0.4 and 0.6.

Another surprise comes when we contrast the number of visited search nodes of exact CP and standard CP. See Figure 9. While we initially expected that exact CP must visit fewer nodes to make up for the computational overhead of its expensive heuristics, this did not turn out to be the case, suggesting that the computational cost of standard CP's lookahead heuristics is just as expensive as the precomputation of $\mathsf{ih}_{adm}(\delta, \mathrm{X}, \mathrm{Y})$.

	heuristic components

Table 3: Admissible heuristics for exact CP. We attach heuristic $h(\delta, \mathrm{X}, \mathrm{Y}, i, j, k)$ to the search node reached by choosing subspans $[\alpha, \delta], [\delta, \beta]$, preconditions X and Y, the i^{th} rule of $\mathsf{rules}(\mathrm{X}, \mathrm{Y})$, the j^{th} item of $\mathsf{item}(\alpha, \delta, \mathrm{X})$, and the k^{th} item of $\mathsf{item}(\delta, \beta, \mathrm{Y})$. To form the heuristic for a particular type of search node (column), compute the following: $\mathsf{cost}(r) + \mathsf{cost}(\iota_1) + \mathsf{cost}(\iota_2) + ih$

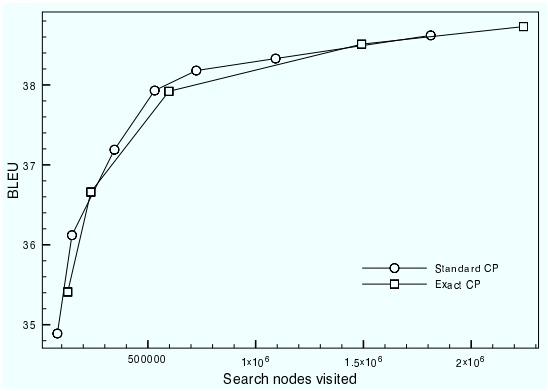

Figure 9: Nodes visited by standard and exact cube pruning.

7 Implications

This paper's core idea is the utility of framing CKY item generation as a heuristic search problem. Once we recognize cube pruning as nothing more than A* on a particular search space with particular heuristics, this deeper understanding makes it easy to create faster and exact variants for other use cases (in this paper, we focus on tree-to-string transducer-based MT). Depending on one's own particular use case, a variety of possibilities may present themselves:

1. *What if we try different heuristics?* In this paper, we do some preliminary inquiry into this question, but it should be clear that our minor changes are just the tip of the iceberg. One can easily imagine clever and creative heuristics that outperform the simple ones we have proposed here.

2. *What if we try a different search space?* Why are we using this particular search space? Perhaps a different one, one that makes decisions in a different order, would be more effective.

3. *What if we try a different search algorithm?* A* has nice guarantees (Dechter and Pearl, 1985), but it is space-consumptive and it is not anytime. For a use case where we would like a finer-grained speed/quality tradeoff, it might be useful to consider an anytime search algorithm, like depth-first branch-and-bound (Zhang and Korf, 1995).

By working towards a deeper and unifying understanding of the smorgasbord of current MT speed-up techniques, our hope is to facilitate the task of implementing such methods, combining them effectively, and adapting them to new use cases.

Abstract

Current methods of using lexical features in machine translation have difficulty in scaling up to realistic MT tasks due to a prohibitively large number of parameters involved. In this paper, we propose methods of using new linguistic and contextual features that do not suffer from this problem and apply them in a state-of-the-art hierarchical MT system. The features used in this work are non-terminal labels, non-terminal length distribution, source string context and source dependency LM scores. The effectiveness of our techniques is demonstrated by significant improvements over a strong baseline. On Arabic-to-English translation, improvements in lower-cased BLEU are 2.0 on NIST MT06 and 1.7 on MT08 newswire data on decoding output. On Chinese-to-English translation, the improvements are 1.0 on MT06 and 0.8 on MT08 newswire data.

1 Introduction

Linguistic and context features, especially sparse lexical features, have been widely used in recent machine translation (MT) research. Unfortunately, existing methods of using such features are not ideal for large-scale, practical translation tasks.

In this paper, we will propose several probabilistic models to effectively exploit linguistic and contextual information for MT decoding, and these new features do not suffer from the scalability problem. Our new models are tested on NIST MT06 and MT08 data, and they provide significant improvement over a strong baseline system.

1.1 Previous Work

The ideas of using labels, length preference and source side context in MT decoding were explored previously. Broadly speaking, two approaches were commonly used in existing work.

One is to use a stochastic gradient descent (SGD) or Perceptron like online learning algorithm to optimize the weights of these features directly for MT (Shen et al., 2004; Liang et al., 2006; Tillmann and Zhang, 2006). This method is very attractive, since it opens the door to rich lexical features. However, in order to robustly optimize the feature weights, one has to use a substantially large development set, which results in significantly slower tuning. Alternatively, one needs to carefully select a development set that simulates the test set to reduce the risk of over-fitting, which however is not always realistic for practical use.

A remedy is to aggressively limit the feature space, e.g. to syntactic labels or a small fraction of the bi-lingual features available, as in (Chiang et al., 2008; Chiang et al., 2009), but that reduces the benefit of lexical features. A possible generic solution is to cluster the lexical features in some way. However, how to make it work on such a large space of bi-lingual features is still an open question.

The other approach is to estimate a single score or likelihood of a translation with rich features, for example, with the maximum entropy (MaxEnt) method as in (Carpuat and Wu, 2007; Ittycheriah and Roukos, 2007; He et al., 2008). This method avoids the over-fitting problem, at the expense of losing the benefit of discriminative training of rich features directly for MT. However, the feature space problem still exists in these published models.

He et al. (2008) extended the WSD-like approached proposed in (Carpuat and Wu, 2007) to hierarchical decoders. In (He et al., 2008), lexical

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 72–80,
Singapore, 6-7 August 2009.

features were limited on each single side due to the feature space problem. In order to further reduce the complexity of MaxEnt training, they "trained a MaxEnt model for each ambiguous hierarchical LHS" (left-hand side or source side) of translation rules. Different target sides were treated as possible labels. Therefore, the sample sets of each individual MaxEnt model were very small, while the number of features could easily exceed the number of samples. Furthermore, optimizing individual MaxEnt models in this way does not lead to global maximum. In addition, MaxEnt models trained on small sets are unstable.

The MaxEnt model in (Ittycheriah and Roukos, 2007) was optimized globally, so that it could better employ the distribution of the training data. However, one has to filter the training data according to the test data to get competitive performance with this model [1]. In addition, the filtering method causes some practical issues. First, such methods are not suitable for real MT tasks, especially for applications with streamed input, since the model has to be retrained with each new input sentence or document and training is slow. Furthermore, the model is ill-posed. The translation of a source sentence depends on other source sentences in the same batch with which the MaxEnt model is trained. If we add one more sentence to the batch, translations of other sentences may become different due to the change of the MaxEnt model.

To sum up, the existing models of employing rich bi-lingual lexical information in MT are imperfect. Many of them are not ideal for practical translation tasks.

1.2 Our Approach

As for our approach, we mainly use simple probabilistic models, i.e. Gaussian and n-gram models, which are more robust and suitable for large-scale training of real data, as manifested in state-of-the-art systems of speech recognition. The unique contribution of our work is to design effective and efficient statistical models to capture useful linguistic and context information for MT decoding. Feature functions defined in this way are robust and ideal for practical translation tasks.

[1] According to footnote 2 of (Ittycheriah and Roukos, 2007), test set adaptation by test set sampling of the training corpus showed an advantage of more than 2 BLEU points over a general system trained on all data.

1.2.1 Features

In this paper, we will introduce four new linguistic and contextual feature functions. Here, we first provide a high-level description of these features. Details of the features are discussed in Section 2.

The first feature is based on non-terminal labels, i.e. POS tags of the head words of target non-terminals in transfer rules. This feature reduces the ambiguity of translation rules. The other benefit is that POS tags help to weed out bad target side tree structures, as an enhancement to the target dependency language model.

The second feature is based on the length distribution of non-terminals. In English as well as in other languages, the same deep structure can be represented in different syntactic structures depending on the complexity of its constituents. We model such preferences by associating each non-terminal of a transfer rule with a probability distribution over its length. Similar ideas were explored in (He et al., 2008). However their length features only provided insignificant improvement of 0.1 BLEU point. A crucial difference of our approach is how the length preference is modeled. We approximate the length distribution of non-terminals with a smoothed Gaussian, which is more robust and gives rise to much larger improvement consistently.

The third feature utilizes source side context information, i.e. the neighboring words of an input span, to influence the selection of the target translation for a span. While the use of context information has been explored in MT, e.g. (Carpuat and Wu, 2007) and (He et al., 2008), the specific technique we used by means of a context language model is rather different. Our model is trained on the whole training data, and it is not limited by the constraint of MaxEnt training.

The fourth feature exploits structural information on the source side. Specifically, the decoder simultaneously generates both the source and target side dependency trees, and employs two dependency LMs, one for the source and the other for the target, for scoring translation hypotheses. Our intuition is that the likelihood of source structures provides another piece of evidence about the plausibility of a translation hypothesis and as such would help weed out bad ones.

1.2.2 Baseline System and Experimental Setup

We take BBN's *HierDec*, a string-to-dependency decoder as described in (Shen et al., 2008), as our baseline for the following two reasons:

- It provides a strong baseline, which ensures the validity of the improvement we would obtain. The baseline model used in this paper showed state-of-the-art performance at NIST 2008 MT evaluation.
- The baseline algorithm can be easily extended to incorporate the features proposed in this paper. The use of source dependency structures is a natural extension of the string-to-tree model to a tree-to-tree model.

To ensure the generality of our results, we tested the features on two rather different language pairs, Arabic-to-English and Chinese-to-English, using two metrics, IBM BLEU (Papineni et al., 2001) and TER (Snover et al., 2006). Our experiments show that each of the first three features: non-terminal labels, length distribution and source side context, improves MT performance. Surprisingly, the source dependency feature does not produce an improvement.

2 Linguistic and Context Features

2.1 Non-terminal Labels

In the original string-to-dependency model (Shen et al., 2008), a translation rule is composed of a string of words and non-terminals on the source side and a well-formed dependency structure on the target side. A well-formed dependency structure could be either a single-rooted dependency tree or a set of sibling trees. As in the Hiero system (Chiang, 2007), there is only one non-terminal X in the string-to-dependency model. Any sub dependency structure can be used to replace a non-terminal in a rule.

For example, we have a source sentence in Chinese as follows.

- jiantao zhuyao baohan liang fangmian

The literal translation for individual words is

- 'review' 'mainly' 'to consist of' 'two' 'part'

The reference translation is

- the review mainly consists of two parts

A single source word can be translated into many English words. For example, *jiantao* can be translated into *a review, the review, reviews, the reviews, reviewing, reviewed*, etc. Suppose we have source-string-to-target-dependency translation rules as shown in Figure 1. Since there is no constraint on substitution, any translation for *jiantao* could replace the X-1 slot.

One way to alleviate this problem is to limit the search space by using a label system. We could assign a label to each non-terminal on the target side of the rules. Furthermore, we could assign a label to the whole target dependency structure, as shown in Figure 2. In decoding, each target dependency sub-structure would be associated with a label. Whenever substitution happens, we would check whether the label of the sub-structure and the label of the slot are the same. Substitutions with unmatched labels would be prohibited.

In practice, we use a soft constraint by penalizing substitutions with unmatched labels. We introduce a new feature: the number of times substitutions with unmatched labels appear in the derivation of a translation hypothesis.

Obviously, to implement this feature we need to associate a label with each non-terminal in the target side of a translation rule. The labels are generated during rule extraction. When we create a rule from a training example, we replace a subtree or dependency structure with a non-terminal and associate it with the POS tag of the head word if the non-terminal corresponds to a single-rooted tree on the target side. Otherwise, it is assigned the generic label X. (In decoding, all substitutions of X are considered unmatched ones and incur a penalty.)

2.2 Length Distribution

In English, the length of a phrase may determine the syntactic structure of a sentence. For example, possessive relations can be represented either as "A's B" or "B of A". The former is preferred if A is a short phrase (e.g. "the boy's mother") while the latter is preferred if A is a complex structure (e.g. "the mother of the boy who is sick").

Our solution is to build a model of length preference for each non-terminal in each translation rule. To address data sparseness, we assume the length distribution of each non-terminal in a transfer rule is a Gaussian, whose mean and variance can be estimated from the training data. In rule extrac-

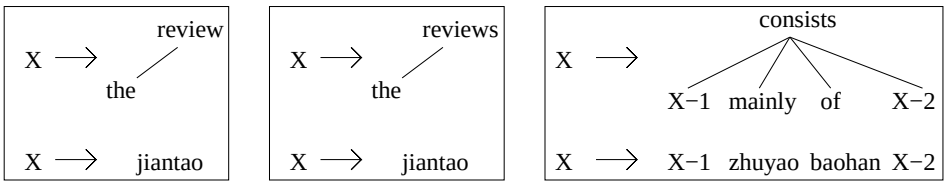

Figure 1: Translation rules with one label X

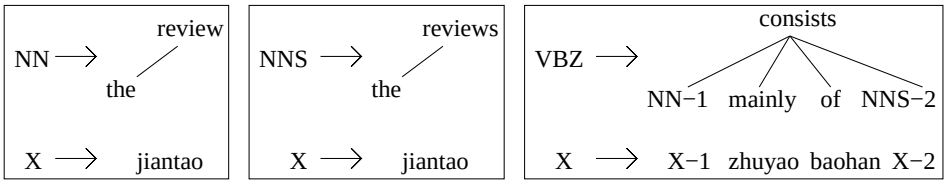

Figure 2: Translation rules with multiple labels

tion, each time a translation rule is generated from a training example, we can record the length of the source span corresponding to a non-terminal. In the end, we have a frequency histogram for each non-terminal in each translation rule. From the histogram, a Gaussian distribution can be easily computed.

In practice, we do not need to collect the frequency histogram. Since all we need to know are the mean and the variance, it is sufficient to collect the sum of the length and the sum of squared length.

Let r be a translation rule that occurs N_r times in training. Let x be a specific non-terminal in that rule. Let $l(r, x, i)$ denote the length of the source span corresponding to non-terminal x in the i-th occurrence of rule r in training. Then, we can compute the following quantities.

$$m_{r,x} = \frac{1}{N_r} \sum_{i=1}^{N_r} l(r, x, i) \quad (1)$$

$$s_{r,x} = \frac{1}{N_r} \sum_{i=1}^{N_r} l(r, x, i)^2, \quad (2)$$

which can be subsequently used to estimate the mean $\mu_{r,x}$ and variance $\sigma^2_{r,x}$ of x's length distribution in rule r as follows.

$$\mu_{r,x} = m_{r,x} \quad (3)$$

$$\sigma^2_{r,x} = s_{r,x} - m^2_{r,x} \quad (4)$$

Since many of the translation rules have few occurrences in training, smoothing of the above estimates is necessary. A common smoothing method is based on maximum a posteriori (MAP) estimation as in (Gauvain and Lee, 1994).

$$\hat{m}_{r,x} = \frac{N_r}{N_r + \tau} m_{r,x} + \frac{\tau}{N_r + \tau} \tilde{m}_{r,x}$$

$$\hat{s}_{r,x} = \frac{N_r}{N_r + \tau} s_{r,x} + \frac{\tau}{N_r + \tau} \tilde{s}_{r,x},$$

where $\hat{}$ stands for an MAP distribution and $\tilde{}$ represents a prior distribution. $\tilde{m}_{r,x}$ and $\tilde{s}_{r,x}$ can be obtained from a prior Gaussian distribution $\mathcal{N}(\tilde{\mu}_{r,x}, \tilde{\sigma}_{r,x})$ via equations (3) and (4), and τ is a weight of smoothing.

There are many ways to approximate the prior distribution. For example, we can have one prior for all the non-terminals or one for individual non-terminal type. In practice, we assume $\tilde{\mu}_{r,x} = \mu_{r,x}$, and approximate $\tilde{\sigma}_{r,x}$ as $(\sigma^2_{r,x} + s_{r,x})^{\frac{1}{2}}$.

In this way, we do not change the mean, but relax the variance with $s_{r,x}$. We tried different smoothing methods, but the performance did not change much, therefore we kept this simplest setup. We also tried the Poisson distribution, and the performance is similar to Gaussian distribution, which is about 0.1 point lower in BLEU.

When a rule r is applied during decoding, we compute a penalty for each non-terminal x in r according to

$$P(l \mid r, x) = \frac{1}{\sigma_{r,x}\sqrt{2\pi}} e^{-\frac{(l-\mu_{r,x})^2}{2\sigma^2_{r,x}}},$$

where l is length of source span corresponding to x.

Our method to address the problem of length bias in rule selection is very different from the maximum entropy method used in existing studies, e.g. (He et al., 2008).

2.3 Context Language Model

In the baseline string-to-dependency system, the probability a translation rule is selected in decoding does not depend on the sentence context. In reality, translation is highly context dependent. To address this defect, we introduce a new feature, called *context language model*. The motivation of this feature is to exploit surrounding words to influence the selection of the desired transfer rule for a given input span.

To illustrate the problem, we use the same example mentioned in Section 2.1. Suppose the source span for rule selection is *zhuyao baohan*, whose literal translation is *mainly* and *to consist of*. There are many candidate translations for this phrase, for example, *mainly consist of, mainly consists of, mainly including, mainly includes*, etc. The surrounding words can help to decide which translation is more appropriate for *zhuyao baohan*. We compare the following two context-based probabilities:

- $P($ jiantao $|$ mainly consist $)$
- $P($ jiantao $|$ mainly consists $)$

Here, *jiantao* is the source word preceding the source span *zhuyao baohan*.

In the training data, *jiantao* is usually translated into *the review*, third-person singular, then the probability $P($ jiantao $|$ mainly consists $)$ will be higher than $P($ jiantao $|$ mainly consist $)$, since we have seen more context events like the former in the training data.

Now we introduce context LM formally. Let the source words be $f_1 f_2 .. f_i .. f_j .. f_n$. Suppose source sub-string $f_i .. f_j$ is translated into $e_p .. e_q$. We can define tri-gram probabilities on the left and right sides of the source span:

- left : $P_L(f_{i-1}|e_p, e_{p+1})$
- right : $P_R(f_{j+1}|e_q, e_{q-1})$

In our implementation, the left and right context LMs are estimated from the training data as part of the rule extraction procedure. When we exact a rule, we collect two 3-gram events, one for the left side and the other for the right side.

In decoding, whenever a partial hypothesis is generated, we calculate the context LM scores based on the leftmost two words and the rightmost two words of the hypothesis as well as the source context. The product of the left and right context LM scores is used as a new feature in the scoring function.

Please note that our approach is very different from other approaches to context dependent rule selection such as (Ittycheriah and Roukos, 2007) and (He et al., 2008). Instead of using a large number of fine grained features with weights optimized using the maximum entropy method, we treat context dependency as an ngram LM problem, and it is smoothed with Witten-Bell discounting. The estimation of the context LMs is very efficient and robust.

The benefit is two fold. The estimation of the context LMs is very efficient. It adds only one new weight to the scoring function.

2.4 Source Dependency Language Model

The context LM proposed in the previous section only employs source words immediately before and after the current source span in decoding. To exploit more source context, we use a source side dependency language model as another feature. The motivation is to take advantage of the long distance dependency relations between source words in scoring a translation theory.

We extended string-to-dependency rules in the baseline system to dependency-to-dependency rules. In each dependency-to-dependency rule, we keep record of the source string as well as the source dependency structure. Figure 3 shows examples of dependency-to-dependency rules.

We extended the string-to-dependency decoding algorithm in the baseline to accommodate dependency-to-dependency theories. In decoding, we build both the source and the target dependency structures simultaneously in chart parsing over the source string. Thus, we can compute the source dependency LM score in the same way we compute the target side score, using a procedure described in (Shen et al., 2008).

We introduce two new features for the source side dependency LM as follows, in a way similar to the target side.

- Source dependency LM score
- Discount on ill-formed source dependency structures

The source dependency LM is trained on the source side of the bi-lingual training data with Witten-Bell smoothing. The source dependency LM score represents the likelihood of the source

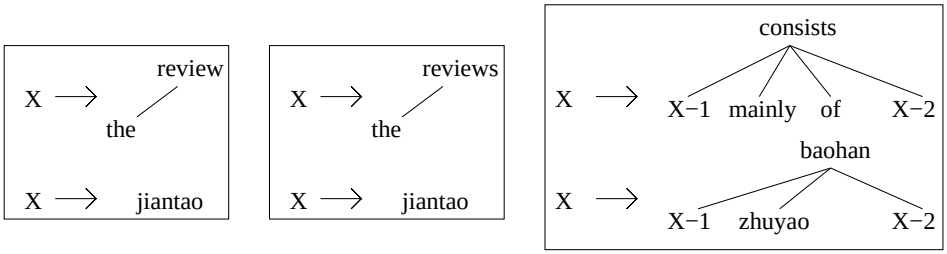

Figure 3: Dependency-to-dependency translation rules

dependency tree generated by the decoder. The source dependency tree with the highest score is the one that is most likely to be generated by the dependency model that created the source side of the training data.

Source dependency trees are composed of fragments embedded in the translation rules. Therefore, a source dependency LM score can be viewed as a measure whether the translation rules are put together in a way similar to the training data. Therefore, a source dependency LM score serves as a feature to represent structural context information that is capable of modeling long-distance relations.

However, unlike source context LMs, the structural context information is used only when two partial dependency structures are combined, while source context LMs work as a look-ahead feature.

3 Experiments

We designed our experiments to show the impact of each feature separately as well as their cumulative impact:

- BASE: baseline string-to-dependency system
- SLM: baseline + source dependency LM
- CLM: baseline + context LM
- LEN: baseline + length distribution
- LBL: baseline + syntactic labels
- LBL+LEN: baseline + syntactic labels + length distribution
- LBL+LEN+CLM: baseline + syntactic labels + length distribution + context LM

All the models were optimized on lower-cased IBM BLEU with Powell's method (Powell, 1964; Brent, 1973) on n-best translations (Ostendorf et al., 1991), but evaluated on both IBM BLEU and TER. The motivation is to detect if an improvement is artificial, i.e., specific to the tuning metric. For both Arabic-to-English and Chinese-to-English MT, we tuned on NIST MT02-05 and tested on MT06 and MT08 newswire sets.

The training data are different from what was usd at MT06 or MT08. Our Arabic-to-English data contain 29M Arabic words and 38M English words from 11 corpora: LDC2004T17, LDC2004T18, LDC2005E46, LDC2006E25, LDC2006G05, LDC2005E85, LDC2006E36, LDC2006E82, LDC2006E95, Sakhr-A2E and Sakhr-E2A. The Chinese-to-English data contain 107M Chinese words and 132M English words from eight corpora: LDC2002E18, LDC2005T06, LDC2005T10, LDC2006E26, LDC2006G05, LDC2002L27, LDC2005T34 and LDC2003E07. They are available under the DARPA GALE program. Traditional 3-gram and 5-gram string LMs were trained on the English side of the parallel data plus the English Gigaword corpus V3.0 in a way described in (Bulyko et al., 2007).

The target dependency LMs were trained on the English side of the parallel training data. For that purpose, we parsed the English side of the parallel data. Two separate models were trained: one for Arabic from the Arabic training data and the other for Chinese from the Chinese training data.

To compute the source dependency LM for Chinese-to-English MT, we parsed the Chinese side of the Chinese-to-English parallel data. Due to the lack of a good Arabic parser compatible with the Sakhr tokenization that we used on the source side, we did not test the source dependency LM for Arabic-to-English MT.

When extracting rules with source dependency structures, we applied the same *well-formedness* constraint on the source side as we did on the target side, using a procedure described by (Shen et al., 2008). Some candidate rules were thrown away due to the source side constraint. On the

other hand, one string-to-dependency rule may split into several dependency-to-dependency rules due to different source dependency structures. The size of the dependency-to-dependency rule set is slightly smaller than the size of the string-to-dependency rule set.

Tables 1 and 2 show the BLEU and TER percentage scores on MT06 and MT08 for Arabic-to-English and Chinese-to-English translation respectively. The context LM feature, the length feature and the syntax label feature all produce a small improvement for most of the conditions. When we combined the three features, we observed significant improvements over the baseline. For Arabic-to-English MT, the LBL+LEN+CLM system improved lower-cased BLEU by 2.0 on MT06 and 1.7 on MT08 on decoding output. For Chinese-to-English MT, the improvements in lower-cased BLEU were 1.0 on MT06 and 0.8 on MT08. After re-scoring, the improvements became smaller, but still noticeable, ranging from 0.7 to 1.4. TER scores were also improved noticeably for all conditions, suggesting there was no metric specific over-tuning.

Surprisingly, source dependency LM did not provide any improvement over the baseline. There are two possible reasons for this. One is that the source and target parse trees were generated by two stand-alone parsers, which may cause incompatible structures on the source and target sides. By applying the *well-formed* constraints on both sides, a lot of useful transfer rules are discarded. A bi-lingual parser, trained on parallel treebanks recently made available to the NLP community, may overcome this problem. The other is that the search space of dependency-to-dependency decoding is much larger, since we need to add source dependency information into the chart parsing states. We will explore techniques to address these problems in the future.

4 Discussion

Linguistic information has been widely used in SMT. For example, in (Wang et al., 2007), syntactic structures were employed to reorder the source language as a pre-processing step for phrase-based decoding. In (Koehn and Hoang, 2007), shallow syntactic analysis such as POS tagging and morphological analysis were incorporated in a phrasal decoder.

In ISI's syntax-based system (Galley et al., 2006) and CMU's Hiero extension (Venugopal et al., 2007), non-terminals in translation rules have labels, which must be respected by substitutions during decoding. In (Post and Gildea, 2008; Shen et al., 2008), target trees were employed to improve the scoring of translation theories. Marton and Resnik (2008) introduced features defined on constituent labels to improve the Hiero system (Chiang, 2005). However, due to the limitation of MER training, only part of the feature space could used in the system. This problem was fixed by

Chiang et al. (2008), which used an online learning method (Crammer and Singer, 2003) to handle a large set of features.

Most SMT systems assume that translation rules can be applied without paying attention to the sentence context. A few studies (Carpuat and Wu, 2007; Ittycheriah and Roukos, 2007; He et al., 2008; Hasan et al., 2008) addressed this defect by selecting the appropriate translation rules for an input span based on its context in the input sentence. The direct translation model in (Ittycheriah and Roukos, 2007) employed syntactic (POS tags) and context information (neighboring words) within a maximum entropy model to predict the correct transfer rules. A similar technique was applied by He et al. (2008) to improve the Hiero system.

Our model differs from previous work on the way in which linguistic and contextual information is used.

5 Conclusions and Future Work

In this paper, we proposed four new linguistic and contextual features for hierarchical decoding. The use of non-terminal labels, length distribution and context LM features gave rise to significant improvement on Arabic-to-English and Chinese-to-English translation on NIST MT06 and MT08 newswire data over a state-of-the-art string-to-dependency baseline. Unlike previous work, we employed robust probabilistic models to capture useful linguistic and contextual information. Our methods are more suitable for practical translation tasks.

In future, we will continue this work in two directions. We will employ a Gaussian model to unify various linguistic and contextual features. We will also improve the dependency-to-dependency method with a better bi-lingual parser.

Abstract

Methods that learn from prior information about input features such as *generalized expectation (GE)* have been used to train accurate models with very little effort. In this paper, we propose an *active learning* approach in which the machine solicits "labels" on *features* rather than instances. In both simulated and real user experiments on two sequence labeling tasks we show that our active learning method outperforms passive learning with features as well as traditional active learning with instances. Preliminary experiments suggest that novel interfaces which intelligently solicit labels on multiple features facilitate more efficient annotation.

1 Introduction

The application of machine learning to new problems is slowed by the need for labeled training data. When output variables are structured, annotation can be particularly difficult and time-consuming. For example, when training a conditional random field (Lafferty et al., 2001) to extract fields such as rent, contact, features, and utilities from apartment classifieds, labeling 22 instances (2,540 tokens) provides only 66.1% accuracy.[1]

Recent work has used unlabeled data and limited prior information about input features to bootstrap accurate structured output models. For example, both Haghighi and Klein (2006) and Mann and McCallum (2008) have demonstrated results better than 66.1% on the *apartments* task described above using only a list of 33 highly discriminative features and the labels they indicate. However, these methods have only been applied in scenarios in which the user supplies such prior knowledge before learning begins.

[1] Averaged over 10 randomly selected sets of 22 instances.

In traditional *active learning* (Settles, 2009), the machine queries the user for only the labels of instances that would be most helpful to the machine. This paper proposes an active learning approach in which the user provides "labels" for input features, rather than instances. A labeled input feature denotes that a particular input feature, for example the word *call*, is highly indicative of a particular label, such as contact. Table 1 provides an excerpt of a feature active learning session.

In this paper, we advocate using generalized expectation (GE) criteria (Mann and McCallum, 2008) for learning with labeled features. We provide an alternate treatment of the GE objective function used by Mann and McCallum (2008) and a novel speedup to the gradient computation. We then provide a pool-based feature active learning algorithm that includes an option to skip queries, for cases in which a feature has no clear label. We propose and evaluate feature query selection algorithms that aim to reduce model uncertainty, and compare to several baselines. We evaluate our method using both real and simulated user experiments on two sequence labeling tasks. Compared to previous approaches (Raghavan and Allan, 2007), our method can be used for both classification and structured tasks, and the feature query selection methods we propose perform better.

We use experiments with simulated labelers on real data to extensively compare feature query selection algorithms and evaluate on multiple random splits. To make these simulations more realistic, the effort required to perform different labeling actions is estimated from additional experiments with real users. The results show that active learning with features outperforms both passive learning with features and traditional active learning with instances.

In the user experiments, each annotator actively labels instances, actively labels features one at a time, and actively labels batches of features orga-

nized using a "grid" interface. The results support the findings of the simulated experiments and provide evidence that the "grid" interface can facilitate more efficient annotation.

2 Conditional Random Fields

In this section we describe the underlying probabilistic model for all methods in this paper. We focus on sequence labeling, though the described methods could be applied to other structured output or classification tasks. We model the probability of the label sequence $\mathbf{y} \in \mathcal{Y}^n$ conditioned on the input sequence $\mathbf{x} \in \mathcal{X}^n$, $p(\mathbf{y}|\mathbf{x};\theta)$ using first-order linear-chain conditional random fields (CRFs) (Lafferty et al., 2001). This probability is

$$p(\mathbf{y}|\mathbf{x};\theta) = \frac{1}{Z_\mathbf{x}} \exp\big(\sum_i \sum_j \theta_j f_j(y_i, y_{i+1}, \mathbf{x}, i)\big),$$

where $Z_\mathbf{x}$ is the partition function and feature functions f_j consider the entire input sequence and at most two consecutive output variables. The most probable output sequence and transition marginal distributions can be computed using variants of Viterbi and forward-backward.

Provided a training data distribution $\tilde{p}$, we estimate CRF parameters by maximizing the conditional log likelihood of the training data.

$$\mathcal{L}(\theta) = E_{\tilde{p}(\mathbf{x},\mathbf{y})}[\log p(\mathbf{y}|\mathbf{x};\theta)]$$

We use numerical optimization to maximize $\mathcal{L}(\theta)$, which requires the gradient of $\mathcal{L}(\theta)$ with respect to the parameters. It can be shown that the partial derivative with respect to parameter j is equal to the difference between the empirical expectation of F_j and the model expectation of F_j, where $F_j(\mathbf{y},\mathbf{x}) = \sum_i f_j(y_i, y_{i+1}, \mathbf{x}, i)$.

$$\frac{\partial}{\partial\theta_j}\mathcal{L}(\theta) = E_{\tilde{p}(\mathbf{x},\mathbf{y})}[F_j(\mathbf{y},\mathbf{x})] - E_{\tilde{p}(\mathbf{x})}[E_{p(\mathbf{y}|\mathbf{x};\theta)}[F_j(\mathbf{y},\mathbf{x})]].$$

We also include a zero-mean variance $\sigma^2 = 10$ Gaussian prior on parameters in all experiments.[2]

2.1 Learning with missing labels

The training set may contain partially labeled sequences. Let $\mathbf{z}$ denote missing labels. We estimate parameters with this data by maximizing the marginal log-likelihood of the observed labels.

$$\mathcal{L}_{MML}(\theta) = E_{\tilde{p}(\mathbf{x},\mathbf{y})}[\log \sum_\mathbf{z} p(\mathbf{y},\mathbf{z}|\mathbf{x};\theta)]$$

We refer to this training method as *maximum marginal likelihood* (MML); it has also been explored by Quattoni et al. (2007).

The gradient of $\mathcal{L}_{MML}(\theta)$ can also be written as the difference of two expectations. The first is an expectation over the empirical distribution of $\mathbf{x}$ and $\mathbf{y}$, and the model distribution of $\mathbf{z}$. The second is a double expectation over the empirical distribution of $\mathbf{x}$ and the model distribution of $\mathbf{y}$ and $\mathbf{z}$.

$$\frac{\partial}{\partial\theta_j}\mathcal{L}_{MML}(\theta) = E_{\tilde{p}(\mathbf{x},\mathbf{y})}[E_{p(\mathbf{z}|\mathbf{y},\mathbf{x};\theta)}[F_j(\mathbf{y},\mathbf{z},\mathbf{x})]] - E_{\tilde{p}(\mathbf{x})}[E_{p(\mathbf{y},\mathbf{z}|\mathbf{x};\theta)}[F_j(\mathbf{y},\mathbf{z},\mathbf{x})]].$$

We train models using $\mathcal{L}_{MML}(\theta)$ with expected gradient (Salakhutdinov et al., 2003).

To additionally leverage unlabeled data, we compare with *entropy regularization* (ER). ER adds a term to the objective function that encourages confident predictions on unlabeled data. Training of linear-chain CRFs with ER is described by Jiao et al. (2006).

3 Generalized Expectation Criteria

In this section, we give a brief overview of *generalized expectation criteria* (GE) (Mann and McCallum, 2008; Druck et al., 2008) and explain how we can use GE to learn CRF parameters with estimates of feature expectations and unlabeled data.

GE criteria are terms in a parameter estimation objective function that express preferences on the

[2] 10 is a default value that works well in many settings.

value of a model expectation of some function. Given a score function S, an empirical distribution $\tilde{p}(\mathbf{x})$, a model distribution $p(\mathbf{y}|\mathbf{x};\theta)$, and a constraint function $G_k(\mathbf{x},\mathbf{y})$, the value of a GE criterion is $\mathcal{G}(\theta) = S(E_{\tilde{p}(\mathbf{x})}[E_{p(\mathbf{y}|\mathbf{x};\theta)}[G_k(\mathbf{x},\mathbf{y})]])$.

GE provides a flexible framework for parameter estimation because each of these elements can take an arbitrary form. The most important difference between GE and other parameter estimation methods is that it does not require a one-to-one correspondence between constraint functions G_k and model feature functions. We leverage this flexibility to estimate parameters of feature-rich CRFs with a very small set of expectation constraints.

Constraint functions G_k can be normalized so that the sum of the expectations of a set of functions is 1. In this case, S may measure the divergence between the expectation of the constraint function and a target expectation $\hat{G}_k$.

$$\mathcal{G}(\theta) = \hat{G}_k \log(E[G_k(\mathbf{x},\mathbf{y})]), \tag{1}$$

where $E[G_k(\mathbf{x},\mathbf{y})] = E_{\tilde{p}(\mathbf{x})}[E_{p(\mathbf{y}|\mathbf{x};\theta)}[G_k(\mathbf{x},\mathbf{y})]]$.

It can be shown that the partial derivative of $\mathcal{G}(\theta)$ with respect to parameter j is proportional to the predicted covariance between the model feature function F_j and the constraint function G_k.[3]

$$\frac{\partial}{\partial\theta_j}\mathcal{G}(\theta) = \frac{\hat{G}_k}{E[G_k(\mathbf{x},\mathbf{y})]}\times \tag{2}$$
$$\Big(E_{\tilde{p}(\mathbf{x})}\big[E_{p(\mathbf{y}|\mathbf{x};\theta)}[F_j(\mathbf{x},\mathbf{y})G_k(\mathbf{x},\mathbf{y})]$$
$$- E_{p(\mathbf{y}|\mathbf{x};\theta)}[F_j(\mathbf{x},\mathbf{y})]E_{p(\mathbf{y}|\mathbf{x};\theta)}[G_k(\mathbf{x},\mathbf{y})]\big]\Big)$$

The partial derivative shows that GE learns parameter values for model feature functions based on their predicted covariance with the constraint functions. GE can thus be interpreted as a bootstrapping method that uses the limited training signal to learn about parameters for related model feature functions.

3.1 Learning with feature-label distributions

Mann and McCallum (2008) apply GE to a linear-chain, first-order CRF. In this section we provide an alternate treatment that arrives at the same objective function from the general form described in the previous section.

Often, feature functions in a first-order linear-chain CRF f are binary, and are the conjunction of an observational test $q(\mathbf{x},i)$ and a label pair test $\mathbf{1}_{\{y_i=y',y_{i+1}=y''\}}$.[4]

$$f(y_i,y_{i+1},\mathbf{x},i) = \mathbf{1}_{\{y_i=y',y_{i+1}=y''\}}q(\mathbf{x},i)$$

The constraint functions G_k we use here decompose and operate similarly, except that they only include a test for a single label. Single label constraints are easier for users to estimate and make GE training more efficient. Label transition structure can be learned automatically from single label constraints through the covariance-based parameter update of Equation 2. For convenience, we can write G_{yk} to denote the constraint function that combines observation test k with a test for label y. We also add a normalization constant $C_k = E_{\tilde{p}(\mathbf{x})}[\sum_i q_k(\mathbf{x},i)]$,

$$G_{yk}(\mathbf{x},\mathbf{y}) = \sum_i \frac{1}{C_k}\mathbf{1}_{\{y_i=y\}}q_k(\mathbf{x},i)$$

Under this construction the expectation of G_{yk} is the predicted conditional probability that the label at some arbitrary position i is y when the observational test at i succeeds, $\tilde{p}(y_i{=}y|q_k(\mathbf{x},i){=}1;\theta)$.

If we have a set of constraint functions $\{G_{yk} : y \in \mathcal{Y}\}$, and we use the score function in Equation 1, then the GE objective function specifies the minimization of the KL divergence between the model and target distributions over labels conditioned on the success of the observational test. In general the objective function will consist of many such KL divergence penalties.

Computing the first term of the covariance in Equation 2 requires a marginal distribution over three labels, two of which will be consecutive, but the other of which could appear anywhere in the sequence. We can compute this marginal using the algorithm of Mann and McCallum (2008). As previously described, this algorithm is $O(n|\mathcal{Y}|^3)$ for a sequence of length n. However, we make the following novel observation: we do not need to compute the extra lattices for feature label pairs with $\hat{G}_{yk} = 0$, since this makes Equation 2 equal to zero. In Mann and McCallum (2008), probabilities were smoothed so that $\forall_y\ \hat{G}_{yk} > 0$. If we assume that only a small number of labels m have non-zero probability, then the time complexity of the gradient computation is $O(nm|\mathcal{Y}|^2)$. In this paper typically $1 \leq m \leq 4$, while $|\mathcal{Y}|$ is 11 or 13.

[3] If we use squared error for S, the partial derivative is the covariance multiplied by $2(\hat{G}_k - E[G_k(\mathbf{x},\mathbf{y})])$.

[4] We this notation for an indicator function that returns 1 if the condition in braces is satisfied, and 0 otherwise.

In experiments in this paper, using this optimization does not significantly affect final accuracy.

We use numerical optimization to estimate model parameters. In general GE objective functions are not convex. Consequently, we initialize 0th-order CRF parameters using a sliding window logistic regression model trained with GE. We also include a Gaussian prior on parameters with $\sigma^2 = 10$ in the objective function.

3.2 Learning with labeled features

The training procedure described above requires a set of observational tests or input features with target distributions over labels. Estimating a distribution could be a difficult task for an annotator. Consequently, we abstract away from specifying a distribution by allowing the user to assign labels to features (c.f. Haghighi and Klein (2006) , Druck et al. (2008)). For example, we say that the word feature *call* has label contact. A label for a feature simply indicates that the feature is a good indicator of the label. Note that features can have multiple labels, as does *included* in the active learning session shown in Table 1. We convert an input feature with a set of labels L into a distribution by assigning probability $1/|L|$ for each $l \in L$ and probability 0 for each $l \notin L$. By assigning 0 probability to labels $l \notin L$, we can use the speed-up described in the previous section.

3.3 Related Work

Other proposed learning methods use labeled features to label unlabeled data. The resulting partially-labeled corpus can be used to train a CRF by maximizing MML. Similarly, *prototype-driven learning* (PDL) (Haghighi and Klein, 2006) optimizes the joint marginal likelihood of data labeled with *prototype* input features for each label. Additional features that indicate similarity to the prototypes help the model to generalize. In a previous comparison between GE and PDL (Mann and McCallum, 2008), GE outperformed PDL without the extra similarity features, whose construction may be problem-specific. GE also performed better when supplied accurate label distributions.

Additionally, both MML and PDL do not naturally generalize to learning with features that have multiple labels or distributions over labels, as in these scenarios labeling the unlabeled data is not straightforward. In this paper, we attempt to address this problem using a simple heuristic: when there are multiple choices for a token's label, sample a label. In Section 5 we use this heuristic with MML, but in general obtain poor results.

Raghavan and Allan (2007) also propose several methods for learning with labeled features, but in a previous comparison GE gave better results (Druck et al., 2008). Additionally, the generalization of these methods to structured output spaces is not straightforward. Chang et al. (2007) present an algorithm for learning with constraints, but this method requires users to set weights by hand. We plan to explore the use of the recently developed related methods of Bellare et al. (2009), Graça et al. (2008), and Liang et al. (2009) in future work. Druck et al. (2008) provide a survey of other related methods for learning with labeled input features.

4 Active Learning by Labeling Features

Feature active learning, presented in Algorithm 1, is a *pool-based* active learning algorithm (Lewis and Gale, 1994) (with a pool of features rather than instances). The novel components of the algorithm are an option to skip a query and the notion that skipping and labeling have different costs. The option to skip is important when using feature queries because a user may not know how to label some features. In each iteration the model is retrained using the train procedure, which takes as input a set of labeled features $\mathcal{C}$ and unlabeled data distribution $\tilde{p}$. For the reasons described in Section 3.3, we advocate using GE for the train procedure. Then, while the iteration cost c is less than the maximum cost c_{max}, the feature query q that maximizes the query selection metric ϕ is selected. The accept function determines whether the labeler will label q. If q is labeled, it is added to the set of labeled features $\mathcal{C}$, and the label cost c_{label} is added to c. Otherwise, the skip cost c_{skip} is added to c. This process continues for N iterations.

4.1 Feature query selection methods

In this section we propose feature query selection methods ϕ. Queries with a higher scores are considered better candidates. Note again that by features we mean observational tests $q_k(\mathbf{x}, i)$. It is also important to note these are not *feature selection* methods since we are determining the features for which supervisory feedback will be most helpful to the model, rather than determining which features will be part of the model.

Algorithm 1 Feature Active Learning

Input: empirical distribution $\tilde{p}$, initial feature constraints $\mathcal{C}$, label cost c_{label}, skip cost c_{skip}, max cost per iteration c_{max}, max iterations N
Output: model parameters θ
for $i = 1$ **to** N **do**
  $\theta = \text{train}(\tilde{p}, \mathcal{C})$
  $c = 0$
  while $c < c_{max}$ **do**
    $q = \text{argmax}_{q_k}\, \phi(q_k)$
    if $\text{accept}(q)$ **then**
      $\mathcal{C} = \mathcal{C} \cup \text{label}(q)$
      $c = c + c_{label}$
    else
      $c = c + c_{skip}$
    end if
  end while
end for
$\theta = \text{train}(\tilde{p}, \mathcal{C})$

We propose to select queries that provide the largest reduction in model uncertainty. We notate possible responses to a query q_k as $\hat{g}$. The **Expected Information Gain (EIG)** of a query is the expectation of the reduction in model uncertainty over all possible responses. Mathematically, IG is

$$\phi_{EIG}(q_k) = E_{p(\hat{g}|q_k;\theta)}[E_{\tilde{p}(\mathbf{x})}[H(p(\mathbf{y}|\mathbf{x};\theta) - H(p(\mathbf{y}|\mathbf{x};\theta_{\hat{g}})]],$$

where $\theta_{\hat{g}}$ are the new model parameters if the response to q_k is $\hat{g}$. Unfortunately, this method is computationally intractable. Re-estimating $\theta_{\hat{g}}$ will typically involve retraining the model, and doing this for each possible query-response pair is prohibitively expensive for structured output models. Computing the expectation over possible responses is also difficult, as in this paper users may provide a set of labels for a query, and more generally $\hat{g}$ could be a distribution over labels.

Instead, we propose a tractable strategy for reducing model uncertainty, motivated by traditional uncertainty sampling (Lewis and Gale, 1994). We assume that when a user responds to a query, the reduction in uncertainty will be equal to the **Total Uncertainty (TU)**, the sum of the marginal entropies at the positions where the feature occurs.

$$\phi_{TU}(q_k) = \sum_i \sum_j q_k(\mathbf{x}_i, j) H(p(y_j|\mathbf{x}_i;\theta))$$

Total uncertainty, however, is highly biased towards selecting frequent features. A mean uncertainty variant, normalized by the feature's count, would tend to choose very infrequent features. Consequently we propose a tradeoff between the two extremes, called **weighted uncertainty (WU)**, that scales the mean uncertainty by the log count of the feature in the corpus.

$$\phi_{WU}(q_k) = \log(C_k)\frac{\phi_{TU}(q_k)}{C_k}.$$

Finally, we also suggest an uncertainty-based metric called **diverse uncertainty (DU)** that encourages diversity among queries by multiplying TU by the mean dissimilarity between the feature and previously labeled features. For sequence labeling tasks, we can measure the relatedness of features using distributional similarity.[5]

$$\phi_{DU}(q_k) = \phi_{TU}(q_k)\frac{1}{|\mathcal{C}|}\sum_{j\in\mathcal{C}} 1 - \text{sim}(q_k, q_j)$$

We contrast the notion of uncertainty described above with another type of uncertainty: the entropy of the predicted label distribution for the feature, or **expectation uncertainty (EU)**. As above we also multiply by the log feature count.

$$\phi_{EU}(q_k) = \log(C_k) H(\tilde{p}(y_i = y | q_k(\mathbf{x}, i) = 1; \theta))$$

EU is flawed because it will have a large value for non-discriminative features.

The methods described above require the model to be retrained between iterations. To verify that this is necessary, we compare against query selection methods that only consider the previously labeled features. First, we consider a feature query selection method called **coverage (cov)** that aims to select features that are dissimilar from existing labeled features, increasing the labeled features' "coverage" of the feature space. In order to compensate for choosing very infrequent features, we multiply by the log count of the feature.

$$\phi_{cov}(q_k) = \log(C_k)\frac{1}{|\mathcal{C}|}\sum_{j\in\mathcal{C}} 1 - \text{sim}(q_k, q_j)$$

Motivated by the feature query selection method of Tandem Learning (Raghavan and Allan, 2007) (see Section 4.2 for further discussion), we consider a feature selection metric **similarity (sim)** that is the maximum similarity to a labeled feature, weighted by the log count of the feature.

$$\phi_{sim}(q_k) = \log(C_k) \max_{j\in\mathcal{C}} \text{sim}(q_k, q_j)$$

[5] $\text{sim}(q_k, q_j)$ returns the cosine similarity between context vectors of words occurring in a window of ± 3.

Features similar to those already labeled are likely to be discriminative, and therefore likely to be labeled (rather than skipped). However, insufficient diversity may also result in an inaccurate model, suggesting that *coverage* should select more useful queries than *similarity*.

Finally, we compare with several passive baselines. **Random (rand)** assigns scores to features randomly. **Frequency (freq)** scores input features using their frequency in the training data.

$$\phi_{freq}(q_k) = \sum_i \sum_j q_k(\mathbf{x}_i, j)$$

Top LDA (LDA) selects the top words from 50 topics learned from the unlabeled data using latent Dirichlet allocation (LDA) (Blei et al., 2003). More specifically, the words w generated by each topic t are ranked using the conditional probability $p(w|t)$. The word feature is assigned its maximum rank across all topics.

$$\phi_{LDA}(q_k) = \max_t \ \mathrm{rank}_{\mathrm{LDA}}(q_k, t)$$

This method will select useful features if the topics discovered are relevant to the task. A similar heuristic was used by Druck et al. (2008).

4.2 Related Work

Tandem Learning (Raghavan and Allan, 2007) is an algorithm that combines feature and instance active learning for classification. The algorithm iteratively queries the user first for instance labels, then for feature labels. Feature queries are selected according to their co-occurrence with important model features and previously labeled features. As noted in Section 3.3, GE is preferable to the methods Tandem Learning uses to learn with labeled features. We address the mixing of feature and instance queries in Section 4.3.

In order to better understand differences in feature query selection methodology, we proposed a feature query selection method motivated[6] by the method used in Tandem Learning in Section 4.1. However, this method performs poorly in the experiments in Section 5.

Liang et al. (2009) simultaneously developed a method for learning with and actively selecting *measurements*, or target expectations with associated noise. The measurement selection method proposed by Liang et al. (2009) is based on Bayesian experimental design and is similar to the expected information gain method described above. Consequently this method is likely to be intractable for real applications. Note that Liang et al. (2009) only use this method in synthetic experiments, and instead use a method similar to total uncertainty for experiments in part-of-speech tagging. Unlike the experiments presented in this paper, Liang et al. (2009) conduct only simulated active learning experiments and do not consider skipping queries.

Sindhwani (Sindhwani et al., 2009) simultaneously developed an active learning method that queries for both instance and feature labels that are then used in a graph-based learning algorithm. They find that querying certain features outperforms querying uncertain features, but this is likely because their query selection method is similar to the expectation uncertainty method described above, and consequently non-discriminative features may be queried often (see also the discussion in Section 4.1). It is also not clear how this graph-based training method would generalize to structured output spaces.

4.3 Expectation Constraint Active Learning

Throughout this paper, we have focussed on labeling input features. However, the proposed methods generalize to queries for expectation estimates of arbitrary functions, for example queries for the label distributions for input features, labels for instances (using a function that is non-zero only for a particular instance), partial labels for instances, and class priors. The uncertainty-based query selection methods described in Section 4.1 apply naturally to these new query types. Importantly this framework would allow principled mixing of different query types, instead of alternating between them as in Tandem Learning (Raghavan and Allan, 2007). When mixing queries, it will be important to use different costs for different annotation types (Vijayanarasimhan and Grauman, 2008), and estimate the probability of obtaining a useful response to a query. We plan to pursue these directions in future work. This idea was also proposed by Liang et al. (2009), but no experiments with mixed active learning were presented.

[6]The query selection method of Raghavan and Allan (2007) requires a stack that is modified between queries within each iteration. Here query scores are only updated after each iteration of labeling.

5 Simulated User Experiments

In this section we experiment with an automated oracle labeler. When presented an instance query, the oracle simply provides the true labels. When presented a feature query, the oracle first decides whether to skip the query. We have found that users are more likely to label features that are relevant for only a few labels. Therefore, the oracle labels a feature if the entropy of its per occurrence label expectation, $\mathrm{H}(\tilde{p}(y_i = y|q_k(\mathbf{x}, i) = 1; \theta)) \leq 0.7$. The oracle then labels the feature using a heuristic: label the feature with the label whose expectation is highest, as well as any label whose expectation is at least half as large.

We estimate the effort of different labeling actions with preliminary experiments in which we observe users labeling data for ten minutes. Users took an average of 4 seconds to label a feature, 2 seconds to skip a feature, and 0.7 seconds to label a token. We setup experiments such that each iteration simulates one minute of labeling by setting $c_{max} = 60$, $c_{skip} = 2$ and $c_{label} = 4$. For instance active learning, we use Algorithm 1 but without the skip option, and set $c_{label} = 0.7$. We use $N = 10$ iterations, so the entire experiment simulates 10 minutes of annotation time. For efficiency, we consider the 500 most frequent unlabeled features in each iteration. To start, ten randomly selected seed labeled features are provided.

We use **random (rand)** selection, **uncertainty sampling (US)** (using sequence entropy, normalized by sequence length) and **information density (ID)** (Settles and Craven, 2008) to select instance queries. We use Entropy Regularization (ER) (Jiao et al., 2006) to leverage unlabeled instances.[7] We weight the ER term by choosing the best[8] weight in $\{10^{-3}, 10^{-2}, 10^{-1}, 1, 10\}$ multiplied by $\frac{\#labeled}{\#unlabeled}$ for each data set and query selection method. Seed instances are provided such that the simulated labeling time is equivalent to labeling 10 features.

We evaluate on two sequence labeling tasks. The *apartments* task involves segmenting 300 apartment classified ads into 11 fields including features, rent, neighborhood, and contact. We use the same feature processing as Haghighi and Klein (2006), with the addition of context features in a window of ± 3. The *cora references* task is to extract 13 BibTeX fields such as author and booktitle from 500 research paper references. We use a standard set of word, regular expressions, and lexicon features, as well as context features in a window of ± 3. All results are averaged over ten random 80:20 splits of the data.

[7] Results using self-training instead of ER are similar.

[8] As measured by test accuracy, giving ER an advantage.

method	apartments		cora	
	mean	**final**	**mean**	**final**
ER rand	48.1	53.6	75.9	81.1

Table 2: Mean and final token accuracy results. A * or † denotes that a GE method significantly outperforms all non-GE or passive GE methods, respectively. Bold entries significantly outperform all others. Methods in *italics* are passive.

5.1 Results

Table 2 presents mean (across all iterations) and final token accuracy results. On the *apartments* task, GE methods greatly outperform MML[9] and ER methods. Each uncertainty-based GE method also outperforms all passive GE methods. On the *cora* task, only GE with *weighted uncertainty* significantly outperforms ER and passive GE methods in terms of *mean* accuracy, but all uncertainty-based GE methods provide higher final accuracy. This suggests that on the *cora* task, active GE methods are performing better in later iterations. Figure 1, which compares the learning curves of the best performing methods of each type, shows this phenomenon. Further analysis reveals that the uncertainty-based methods are choosing frequent features that are more likely to be skipped than those selected randomly in early iterations.

We next compare with the results of related methods published elsewhere. We cannot make claims about statistical significance, but the results

[9] Only the best MML results are shown.

illustrate the competitiveness of our method. The 74.6% final accuracy on *apartments* is higher than any result obtained by Haghighi and Klein (2006) (the highest is 74.1%), higher than the *supervised* HMM results reported by Grenager et al. (2005) (74.4%), and matches the results of Mann and McCallum (2008) with GE with more accurate sampled label distributions and 10 labeled examples. Chang et al. (2007) only obtain better results than 88.2% on *cora* when using 300 labeled examples (two hours of estimated annotation time), 5000 additional unlabeled examples, and extra test time inference constraints. Note that obtaining these results required only 10 simulated minutes of annotation time, and that GE methods are provided no information about the label transition matrix.

6 User Experiments

Another advantage of feature queries is that feature names are concise enough to be browsed, rather than considered individually. This allows the design of improved interfaces that can further increase the speed of feature active learning. We built a prototype interface that allows the user to quickly browse many candidate features. The features are split into groups of five features each. Each group contains features that are related, as measured by distributional similarity. The features within each group are sorted according to the active learning metric. This interface, displayed in Figure 3, may be useful because features in the same group are likely to have the same label.

We conduct three types of experiments. First, a user labels instances selected by *information density*, and models are trained using ER. The instance labeling interface allows the user to label tokens quickly by extending the current selection one token at a time and only requiring a single keystroke to label an entire segment. Second, the user labels features presented one-at-a-time by *weighted uncertainty*, and models are trained using GE. To aid the user in understanding the function of the feature quickly, we provide several examples of the feature occurring in context and the model's current predicted label distribution for the feature. Finally, the user labels features organized using the grid interface described in the previous paragraph. *Weighted uncertainty* is used to sort feature queries within each group, and GE is used to train models. Each iteration of labeling lasts two minutes, and there are five iterations. Retraining with ER between iterations takes an average of 5 minutes on *cora* and 3 minutes on *apartments*. With GE, the retraining times are on average 6 minutes on *cora* and 4 minutes on *apartments*. Consequently, even when viewed with *total time*, rather than *annotation time*, feature active learning is beneficial. While waiting for models to retrain, users can perform other tasks.

Figure 2 displays the results. User 1 labeled *apartments* data, while Users 2 and 3 labeled *cora* data. User 1 was able to obtain much better results with feature labeling than with instance labeling, but performed slightly worse with the grid interface than with the serial interface. User 1 commented that they found the label definitions for *apartments* to be imprecise, so the other experiments were conducted on the *cora* data. User 2 obtained better results with feature labeling than instance labeling, and obtained higher mean accuracy with the grid interface. User 3 was much better at labeling features than instances, and performed especially well using the grid interface.

7 Conclusion

We proposed an active learning approach in which features, rather than instances, are labeled. We presented an algorithm for active learning with features and several feature query selection methods that approximate the expected reduction in model uncertainty of a feature query. In simulated experiments, active learning with features outperformed passive learning with features, and uncertainty-based feature query selection outperformed other baseline methods. In both simulated and real user experiments, active learning with features outperformed passive and active learning with instances. Finally, we proposed a new labeling interface that leverages the conciseness of feature queries. User experiments suggested that this grid interface can improve labeling efficiency.

Abstract

In this paper, we propose a novel class of graphs, the tripartite directed acyclic graphs (tDAGs), to model first-order rule feature spaces for sentence pair classification. We introduce a novel algorithm for computing the similarity in first-order rewrite rule feature spaces. Our algorithm is extremely efficient and, as it computes the similarity of instances that can be represented in explicit feature spaces, it is a valid kernel function.

1 Introduction

Natural language processing models are generally positive combinations between linguistic models and automatically learnt classifiers. As trees are extremely important in many linguistic theories, a large amount of works exploiting machine learning algorithms for NLP tasks has been developed for this class of data structures (Collins and Duffy, 2002; Moschitti, 2004). These works propose efficient algorithms for determining the similarity among two trees in tree fragment feature spaces.

Yet, some NLP tasks such as textual entailment recognition (Dagan and Glickman, 2004; Dagan et al., 2006) and some linguistic theories such as HPSG (Pollard and Sag, 1994) require more general graphs and, then, more general algorithms for computing similarity among graphs. Unfortunately, algorithms for computing similarity among two general graphs in term of common subgraphs are still exponential (Ramon and Gärtner, 2003). In these cases, approximated algorithms have been proposed. For example, the one proposed in (Gärtner, 2003) counts the number of subpaths in common. The same happens for the one proposed in (Suzuki et al., 2003) that is applicable to a particular class of graphs, i.e. the hierarchical directed acyclic graphs. These algorithms do not compute the number of subgraphs in common between two graphs. Then, these algorithms approximate the feature spaces we need in these NLP tasks. For computing similarities in these feature spaces, we have to investigate if we can define a particular class of graphs for the class of tasks we want to solve. Once we focused the class of graph, we can explore efficient similarity algorithms.

A very important class of graphs can be defined for tasks involving sentence pairs. In these cases, an important class of feature spaces is the one that represents first-order rewrite rules. For example, in textual entailment recognition (Dagan et al., 2006), we need to determine whether a text T implies a hypothesis H, e.g., whether or not "*Farmers feed cows animal extracts*" entails "*Cows eat animal extracts*" (T_1, H_1). If we want to learn textual entailment classifiers, we need to exploit first-order rules hidden in training instances. To positively exploit the training instance "*Pediatricians suggest women to feed newborns breast milk*" entails "*Pediatricians suggest that newborns eat breast milk*" (T_2, H_2) for classifying the above example, learning algorithms should learn that the two instances hide the first-order rule $\rho = feed\boxed{Y}\boxed{Z} \rightarrow \boxed{Y}eat\boxed{Z}$. The first-order rule feature space, introduced by (Zanzotto and Moschitti, 2006), gives high performances in term of accuracy for textual entailment recognition with respect to other features spaces.

In this paper, we propose a novel class of graphs, the tripartite directed acyclic graphs (tDAGs), that model first-order rule feature spaces and, using this class of graphs, we introduce a novel algorithm for computing the similarity in first-order rewrite rule feature spaces. The possibility of explicitly representing the first-order feature space as subgraphs of tDAGs makes the derived similarity function a valid kernel. With respect to the algorithm proposed in (Moschitti and Zanzotto, 2007), our algorithm is more efficient

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 91–100,
Singapore, 6-7 August 2009.

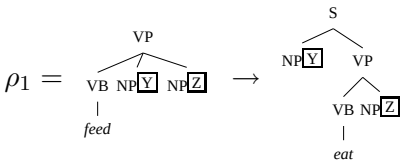
and it is a valid kernel function.

The paper is organized as follows. In Sec. 2, we firstly describe tripartite directed acyclic graphs (tDAGs) to model first-order feature (FOR) spaces. In Sec. 3, we then present the related work. In Sec. 4, we introduce the similarity function for these FOR spaces. This can be used as kernel function in kernel-based machines (e.g., support vector machines (Cortes and Vapnik, 1995)). We then introduce our efficient algorithm for computing the similarity among tDAGs. In Sec. 5, we analyze the computational efficiency of our algorithm showing that it is extremely more efficient than the algorithm proposed in (Moschitti and Zanzotto, 2007). Finally, in Sec. 6, we draw conclusions and plan the future work.

2 Representing first-order rules and sentence pairs as tripartite directed acyclic graphs

As first step, we want to define the *tripartite directed acyclic graphs* ($tDAGs$). This is an extremely important class of graphs for the first-order rule feature spaces we want to model. We want here to intuitively show that, if we model first-order rules and sentence pairs as $tDAG$s, determining whether or not a sentence pair can be unified with a first-order rewrite rule is a graph matching problem. This intuitive idea helps in determining our efficient algorithm for exploiting first-order rules in learning examples.

To illustrate the above idea we will use an example based on the above rule ρ= $feed$ Y Z $\rightarrow$ Y eat Z and the above sentence pair (T_1, H_1). The rule ρ encodes the entailment relation of the verb *to feed* and the verb *to eat*. If represented over a syntactic interpretation, the rule has the following aspect:



As in the case of feature structures (Carpenter, 1992), we can observe this rule as a graph. As we are not interested in the variable names but we need to know the relation between the right hand side and the left hand side of the rule, we can substitute each variable with an unlabelled node. We then connect tree nodes having variables with the corresponding unlabelled node. The result is a graph as the one in Fig. 1. The variables Y and Z are represented by the unlabelled nodes between the trees.

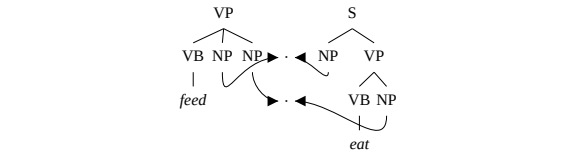


Figure 1: A simple rewrite rule seen as a graph

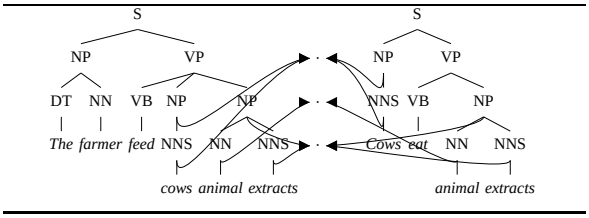

Figure 2: A sample pair seen as a graph

In the same way we can represent the sentence pair (T_1, H_1) using graph with explicit links between related words and nodes (see Fig. 2). We can link words using anchoring methods as in (Raina et al., 2005). These links can then be propagated in the syntactic tree using semantic heads of the constituents (Pollard and Sag, 1994). The rule ρ_1 matches over the pair (T_1, H_1) if the graph ρ_1 is among the subgraphs of the graph in Fig. 2.

Both rules and sentence pairs are graphs of the same type. These graphs are basically two trees connected through an intermediate set of nodes representing variables in the rules and relations between nodes in the sentence pairs. We will hereafter call these graphs *tripartite directed acyclic graphs* (tDAGs). The formal definition follows.

Definition tDAG: A *tripartite directed acyclic graph* is a graph $G = (N, E)$ where

- the set of nodes N is partitioned in three sets N_t, N_g, and A
- the set of edges is partitioned in four sets E_t, E_g, E_{A_t}, and E_{A_g}

such that $t = (N_t, E_t)$ and $g = (N_g, E_g)$ are two trees and $E_{A_t} = \{(x, y)|x \in N_t \text{ and } y \in A\}$ and $E_{A_g} = \{(x, y)|x \in N_g \text{ and } y \in A\}$ are the edges connecting the two trees.

A $tDAG$ is a partially labeled graph. The labeling function L only applies to the subsets of nodes related to the two trees, i.e., $L : N_t \cup N_g \rightarrow \mathcal{L}$. Nodes in the set A are not labeled.

The explicit representation of the tDAG in Fig. 2 has been useful to show that the unification of a rule and a sentence pair is a graph matching problem. Yet, it is complex to follow. We will then describe a tDAG with an alternative and more convenient representation. A tDAG $G = (N, E)$ can be seen as pair $G = (\tau, \gamma)$ of *extended trees* τ and γ where $\tau = (N_t \cup A, E_t \cup E_{A_t})$ and $\gamma = (N_g \cup A, E_g \cup E_{A_g})$. These are extended trees as each tree contains the relations with the other tree.

As for the feature structures, we will graphically represent a $(x, y) \in E_{A_t}$ and a $(z, y) \in E_{A_g}$ as boxes $\boxed{y}$ respectively on the node x and on the node z. These nodes will then appear as $L(x)\boxed{y}$ and $L(z)\boxed{y}$, e.g., NP$\boxed{1}$. The name y is not a label but a placeholder representing an unlabelled node. This representation is used for rules and for sentence pairs. The sentence pair in Fig. 2 is then represented as reported in Fig. 3.

3 Related work

Automatically learning classifiers for sentence pairs is extremely important for applications like textual entailment recognition, question answering, and machine translation.

In textual entailment recognition, it is not hard to see graphs similar to tripartite directed acyclic graphs as ways of extracting features from examples to feed automatic classifiers. Yet, these graphs are generally not tripartite in the sense described in the previous section and they are not used to extract features representing first-order rewrite rules. In (Raina et al., 2005; Haghighi et al., 2005; Hickl et al., 2006), two connected graphs representing the two sentences s_1 and s_2 are used to compute distance features, i.e., features representing the distance between s_1 and s_2. The underlying idea is that lexical, syntactic, and semantic similarities between sentences in a pair are relevant features to classify sentence pairs in classes such as *entail* and *not-entail*.

In (de Marneffe et al., 2006), first-order rewrite rule feature spaces have been explored. Yet, these spaces are extremely small. Only some features representing first-order rules have been explored. Pairs of graphs are used here to determine if a feature is active or not, i.e., the rule fires or not. A larger feature space of rewrite rules has been implicitly explored in (Wang and Neumann, 2007) but this work considers only ground rewrite rules.

In (Zanzotto and Moschitti, 2006), tripartite directed acyclic graphs are implicitly introduced and exploited to build first-order rule feature spaces. Yet, both in (Zanzotto and Moschitti, 2006) and in (Moschitti and Zanzotto, 2007), the model proposed has two major limitations: it can represent rules with less than 7 variables and the proposed kernel is not a completely valid kernel as it uses the max function.

In machine translation, some methods such as (Eisner, 2003) learn graph based rewrite rules for generative purposes. Yet, the method presented in (Eisner, 2003) can model first-order rewrite rules only with a very small amount of variables, i.e., two or three variables.

4 An efficient algorithm for computing the first-order rule space kernel

In this section, we present our idea for an efficient algorithm for exploiting first-order rule feature spaces. In Sec. 4.1, we firstly define the similarity function, i.e., the kernel $K(G_1, G_2)$, that we need to determine for correctly using first-order rules feature spaces. This kernel is strongly based on the isomorphism between graphs. A relevant idea of this paper is the observation that we can define an efficient way to detect the isomorphism between the tDAGs (Sec. 4.2). This algorithm exploits the efficient algorithms of tree isomorphism as the one implicitly used in (Collins and Duffy, 2002). After describing the isomorphism between tDAGs, We can present the idea of our efficient algorithm for computing $K(G_1, G_2)$ (Sec. 4.3). We introduce the algorithms to make it a viable solution (Sec. 4.4). Finally, in Sec. 4.5, we report the kernel computation we compare against presented by (Zanzotto and Moschitti, 2006; Moschitti and Zanzotto, 2007).

4.1 Kernel functions over first-order rule feature spaces

The first-order rule feature space we want to model is huge. If we use kernel-based machine learning models such as SVM (Cortes and Vapnik, 1995), we can implicitly define the space by defining its similarity functions, i.e., its kernel functions. We firstly introduce the first-order rule feature space and we then define the prototypical kernel function over this space.

The first-order rule feature space (FOR) is in general the space of all the possible first-order

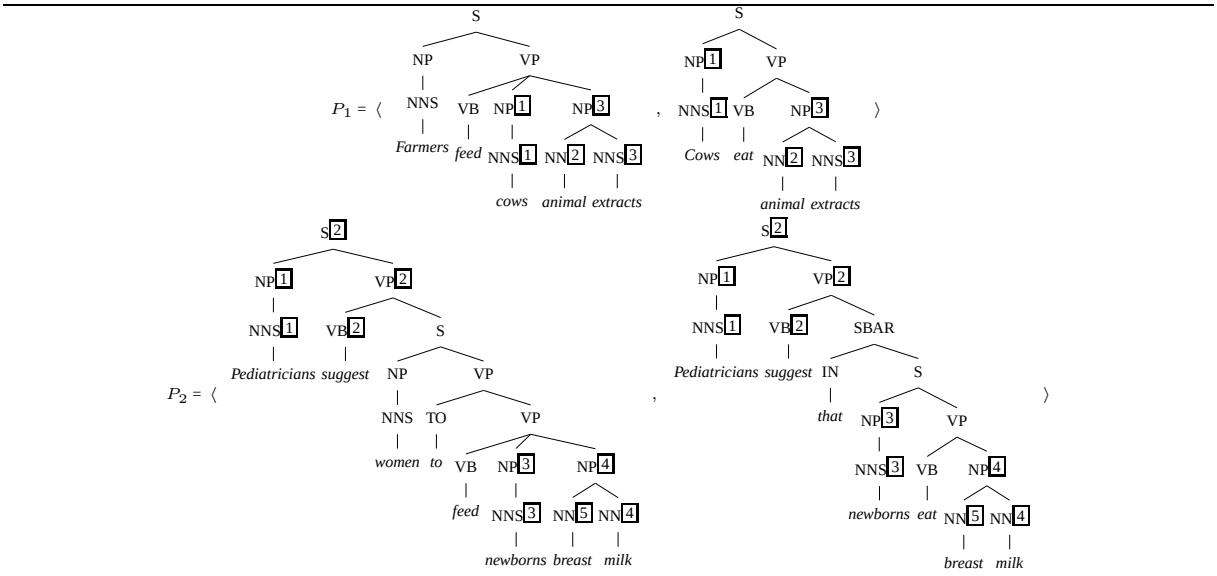

Figure 3: Two tripartite DAGs

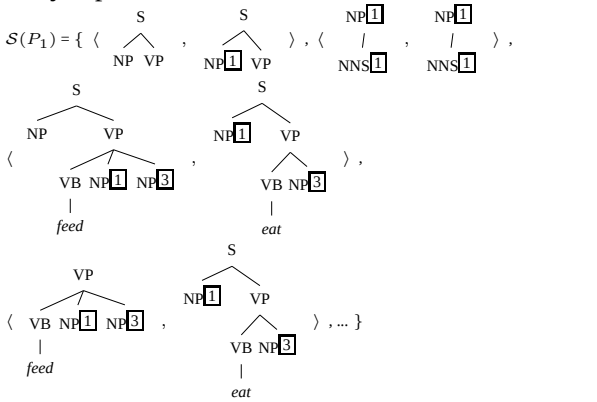
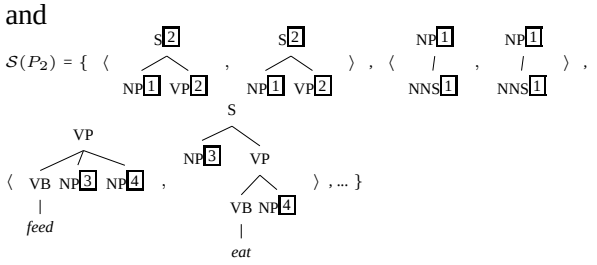
rules defined as tDAGs. Within this space it is possible to define the function $\mathcal{S}(G)$ that determines all the possible active features of the tDAG G in FOR. The function $\mathcal{S}(G)$ determines all the possible and meaningful subgraphs of G. We want that these subgraphs represent first-order rules that can be matched with the pair G. Then, meaningful subgraphs of $G = (\tau, \gamma)$ are graphs as (t, g) where t and g are subtrees of τ and γ. For example, the subgraphs of P_1 and P_2 in Fig. 3 are hereafter partially represented:



and



In the FOR space, the kernel function K should then compute the number of subgraphs in common. The trivial way to describe the former kernel function is using the intersection operator, i.e., the kernel $K(G_1, G_2)$ is the following:

$$K(G_1, G_2) = |\mathcal{S}(G_1) \cap \mathcal{S}(G_2)| \qquad (1)$$

This is very simple to write and it is in principle correct. A graph g in the intersection $\mathcal{S}(G_1) \cap \mathcal{S}(G_2)$ is a graph that belongs to both $\mathcal{S}(G_1)$ and $\mathcal{S}(G_2)$. Yet, this hides a very important fact: determining whether two graphs, g_1 and g_2, are the *same* graph $g_1 = g_2$ is not trivial. For example, it is not sufficient to superficially compare graphs to determine that ρ_1 belongs both to $\mathcal{S}_1$ and $\mathcal{S}_2$. We need to use the correct property for $g_1 = g_2$, i.e., the *isomorphism* between two graphs. We can call the operator $Iso(g_1, g_2)$. When two graphs verify the property $Iso(g_1, g_2)$, both g_1 and g_2 can be taken as the graph g representing the two graphs. Detecting $Iso(g_1, g_2)$ has an exponential complexity (Köbler et al., 1993).

This complexity of the intersection operator between sets of graphs deserves a different way to represent the operation. We will use the same symbol but we will use the prefix notation. The operator is hereafter re-defined:

$$\cap(\mathcal{S}(G_1), \mathcal{S}(G_2)) =$$
$$= \{g_1 | g_1 \in \mathcal{S}(G_1), \exists g_2 \in \mathcal{S}(G_2), Iso(g_1, g_2)\}$$

4.2 Isomorphism between tDAGs

As isomorphism between graphs is an essential activity for learning from structured data, we here review its definition and we adapt it to tDAGs.

We then observe that isomorphism between two tDAGs can be divided in two sub-problems:

- finding the isomorphism between two pairs of *extended trees*
- checking whether the partial isomorphism found between the two pairs of *extended trees* are compatible.

In general, two tDAGs, $G_1 = (N_1, E_1)$ and $G_2 = (N_2, E_2)$ are *isomorphic* (or match) if $|N_1| = |N_2|$, $|E_1| = |E_2|$, and a bijective function $f : N_1 \rightarrow N_2$ exists such that these properties hold:

- for each node $n \in N_1$, $L(f(n)) = L(n)$
- for each edge $(n_1, n_2) \in E_1$ an edge $(f(n_1), f(n_2))$ is in E_2

The bijective function f is a member of the combinatorial set $\mathcal{F}$ of all the possible bijective functions between the two sets N_1 and N_2.

The trivial algorithm for detecting if two graphs are isomorphic is exponential (Köbler et al., 1993). It explores all the set $\mathcal{F}$. It is still undetermined if the general graph isomorphism problem is NP-complete. Yet, we can use the fact that tDAGs are two extended trees for building a better algorithm. There is an efficient algorithm for computing isomorphism between trees (as the one implicitly used in (Collins and Duffy, 2002)).

Given two tDAGs $G_1 = (\tau_1, \gamma_1)$ and $G_2 = (\tau_2, \gamma_2)$ the isomorphism problem can be divided in detecting two properties:

1. *Partial isomorphism*. Two tDAGs G_1 and G_2 are *partially isomorphic*, if τ_1 and τ_2 are isomorphic and if γ_1 and γ_2 are isomorphic. The partial isomorphism produces two bijective functions f_τ and f_γ.
2. *Constraint compatibility*. Two bijective functions f_τ and f_γ are compatible on the sets of nodes A_1 and A_2, if for each $n \in A_1$, it happens that $f_\tau(n) = f_\gamma(n)$.

We can rephrase the second property, i.e., the constraint compatibility, as follows. We define two constraints $c(\tau_1, \tau_2)$ and $c(\gamma_1, \gamma_2)$ representing the functions f_τ and f_γ on the sets A_1 and A_2. The two constraints are defined as $c(\tau_1, \tau_2) = \{(n, f_\tau(n)) | n \in A_1\}$ and $c(\gamma_1, \gamma_2) = \{(n, f_\gamma(n)) | n \in A_1\}$. Two partially isomorphic tDAGs are isomorphic if the constraints match, i.e., $c(\tau_1, \tau_2) = c(\gamma_1, \gamma_2)$.

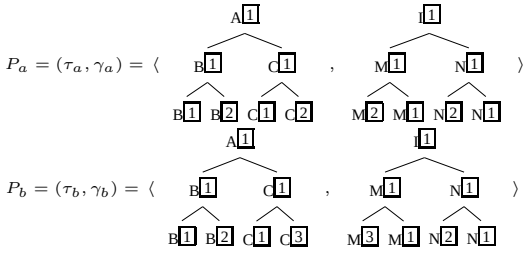


Figure 5: Simple non-linguistic tDAGs

For example, the third pair of $\mathcal{S}(P_1)$ and the second pair of $\mathcal{S}(P_2)$ are isomorphic as: (1) these are partially isomorphic, i.e., the right hand sides τ and the left hand sides γ are isomorphic; (2) both pairs of extended trees generate the constraint $c_1 = \{(\boxed{1}, \boxed{3}), (\boxed{3}, \boxed{4})\}$. In the same way, the fourth pair of $\mathcal{S}(P_1)$ and the third pair of $\mathcal{S}(P_2)$ generate $c_2 = \{(\boxed{1}, \boxed{1})\}$

4.3 General idea for an efficient kernel function

As above discussed, two tDAGs are isomorphic if the two properties, the *partial isomorphism* and the *constraint compatibility*, hold. To compute the kernel function $K(G_1, G_2)$ defined in Sec. 4.1, we can exploit these properties in the reverse order. Given a constraint c, we can select all the graphs that meet the constraint c (*constraint compatibility*). Having the two set of all the tDAGs meeting the constraint, we can detect the *partial isomorphism*. We split each pair of tDAGs in the four extended trees and we determine if these extended trees are compatible.

We introduce this innovative method to compute the kernel $K(G_1, G_2)$ in the FOR space in two steps. Firstly, we give an intuitive explanation and, secondly, we formally define the kernel.

4.3.1 Intuitive explanation

To give an intuition of the kernel computation, without loss of generality and for sake of simplicity, we use two non-linguistic tDAGs, P_a and P_b (see Fig. 5), and the subgraph function $\widetilde{\mathcal{S}}(\theta)$. This latter is an approximated version of $\mathcal{S}(\theta)$ that generates tDAGs with subtrees rooted in the root of the initial trees of θ.

To exploit the *constraint compatibility* property, we define C as *the set of all the relevant alternative constraints*, i.e., the constraints c that are likely to be generated when detecting the *partial isomorphism*. For P_a and P_b, this set is $C = \{c_1, c_2\} =$

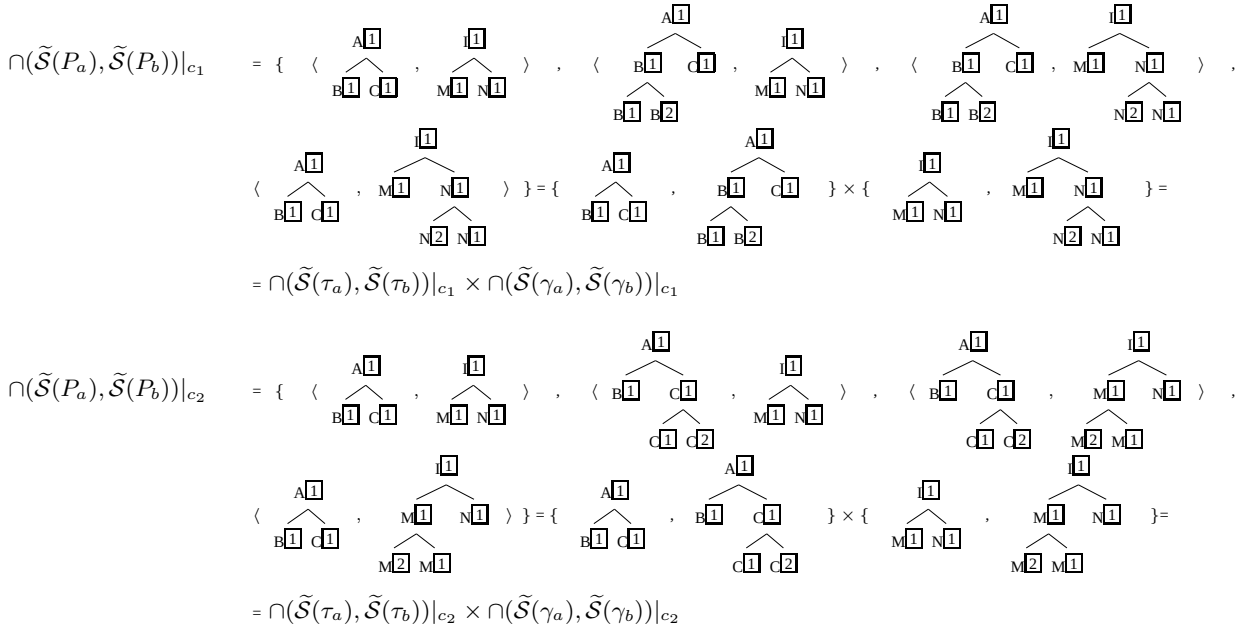

Figure 4: Intuitive idea for the kernel computation

$\{\{(\boxed{1},\boxed{1}),(\boxed{2},\boxed{2})\},\{(\boxed{1},\boxed{1}),(\boxed{2},\boxed{3})\}\}$. We can then determine the kernel $K(P_a, P_b)$ as:

$$K(P_a,P_b) = |\cap(\widetilde{\mathcal{S}}(P_a),\widetilde{\mathcal{S}}(P_b))| = \left|\cap(\widetilde{\mathcal{S}}(P_a),\widetilde{\mathcal{S}}(P_b))|_{c_1} \bigcup \cap(\widetilde{\mathcal{S}}(P_a),\widetilde{\mathcal{S}}(P_b))|_{c_2}\right|$$

where $\cap(\widetilde{\mathcal{S}}(P_a),\widetilde{\mathcal{S}}(P_b))|_c$ are the common subgraphs that meet the constraint c. A tDAG $g' = (\tau', \gamma')$ in $\widetilde{\mathcal{S}}(P_a)$ is in $\cap(\widetilde{\mathcal{S}}(P_a),\widetilde{\mathcal{S}}(P_b))|_c$ if $g'' = (\tau'', \gamma'')$ in $\widetilde{\mathcal{S}}(P_b)$ exists, g' is partially isomorphic to g'', and $c' = c(\tau', \tau'') = c(\gamma', \gamma'')$ is *covered* by and *compatible* with the constraint c, i.e., $c' \subseteq c$. For example in Fig. 4, the first tDAG of the set $\cap(\widetilde{\mathcal{S}}(P_a),\widetilde{\mathcal{S}}(P_b))|_{c_1}$ belongs to the set as its constraint $c' = \{(\boxed{1},\boxed{1})\}$ is a subset of c_1.

Observing the kernel computation in this way is important. Elements in $\cap(\widetilde{\mathcal{S}}(P_a),\widetilde{\mathcal{S}}(P_b))|_c$ already satisfy the property of *constraint compatibility*. We only need to determine if the *partially isomorphic* properties hold for elements in $\cap(\widetilde{\mathcal{S}}(P_a),\widetilde{\mathcal{S}}(P_b))|_c$. Then, we can write the following equivalence:

$$\cap(\widetilde{\mathcal{S}}(P_a),\widetilde{\mathcal{S}}(P_b))|_c = \cap(\widetilde{\mathcal{S}}(\tau_a),\widetilde{\mathcal{S}}(\tau_b))|_c \times \cap(\widetilde{\mathcal{S}}(\gamma_a),\widetilde{\mathcal{S}}(\gamma_b))|_c \quad (2)$$

Figure 4 reports this equivalence for the two sets derived using the constraints c_1 and c_2. Note that this equivalence is not valid if a constraint is not applied, i.e., $\cap(\widetilde{\mathcal{S}}(P_a),\widetilde{\mathcal{S}}(P_b)) \neq \cap(\widetilde{\mathcal{S}}(\tau_a),\widetilde{\mathcal{S}}(\tau_b)) \times \cap(\widetilde{\mathcal{S}}(\gamma_a),\widetilde{\mathcal{S}}(\gamma_b))$. The pair P_a itself does not belong to $\cap(\widetilde{\mathcal{S}}(P_a),\widetilde{\mathcal{S}}(P_b))$ but it does belong to $\cap(\widetilde{\mathcal{S}}(\tau_a),\widetilde{\mathcal{S}}(\tau_b)) \times \cap(\widetilde{\mathcal{S}}(\gamma_a),\widetilde{\mathcal{S}}(\gamma_b))$.

The equivalence (2) allows to compute the cardinality of $\cap(\widetilde{\mathcal{S}}(P_a),\widetilde{\mathcal{S}}(P_b))|_c$ using the cardinalities of $\cap(\widetilde{\mathcal{S}}(\tau_a),\widetilde{\mathcal{S}}(\tau_b))|_c$ and $\cap(\widetilde{\mathcal{S}}(\gamma_a),\widetilde{\mathcal{S}}(\gamma_b))|_c$. These latter sets contain only extended trees where the equivalences between unlabelled nodes are given by c. We can then compute the cardinalities of these two sets using methods developed for trees (e.g., the kernel function $K_S(\theta_1, \theta_2)$ introduced in (Collins and Duffy, 2002)).

4.3.2 Formal definition

Given the idea of the previous section, it is easy to demonstrate that the kernel $K(G_1, G_2)$ can be written as follows:

$$K(G_1,G_2) = \left|\bigcup_{c\in C} \cap(\mathcal{S}(\tau_1),\mathcal{S}(\tau_2))|_c \times \cap(\mathcal{S}(\gamma_1),\mathcal{S}(\gamma_2))|_c\right|$$

where C is set of alternative constraints and $\cap(\mathcal{S}(\theta_1),\mathcal{S}(\theta_2))|_c$ are all the common extended trees compatible with the constraint c.

We can compute the above kernel using the inclusion-exclusion property, i.e.,

$$|A_1 \cup \cdots \cup A_n| = \sum_{J\in 2^{\{1,\ldots,n\}}} (-1)^{|J|-1}|A_J| \quad (3)$$

where $2^{\{1,\ldots,n\}}$ is the set of all the subsets of $\{1, \ldots, n\}$ and $A_J = \bigcap_{i\in J} A_i$.

To describe the application of the inclusion-exclusion model in our case, let firstly define:

$$K_S(\theta_1, \theta_2, c) = |\cap(\mathcal{S}(\theta_1),\mathcal{S}(\theta_2))|_c| \quad (4)$$

where θ_1 can be both τ_1 and γ_1 and θ_2 can be both τ_2 and γ_2. Trivially, we can demonstrate that:

$$K(G_1, G_2) = \\ = \sum_{J \in 2^{\{1,\ldots,|C|\}}} (-1)^{|J|-1} K_S(\tau_1, \tau_2, c(J)) K_S(\gamma_1, \gamma_2, c(J)) \quad (5)$$

where $c(J) = \bigcap_{i \in J} c_i$.

Given the nature of the constraint set C, we can compute efficiently the previous equation as it often happens that two different J_1 and J_2 in $2^{\{1,\ldots,|C|\}}$ generate the same c, i.e.

$$c = \bigcap_{i \in J_1} c_i = \bigcap_{i \in J_2} c_i \quad (6)$$

Then, we can define C^* as the set of all intersections of constraints in C, i.e. $C^* = \{c(J) | J \in 2^{\{1,\ldots,|C|\}}\}$. We can rewrite the equation as:

$$K(G_1, G_2) = \\ = \sum_{c \in C^*} K_S(\tau_1, \tau_2, c) K_S(\gamma_1, \gamma_2, c) N(c) \quad (7)$$

where

$$N(c) = \sum_{\substack{J \in 2^{\{1,\ldots,|C|\}} \\ c = c(J)}} (-1)^{|J|-1} \quad (8)$$

The complexity of the above kernel strongly depends on the cardinality of C and the related cardinality of C^*. The worst-case computational complexity is still exponential with respect to the size of A_1 and A_2. Yet, the average case complexity (Wang, 1997) is promising.

The set C is generally very small with respect to the worst case. If $\mathcal{F}_{(A_1,A_2)}$ are all the possible correspondences between the nodes A_1 and A_2, it happens that $|C| << |\mathcal{F}_{(A_1,A_2)}|$ where $|\mathcal{F}_{(A_1,A_2)}|$ is the worst case. For example, in the case of P_1 and P_2, the cardinality of $C = \{\{(1,1)\}, \{(1,3),(3,4),(2,5)\}\}$ is extremely smaller than the one of $\mathcal{F}_{(A_1,A_2)} = \{\{(1,1),(2,2),(3,3)\}, \{(1,2),(2,1),(3,3)\}, \{(1,2),(2,3),(3,1)\}, ..., \{(1,3),(2,4),(3,5)\}\}$. In Sec. 4.5 we argue that the algorithm presented in (Moschitti and Zanzotto, 2007) has the worst-case complexity.

Moreover, the set C^* is extremely smaller than $2^{\{1,\ldots,|C|\}}$ due to the above property (6).

We will analyze the average-case complexity with respect to the worst-case complexity in Sec. 5.

4.4 Enabling the efficient kernel function

The above idea for computing the kernel function is extremely interesting. Yet, we need to make it viable by describing the way we can determine efficiently the three main parts of the equation (7): 1) the set of alternative constraints C (Sec. 4.4.1); 2) the set C^* of all the possible intersections of constraints in C (Sec. 4.4.2); and, finally, 3) the numbers $N(c)$ (Sec. 4.4.3).

4.4.1 Determining the set of alternative constraints

The first step of equation (7) is to determine the alternative constraints C. We can here strongly use the possibility of dividing tDAGs in two trees. We build C as $C_\tau \cup C_\gamma$ where: 1) C_τ are the constraints obtained from pairs of isomorphic extended trees $t_1 \in \mathcal{S}(\tau_1)$ and $t_2 \in \mathcal{S}(\tau_2)$; 2) C_γ are the constraints obtained from pairs of isomorphic extended trees $t_1 \in \mathcal{S}(\gamma_1)$ and $t_2 \in \mathcal{S}(\gamma_2)$.

The idea for an efficient algorithm is that we can compute the C without explicitly looking at all the subgraphs involved. We instead use and combine the constraints derived comparing the productions of the extended trees. We can compute then C_τ with the productions of τ_1 and τ_2 and C_γ with the productions of γ_1 and γ_2. For example (see Fig. 3), focusing on the τ, the rule $NP\boxed{3} \rightarrow NN\boxed{2}NNS\boxed{3}$ of G_1 and $NP\boxed{4} \rightarrow NN\boxed{5}NNS\boxed{4}$ of G_2 generates the constraint $c = \{(\boxed{3},\boxed{4}),(\boxed{2},\boxed{5})\}$.

Using the above intuition it is possible to define an algorithm that builds an alternative constraint set C with the following two properties:

1. for each common subtree according to a set of constraints c, $\exists c' \in C$ such that $c \subseteq c'$;
2. $\nexists c', c'' \in C$ such that $c' \subset c''$ and $c' \neq \emptyset$.

4.4.2 Determining the set C^*

The set C^* is defined as the set of all possible intersections of alternative constraints in C. Figure 6 presents the algorithm determining C^*. Due to the property (6) discussed in Sec. 4.3, we can empirically demonstrate that the average complexity of the algorithm is not bigger than $O(|C|^2)$. Yet, again, the worst case complexity is exponential.

4.4.3 Determining the values of $N(c)$

The multiplier $N(c)$ (Eq. 8) represents the number of times the constraint c is considered in the sum of equation 5, keeping into account the sign of

Algorithm *Build the set C^* from the set C*

$C^+ \leftarrow C$; $C_1 \leftarrow C$; $C_2 \leftarrow \emptyset$
WHILE $|C_1| > 1$
  FORALL $c' \in C_1$
    FORALL $c'' \in C_1$ such that $c' \neq c''$
      $c \leftarrow c' \cap c''$
      IF $c \notin C^+$ add c to C_2
  $C^+ \leftarrow C^+ \cup C_2$; $C_1 \leftarrow C_2$; $C_2 \leftarrow \emptyset$
$C^* \leftarrow C \cup C^+ \cup \{\emptyset\}$

Figure 6: Algorithm for computing C^*

the corresponding addend. It is possible to demonstrate that:

$$N(c) = 1 - \sum_{\substack{c' \in C^* \\ c' \supset c}} N_{c'} \quad (9)$$

This recursive formulation of the equation allows us to easily determine the value of $N(c)$ for every c belonging to C^*. It is possible to prove this property using set properties and the binomial theorem. The proof is omitted for lack of space.

4.5 Reviewing the strictly related work

To understand if ours is an efficient algorithm, we compare it with the algorithm presented by (Moschitti and Zanzotto, 2007). We will hereafter call this algorithm K_{max}. The K_{max} algorithm and kernel is an approximation of what is a kernel needed for a FOR space as it is not difficult to demonstrate that $K_{max}(G_1, G_2) \leq K(G_1, G_2)$. The K_{max} approximation is based on maximization over the set of possible correspondences of the placeholders. Following our formulation, this kernel appears as:

$$K_{max}(G_1, G_2) = \\ = \max_{c \in \mathcal{F}_{(A_1, A_2)}} K_S(\tau_1, \tau_2, c) K_S(\gamma_1, \gamma_2, c) \quad (10)$$

where $\mathcal{F}_{(A_1,A_2)}$ are all the possible correspondences between the nodes A_1 and A_2 of the two tDAGs as the one presented in Sec. 4.3. This formulation of the kernel has the worst case complexity of our formulation, i.e., Eq. 7.

For computing the basic kernel for the extended trees, i.e. $K_S(\theta_1, \theta_2, c)$ we use the model algorithm presented by (Zanzotto and Moschitti, 2006) and refined by (Moschitti and Zanzotto, 2007) based on the algorithm for tree fragment feature spaces (Collins and Duffy, 2002). As we are using the same basic kernel, we can empirically compare the two methods.

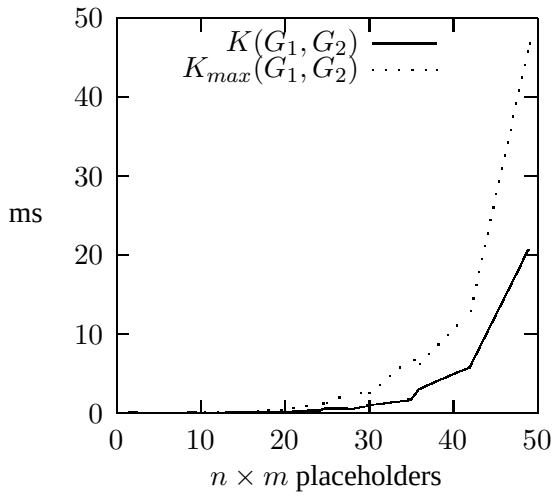

Figure 7: Mean execution time in milliseconds (ms) of the two algorithms wrt. $n \times m$ where n and m are the number of placeholders of the two tDAGs

5 Experimental evaluation

In this section we want to empirically estimate the benefits on the computational cost of our novel algorithm with respect to the algorithm proposed by (Moschitti and Zanzotto, 2007). Our algorithm is in principle exponential with respect to the set of alternative constraints C. Yet, due to what presented in Sec. 4.4 and as the set C^* is usually very small, the average complexity is extremely low. Following the theory on the average-cost computational complexity (Wang, 1997), we estimated the behavior of the algorithms on a large distribution of cases. We then compared the computing times of the two algorithms. Finally, as K and K_{max} compute slightly different kernels, we compare the accuracy of the two methods. We implemented both algorithms $K(G_1, G_2)$ and $K_{max}(G_1, G_2)$ in support vector machine classifier (Joachims, 1999) and we experimented with both implementations on the same machine. We hereafter analyze the results in term of execution time (Sec. 5.1) and in term of accuracy (Sec. 5.2).

5.1 Average computing time analysis

For this first set of experiments, the source of examples is the one of the recognizing textual entailment challenge, i.e., RTE2 (Bar-Haim et al.,

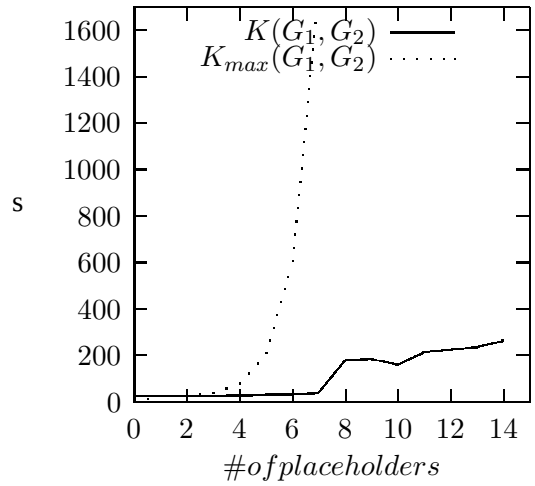

Figure 8: Total execution time in seconds (s) of the training phase on RTE2 wrt. different numbers of allowed placeholders

2006). The dataset of the challenge has 1,600 sentence pairs.

The computational cost of both $K(G_1, G_2)$ and $K_{max}(G_1, G_2)$ depends on the number of placeholders $n = |A_1|$ of G_1 and on $m = |A_2|$ the number of placeholders of G_2. Then, in the first experiment we want to determine the relation between the computational time and the factor $n \times m$. Results are reported in Fig. 7 where the computation times are plotted with respect to $n \times m$. Each point in the curve represents the average execution time for the pairs of instances having $n \times m$ placeholders. As expected, the computation of the function K is more efficient than the computation K_{max}. The difference between the two execution times increases with $n \times m$.

We then performed a second experiment that wants to determine the relation of the total execution with the maximum number of placeholders in the examples. This is useful to estimate the behavior of the algorithm with respect to its application in learning models. Using the RTE2 data, we artificially build different versions with increasing number of placeholders. We then have RTE2 with 1 placeholder at most in each pair, RTE2 with 2 placeholders, etc. The number of pairs in each set is the same. What changes is the maximal number of placeholders. Results are reported in Fig. 8 where the execution time of the training phase in seconds (s) is plotted for each different set. We see that the computation of K_{max} is exponential with respect to the number of placeholders and it becomes intractable after 7 placeholders. The computation of K is instead more flat. This can be explained as the computation of K is related to the real alternative constraints that appears in the dataset. The computation of the kernel K then outperforms the computation of the kernel K_{max}.

Kernel	Accuracy	Used training examples	Support Vectors
K_{max}	59.32	4223	4206
K	60.04	4567	4544

Table 1: Comparative performances of K_{max} and K

5.2 Accuracy analysis

As K_{max} that has been demonstrated very effective in term of accuracy for RTE and K compute a slightly different similarity function, we want to show that the performance of our more computationally efficient K is comparable, and even better, to the performances of K_{max}. We then performed an experiment taking as training all the data derived from RTE1, RTE2, and RTE3, (i.e., 4567 training examples) and taking as testing RTE-4 (i.e., 1000 testing examples). The results are reported in Tab. 1. As the table shows, the accuracy of K is higher than the accuracy of K_{max}. There are two main reasons. The first is that K_{max} is an approximation of K. The second is that we can now consider sentence pairs with more than 7 placeholders. Then, we can use the complete training set as the third column of the table shows.

6 Conclusions and future work

We presented an interpretation of first order rule feature spaces as *tripartite directed acyclic graphs* ($tDAG$s). This view on the problem gave us the possibility of defining a novel and efficient algorithm for computing the kernel function for first order rule feature spaces. Moreover, the resulting algorithm is a valid kernel as it can be written as dot product in the explicit space of the tDAG fragments. We demonstrated that our algorithm outperforms in term of average complexity the previous algorithm and it yields to better accuracies for the final task. We are investigating if this is a valid algorithm for two general directed acyclic graphs.

Graphical Models over Multiple Strings*

Markus Dreyer and **Jason Eisner**
Department of Computer Science / Johns Hopkins University
Baltimore, MD 21218, USA
{markus,jason}@cs.jhu.edu

Abstract

We study graphical modeling in the case of *string-valued* random variables. Whereas a weighted finite-state transducer can model the probabilistic relationship between *two* strings, we are interested in building up joint models of *three or more strings*. This is needed for inflectional paradigms in morphology, cognate modeling or language reconstruction, and multiple-string alignment. We propose a Markov Random Field in which each factor (potential function) is a weighted finite-state machine, typically a transducer that evaluates the relationship between just two of the strings. The full joint distribution is then a product of these factors. Though decoding is actually undecidable in general, we can still do efficient joint inference using approximate belief propagation; the necessary computations and messages are all finite-state. We demonstrate the methods by jointly predicting morphological forms.

1 Overview

This paper considers what happens if a graphical model's variables can range over *strings* of unbounded length, rather than over the typical *finite* domains such as booleans, words, or tags. Variables that are connected in the graphical model are related by some weighted finite-state transduction.

Graphical models have become popular in machine learning as a principled way to work with collections of interrelated random variables. Most often they are used as follows:

1. **Build:** Manually specify the n variables of interest; their domains; and the possible direct interactions among them.
2. **Train:** Train this model's parameters θ to obtain a specific joint probability distribution $p(V_1, \ldots, V_n)$ over the n variables.
3. **Infer:** Use this joint distribution to predict the values of various unobserved variables from observed ones.

*Supported by the Human Language Technology Center of Excellence at Johns Hopkins University, and by National Science Foundation grant No. 0347822 to the second author.

Note that 1. requires intuitions about the domain; 2. requires some choice of training procedure; and 3. requires a choice of exact or approximate inference algorithm.

Our graphical models over strings are natural objects to investigate. We motivate them with some natural applications in computational linguistics (section 2). We then give our formalism: a Markov Random Field whose potential functions are rational weighted languages and relations (section 3). Next, we point out that inference is in general undecidable, and explain how to do approximate inference using message-passing algorithms such as belief propagation (section 4). The messages are represented as weighted finite-state machines.

Finally, we report on some initial experiments using these methods (section 7). We use incomplete data to train a joint model of morphological paradigms, then use the trained model to complete the data by predicting unseen forms.

2 Motivation

The problem of mapping between different forms and representations of strings is ubiquitous in natural language processing and computational linguistics. This is typically done between string *pairs*, where a pronunciation is mapped to its spelling, an inflected form to its lemma, a spelling variant to its canonical spelling, or a name is transliterated from one alphabet into another.
However, many problems involve more than just two strings:

- in *morphology*, the inflected forms of a (possibly irregular) verb are naturally considered together as a whole morphological paradigm in which different forms reinforce one another;
- mapping an English word to its foreign *transliteration* may be easier when one considers the orthographic *and* phonological forms of both words;
- similar *cognates* in multiple languages are naturally described together, in orthographic or phonological representations, or both;

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 101–110,
Singapore, 6-7 August 2009.

- modern and ancestral word forms form a phylogenetic tree in *historical linguistics*;
- in *bioinformatics* and in *system combination*, multiple sequences need to be aligned in order to identify regions of similarity.

We propose a unified model for multiple strings that is suitable for all the problems mentioned above. It is robust and configurable and can make use of task-specific overlapping features. It learns from observed and unobserved, or latent, information, making it useful in supervised, semi-supervised, and unsupervised settings.

3 Formal Modeling Approach

3.1 Variables

A **Markov Random Field** (MRF) is a joint model of a set of random variables, $\mathcal{V} = \{V_1, \ldots, V_n\}$. We assume that all variables are string-valued, i.e. the value of V_i may be any string $\in \Sigma_i^*$, where Σ_i is some finite alphabet.

We may use meaningful names for the integers i, such as $V_{2\mathrm{SA}}$ for the ***2nd singular past*** form of a verb.

The assumption that *all* variables are string-valued is not crucial; it merely simplifies our presentation. It is, however, sufficient for many practical purposes, since most other discrete objects can be easily encoded as strings. For example, if V_1 is a part of speech tag, it may be encoded as a length-1 string over the finite alphabet $\Sigma_1 \stackrel{\text{def}}{=} \{\mathsf{Noun}, \mathsf{Verb}, \ldots\}$.

3.2 Factors

A Markov Random Field defines a probability for each assignment $\mathcal{A}$ of values to the variables in $\mathcal{V}$:

$$p(\mathcal{A}) \stackrel{\text{def}}{=} \frac{1}{Z} \prod_{j=1}^{m} F_j(\mathcal{A}) \qquad (1)$$

This distribution over assignments is specified by the collection of **factors** $F_j : \mathcal{A} \mapsto \mathbb{R}_{\geq 0}$. Each factor (or **potential function**) is a function that depends on only a *subset* of $\mathcal{A}$.

Fig. 1 displays an undirected **factor graph**, in which each factor is connected to the variables that it depends on. F_1, F_3, F_5 in this example are **unary** factors because each one scores the value of a single variable, while F_2, F_4, F_6 are **binary** factors.

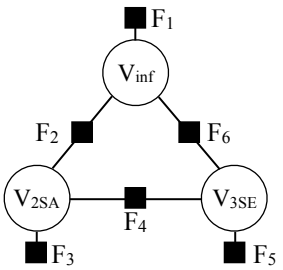

Figure 1: Example of a factor graph. Black boxes represent factors, circles represent variables (infinitive, 2nd past, and 3rd present-tense forms of the same verb; different samples from the MRF correspond to different verbs). Binary factors evaluate how well one string can be transduced into another, summing over all transducer paths (i.e., alignments, which are not observed in training).

In our setting, we will assume that each unary factor is specified by a **weighted finite-state automaton** (WFSA) whose weights fall in the semiring $(\mathbb{R}_{\geq 0}, +, \times)$. Thus the score $F_3(\ldots, V_{2SA} = x, \ldots)$ is the total weight of all paths in the F_3's WFSA that accept the string $x \in \Sigma_{2SA}^*$. Each path's weight is the product of its component arcs' weights, which are non-negative.

Similarly, we assume that each binary factor is specified by a **weighted finite-state transducer** (WFST). Such a model is essentially a generalization of stochastic edit distance (Ristad and Yianilos, 1996) in which the edit probabilities can be made sensitive to a finite summary of context.

Formally, a WFST is an automaton that resembles a weighted FSA, but it nondeterministically reads *two* strings x, y in parallel from left to right. The score of (x, y) is given by the total weight of all accepting paths in the WFST that map x to y. For example, different paths may consider various monotonic alignments of x with y, and we sum over these mutually exclusive possibilities.[1]

A factor might depend on $k > 2$ variables. This requires a k-tape **weighted finite-state machine** (WFSM), an obvious generalization where each path reads k strings in some alignment.[2]

To ensure that Z is finite in equation (1), we can require each factor to be a **"proper" WFSM**, i.e., its accepting paths have finite total weight (even if the WFSM is cyclic, with infinitely many paths).

[1] Each string is said to be on a different "tape," which has its own "read head," allowing the WFSM to maintain a separate position in each string. Thus, a path in a WFST may consume any number of characters from x before consuming the next character from y.

[2] Weighted acceptors and transducers are the cases $k = 1$ and $k = 2$, which are said to define **rational languages** and **rational relations**.

3.3 Parameters

Our probability model has trainable parameters: a vector of **feature weights** $\theta \in \mathbb{R}$. Each arc in each WFSM has a real-valued weight that depends on θ. Thus, tuning θ during training will change the arc weights, hence the path weights, the factor functions, and the whole probability distribution $p(\mathcal{A})$.

Designing the probability model includes specifying the topology and weights of each WFSM. Eisner (2002) explains how to specify and train such **parameterized WFSMs**. Typically, the weight of an arc is a simple sum like $\theta_{12} + \theta_{55} + \theta_{72}$, where θ_{12} is included on all arcs that share feature 12. However, more interesting parameterizations arise if the WFSM is constructed by operations such as transducer composition, or from a weighted regular expression.

3.4 Power of the formalism

Factored finite-state string models (1) were originally suggested by the second author, in Kempe et al. (2004). That paper showed that even in the unweighted case, such models could be used to encode relations that could not be recognized by any k-tape FSM. We offer a more linguistic example as a small puzzle. We invite the reader to specify a factored model (consisting of three FSTs as in Fig. 1) that assigns positive probability to just those triples of character strings (x, y, z) that have the form (*red_ball*, *ball_red*, *red*), (*white_house*, *house_white*, *white*), etc. This uses the auxiliary variable Z to help encode a relation between X and Y that swaps words of unbounded length. By contrast, no FSM can accomplish such unbounded swapping, even with 3 or more tapes.

Such extra power might be linguistically useful. Troublingly, however, Kempe et al. (2004) also observed that the framework is powerful enough to express computationally *undecidable* problems.[3] This implies that to work with arbitrary models, we will need approximate methods.[4] Fortunately, the graphical models community has already developed many such methods, to deal with the computational intractability (if not undecidability) of exact inference.

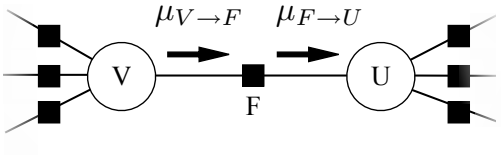

Figure 2: Illustration of messages being passed from variable to factor and factor to variable. Each message is represented by a finite-state acceptor.

4 Approximate Inference

In this paper, we focus on how **belief propagation** (BP)—a simple well-known method for approximate inference in MRFs (Bishop, 2006)—can be used in our setting. BP in its general form has not yet been widely used in the NLP community.[5] However, it is just a generalization to *arbitrary* factor graphs of the familiar forward-backward algorithm (which operates only on chain-structured factor graphs). The algorithm becomes approximate (and may not even converge) when the factor graphs have cycles. (In that case it is more properly called "loopy belief propagation.")

4.1 Belief propagation

We first sketch how BP works in general. Each variable V in the graphical model maintains a **belief** about its value, in the form of a marginal distribution $\tilde{p}_V$ over the possible values of V. The final beliefs are the output of the algorithm.

Beliefs arise from **messages** that are sent between the variables and factors along the edges of the factor graph. Variable V sends factor F a message $\mu_{V \to F}$, which is an (unnormalized) probability distribution over V's values v, computed by

$$\mu_{V \to F}(v) := \prod_{F' \in \mathcal{N}(V), F' \neq F} \mu_{F' \to V}(v) \quad (2)$$

where $\mathcal{N}$ is the set of neighbors of V in the graphical model. This message represents a consensus of V's *other* neighboring factors concerning V's value. It is how V tells F what its belief $\tilde{p}_V$ would be if F were absent. Informally, it communicates to F: *Here is what my value would be if it were up to my other neighboring factors F' to determine.*

[3] Consider a simple model with two variables and two binary factors: $p(V_1, V_2) \stackrel{\text{def}}{=} \frac{1}{Z} \cdot F_1(V_1, V_2) \cdot F_2(V_1, V_2)$. Suppose F_1 is 1 or 0 according to whether its arguments are equal. Under this model, $p(\epsilon) < 1$ iff there exists a string $x \neq \epsilon$ that can be transduced to itself by the unweighted transducer F_2. This question can be used to encode any instance of Post's Correspondence Problem, so is undecidable.

[4] Notice that the simplest approximation to cure undecidability would be to impose an arbitrary maximum on string length, so that the random variables have a finite domain, just as in most discrete graphical models.

[5] Notable exceptions are Sutton et al. (2004) for chunking and tagging, Sutton and McCallum (2004) for information extraction, Smith and Eisner (2008) for dependency parsing, and Cromierès and Kurohashi (2009) for alignment.

The factor F can then collect such incoming messages from neighboring variables and send its own message on to another neighbor U. Such a message $\mu_{F\to U}$ suggests good values for U, in the form of an (unnormalized) distribution over U's values u, computed by

$$\mu_{F\to U}(u) := \sum_{\mathcal{A}\ s.t. \mathcal{A}[U]=u} F(\mathcal{A}) \prod_{U'\in\mathcal{N}(F), U'\neq U} \mu_{U'\to F}(\mathcal{A}[U']) \tag{3}$$

where $\mathcal{A}$ is an assignment to all variables, and $\mathcal{A}[U]$ is the value of variable U in that assignment. This message represents F's prediction of U's value based on its *other* neighboring variables U'. Informally, via this message, F tells U: *Here is what I would like your value to be, based on the messages that my other neighboring variables have sent me about their values, and how I would prefer you to relate to them.*

Thus, each edge of the factor graph maintains two messages $\mu_{V\to F}, \mu_{F\to V}$. All messages are updated repeatedly, in some order, using the two equations above, until some stopping criterion is reached.[6] The *beliefs* are then computed:

$$\tilde{p}_V(v) \stackrel{\text{def}}{=} \prod_{F\in\mathcal{N}(V)} \mu_{F\to V}(v) \tag{4}$$

If variable V is *observed*, then the right-hand sides of equations (2) and (4) are modified to tell V that it *must* have the observed value v. This is done by multiplying in an extra message $\mu_{\text{obs}\to V}$ that puts probability 1 on v[7] and 0 on other values. That affects *other* messages and beliefs. The final belief at each variable estimates its *posterior* marginal under the MRF (1), *given all observations*.

4.2 Finite-state messages in BP

Both $\mu_{V\to F}$ and $\mu_{F\to V}$ are unnormalized distributions over the possible values of V—in our case, strings. A distribution over strings is naturally represented by a WFSA. Thus, belief propagation translates to our setting as follows:

- Each message is a WFSA.
- Messages are typically initialized to a one-state WFSA that accepts all strings in Σ^*, each with weight 1.[8]
- Taking a pointwise product of messages to V in equation (2) corresponds to WFSA intersection.
- If F in equation (3) is binary,[9] then there is only one U'. Then the outgoing message $\mu_{F\to U}$, a WFSA, is computed as $\text{domain}(F \circ \mu_{U'\to F})$.

  Here $\circ$ composes the factor WFST with the incoming message WFSA, yielding a WFST that gives a joint distribution over (U, U'). The domain operator projects this WFST onto the U side to obtain a WFSA, which corresponds to marginalizing to obtain a distribution over U.
- In general, F is a k-tape WFSM. Equation (3) "composes" $k-1$ of its tapes with $k-1$ incoming messages $\mu_{U'\to F}$, to construct a joint distribution over the k variables in $\mathcal{N}(F)$, then projects onto the k^{th} tape to marginalize over the $k-1$ U' variables and get a distribution over U. All this can be accomplished by the WFSM generalized composition operator $\boxtimes$ (Kempe et al., 2004).

After projecting, it is desirable to determinize the WFSA. Otherwise, the summation in (3) is only implicit—the summands remain as distinct paths in the WFSA[10]—and thus the WFSAs would get larger and larger as BP proceeds. Unfortunately, determinizing a WFSA still does not guarantee a small result. In fact it can lead to exponential blowup, or even infinite blowup.[11] Thus, in practice we recommend against determinizing the messages, which may be inherently complex. To shrink a message, it is safer to *approximate* it with a small deterministic WFSA, as discussed in the next section.

4.3 Approximation of messages

In our domain, it is possible for the finite-state messages to *grow unboundedly in size* as they flow around a cycle. After all, our messages are not just multinomial distributions over a fixed finite

[6] Preferably when the beliefs converge to some fixed point (a local minimum of the Bethe free energy). However, convergence is not guaranteed.

[7] More generally, on *all* possible observed variables.

[8] This is an (improper) uniform distribution over Σ^*. Although is *not* a proper WFSA (see section 3.2), there is an upper bound on the weights it assigns to strings. That guarantees that all the messages and beliefs computed by (2)–(4) will be proper FSMs, provided that all the factors are proper WFSMs.

[9] If it is unary, (3) trivially reduces to $\mu_{F\to U} = F$.

[10] The usual implementation of projection does not change the topology of the WFST, but only deletes the U' part of its arc labels. Thus, multiple paths that accept the same value of U remain distinct according to the distinct values of U' that they were paired with before projection.

[11] If there is no deterministic equivalent (Mohri, 1997).

set. They are distributions over the infinite set Σ^*. A WFSA represents this in finite space, but more complex distributions require bigger WFSAs, with more distinct states and arc weights.

Facing the same problem for distributions over the infinite set $\mathbb{R}$, Sudderth et al. (2002) simplified each message $\mu_{V \to F}$, approximating a complex Gaussian mixture by using fewer components.

We could act similarly, variationally approximating a large WFSA P with a smaller one Q. Choose a family of message approximations (such as bigram models) by specifying the topology for a (small) deterministic WFSA Q. Then choose Q's edge weights to minimize the KL divergence $\mathrm{KL}(P \,\|\, Q)$. This can be done in closed form.[12]

Another possible procedure—used in the experiments of this paper—approximates $\mu_{V \to F}$ by pruning it back to a finite set of most plausible strings.[13] Equation (2) requests an intersection of several WFSAs, e.g., $\mu_{F_1 \to V} \cap \mu_{F_2 \to V} \cap \cdots$. List all strings that appear on any of the 1000-best paths in any of these WFSAs, removing duplicates. Let $\bar{Q}$ be a uniform distribution over this combined list of plausible strings, represented as a determinized, minimized, acyclic WFSA. Now approximate the intersection of equation (2) as $((\bar{Q} \cap \mu_{F_1 \to V}) \cap \mu_{F_2 \to V}) \cap \cdots$. This is efficient to compute and has the same topology as $\bar{Q}$.

5 Training the Model Parameters

Any standard training method for MRFs will transfer naturally to our setting. In all cases we draw on Eisner (2002), who showed how to train the parameters θ of a *single* WFST, F, to (locally) maximize the joint or conditional probability of fully or partially observed training data. This involves computing the gradient of that likelihood function with respect to θ.[14]

We must generalize this to train a *product* of WFSMs. Typically, training data for an MRF (1) consists of some fully or partially observed IID samples of the joint distribution $p(V_1, \ldots V_n)$. It is well-known how to tune an MRF's parameters θ by stochastic gradient descent to locally maximize the probability of this training set, even though both the probability and its gradient are in general intractable to compute in an MRF. The gradient is a sum of quantities, one for each factor F_j. While the summand for F_j cannot be computed exactly, it can be estimated using the BP messages to F_j. Roughly speaking, the gradient for F_j is computed much as in supervised training (see above), but treating any message $\mu_{V_i \to F_j}$ as an uncertain observation of V_i—a form of noisy supervision.[15]

Our concerns about training are the same as for any MRF. First of all, BP is approximate. Kulesza and Pereira (2008) warn that its estimates of the gradient can be misleading. Second, semi-supervised training (which we will attempt below) is always difficult and prone to local optima. As in EM, a small number of supervised examples for some variable may be drowned out by many noisily reconstructed examples.

Faster and potentially more stable approaches include the **piecewise training** methods of Sutton and McCallum (2008), which train the factors independently or in small groups. In the semi-supervised case, each factor can be trained on only the supervised forms available for it. It might be useful to reweight the trained factors (cf. Smith et al. (2005)), or train the factors consecutively (cf. Fahlman and Lebiere (1990)), in a way that minimizes the loss of BP decoding on held-out data.

6 Comparison With Other Approaches

6.1 Multi-tape WFSMs

In principle, one could use a 100-tape WFSM to jointly model the 100 distinct forms of a typical Polish verb. In other words, the WFSM would describe the distribution of a random variable $\vec{V} = \langle V_1, \ldots, V_{100} \rangle$, where each V_i is a string. One would train the parameters of the WFSM on a sample of $\vec{V}$, each sample being a fully or partially observed paradigm for some Polish verb. The resulting distribution could be used to infer missing forms for these or other verbs.

[12] See Li et al. (2009, footnote 9) for a sketch of the construction, which finds locally normalized edge weights. Or if Q is large but parameterized by some compact parameter vector ϕ, so we are only allowed to control its edge weights via ϕ, then Li and Eisner (2009, section 6) explain how to minimize $\mathrm{KL}(P \,\|\, Q)$ by gradient descent. In both cases Q must be deterministic.

We remark that if a factor F were specified by a synchronous grammar rather than a WFSM, then its outgoing messages would be weighted context-free languages. Exact intersection of these is undecidable, but they too can be approximated variationally by WFSAs, with the same methods.

[13] We are also considering other ways of adaptively choosing the topology of WFSA approximations at runtime, particularly in conjunction with expectation propagation.

[14] The likelihood is usually non-convex; even when the two strings are observed (supervised training), their accepting path through the WFST may be ambiguous and unobserved.

[15] See Bishop (2006), or consult Smith and Eisner (2008) for notation close to that of this paper.

As a simple example, either a morphological generator or a morphological analyzer might need the probability that *krzyczałoby* is the neuter third-person singular conditional imperfective of *krzyczeć*, despite never having observed it in training. The model determines this probability based on other observed and hypothesized forms of *krzyczeć*, using its knowledge of how neuter third-person singular conditional imperfectives are related to these other forms in other verbs.

Unfortunately, such a 100-tape WFSM would be huge, with an astronomical number of arcs (each representing a possible 100-way edit operation). Our approach is to factor the problem into a number of (e.g.) pairwise relationships among the verb forms. Using a factored distribution has several benefits over the k-tape WFSM: (1) a smaller representation in memory, (2) a small number of parameters to learn, (3) efficient approximate computation that takes advantage of the factored structure, (4) the ability to reuse WFSAs and WFSTs previously developed for smaller problems, (5) additional modeling power.

6.2 Simpler graphical models on strings

Some previous researchers have used factored joint models of several strings. To our knowledge, they have all chosen *acyclic*, *directed* graphical models. The acyclicity meant that exact inference was at least possible for them, if not necessarily efficient. The factors in these past models have been WFSTs (though typically simpler than the ones we will use).

Many papers have used cascades of probabilistic finite-state transducers. Such a cascade may be regarded as a directed graphical model with a linear-chain structure. Pereira and Riley (1997) built a speech recognizer in this way, relating acoustic to phonetic to lexical strings. Similarly, Knight and Graehl (1997) presented a generative cascade using 4 variables and 5 factors: $p(w, e, j, k, o) \stackrel{\text{def}}{=} p(w) \cdot p(e \mid w) \cdot p(j \mid e) \cdot p(k \mid j) \cdot p(o \mid k)$ where e is an English word sequence, w its pronunciation, j a Japanese version of the pronunciation, k a katakana rendering of the Japanese pronunciation, and o an OCR-corrupted version of the katakana. Knight and Graehl used finite-state operations to perform inference at test time, observing o and recovering the most likely w, while marginalizing out e, j, and k.

Bouchard-Côté et al. (2009) reconstructed ancient word forms given modern equivalents. They used a directed graphical model, whose tree structure reflected the evolutionary development of the modern languages, and which included latent variables for historical intermediate forms that were never observed in training data. They used Gibbs sampling rather than an exact solution (possible on trees) or a variational approximation (like our BP).

Our work seeks to be general in terms of the graphical model structures used, as well as efficient through the use of BP with approximate messages. We also seek to avoid local normalization, using a globally normalized model.[16]

6.3 Unbounded objects in graphical models

We distinguish our work from "dynamic" graphical models such as Dynamic Bayesian Networks and Conditional Random Fields, where the string *brechen* would be represented by creating 7 letter-valued variables. Those methods can represent strings (or paths) of any length—but the length for each training or test string must be specified in advance, not inferred. Furthermore, it is awkward and costly to model unknown alignments, since the variables are position-specific, and any position in *brechen* could in principle align with any position in *brichst*. WFSTs are a much more natural and flexible model of string pairs.

We also distinguish our work from current nonparametric Bayesian models, which sometimes generate unbounded strings, trees, or grammars. If they generate two unbounded objects, they model their relationship by a single synchronous generation process (akin to Section 6.1), rather than by a globally normalized product of overlapping factors.

7 Experiments

To study our approach, we conducted initial experiments that reconstruct missing word forms in morphological paradigms. In *inflectional morphology*, each uninflected verb form (**lemma**) is associated with a vector of forms that are inflected for tense, person, number, etc. Some inflected forms may be observed frequently in natural text, others rarely. Two variables that are usually predictable from each other may or may not keep this relationship in the case of an irregular verb.

[16] Although we do normalize locally during piecewise training (see section 7.3).

(a) # paradigms	9,393
(b) # finite forms per paradigm	9
(c) # hidden finite forms per paradigm (avg.)	8.3
(d) # paradigms with some finite form(s) observed	2,176
(e) In (d), # of finite forms observed (avg.)	3.4

Table 1: Statistics of our training data.

Our task is to reconstruct (*generate*) specific unobserved morphological forms in a paradigm by learning from observed ones. This is a particularly interesting semisupervised scenario, because different subsets of the variables are observed on different examples.

7.1 Experimental data

We used orthographic rather than phonological forms. We extracted morphological paradigms for all 9393 German verbs in the CELEX morphological database. Each paradigm lists 5 present-tense and 4 past-tense indicative forms, as well as the verb's lemma, for a total of 10 string-valued variables.[17] In each paradigm, we removed, or hid, verb forms that occur only rarely in natural text, i.e, verb forms with a small frequency figure provided by CELEX.[18] All paradigms other than *sein* ('to be') were now incompletely observed. Table 1 gives some statistics.

7.2 Model factors and parameters

Our current MRF uses only binary factors. Each factor is a WFST that is trained to relate 2 of the 10 variables (morphological forms). Each WFST can score an aligned pair using a log-linear model that counts features in a sliding 3-character window. To score an unaligned pair, it sums over all possible alignments. Specifically, our WFST topology and parameterization follow the state-of-the-art approach to *supervised* morphology in Dreyer et al. (2008), although we dropped some of their features to speed up these early experiments.[19] We implemented and manipulated all WFSMs using the OpenFST library (Allauzen et al., 2007).

7.3 Training in the experiments

We trained θ on the incompletely observed paradigms. As suggested in section 5, we used a variant of piecewise pseudolikelihood training (Sutton and McCallum, 2008). Suppose there is a binary factor F attached to forms U and V. For any value of θ, we can define $p_{UV}(U \mid V)$ from the tiny MRF consisting only of U, V, and F. We can therefore compute the goodness $L_{UV} \stackrel{\text{def}}{=} \log p_{UV}(u_i \mid v_i) + \log_{VU}(v_i \mid u_i)$,[20] summed over all *observed* (U, V) pairs in training data. We attempted to tune θ to maximize the total L_{UV} over all U, V pairs,[21] regularized by subtracting $||\theta||^2$. Note that different factors thus enjoyed different amounts of observed training data, but training was fully supervised (except for the unobserved alignments between u_i and v_i).

7.4 Inference in the experiments

At test time, we are given each lemma (e.g. *brechen*) and all its observed (frequent) inflected forms (e.g., *brachen*, *bricht*,...), and are asked to predict the remaining (rarer) forms (e.g., *breche, brichst,* ...).

We run approximate joint inference using belief propagation.[22] We extract our output from the final beliefs: for each unseen variable V, we pre-

[17] Some pairs of forms are always identical in German, hence are treated as a single form by CELEX. We likewise use a single variable—these are the "1,3" variables in Fig. 3.

Occasionally a form is listed as UNKNOWN. We neither train nor evaluate on such forms, although the model will still predict them.

[18] The frequency figure for each word form is based on counts in the Mannheim News corpus. We hide forms with frequency < 10.

[19] We dropped their latent classes and regions as well as features that detected which characters were orthographic vowels. Also, we retained their "target language model features" only in the baseline "U" model, since elsewhere they seemed to hurt in our current training setup.

We followed Dreyer et al. (2008) in slightly pruning the space of possible alignments. We compensated by replacing their WFST, F, with the union $F \cup 10^{-12}(0.999\Sigma \times \Sigma)^*$. This ensured that the factor could still map any string to any other string (though perhaps with very low weight), guaranteeing that the intersection at the end of section 4.3 would be non-empty.

[20] The second term is omitted if V is the lemma. We do not train the model to predict the lemma since it is always observed in test data.

[21] Unfortunately, just before press time we discovered that this was not quite what we had done. A shortcut in our implementation trained $p_{UV}(U \mid V)$ and $p_{VU}(V \mid U)$ separately. This let them make different use of the (unobserved) alignments—so that even if each individually liked the pair (u, v), they might not have been able to agree on the same accepting path for it at test time. This could have slightly harmed our joint inference results, though not our baselines.

[22] To derive the update order for message passing, we take an arbitrary spanning tree over the factor graph, and let O be a list of all factors and variables that is topologically sorted according to the spanning tree, with the leaves of the tree coming first. We then discard the spanning tree. A single iteration visits all factors and variables in order of O, updating each one's messages to later variables and factors, and then visits all factors and variables in reverse order, updating each one's messages to earlier variables and factors.

dict its value to be $\text{argmax}_v \tilde{p}_V(v)$. This prediction considers the values of all other unseen variables but sums over their possibilities. This is the Bayes-optimal decoder for our scoring function, since that function reports the fraction of *individual forms* that were predicted *perfectly*.[23]

7.5 Model selection of MRF topology

It is hard to know *a priori* what the causal relationships might be in a morphological paradigm. In principle, one would like to *automatically* choose which factors to have in the MRF. Or one could start with many factors, but use methods such as those suggested in section 5 to learn that certain less useful factors should be left weak to avoid confusing loopy BP.

For our present experiments, we simply compared several fixed model topologies (Fig. 3). These were variously unconnected (U), chain graphs (C1,. . . , C4), trees (T1, T2), or loopy graphs (L1,. . . , L4). We used several factor graphs that differ only by one or two added factors and compared the results. The graphs were designed by hand; they connect some forms with similar morphological properties more or less densely.

We trained different models using the observed forms in the 9393 paradigms as training data. The first 100 paradigms were then used as development data for *model selection*:[24] we were given the answers to their hidden forms, enabling us to compare the models. The best model was then evaluated on the 9293 remaining paradigms.

7.6 Development data results

The models are compared on development data in Table 2. Among the factor graphs we evaluated, we find that L4 (see Fig. 3) performs best overall (whole-word accuracy 82.1). Note that the unconnected graph U does not perform very well (69.0), but using factor graphs with more connecting factors generally helps overall accuracy (see C1–C3). Note, however, that in some cases the additional structure hurts: The chain model C4 and the loopy model L1 perform relatively badly. The

[23] If we instead wished to maximize the fraction of entire paradigms that were predicted perfectly, then we would have approximated full MAP decoding over the paradigm (Viterbi decoding) by using max-product BP. Other loss functions (e.g., edit distance) would motivate other decoding methods.

[24] Using these paradigms was simply a quick way to avoid model selection by cross-validation. If data were really as sparse as our training setup pretends (see Table 2), then 100 complete paradigms would be too valuable to squander as mere development data.

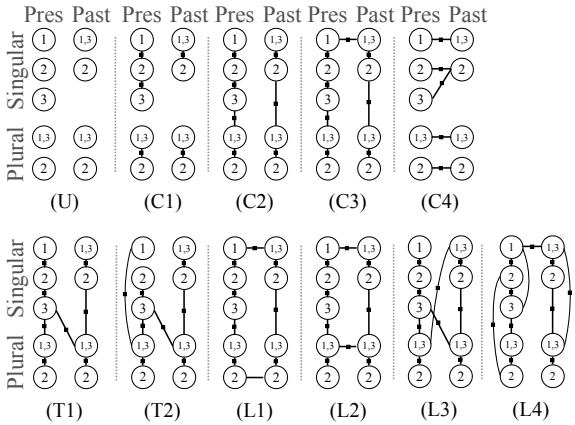

Figure 3: The graphs that we evaluate on development data. The nodes represent morphological forms, e.g. the first node in the left of each graph represents the first person singular present. Each variable is also connected to the lemma (not shown). See results in Table 2.

reason for such a performance degradation is that undertrained factors were used: The factors relating second-person to second-person forms, for example, are trained from only 8 available examples.

Non-loopy models always converge (exactly) in one iteration (see footnote 22). But even our loopy models appeared to converge in accuracy within two iterations. Only L3 and L4 required the second iteration, which made tiny improvements.

7.7 Test data results

Based on the development results, we selected model L4 and tested on the remaining 9293 paradigms.

We regard the unconnected model U as a baseline to improve upon. We also tried a rather different baseline as in (Dreyer et al., 2008). We trained the machine translation toolkit Moses (Koehn et al., 2007) to translate groups of letters rather than groups of words ("phrases"). For each form f to be predicted, we trained a Moses model on all supervised form pairs (l, f) available in the data, to learn a prediction for the form given the lemma l. The M,3 condition restricted Moses use "phrases" no longer than 3 letters, comparable to our own trigram-based factors (see section 7.2). M,15 could use up to 15 letters.

Again, our novel L4 model far outperformed the others overall. Breaking the results down by form, we find that this advantage mainly comes from the 3 forms with the fewest observed training examples (Table 3, first 3 rows). The M and U models are barely able to predict these forms at all from the lemma, but L4 can predict them bet-

Unconn.	Chains				Trees		Loops			
U	C1	C2	C3	C4	T1	T2	L1	L2	L3	L4
69.0	72.9	73.4	74.8	65.2	78.1	78.7	62.3	79.6	78.9	**82.1**

Table 2: Whole-word accuracies of the different models in reconstructing the missing forms in morphological paradigms, here on 100 verbs (development data). The names refer to the graphs in Fig. 3. We selected L4 as final model (Table 3).

Form	# obs.	M,3	M,15	U	L4
2.Sg.Pa.	4	0.0	0.2	0.8	**69.7**
2.Pl.Pa.	9	0.9	1.1	1.4	**45.6**
2.Sg.Pr.	166	49.4	62.6	74.7	**90.5**
1.Sg.Pr.	285	**99.6**	98.8	99.3	97.2
1,3.Pl.Pa.	673	46.5	**78.3**	75.0	75.6
1,3.Sg.Pa.	1124	65.0	**88.8**	84.0	74.8
2.Pl.Pr.	1274	98.3	**99.2**	99.0	96.4
3.Sg.Pr.	1410	91.0	**95.9**	95.2	88.2
1,3.Pl.Pr.	1688	**99.8**	98.9	**99.8**	98.0
All	6633	59.2	67.3	68.0	**81.2**

Table 3: Whole-word accuracies on the missing forms from 9293 test paradigms. The Moses baselines and our unconnected model (U) predict each form separately from the lemma, which is always observed. L4 uses all observations jointly, running belief propagation for decoding. Moses,15 memorizes phrases of length up to 15, all other models use max length 3. The table is sorted by the column "# obs.", which reports the numbers of observations for a given form.

ter by exploiting other observed or latent forms. By contrast, well-trained forms were already easy enough for the M and U models that L4 had little new to offer and in fact suffered from its approximate training and/or inference.

Leaving aside the comparisons, it was useful to confirm that loopy BP could be used in this setting at all. 8014 of the 9293 test paradigms had ≤ 2 observed forms (in addition to the lemma) but ≥ 7 missing forms. One might have expected that loopy BP would have failed to converge, or converged to the wrong thing. Nonetheless, it achieved quite respectable success at exactly predicting various inflected forms.

For the curious, Table 4 shows accuracies grouped by different categories of paradigms, where the category is determined by the number of missing forms to predict. Most paradigms fall in the category where 7 to 9 forms are missing, so the accuracies in that line are similar to the overall accuracies in Table 3.

# missing	# paradig.	M,3	M,15	U	L4
1–3	205	20.3	20.8	26.8	**74.4**
4–6	1037	44.2	50.5	52.7	**82.8**
7–9	8014	60.6	68.8	69.4	**81.1**

Table 4: Accuracy on test data, reported separately for paradigms in which 1–3, 4–6, or 7–9 forms are missing. Missing words have CELEX frequency count < 10; these are the ones to predict. (The numbers in col. 2 add up to 9256, not 9293, since some paradigms are incomplete in CELEX to begin with, with no forms to be removed or evaluated.)

8 Conclusions

We have proposed that one can jointly model several multiple strings by using Markov Random Fields. We described this formally as an undirected graphical model with string-valued variables and whose factors (potential functions) are defined by weighted finite-state transducers. Each factor evaluates some subset of the strings.

Approximate inference can be done by loopy belief propagation. The messages take the form of weighted finite-state acceptors, and are constructed by standard operations. We explained why the messages might become large, and gave methods for approximating them with smaller messages. We also discussed training methods.

We presented some pilot experiments on the task of jointly predicting multiple missing verb forms in morphological paradigms. The factors were simplified versions of statistical finite-state models for supervised morphology. Our MRF for this task might be used not only to conjugate verbs (e.g., in MT), but to guide further learning of morphology—either active learning from a human or semi-supervised learning from the distributional properties of a raw text corpus.

Our modeling approach is potentially applicable to a wide range of other tasks, including transliteration, phonology, cognate modeling, multiple-sequence alignment and system combination.

Our work ties into a broader vision of using algorithms like belief propagation to coordinate the work of several NLP models and algorithms. Each individual factor considers some portion of a joint problem, using classical statistical NLP methods (weighted grammars, transducers, dynamic programming). The factors coordinate their work by passing marginal probabilities. Smith and Eisner (2008) reported complementary work in this vein.

Abstract

We present a framework to extract the most important features (tree fragments) from a Tree Kernel (TK) space according to their importance in the target kernel-based machine, e.g. Support Vector Machines (SVMs). In particular, our mining algorithm selects the most relevant features based on SVM estimated weights and uses this information to automatically infer an explicit representation of the input data. The explicit features (a) improve our knowledge on the target problem domain and (b) make large-scale learning practical, improving training and test time, while yielding accuracy in line with traditional TK classifiers. Experiments on semantic role labeling and question classification illustrate the above claims.

1 Introduction

The last decade has seen a massive use of Support Vector Machines (SVMs) for carrying out NLP tasks. Indeed, their appealing properties such as 1) solid theoretical foundations, 2) robustness to irrelevant features and 3) outperforming accuracy have been exploited to design state-of-the-art language applications.

More recently, kernel functions, which implicitly represent data in some high dimensional space, have been employed to study and further improve many natural language systems, e.g. (Collins and Duffy, 2002), (Kudo and Matsumoto, 2003), (Cumby and Roth, 2003), (Cancedda et al., 2003), (Culotta and Sorensen, 2004), (Toutanova et al., 2004), (Kazama and Torisawa, 2005), (Shen et al., 2003), (Gliozzo et al., 2005), (Kudo et al., 2005), (Moschitti et al., 2008), (Diab et al., 2008). Unfortunately, the benefit to easily and effectively model the target linguistic phenomena is reduced by the the implicit nature of the kernel space, which prevents to directly observe the most relevant features. As a consequence, even very accurate models generally fail in providing useful feedback for improving our understanding of the problems at study. Moreover, the computational burden induced by high dimensional kernels makes the application of SVMs to large corpora still more problematic.

In (Pighin and Moschitti, 2009), we proposed a feature extraction algorithm for Tree Kernel (TK) spaces, which selects the most relevant features (tree fragments) according to the gradient components (weight vector) of the hyperplane learnt by an SVM, in line with current research, e.g. (Rakotomamonjy, 2003; Weston et al., 2003; Kudo and Matsumoto, 2003). In particular, we provided algorithmic solutions to deal with the huge dimensionality and, consequently, high computational complexity of the fragment space. Our experimental results showed that our approach reduces learning and classification processing time leaving the accuracy unchanged.

In this paper, we present a new version of such algorithm which, under the same parameterization, is almost three times as fast while producing the same results. Most importantly, we explored tree fragment spaces for two interesting natural language tasks: Semantic Role Labeling (SRL) and Question Classification (QC). The results show that: (a) on large data sets, our approach can improve training and test time while yielding almost unaffected classification accuracy, and (b) our framework can effectively exploit the ability of TKs and SVMs to, respectively, generate and recognize relevant structured features. In particular, we (i) study in more detail the relevant fragments identfied for the boundary classification task of SRL, (ii) closely observe the most relevant fragments for each QC class and (iii) look at the diverse syntactic patterns characterizing each ques-

tion category.

The rest of the paper is structured as follows: Section 2 will briefly review SVMs and TK functions; Section 3 will detail our proposal for the linearization of a TK feature space; Section 4 will review previous work on related subjects; Section 5 will detail the outcome of our experiments, and Section 6 will discuss some relevant aspects of the evaluation; finally, in Section 7 we will draw our conclusions.

2 Tree Kernel Functions

The decision function of an SVM is:

$$f(\vec{x}) = \vec{w} \cdot \vec{x} + b = \sum_{i=1}^{n} \alpha_i y_i \vec{x_i} \cdot \vec{x} + b \qquad (1)$$

where $\vec{x}$ is a classifying example and $\vec{w}$ and b are the separating hyperplane's *gradient* and its *bias*, respectively. The gradient is a linear combination of the training points $\vec{x_i}$, their labels y_i and their weights α_i. Applying the so-called *kernel trick* it is possible to replace the scalar product with a *kernel function* defined over pairs of *objects*:

$$f(o) = \sum_{i=1}^{n} \alpha_i y_i \mathrm{k}(o_i, o) + b$$

with the advantage that we do not need to provide an explicit mapping $\phi(\cdot)$ of our examples in a vector space.

A Tree Kernel function is a convolution kernel (Haussler, 1999) defined over pairs of trees. Practically speaking, the kernel between two trees evaluates the number of substructures (or *fragments*) they have in common, i.e. it is a measure of their overlap. The function can be computed recursively in closed form, and quite efficient implementations are available (Moschitti, 2006). Different TK functions are characterized by alternative fragment definitions, e.g. (Collins and Duffy, 2002) and (Kashima and Koyanagi, 2002). In the context of this paper we will be focusing on the SubSet Tree (SST) kernel described in (Collins and Duffy, 2002), which relies on a fragment definition that does not allow to break production rules (i.e. if any child of a node is included in a fragment, then also all the other children have to). As such, it is especially indicated for tasks involving constituency parsed texts.

Implicitly, a TK function establishes a correspondence between distinct fragments and dimensions in some *fragment space*, i.e. the space of all the possible fragments. To simplify, a tree t can be represented as a vector whose attributes count the occurrences of each fragment within the tree. The kernel between two trees is then equivalent to the scalar product between pairs of such vectors, as exemplified in Figure 1.

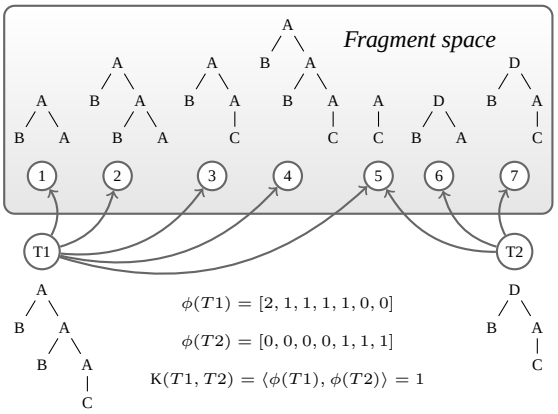

Figure 1: Esemplification of a fragment space and the kernel product between two trees.

3 Linearization of a TK function

Our objective is to efficiently mine the most relevant fragments from the huge fragment space, so that we can explicitly represent our input trees in terms of these fragments and learn fast and accurate linear classifiers.

The framework defines five distinct activities, detailed in the following paragraphs.

3.1 Kernel Space Learning (*KSL*)

The first step involves the generation of an approximation of the whole fragment space, i.e. we can consider only the trees that encode the most relevant fragments. To this end, we can partition our training data into S smaller sets, and use the SVM and the SST kernel to learn S models. We will only consider the fragments encoded by the support vectors of the S models. In the next stage, we will use the SVM estimated weights to drive our feature selection process.

Since time complexity of SVM training is approximately quadratic in the number of examples, by breaking training data into smaller sets we can considerably accelerate the process of filtering trees and estimating support vector weights. According to statistical learning theory, being trained on smaller subsets of the available data these models will be less robust with respect to the minimization of the empirical risk (Vapnik, 1998).

Algorithm 3.1: MINE_MODEL(M, L, λ)

```
global maxexp
prev ← ∅ ; CLEAR_INDEX()
for each ⟨αy, t⟩ ∈ M
do { T_i ← α · y/‖t‖
     for each n ∈ N_t
     do { f ← FRAG(n) ; rel = λ · T_i
          prev ← prev ∪ {f, rel}
          PUT(f, rel) }
best_pr ← BEST(L) ;
while true
do { next ← ∅
     for each ⟨f, rel⟩ ∈ prev if f ∈ best_pr
     do { X = EXPAND(f, maxexp)
          rel_exp ← λ · rel
          for each frag ∈ X
          do { temp = {frag, rel_exp}
               next ← next ∪ temp
               PUT(frag, rel_exp) }
     best ← BEST(L)
     if not CHANGED()
       then break
     best_pr ← best
     prev ← next }
F_L ← best_pr
return (F_L)
```

Nonetheless, since we do not need to employ them for classification (but just to direct our feature selection process, as we will describe shortly), we can accept to rely on sub-optimal weights. Furthermore, research results in the field of SVM parallelization using cascades of SVMs (Graf et al., 2004) suggest that support vectors collected from locally learnt models can encode many of the relevant features retained by models learnt globally. Henceforth, let M_s be the model associated with the s-th split, and $\mathcal{F}_s$ the fragment space that can describe all the trees in M_s.

3.2 Fragment Mining and Indexing (*FMI*)

In Equation 1 it is possible to isolate the gradient $\vec{w} = \sum_{i=1}^{n} \alpha_i y_i \vec{x_i}$, with $\vec{x_i} = [x_i^{(1)}, \ldots, x_i^{(N)}]$, N being the dimensionality of the feature space. For a tree kernel function, we can rewrite $x_i^{(j)}$ as:

$$x_i^{(j)} = \frac{t_{i,j}\lambda^{\ell(f_j)}}{\|t_i\|} = \frac{t_{i,j}\lambda^{\ell(f_j)}}{\sqrt{\sum_{k=1}^{N}(t_{i,k}\lambda^{\ell(f_k)})^2}} \quad (2)$$

where: $t_{i,j}$ is the number of occurrences of the fragment f_j, associated with the j-th dimension of the feature space, in the tree t_i; λ is the kernel decay factor; and $\ell(f_j)$ is the depth of the fragment.

The relevance $|w^{(j)}|$ of the fragment f_j can be measured as:

$$|w^{(j)}| = \left|\sum_{i=1}^{n} \alpha_i y_i x_i^{(j)}\right| = \frac{\left|\sum_{i=1}^{n} \alpha_i y_i t_{i,j} \lambda^{\ell(f_j)}\right|}{\|t_i\|} . \quad (3)$$

We fix a threshold L and from each model M_s (learnt during KSL) we select the L most relevant fragments, i.e. we build the set $\mathcal{F}_{s,L} = \cup_k \{f_k\}$ so that:

$$|\mathcal{F}_{s,L}| = L \text{ and } |w^{(k)}| \geq |w^{(i)}| \forall f_i \in \mathcal{F} \setminus \mathcal{F}_{s,L} .$$

To generate all the fragments encoded in a model, we adopt the greedy strategy described in Algorithm 3.1. Its arguments are: an SVM model M represented as $\langle \alpha y, t \rangle$ pairs, where t is a tree structure; the threshold value L; and the kernel decay factor λ.

The function FRAG(n) generates the smallest fragment rooted in node n (i.e. for an SST kernel, the fragment consisting of n and its direct children). We call such fragment a *base* fragment. The function EXPAND($f, maxexp$) generates all the fragments that can be derived from the fragment f by expanding, i.e. including in the fragment the direct children of some of its nodes. These fragments are *derived* from f. The parameter $maxexp$ limits fragment proliferation by setting the maximum number of nodes which can be expanded in a fragment expansion operation. For example, if there are 10 nodes which can be expanded in fragment f, then only the fragments where at most 3 of the 10 nodes are expanded will be generated by a call to EXPAND($f, 3$).

Every time we generate a fragment f, the function PUT(f, rel) saves the fragment along with its relevance rel in an *index*. The index keeps track of the cumulative relevance of a fragment, and its implementation has been optimized for fast insertions and spatial compactness.

A whole cycle of expansions is considered as an iteration of the mining process: we take into account all the fragments that have undergone k expansions and produce all the fragments that result from a further expansion, i.e. all the fragments expanded $k+1$ times.

We keep iterating until we reach a stop criterion, which we base on the threshold value L, i.e. the limit on the number of fragments that we are interested in mining from a model. During each iteration $k+1$, we only expand the best L fragments identified during the previous iteration k. When

the iteration is complete we re-evaluate the set of L best fragments in the index, and we stop only if the worst of them, i.e. the L-th ranked fragment at the step $k+1$, and its score are the same as at the end of the previous iteration. That is, we assume that if none of the fragments mined during the $(k+1)$-th iteration managed to affect the bottom of the pool of the L most relevant fragments, then none of their expansions is likely to succeed. In the algorithm, $\mathcal{N}_t$ is the set of nodes of the tree t; BEST(L) returns the L highest ranked fragments in the index; CHANGED$()$ verifies whether the bottom of the L-best set has been affected by the last iteration or not.

We call MINE_MODEL$(\cdot)$ on each of the models M_s that we learnt from the S initial splits. For each model, the function returns the set of L-best fragments in the model. The union of all the fragments harvested from each model is then saved into a dictionary $\mathcal{D}_L$ which will be used by the next stage.

3.2.1 Discussion on FMI algorithm

With respect to the algorithm presented in (Pighin and Moschitti, 2009), the one presented here has the following advantages:

- the process of building fragments is strictly small-to-large: fragments that span $n+1$ levels of the tree may be generated only after all those spanning n levels;
- the threshold value L is a parameter of the mining process, and it is used to prevent the algorithm from generating more fragments than necessary, thus making it more efficient;
- it has one less parameter ($maxdepth$) which was used to force fragments to span at-most a given number of levels. The new algorithm does not need it since the maximum number of iterations is implicitly set via L.

These differences result in improved efficiency for the FMI stage. For example, on the data for the boundary classification task (see Section 5), using comparable parameters the old algorithm required 85 minutes to mine the most relevant fragments, whereas the new one only takes 31, i.e. it is 2.74 times as fast.

3.3 Tree Fragment Extraction (*TFX*)

During this phase we actually linearize our data: a file encoding label-tree pairs $\langle y_i, t_i \rangle$ is transformed to encode label-vector pairs $\langle y_i, \vec{v_i} \rangle$. To do so, we generate the fragment space of t_i, using a variant of the mining algorithm described in Algorithm 3.1, and encode in $\vec{v_i}$ all and only the fragments $t_{i,j}$ so that $t_{i,j} \in \mathcal{D}_L$. The algorithm exploits labels and production rules found in the fragments listed in the dictionary to generate only the fragments that *may be* in the dictionary. For example, if the dictionary does not contain a fragment whose root is labeled N, then if a node N is encountered during TFX neither its base fragment nor its expansions are generated. The process is applied to the whole training (*TFX-train*) and test (*TFX-test*) sets. The fragment space is now *explicit*, as there is a mapping between the input vectors and the fragments they encode.

3.4 Explicit Space Learning (*ESL*)

Linearized training data is used to learn a very fast model by using all the available data and a linear kernel.

3.5 Explicit Space Classification (*ESC*)

The linear model is used to classify linearized test data and evaluate the accuracy of the resulting classifier.

4 Previous work

A rather comprehensive overview of feature selection techniques is carried out in (Guyon and Elisseeff, 2003). Non-filter approaches for SVMs and kernel machines are often concerned with polynomial and Gaussian kernels, e.g. (Weston et al., 2001) and (Neumann et al., 2005). Weston et al. (2003) use the ℓ_0 norm in the SVM optimizer to stress the feature selection capabilities of the learning algorithm. In (Kudo and Matsumoto, 2003), an extension of the PrefixSpan algorithm (Pei et al., 2001) is used to efficiently mine the features in a low degree polynomial kernel space. The authors discuss an approximation of their method that allows them to handle high degree polynomial kernels.

Suzuki and Isozaki (2005) present an embedded approach to feature selection for convolution kernels based on χ^2-driven relevance assessment. To our knowledge, this is the only published work clearly focusing on feature selection for tree kernel functions, and indeed has been one of the major sources of inspiration for our methodology. With respect to their work, the difference

in our approach is that we want to exploit the SVM optimizer to select the most relevant features instead of a relevance assessment measure that moves from different statistical assumptions than the learning algorithm.

In (Graf et al., 2004), an approach to SVM parallelization is presented which is based on a divide-et-impera strategy to reduce optimization time. The idea of using a compact graph representation to represent the support vectors of a TK function is explored in (Aiolli et al., 2006), where a Direct Acyclic Graph (DAG) is employed. In (Moschitti, 2006; Bloehdorn and Moschitti, 2007a; Bloehdorn and Moschitti, 2007b; Moschitti et al., 2007), the SST kernel along with other tree and combined kernels are employed for question classification and semantic role labeling with interesting results.

5 Experiments

We evaluated the capability of our model to extract relevant features on two data sets: the CoNLL 2005 shared task on Semantic Role Labeling (SRL) (Carreras and Màrquez, 2005), and the Question Classification (QC) task based on data from the TREC 10 QA competition (Voorhees, 2001). The next sections will detail the setup and outcome of the two sets of experiments.

All the experiments were run on a machine equipped with 4 Intel® Xeon® CPUs clocked at 1.6 GHz and 4 GB of RAM. As a supervised learning framework we used SVM-Light-TK[1], which extends the SVM-Light optimizer (Joachims, 2000) with tree kernel support. For each classification task, we compare the accuracy of a vanilla SST classifier against the corresponding linearized SST classifier (SST$_\ell$). For KSL and SST training we used the default decay factor $\lambda = 0.4$. For ESL, we use a non-normalized, linear kernel. No further parametrization of the learning algorithms is carried out. Indeed, our focus is on showing that, under the same conditions, our linearized tree kernel can be as accurate as the original kernel, and choosing of parameters may just bias such test.

5.1 Semantic Role Labeling

For our experiments on semantic role labeling we used PropBank annotations (Palmer et al., 2005) and automatic Charniak parse trees (Charniak, 2000) as provided for the CoNLL 2005 evaluation campaign (Carreras and Màrquez, 2005). SRL can be decomposed into two tasks: *boundary detection*, where the word sequences that are arguments of a predicate word w are identified, and *role classification*, where each argument is assigned the proper role. The former task requires a binary *Boundary Classifier* (BC), whereas the second involves a *Role Multi-class Classifier* (RM).

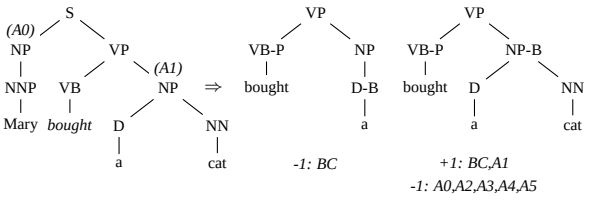

Figure 2: Examples of AST$_m$ structured features.

5.1.1 Setup

If the constituency parse tree t of a sentence s is available, we can look at all the pairs $\langle p, n_i \rangle$, where n_i is any node in the tree and p is the node dominating w, and decide whether n_i is an *argument node* or not, i.e. whether it exactly dominates all and only the words encoding any of w's arguments. The objects that we classify are subsets of the input parse tree that encompass both p and n_i. Namely, we use the AST$_m$ structure defined in (Moschitti et al., 2008), which is the minimal tree that covers all and only the words of p and n_i. In the AST$_m$, p and n_i are marked so that they can be distinguished from the other nodes. An AST$_m$ is regarded as a positive example for BC if n_i is an argument node, otherwise it is considered a negative example. Positive BC examples can be used to train an efficient RM: for each role r we can train a classifier whose positive examples are argument nodes whose label is exactly r, whereas negative examples are argument nodes labeled $r' \neq r$. Two AST$_m$s extracted from an example parse tree are shown in Figure 2: the first structure is a negative example for BC and is not part of the data set of RM, whereas the second is a positive instance for BC and A1.

To train BC we used PropBank sections 1 through 6, extracting AST$_m$ structures out of the first 1 million $\langle p, n_i \rangle$ pairs from the corresponding parse trees. As a test set we used the 149,140 instance collected from the annotations in Section 24. There are 61,062 positive examples in the training set (i.e. 6.1%) and 8,515 in the test set

[1] `http://disi.unitn.it/~moschitt/Tree-Kernel.htm`

(i.e. 5.7%).

For RM we considered all the argument nodes of any of the six PropBank core roles (i.e. A0, ..., A5) from all the available training sections, i.e. 2 through 21, for a total of 179,091 training instances. Similarly, we collected 5,928 test instances from the annotations of Section 24. Columns *Tr*$^+$ and *Te*$^+$ of Table 1 show the number of positive training and test examples, respectively, for BC and the role classifiers.

For all the linearized classifiers, we used 50 splits for the FMI stage and we set the threshold value $L = 50k$ and $maxexp = 1$ during FMI and TFX. We did not validate these parameters, which we know to be sub-optimal. These values were selected during the development of the software because, on a very small test bed, they resulted in a responsive and accurate system.

We should point out that other experiments have shown that linearization is very robust with respect to parametrization: due to the huge number and variety of fragments in the TK space, different choices of the parameters result in different explicit spaces and more or less efficient solutions, but in most cases the final accuracy of the linearized classifiers is affected only marginally. For example, it could be expected that reducing the number of splits during KSL would improve the final accuracy of a linearized classifier, as the weights used for FMI would then converge to the global optimum. Instead, we have observed that increasing the number of splits does not necessarily decrease the accuracy of the linearized classifier.

The evaluation on the whole SRL task using the official CoNLL'05 evaluator was not carried out because producing complete annotations requires several steps (e.g. overlap resolution, OvA or Pairwise combination of individual role classifiers) that would shade off the actual impact of the methodology on classification.

5.1.2 Results

The left side of Table 1 shows the distribution of positive data points in the training and test sets of each classifier. Columns *SST* and *SST*$_\ell$ compare side by side the F_1 measure of the non-linearized and linearized classifier for each class. The accuracy of the RM classifier is the percentage of correct class assignments.

We can see that the accuracy of linearized classifiers is always in line with vanilla SST, even if the selected linearization parameters generate a very rough approximation of the original fragment space, generally consisting of billions of fragments. BC$_\ell$ (i.e. the linearized BC) has an F_1 of 81.3, just 0.5% less than BC, i.e. 81.8. Concerning RM$_\ell$, its accuracy is the same as the non linearized classifier, i.e. 87.8.

	Data set		Accuracy	
Class	Tr$^+$	Te$^+$	SST	SST$_\ell$
BC	61,062	8,515	81.8	81.3
A0	60,900	2,014	91.6	91.1
A1	90,636	3,041	89.0	89.4
A2	21,291	697	73.1	73.0
A3	3,481	105	56.8	53.0
A4	2,713	69	69.1	67.9
A5	69	2	66.7	0.0
RM			87.8	87.8

Table 1: Number of positive training (Tr$^+$) and test (Te$^+$) examples in the SRL dataset. Accuracy of the non-linearized (SST) and linearized (SST$_\ell$) binary classifiers (i.e. BC, A0, ... A5) is F_1 measure. Accuracy of RM is the percentage of correct class assignments.

We should consider that the linearization framework can drastically improve the efficiency of learning and classification when dealing with large amounts of data. For a linearized classifier, we consider *training time* to be the overall time required to carry out the following activities: KSL, FMI, TFX on training data and ESL. Similarly, we consider test time the time necessary to perform TFX on test data and ESC. Training BC took more than two days of CPU time and testing about 4 hours, while training and testing the linearized boundary classifier required only 381 and 25 minutes, respectively. That is, on the same amount of data we can train a linearized classifier about 8 times as fast, and test it in about 1 tenth of the time. Concerning RM, sequential training of the 6 models took 2,596 minutes, while testing took 27 minutes. The linearized role multi classifier required 448 and 24 minutes for training and testing, respectively, i.e. training is about 5 times as fast while testing time is about the same. If compared with the boundary classifier, the improvement in efficiency is less evident: indeed, the relatively small size of the role classifiers data sets limits the positive effect of splitting training data into smaller chunks.

SRL fragment space. Table 3 lists the best fragments identified for the Boundary Classifier. We should remember that we are using AST$_m$ struc-

tures as input to our classifiers: nodes whose label end with "-P" are predicate nodes, while nodes whose label ends with "-B" are candidate argument nodes.

All the most relevant fragments encode the minimum sub-tree encompassing the predicate and the argument node. This kind of structured feature subsumes several features traditionally employed for explicit SRL models: the Path (i.e. the sequence of nodes connecting the predicate and the candidate argument node), Phrase Type (i.e. the label of the candidate argument node), Predicate POS (i.e. the POS of the predicate word), Position (i.e. whether the argument is to the left or to the right of the predicate) and Governing Category (i.e. the label of the common ancestor) defined in (Gildea and Jurafsky, 2002).

The linearized model for BC contains about 160 thousand fragments. Of these, about 70 and 33 thousand encompass the candidate argument or the predicate node, respectively. About 16 thousand fragments contain both.

5.2 Question Classification

For question classification we used the data set from the TREC 10 QA evaluation campaign[2], consisting of 5,500 training and 500 test questions.

5.2.1 Setup

Given a question, the QC task consists in selecting the most appropriate expected answer type from a given set of possibilities. We adopted the question taxonomy known as *coarse grained*, which has been described in (Zhang and Lee, 2003) and (Li and Roth, 2006), consisting of six non overlapping classes: Abbreviations (ABBR), Descriptions (DESC, e.g. definitions or explanations), Entity (ENTY, e.g. animal, body or color), Human (HUM, e.g. group or individual), Location (LOC, e.g. cities or countries) and Numeric (NUM, e.g. amounts or dates).

For each question, we generate the full parse of the sentence and use it to train SST and (linearized) SST_ℓ models. The automatic parses are obtained with the Stanford parser[3] (Klein and Manning, 2003). We actually have only 5,483 sentences in our training set, due to parsing issues with a few of them.

[2] `http://l2r.cs.uiuc.edu/cogcomp/Data/QA/QC/`

[3] `http://nlp.stanford.edu/software/lex-parser.shtml`

Class	Data set Tr^+	Te^+	Accuracy SST	SST_ℓ
ABBR	89	9	80.0	87.5
DESC	1,164	138	96.0	94.5
ENTY	1,269	94	63.9	63.5
HUM	1,231	65	88.1	87.2
LOC	834	81	77.6	77.9
NUM	896	113	80.4	80.8
Overall			86.2	86.6

Table 2: Number of positive training (Tr^+) and test (Te^+) examples in the QA dataset. Accuracy of the non-linearized (SST) and linearized (SST_ℓ) binary classifiers is F_1 measure. Overall accuracy is the percentage of correct class assignments.

The classifiers are arranged in a one-vs.-all (OvA) configuration, where each sentence is a positive example for one of the six classes, and negative for the other five. Given the very small size of the data set, we used $S = 1$ during KSL for the linearized classifier (i.e. we didn't partition training data). We carried out no validation of the parameters, and we used $maxexp = 4$ and $L = 50k$ in order to generate a rich fragment space.

5.2.2 Results

Table 2 shows the number of positive examples in the training and test set of each individual binary classifiers. Columns SST and SST_ℓ compare the F_1 measure of the vanilla and linearized classifiers on the individual classes, and the accuracy of the complete QC task (Row *Overall*) in terms of percentage of correct class assignments. Also in this case, we can notice that the accuracy of the linearized classifiers is always in line with non-linearized ones, e.g. 86.6 vs. 86.2 for the multi-classifiers. These results are lower than those derived in (Moschitti, 2006; Moschitti et al., 2007), i.e. 88.2 and 90.4, respectively, where the parameters for each classifier were carefully optimized.

QC Fragment space. Tables from 4 to 9 list the top fragments identified for each class [4].

As expected, for all the categories the domain lexical information is very relevant. For example, *film*, *color*, *book*, *novel* and *sport* for ENTY or *city*, *country*, *state* and *capital* for LOC. Of the six classes, ENTY (Table 6) is mostly characterized by lexical features. Interestingly, function words, which would have been eliminated by a pure Information Retrieval approach (i.e. by means of

[4] Some categories show meaningful syntactic fragments after the first 10, so for them we report more subtrees.

standard stop-list), are in the top positions, e.g.: *why* and *how* for DESC, *what* for ENTY, *who* for HUM, *where* for LOC and *when* for NUM. For the latter, also *how* seems to be important suggesting that features may strongly characterize more than one given class.

Characteristic syntactic features appear in the top positions for each class, for example: *(VP (VB (stand)) (PP))*, which suggests that *stand* should be followed by a prepositional phrase to characterize ABBR; or *(NP (NP (DT) (NN (abbreviation))) (PP))*, which suggests that, to be in a relevant pattern, *abbreviation* should be preceded by an article and followed by a PP. Also, the syntactic structure is useful to differentiate the use of the same important words, e.g. *(SBARQ (WHADVP (WRB (How))) (SQ) (.))* for DESC better characterizes the use of *how* with respect to NUM, in which a relevant use is *(WHADJP (WRB (How)) (JJ))*.

In (Moschitti et al., 2007) it was shown that the use of TK improves QC of 1.2 percent points, i.e. from 90.6 to 91.8: further analysis of these fragments may help us to device compact, less sparse syntactic features and design more accurate models for the task.

6 Discussion

The fact that our model doesn't always improve the accuracy of a standard SST model might be related to the process of splitting training data and employing locally estimated weights during FMI.

Concerning the experiments presented in this paper, this objection might apply to the results on SRL, where we used 50 splits to identify the most relevant fragments, but not to those on QC, where given the limited size of the data set we decided not to split training data at all as explained in Section 5.2. Furthermore, as we already discussed, we have evidence that there is no direct correlation between the number of splits used for KSL and the accuracy of the resulting classifier. After all, the optimization carried out during ESL is global, and we can assume that, if we mined enough fragments during FMI, than those actually retained by the global linear model would be by and large the same, regardless of the split configuration.

More in general, feature selection may give an improvement to some learning algorithm but if it can help SVMs is debatable, since its related theory show that they are robust to irrelevant features. In our specific case, we remove features

whose SVM weights are the lowest, i.e. those that are (almost) irrelevant for the SVM. Therefore, the chance of this resulting in an improvement is rather low.

With respect to cases where our model is less accurate than a standard SST, we should consider that our choice of parameters is sub-optimal and we adopt a *very* aggressive feature selection strategy, that only retains a few thousand features from a space where there are hundreds of millions of different features.

7 Conclusions

We introduced a novel framework for support vector classification that combines advantages of convolution kernels, i.e. the generation of a very high dimensional structure space, with the efficiency and clarity of explicit representations in a linear space.

For this paper, we focused on the SubSet Tree kernel and verified the potential of the proposed solution on two NLP tasks, i.e. semantic role labeling and question classification. The experiments show that our framework drastically reduces processing time, e.g. boundary classification for SRL, while preserving the accuracy.

We presented a selection of the most relevant fragments identified for the SRL boundary classifier as well as for each class of the coarse grained QC task. Our analysis shows that our framework can discover state-of-the-art features, e.g. the Path feature for SRL. We believe that sharing these fragments with the NLP community and studying them in more depth will be useful to identify new, relevant features for the characterization of several learning problems. For this purpose, we made available the fragment spaces at `http://danielepighin.net` and we will keep them updated with new set of experiments on new tasks, e.g. SRL based on FrameNet and VerbNet, e.g. (Giuglea and Moschitti, 2004).

In our future work, we plan to widen the list of covered tasks and to extend our algorithm to cope with different kernel families, such as the partial tree kernel and kernels defined over pairs of trees, e.g. the ones used for textual entailment in (Moschitti and Zanzotto, 2007). We also plan to move from mining fragments to mining classes of fragments, i.e. to identify prototypical fragments in the fragment space that generalize topological sub-classes of the most relevant fragments.

Abstract

Because of the importance of protein-protein interaction (PPI) extraction from text, many corpora have been proposed with slightly differing definitions of proteins and PPI. Since no single corpus is large enough to saturate a machine learning system, it is necessary to learn from multiple different corpora. In this paper, we propose a solution to this challenge. We designed a rich feature vector, and we applied a support vector machine modified for corpus weighting (SVM-CW) to complete the task of multiple corpora PPI extraction. The rich feature vector, made from multiple useful kernels, is used to express the important information for PPI extraction, and the system with our feature vector was shown to be both faster and more accurate than the original kernel-based system, even when using just a single corpus. SVM-CW learns from one corpus, while using other corpora for support. SVM-CW is simple, but it is more effective than other methods that have been successfully applied to other NLP tasks earlier. With the feature vector and SVM-CW, our system achieved the best performance among all state-of-the-art PPI extraction systems reported so far.

1 Introduction

The performance of an information extraction program is highly dependent on various factors, including text types (abstracts, complete articles, reports, etc.), exact definitions of the information to be extracted, shared sub-topics of the text collections from which information is to be extracted. Even if two corpora are annotated in terms of the same type of information by two groups, the performance of a program trained by one corpus is unlikely to be reproduced in the other corpus. On the other hand, from a practical point of view, it is worth while to effectively use multiple existing annotated corpora together, because it is very costly to make new annotations.

One problem with several different corpora is protein-protein interaction (PPI) extraction from text. While PPIs play a critical role in understanding the working of cells in diverse biological contexts, the manual construction of PPI databases such as BIND, DIP, HPRD, IntAct, and MINT (Mathivanan et al., 2006) is known to be very time-consuming and labor-intensive. The automatic extraction of PPI from published papers has therefore been a major research topic in Natural Language Processing for Biology (BioNLP).

Among several PPI extraction task settings, the most common is sentence-based, pair-wise PPI extraction. At least four annotated corpora have been provided for this setting: AIMed (Bunescu et al., 2005), HPRD50 (Fundel et al., 2006), IEPA (Ding et al., 2002), and LLL (Nédellec, 2005). Each of these corpora have been used as the standard corpus for training and testing PPI programs. Moreover, several corpora are annotated for more types of events than just for PPI. Such examples include BioInfer (Pyysalo et al., 2007), and GENIA (Kim et al., 2008a), and they can be reorganized into PPI corpora. Even though all of these corpora were made for PPI extraction, they were constructed based on different definitions of proteins and PPI, which reflect different biological research interests (Pyysalo et al., 2008).

Research on PPI extraction so far has revealed that the performance on each of the corpora could

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 121–130,
Singapore, 6-7 August 2009.

benefit from additional examples (Airola et al., 2008). Learning from multiple annotated corpora could lead to better PPI extraction performance. Various research paradigms such as inductive transfer learning (ITL) and domain adaptation (DA) have mainly focused on how to effectively use corpora annotated by other groups, by reducing the incompatibilities (Pan and Yang, 2008).

In this paper, we propose the extraction of PPIs from multiple different corpora. We design a rich feature vector, and as an ITL method, we apply a support vector machine (SVM) modified for corpus weighting (SVM-CW) (Schweikert et al., 2008), in order to evaluate the use of multiple corpora for the PPI extraction task. Our rich feature vector is made from multiple useful kernels, each of which is based on multiple parser inputs, proposed by Miwa et al. (2008). The system with our feature vector was better than or at least comparable to the state-of-the-art PPI extraction systems on every corpus. The system is a good starting point to use the multiple corpora. Using one of the corpora as the target corpus, SVM-CW weights the remaining corpora (we call them the source corpora) with "goodness" for training on the target corpus. While SVM-CW is simple, we show that SVM-CW can improve the performance of the system more effectively and more efficiently than other methods proven to be successful in other NLP tasks earlier. As a result, SVM-CW with our feature vector is comprised of a PPI system with five different models, of which each model is superior to the best model in the original PPI extraction task, which used only the single corpus.

2 Related Works

While sentence-based, pair-wise PPI extraction was initially tackled by using simple methods based on co-occurrences, lately, more sophisticated machine learning systems augmented by NLP techniques have been applied (Bunescu et al., 2005). The task has been tackled as a classification problem. To pull out useful information from NLP tools including taggers and parsers, several kernels have been applied to calculate the similarity between PPI pairs. Miwa et al. (2008) recently proposed the use of multiple kernels using multiple parsers. This outperformed other systems on the AIMed, which is the most frequently used corpus for the PPI extraction task, by a wide margin.

To improve the performance using external

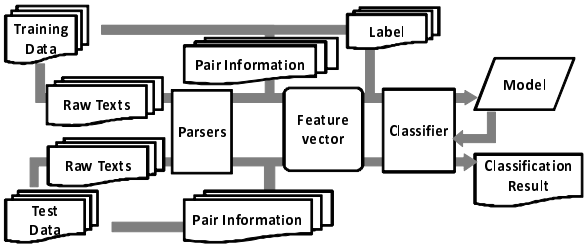

Figure 1: Overview of our PPI extraction system

training data, many ITL and DA methods have been proposed. Most of ITL methods assume that the feature space is same, and that the labels may be different in only some examples, while most of DA methods assume that the labels are the same, and that the feature space is different. Among the methods, we use adaptive SVM (aSVM) (Yang et al., 2007), singular value decomposition (SVD) based alternating structure optimization (SVD-ASO) (Ando et al., 2005), and transfer AdaBoost (TrAdaBoost) (Dai et al., 2007) to compare with SVM-CW. We do not use semi-supervised learning (SSL) methods, because it would be considerably costly to generate enough clean unlabeled data needed for SSL (Erkan et al., 2007). aSVM is seen as a promising DA method among several modifications of SVM including SVM-CW. aSVM tries to find a model that is close to the one made from other classification problems. SVD-ASO is one of the most successful SSL, DA, or multi-task learning methods in NLP. The method tries to find an additional useful feature space by solving auxiliary problems that are close to the target problem. With well-designed auxiliary problems, the method has been applied to text classification, text chunking, and word sense disambiguation (Ando, 2006). The method was reported to perform better than or comparable to the best state-of-the-art systems in all of these tasks. TrAdaBoost was proposed as an ITL method. In training, the method reduces the effect of incompatible examples by decreasing their weights, and thereby tries to use useful examples from source corpora. The method has been applied to text classification, and the reported performance was better than SVM and transductive SVM (Dai et al., 2007).

3 PPI Extraction System

The target task of our system is a sentence-based, pair-wise PPI extraction. It is formulated as a classification problem that judges whether a given pair

XPG$_{p1}$ protein interacts with multiple subunits of **TFIIH**$_{prot}$ and with **CSB**$_{p2}$ protein.

Figure 2: A sentence including an interacting protein pair (p1, p2). (AIMed PMID 8652557, 9th sentence, 3rd pair)

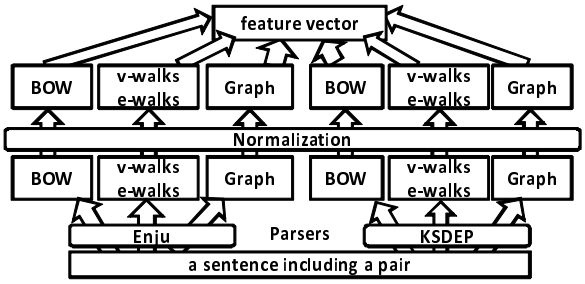

Figure 3: Extraction of a feature vector from the target sentence

of proteins in a sentence is interacting or not. Figure 2 shows an example of a sentence in which the given pair (p1 and p2) actually interacts.

Figure 1 shows the overview of the proposed PPI extraction system. As a classifier using a single corpus, we use the 2-norm soft-margin linear SVM (L2-SVM) classifier, with the dual coordinate decent (DCD) method, by Hsieh et al. (2008). In this section, we explain the two main features: the feature vector, and the corpus weighting method for multiple corpora.

3.1 Feature Vector

We propose a feature vector with three types of features, corresponding to the three different kernels, which were each combined with the two parsers: the Enju 2.3.0, and KSDEP beta 1 (Miyao et al., 2008); this feature vector is used because the kernels with these parsers were shown to be effective for PPI extraction by Miwa et al. (2008), and because it is important to start from a good performance single corpus system. Both parsers were retrained using the GENIA Treebank corpus provided by Kim et al. (2003). By using our linear feature vector, we can perform calculations faster by using fast linear classifiers like L2-SVM, and we also obtain a more accurate extraction, than by using the original kernel method.

Figure 3 summarizes the way in which the feature vector is constructed. The system extracts Bag-of-Words (BOW), shortest path (SP), and graph features from the output of two parsers. The

PROT_M:1, and_M:1, interact_M:1, multiple_M:1, of_M:1, protein_M:1, subunit_M:1, with_M:2, protein_A:1

Figure 4: Bag-of-Words features of the pair in Figure 2 with their positions (B:Before, M:in the Middle of, A:After) and frequencies.

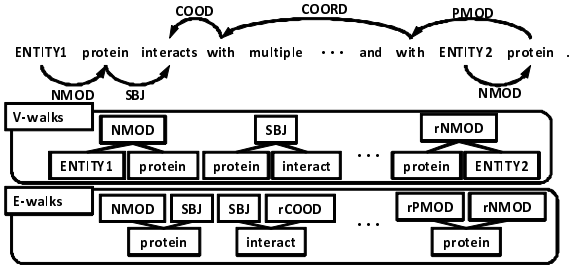

Figure 5: Vertex walks, edge walks in the upper shortest path between the proteins in the parse tree by KSDEP. The walks and their subsets are used as the shortest path features of the pair in Figure 2.

output is grouped according to the feature-type and parser, and each group of features is separately normalized by the L2-norm[1]. Finally, all values are put into a single feature vector, and the whole feature vector is then also normalized by the L2-norm. The features are constructed by using predicate argument structures (PAS) from Enju, and by using the dependency trees from KSDEP.

3.1.1 Bag-of-Words (BOW) Features

The BOW feature includes the lemma form of a word, its relative position to the target pair of proteins (Before, Middle, After), and its frequency in the target sentence. BOW features form the BOW kernel in the original kernel method. BOW features for the pair in Figure 2 are shown in Figure 4.

3.1.2 Shortest Path (SP) Features

SP features include vertex walks (v-walks), edge walks (e-walks), and their subsets (Kim et al., 2008b) on the target pair in a parse structure, and represent the connection between the pair. The features are the subsets of the tree kernels on the shortest path (Sætre et al., 2007). Figure 5 illustrates the shortest path between the pair in Figure 2, and its v-walks and e-walks extracted from the shortest path in the parse tree by KSDEP. A v-walk includes two lemmas and their link, while

[1]The vector normalized by the L2-norm is also called a unit vector.

an e-walk includes a lemma and its two links. The links indicates the predicate argument relations for PAS, and the dependencies for dependency trees.

3.1.3 Graph Features

Graph features are made from the all-paths graph kernel proposed by Airola et al. (2008). The kernel represents the target pair using graph matrices based on two subgraphs, and the graph features are all the non-zero elements in the graph matrices.

The two subgraphs are a parse structure subgraph (PSS) and a linear order subgraph (LOS). Figure 6 describes the subgraphs of the sentence parsed by KSDEP in Figure 2. PSS represents the parse structure of a sentence. PSS has word vertices or link vertices. A word vertex contains its lemma and its part-of-speech (POS), while a link vertex contains its link. Additionally, both types of vertices contain their positions relative to the shortest path. The "IP"s in the vertices on the shortest path represent the positions, and the vertices are differentiated from the other vertices like "P", "CC", and "and:CC" in Figure 6. LOS represents the word sequence in the sentence. LOS has word vertices, each of which contains its lemma, its relative position to the target pair, and its POS.

Each subgraph is represented by a graph matrix $\boldsymbol{G}$ as follows:

$$\boldsymbol{G} = \boldsymbol{L}^T \sum_{n=1}^{\infty} \boldsymbol{A}^n \boldsymbol{L}, \qquad (1)$$

where $\boldsymbol{L}$ is a $N \times L$ label matrix, $\boldsymbol{A}$ is an $N \times N$ edge matrix, N represents the number of vertices, and L represents the number of labels. The label of a vertex includes all information described above (e.g. "ENTITY1:NN:IP" in Figure 6). If two vertices have exactly same information, the labels will be same. $\boldsymbol{G}$ can be calculated efficiently by using the Neumann Series (Airola et al., 2008). The label matrix represents the correspondence between labels and vertices. $\boldsymbol{L}_{ij}$ is 1 if the i-th vertex corresponds to the j-th label, and 0 otherwise. The edge matrix represents the connection between the pairs of vertices. $\boldsymbol{A}_{ij}$ is a weight w_{ij} (0.9 or 0.3 in Figure 6 (Airola et al., 2008)) if the i-th vertex is connected to the j-th vertex, and 0 otherwise. By this calculation, $\boldsymbol{G}_{ij}$ represent the sum of the weights of all paths between the i-th label and the j-th label.

	A	B	H	I	L

Table 1: The sizes of used PPI corpora. A:AIMed, B:BioInfer, H:HPRD50, I:IEPA, and L:LLL.

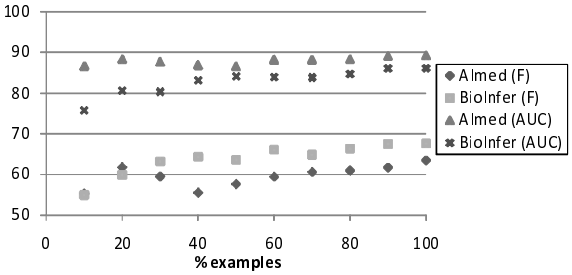

Figure 7: Learning curves on two large corpora. The x-axis is related to the percentage of the examples in a corpus. The curves are obtained by a 10-fold CV with a random split.

3.2 Corpus Weighting for Mixing Corpora

Table 1 shows the sizes of the PPI corpora that we used. Their widely-ranged differences including the sizes were manually analyzed by Pyysalo et al. (2008). While AIMed, HPRD50, IEPA, and LLL were all annotated as PPI corpora, BioInfer in its original form contains much more fine-grained information than does just the PPI. BioInfer was transformed into a PPI corpus by a program, so making it the largest of the five. Among them, AIMed alone was created by annotating whole abstracts, while the other corpora were made by annotating single sentences selected from abstracts.

Figure 7 shows the learning curves on two large corpora: AIMed and BioInfer. The curves are obtained by performing a 10-fold cross validation (CV) on each corpus, with random splits, using our system. The curves show that the performances can benefit from the additional examples. To get a better PPI extraction system for a chosen target, we need to draw useful shared information from external source corpora. We refer to examples in the source corpora as "source examples", and examples in a target corpus as "target examples". Among the corpora, we assume that the labels in some examples are incompatible, and that their distributions are also different, but that the feature space is shared.

In order to draw useful information from the source corpora to get a better model for the target

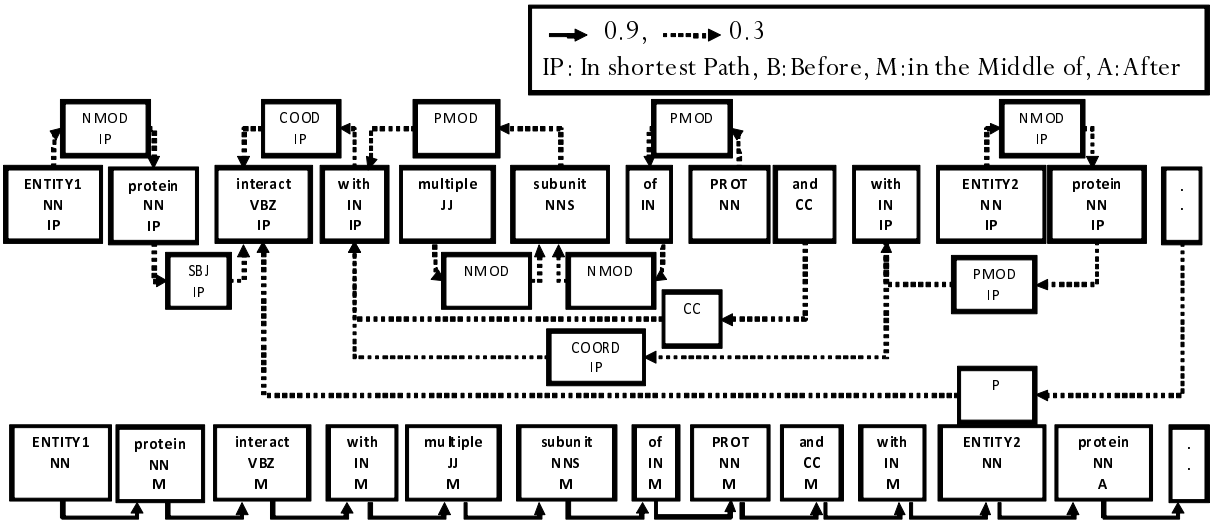

Figure 6: Parse structure subgraph and linear order subgraph to extract graph features of the pair in Figure 2. The parse structure subgraph is from the parse tree by KSDEP.

corpus, we use SVM-CW, which has been used as a DA method. Given a set of instance-label pairs ($\boldsymbol{x_i}$, y_i), $i = 1, \ldots, ls + lt$, $\boldsymbol{x_i} \in R^n$, and $y_i \in \{-1, +1\}$, we solve the following problem:

$$\min_{\boldsymbol{w}} \ \frac{1}{2}\boldsymbol{w}^T\boldsymbol{w} + C_s \sum_{i=1}^{ls} \ell_i + C_t \sum_{i=ls+1}^{ls+lt} \ell_i, \quad (2)$$

where $\boldsymbol{w}$ is a weight vector, ℓ is a loss function, and ls and lt are the numbers of source and target examples respectively. $C_s \geq 0$ and $C_t \geq 0$ are penalty parameters. We use a squared hinge loss $\ell_i = max(0, 1 - y_i \boldsymbol{w}^T \boldsymbol{x_i})^2$. Here, the source corpora are treated as one corpus. The problem, excluding the second term, is equal to L2-SVM. The problem can be solved using the DCD method.

As an ITL method, SVM-CW weights each corpus, and tries to benefit from the source corpora, by adjusting the effect of their compatibility and incompatibility. For the adjustment, these penalty parameters should be set properly. Since we are unaware of the widely ranged differences among the corpora, we empirically estimated them by performing 10-fold CV on the training data.

4 Evaluation

4.1 Evaluation Settings

We used five corpora for evaluation: AIMed, BioInfer, HPRD50, IEPA, and LLL. For the comparison with other methods, we report the F-score (%), and the area under the receiver operating characteristic (ROC) curve (AUC) (%) using (abstract-wise) a 10-fold CV and a one-answer-per-occurrence criterion. These measures are commonly used for the PPI extraction tasks. The F-score is a harmonic mean of Precision and Recall. The ROC curve is a plot of a true positive rate (TPR) vs a false positive rate (FPR) for different thresholds. We tuned the regularization parameters of all classifiers by performing a 10-fold CV on the training data using a random split. The other parameters were fixed, and we report the highest of the macro-averaged F-scores as our final F-score. For 10-fold CV, we split the corpora as recommended by Airola et al. (2008).

4.2 PPI Extraction on a Single Corpus

In this section, we evaluate our system on a single corpus, in order to evaluate our feature vector and to justify the use of the following modules: normalization methods and classification methods.

First, we compare our preprocessing method with other preprocessing methods to confirm how our preprocessing method improves the performance. Our method produced 64.2% in F-score using L2-SVM on AIMed. Scaling all features individually to have a maximal absolute value of 1, produced only 44.2% in the F-score, while normalizing the feature vector by L2-norm produced 61.5% in the F-score. Both methods were inferior to our method, because the values of features in the same group should be treated together, and because the values of features in the different groups should not have a big discrepancy. Weighting each

	L2	L1	LR	AP	CW
F	**64.2**	64.0	**64.2**	62.7	63.0
AUC	**89.1**	88.8	89.0	88.5	87.8

Table 2: Classification performance on AIMed using five different linear classifiers. The F-score (F) and Area Under the ROC curve (AUC) are shown. L2 is L2-SVM, L1 is L1-SVM, LR is logistic regression, AP is averaged perceptron, and CW is confidence weighted linear classification.

group with different values can produce better results, as will be explored in our future work.

Next, using our feature vector, we applied five different linear classifiers to extract PPI from AIMed: L2-SVM, 1-norm soft-margin SVM (L1-SVM), logistic regression (LR) (Fan et al., 2008), averaged perceptron (AP) (Collins, 2002), and confidence weighted linear classification (CW) (Dredze et al., 2008). Table 2 indicates the performance of these classifiers on AIMed. We employed better settings for the task than did the original methods for AP and CW. We used a Widrow-Hoff learning rule (Bishop, 1995) for AP, and we performed one iteration for CW. L2-SVM is as good as, if not better, than other classifiers (F-score and AUC). In the least, L2-SVM is as fast as these classifiers. AP and CW are worse than the other three methods, because they require a large number of examples, and are un-suitable for the current task. This result indicates that all linear classifiers, with the exception of AP and CW, perform almost equally, when using our feature vector.

Finally, we implemented the kernel method by Miwa et al. (2008). For a 10-fold CV on AIMed, the running time was 9,507 seconds, and the performance was 61.5% F-score and 87.1% AUC. Our system used 4,702 seconds, and the performance was 64.2% F-score and 89.1% AUC. This result displayed that our system, with L2-SVM, and our new feature vector, is better, and faster, than the kernel-based system.

4.3 Evaluation of Corpus Weighting

In this section, we first apply each model from a source corpus to a target corpus, to show how different the corpora are. We then evaluate SVM-CW by comparing it with three other methods (see Section 2) with limited features, and apply it to every corpus.

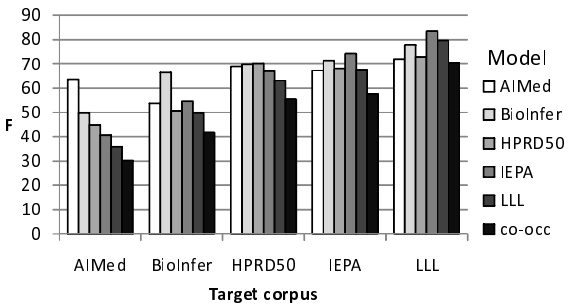

Figure 8: F-score on a target corpus using a model on a source corpus. For the comparison, we show the 10-fold CV result on each target corpus and co-occurrences. The regularization parameter was fixed to 1.

First, we apply the model from a source corpus to a target corpus. Figure 8 shows how the model from a source corpus performs on the target corpus. Interestingly, the model from IEPA performs better on LLL than the model from LLL itself. All the results showed that using different corpora (except IEPA) is worse than just using the same corpora. However, the cross-corpora scores are still better than the co-occurrences base-line, which indicates that the corpora share some information, even though they are not fully compatible.

Next, we compare SVM-CW with three other methods: aSVM, SVD-ASO, and TrAdaBoost. For this comparison, we used our feature vector without including the graph features, because SVD-ASO and TrAdaBoost require large computational resources. We applied SVD-ASO and TrAdaBoost in the following way. As for SVD-ASO, we made 400 auxiliary problems from the labels of each corpus by splitting features randomly, and extracted 50 additional features each for 4 feature groups. In total, we made new 200 additional features from 2,000 auxiliary problems. As recommended by Ando et al. (2005), we removed negative weights, performed SVD to each feature group, and iterated ASO once. Since AdaBoost easily overfitted with our rich feature vector, we applied soft margins (Ratsch et al., 2001) to TrAdaBoost. The update parameter for source examples was calculated using the update parameter on the training data in AdaBoost and the original parameter in TrAdaBoost. This ensures that the parameter would be the same as the original parameter, when the C value in the soft margin approaches infinity.

	aSVM		SVD-ASO		TrAdaBoost		SVM-CW		L2-SVM	
	F	AUC	F	AUC	F	AUC	F	AUC	F	AUC
AIMed	63.6	88.4	62.9	88.3	63.4	88.4	**64.0**	**88.6**	63.2	88.4

L	83.2	85.9	82.0	**86.7**	(80.5)	84.1	86.3	87.1	87.4	**90.8**	(86.0)	86.2

Table 4: F-score and AUC by SVM-CW. Rows correspond to a target corpus, and columns a source corpus. A:AIMed, B:BioInfer, H:HPRD50, I:IEPA, and L:LLL corpora. "all" signifies that all source corpora are used as one source corpus, ignoring the differences among the corpora. For the comparison, we show the 10-fold CV result on each target corpus.

In Table 3, we demonstrate the results of the comparison. SVM-CW improved the classification performance at least as much as all the other methods. The improvement is mainly attributed to the aggressive use of source examples while learning the model. Some source examples can be used as training data, as indicated in Figure 8. SVM-CW does not set the restriction between C_s and C_t in Equation (2), so it can use source examples aggressively while learning the model. Since aSVM transfers a model, and SVD-ASO transfers an additional feature space, aSVM and SVD-ASO do not use the source examples while learning the model. In addition to the difference in the data usage, the settings of aSVM and SVD-ASO do not match the current task. As for aSVM, the DA assumption (that the labels are the same) does not match the task. In SVD-ASO, the numbers of both source examples and auxiliary problems are much smaller than those reported by Ando et al. (2005). TrAdaBoost uses the source examples while learning the model, but never increases the weight of the examples, and it attempts to reduce their effects.

Finally, we apply SVM-CW to all corpora using all features. Table 4 summarizes the F-score and AUC by SVM-CW with all features. SVM-CW is especially effective for small corpora, showing that SVM-CW can adapt source corpora to a small annotated target corpus. The improvement on AIMed is small compared to the improvement on BioInfer, even though these corpora are similar in size. One of the reasons for this is that whole abstracts are annotated in AIMed, therefore making the examples biased. The difference between L2-SVM and SVM-CW + IEPA on AIMed is small, but statistically, it is significant (McNemar test (McNemar, 1947), P = 0.0081). In the cases of HPRD50 + IEPA, LLL + IEPA, and two folds in BioInfer + IEPA, C_s is larger than C_t in Equation (2). This is worth noting, because the source corpus is more weighted than the target corpus, and the prediction performance on the target corpus is improved. Most methods put more trust in the target corpus than in the source corpus, and our results show that this setting is not always effective for mixing corpora. The results also indicate that IEPA contains more useful information for extracting PPI than other corpora, and that using source examples aggressively is important for these combinations. We compared the results of L2-SVM and SVM-CW + IEPA on AIMed, and found that 38 pairs were described as "interaction" or "binding" in the sentences among 61

	SVM-CW		L2-SVM		Airola et al.

L	**86.7**	**90.8**	80.5	86.0	76.8	83.4

Table 6: Comparison with the results by Airola et al. (2008). A:AIMed, B:BioInfer, H:HPRD50, I:IEPA, and L:LLL corpora. The results with the highest F-score from Table 4 are reported as the results for SVM-CW.

newly found pairs. This analysis is evidence that IEPA contains instances to help find such interactions, and that SVM-CW helps to collect gold pairs that lack enough supporting instances in a single corpus, by adding instances from other corpora. SVM-CW missed coreferential relations that were also missed by L2-SVM. This can be attributed to the fact that the coreferential information is not stored in our current feature vector; so we need an even more expressive feature space. This is left as future work.

SVM-CW is effective on most corpus combinations, and all the models from single corpora can be improved by adding other source corpora. This result is impressive, because the baselines by L2-SVM on just single corpora are already better than or at least comparable to other state-of-the-art PPI extraction systems, and also because the variety of the differences among different corpora is quite wide depending on various factors including annotation policies of the corpora (Pyysalo et al., 2008). The results suggest that SVM-CW is useful as an ITL method.

4.4 Comparison with Other PPI Systems

We compare our system with other previously published PPI extraction systems. Tables 5 and 6 summarize the comparison. Table 5 summarizes the comparison of several PPI extraction systems evaluated on the AIMed corpus. As indicated, the performance of the heavy kernel method is lower than our fast rich feature-vector method. Our system is, to the extent of our knowledge, the best performing PPI extraction system evaluated on the AIMed corpus, both in terms of AUC and F-scores. Airola et al. (2008) first reported results using all five corpora. We cannot directly compare our result with the F-score results, because they tuned the threshold, but our system still outperforms the system by Airola et al. (2008) on every corpus in AUC values. The results also indicate that our system outperforms other systems on all PPI corpora, and that both the rich feature vector and the corpus weighting are effective for the PPI extraction task.

5 Conclusion

In this paper, we proposed a PPI extraction system with a rich feature vector, using a corpus weighting method (SVM-CW) for combining the multiple PPI corpora. The feature vector extracts as much information as possible from the main training corpus, and SVM-CW incorporate other external source corpora in order to improve the performance of the classifier on the main target corpus. To the extent of our knowledge, this is the first application of ITL and DA methods to PPI extraction. As a result, the system, with SVM-CW and the feature vector, outperformed all other PPI extraction systems on all of the corpora. The PPI corpora share some information, and it is shown to be effective to add other source corpora when working with a specific target corpus.

The main contributions of this paper are: 1) conducting experiments in extracting PPI using multiple corpora, 2) suggesting a rich feature vector using several previously proposed features and normalization methods, 3) the combination of SVM with corpus weighting and the new feature vector improved results on this task compared with prior work.

There are many differences among the corpora that we used, and some of the differences are still unresolved. For further improvement, it would be necessary to investigate what is shared and what is different among the corpora. The SVM-CW method, and the PPI extraction system, can be applied generally to other classification tasks, and to other binary relation extraction tasks, without the need for modification. There are several other tasks in which many different corpora, which at first glance seem compatible, exist. By applying SVM-CW to such corpora, we will analyze which differences can be resolved by SVM-CW, and what differences require a manual resolution.

For the PPI extraction system, we found many false negatives that need to be resolved. For further improvement, we need to analyze the cause

	positive	all	P	R	F	AUC

Abstract

Traditionally, machine learning approaches for information extraction require human annotated data that can be costly and time-consuming to produce. However, in many cases, there already exists a database (DB) with schema related to the desired output, and records related to the expected input text. We present a conditional random field (CRF) that aligns tokens of a given DB record and its realization in text. The CRF model is trained using only the available DB and unlabeled text with generalized expectation criteria. An annotation of the text induced from inferred alignments is used to train an information extractor. We evaluate our method on a citation extraction task in which alignments between DBLP database records and citation texts are used to train an extractor. Experimental results demonstrate an error reduction of 35% over a previous state-of-the-art method that uses heuristic alignments.

1 Introduction

A substantial portion of information on the Web consists of unstructured and semi-structured text. Information extraction (IE) systems segment and label such text to populate a structured database that can then be queried and mined efficiently.

In this paper, we mainly deal with information extraction from text fragments that closely resemble structured records. Examples of such texts include citation strings in research papers, contact addresses on person homepages and apartment listings in classified ads. Pattern matching and rule-based approaches for IE (Brin, 1998; Agichtein and Gravano, 2000; Etzioni et al., 2005) that only use specific patterns, and delimiter and font-based cues for segmentation are prone to failure on such data because these cues are generally not broadly reliable. Statistical machine learning methods such as hidden Markov models (HMMs) (Rabiner, 1989; Seymore et al., 1999; Freitag and McCallum, 1999) and conditional random fields (CRFs) (Lafferty et al., 2001; Peng and McCallum, 2004; Sarawagi and Cohen, 2005) have become popular approaches to address the text extraction problem. However, these methods require labeled training data, such as annotated text, which is often scarce and expensive to produce.

In many cases, however, there already exists a database with schema related to the desired output, and records that are imperfectly rendered in the available unlabeled text. This database can serve as a source of significant supervised guidance to machine learning methods. Previous work on using databases to train information extractors has taken one of three simpler approaches. In the first, a separate language model is trained on each column of the database and these models are then used to segment and label a given text sequence (Agichtein and Ganti, 2004; Canisius and Sporleder, 2007). However, this approach does not model context, errors or different formats of fields in text, and requires large number of database entries to learn an accurate language model. The second approach (Sarawagi and Cohen, 2004; Michelson and Knoblock, 2005; Mansuri and Sarawagi, 2006) uses database or dictionary lookups in combination with similarity measures to add features to the text sequence. Although these features are very informative, learning algorithms still require annotated data to make use of them. The final approach heuristically labels texts using matching records and learns extractors from these annotations (Ramakrishnan and Mukherjee, 2004; Bellare and McCallum, 2007; Michelson and Knoblock, 2008). Heuris-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 131–140,
Singapore, 6-7 August 2009.

tic labeling decisions, however, are made independently without regard for the Markov dependencies among labels in text and are sensitive to subtle changes in text.

Here we propose a method that automatically induces a labeling of an input text sequence using a word *alignment* with a matching database record. This induced labeling is then used to train a text extractor. Our approach has several advantages over previous methods. First, we are able to model field ordering and context around fields by learning an extractor from annotations of the text itself. Second, a probabilistic model for word alignment can exploit dependencies among alignments, and is also robust to errors, formatting differences, and missing fields in text and the record.

Our word alignment model is a conditional random field (CRF) (Lafferty et al., 2001) that generates alignments between tokens of a text sequence and a matching database record. The structure of the graphical model resembles IBM Model 1 (Brown et al., 1993) in which each target (record) word is assigned one or more source (text) words. The alignment is generated conditioned on both the record and text sequence, and therefore supports large sets of rich and non-independent features of the sequence pairs. Our model is trained without the need for labeled word alignments by using generalized expectation (GE) criteria (Mann and McCallum, 2008) that penalize the divergence of specific model expectations from target expectations. Model parameters are estimated by minimizing this divergence. To limit over-fitting we include a $\mathbb{L}_2$-regularization term in the objective. The model expectations in GE criteria are taken with respect to a set of alignment latent variables that are either specific to each sequence pair (local) or summarizing the entire data set (global). This set is constructed by including all alignment variables a that satisfy a certain binary feature (e.g., $f(a, \mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2) = 1$, for labeled record $(\mathbf{x}_1, \mathbf{y}_1)$, and text sequence $\mathbf{x}_2$). One example global criterion is that "an alignment exists between two orthographically similar[1] words 95% of the time." Here the criterion has a *target expectation* of 95% and is defined over alignments $\{a = \langle i, j \rangle \mid \mathbf{x}_1[i] \sim \mathbf{x}_2[j], \forall \mathbf{x}_1, \mathbf{x}_2\}$. Another criterion for extraction can be "the word 'EMNLP' is always aligned with the record label *booktitle*". This criterion has a *target* of 100% and defined for $\{a = \langle i, j \rangle \mid \mathbf{y}_1[i] = \textit{booktitle} \wedge \mathbf{x}_2[j] = \text{'EMNLP'}, \forall \mathbf{y}_1, \mathbf{x}_2\}$. One-to-one correspondence between words in the sequence pair can be specified as collection of local expectation constraints. Since we directly encode prior knowledge of how alignments behave in our criteria, we obtain sufficiently accurate alignments with little supervision.

We apply our method to the task of citation extraction. The input to our training algorithm is a set of matching DBLP[2]-record/citation-text pairs and global GE criteria[3] of the following two types: (1) *alignment* criteria that consider features of mapping between record and text words, and, (2) *extraction* criteria that consider features of the schema label assigned to a text word. In our experiments, the parallel record-text pairs are collected manually but this process can be automated using systems that match text sequences to records in the DB (Michelson and Knoblock, 2005; Michelson and Knoblock, 2008). Such systems achieve very high accuracy close to 90% F1 on semi-structured domains similar to ours.[4] Our trained alignment model can be used to directly align new record-text pairs to create a labeling of the texts. Empirical results demonstrate a 20.6% error reduction in token labeling accuracy compared to a strong baseline method that employs a set of high-precision alignments. Furthermore, we provide a 63.8% error reduction compared to IBM Model 4 (Brown et al., 1993). Alignments learned by our model are used to train a linear-chain CRF extractor. We obtain an error reduction of 35.1% over a previous state-of-the-art extraction method that uses heuristically generated alignments.

2 Record-Text Alignment

Here we provide a brief description of the record-text alignment task. For the sake of clarity and space, we describe our approach on a *fictional* restaurant address data set. The input to our system is a database (DB) consisting of records (possibly containing errors) and corresponding texts that are realizations of these DB records. An example of a matching record-text pair is shown in

[1] Two words are orthographically similar if they have low edit distance.

[2] http://www.informatik.uni-trier.de/~ley/db/

[3] Expectation criteria used in our experiments are listed at *http://www.cs.umass.edu/~kedarb/dbie_expts.txt*.

[4] To obtain more accurate record-text pairs, matching methods can be tuned for high precision at the expense of recall. Alternatively, humans can cheaply provide match/mismatch labels on automatically matched pairs.

Table 1: An example of a matching record-text pair for restaurant addresses.

Table 1. This example displays the differences between the record and text: (1) spelling errors: *katsu* → *katzu*, (2) word insertions (*restaurant*), deletions (*1972*), substitutions (*angeles* → *feliz*), (3) abbreviations (*avenue* → *ave.*), (4) missing fields in text (**phone**=*665-1891*), and (5) extra fields in text (**state**=*california*). These discrepancies plus the unknown ordering of fields within text can be addressed through word alignment.

Table 2: Example of a word alignment. ■ represents aligned tokens. Vertical text at the bottom are the text tokens. Horizontal text on the left are tokens from the DB record with labels shown in braces.

An example word alignment between the record and text is shown in Table 2. Tokenization of record/text string is based on whitespace characters. We add a special *null* token at the field boundaries for each label in the schema to model word insertions. The record sequence is obtained by concatenating individual fields according to the DB schema order. As in statistical word alignment, we assume the DB record to be our source and the text to be our target. The induced labeling of the text is given by (**name**, **address**, **address**, **city**, **city**, **state**) which can be used to train an information extractor. In the next section, we present our approach to address this task.

3 Approach

We first define notation that will be used throughout this section. Let $(\mathbf{x}_1, \mathbf{y}_1)$ be a database record with token sequence $\mathbf{x}_1 = \langle x_1[1], x_1[2], \ldots, x_1[m] \rangle$ and label sequence $\mathbf{y}_1 = \langle y_1[1], y_1[2], \ldots, y_1[m] \rangle$ with $y_1[*] \in \mathcal{Y}$ where $\mathcal{Y}$ is the database schema. Let $\mathbf{x}_2 = \langle x_2[1], x_2[2], \ldots, x_2[n] \rangle$ be the text sequence. Let $\mathbf{a} = \langle a_1, a_2, \ldots, a_n \rangle$ be an alignment sequence of same length as the target text sequence. The alignment $a_i = j$ assigns the DB token-label pair $(x_1[j], y_1[j])$ to the text token $x_2[i]$.

3.1 Conditional Random Field for Alignment

Our conditional random field (CRF) for alignment has a graphical model structure that resembles that of IBM Model 1 (Brown et al., 1993). The CRF is an undirected graphical model that defines a probability distribution over alignment sequences $\mathbf{a}$ conditioned on the inputs $(\mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2)$ as:

$$p_\Theta(\mathbf{a}|\mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2) = \frac{\exp(\sum_{t=1}^{n} \Theta^\top \vec{f}(a_t, \mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2, t))}{Z_\Theta(\mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2)}, \quad (1)$$

where $\vec{f}(a_t, \mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2, t)$ are feature functions defined over the alignments and inputs, Θ are the model parameters and $Z_\Theta(\mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2) = \sum_{\mathbf{a}'} \exp(\sum_{t=1}^{n} \Theta^\top \vec{f}(a'_t, \mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2, t))$ is the partition function.

The feature vector $\vec{f}(a_t, \mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2, t)$ is the concatenation of two types of feature functions: (1) *alignment* features $f_{align}(a_t, \mathbf{x}_1, \mathbf{x}_2, t)$ defined on source-target tokens, and, (2) *extraction* features $f_{extr}(a_t, \mathbf{y}_1, \mathbf{x}_2, t)$ defined on source labels and target text. To obtain the probability of an alignment in a particular position t we marginalize out the alignments over the rest of the positions $\{1, \ldots, n\} \backslash \{t\}$,

$$p_\Theta(a_t|\mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2) = \sum_{\{a[1\ldots n]\} \backslash \{a_t\}} p_\Theta(\mathbf{a}|\mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2)$$

$$= \frac{\exp(\Theta^\top \vec{f}(a_t, \mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2, t))}{\exp(\sum_{a'} \Theta^\top \vec{f}(a', \mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2, t))} \quad (2)$$

Furthermore, the marginal over label y_t assigned to the text token $x_2[t]$ at time step t during alignment is given by

$$p_\Theta(y_t|\mathbf{x}_2) = \sum_{\{a_t|\mathbf{y}_1[a_t]=y_t\}} p_\Theta(a_t|\mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2), \quad (3)$$

where $\{a_t \mid \mathbf{y}_1[a_t] = y_t\}$ is the set of alignments that result in a labeling y_t for token $x_2[t]$. Henceforth, we abbreviate $p_\Theta(a_t|\mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2)$ to $p_\Theta(a_t)$. The gradient of $p_\Theta(a_t)$ with respect to parameters Θ is given by

$$\frac{\partial p_\Theta(a_t)}{\partial \Theta} = p_\Theta(a_t) \left[\vec{f}(a_t, \mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2, t) - E_{p_\Theta(a)} \left(\vec{f}(a, \mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2, t) \right) \right], \quad (4)$$

where the expectation term in the above equation sums over all alignments a at position t. We use the Baum-Welch and Viterbi algorithms to compute marginal probabilities and best alignment sequences respectively.

3.2 Expectation Criteria and Parameter Estimation

Let $\mathcal{D} = \langle (\mathbf{x}_1^{(1)}, \mathbf{y}_1^{(1)}, \mathbf{x}_2^{(1)}), \ldots, (\mathbf{x}_1^{(K)}, \mathbf{y}_1^{(K)}, \mathbf{x}_2^{(K)}) \rangle$ be a data set of K record-text pairs gathered manually or automatically through matching (Michelson and Knoblock, 2005; Michelson and Knoblock, 2008). A global expectation criterion is defined on the set of alignment latent variables $\mathbf{A}_f = \{a | f(a, \mathbf{x}_1^{(i)}, \mathbf{y}_1^{(i)}, \mathbf{x}_2^{(i)}) = 1, \forall i = 1 \ldots K\}$ on the entire data set that satisfy a given binary feature $f(a, \mathbf{x}_1, \mathbf{y}_1, \mathbf{x}_2)$. Similarly a local expectation criterion is defined only for a specific instance $(\mathbf{x}_1^{(i)}, \mathbf{y}_1^{(i)}, \mathbf{x}_2^{(i)})$ with the set $\mathbf{A}_f = \{a | f(a, \mathbf{x}_1^{(i)}, \mathbf{y}_1^{(i)}, \mathbf{x}_2^{(i)}) = 1\}$. For a feature function f, a target expectation p, and, a weight w, our criterion minimizes the squared divergence

$$\Delta(f, p, w, \Theta) = w \left(\frac{E_{p_\Theta}(\mathbf{A}_f)}{|\mathbf{A}_f|} - p \right)^2, \quad (5)$$

where $E_{p_\Theta}(\mathbf{A}_f) = \sum_{a \in \mathbf{A}_f} p_\Theta(a)$ is the sum of marginal probabilities given by Equation (2) and $|\mathbf{A}_f|$ is the size of the variable set. The weight w influences the importance of satisfying a given expectation criterion. Equation (5) is an instance of generalized expectation criteria (Mann and McCallum, 2008) that penalizes the divergence of a specific model expectation from a given target value. The gradient of the divergence with respect to Θ is given by,

$$\frac{\partial \Delta(f, p, w, \Theta)}{\partial \Theta} = 2w \left(\frac{E_{p_\Theta}(\mathbf{A}_f)}{|\mathbf{A}_f|} - p \right) \times \left[\frac{1}{|\mathbf{A}_f|} \sum_{a \in \mathbf{A}_f} \frac{\partial p_\Theta(a)}{\partial \Theta} - p \right], \quad (6)$$

where the gradient $\frac{\partial p_\Theta(a)}{\partial \Theta}$ is given by Eq. (4). Given expectation criteria $\mathcal{C} = \langle \mathbf{F}, \mathbf{P}, \mathbf{W} \rangle$ with a set of binary feature functions $\mathbf{F} = \langle f_1, \ldots, f_l \rangle$, target expectations $\mathbf{P} = \langle p_1, \ldots, p_l \rangle$ and weights $\mathbf{W} = \langle w_1, \ldots, w_l \rangle$, we maximize the objective

$$\mathcal{O}(\theta; \mathcal{D}, \mathcal{C}) = \max_\Theta - \sum_{i=1}^{l} \Delta(f_i, p_i, w_i, \Theta) - \frac{||\Theta||^2}{2}, \quad (7)$$

where $||\Theta||^2/2$ is the regularization term added to limit over-fitting. Hence the gradient of the objective is

$$\frac{\partial \mathcal{O}(\theta; \mathcal{D}, \mathcal{C})}{\partial \Theta} = - \sum_{i=1}^{l} \frac{\partial \Delta(f_i, p_i, w_i, \Theta)}{\partial \Theta} - \Theta.$$

We maximize our objective (Equation 7) using the L-BFGS algorithm. It is sometimes necessary to restart maximization after resetting the Hessian calculation in L-BFGS due to non-convexity of our objective.[5] Also, non-convexity may lead to a local instead of a global maximum. Our experiments show that local maxima do not adversely affect performance since our accuracy is within 4% of a model trained with gold-standard labels.

3.3 Linear-chain CRF for Extraction

The alignment CRF (**AlignCRF**) model described in Section 3.1 is able to predict labels for a text sequence given a matching DB record. However, without corresponding records for texts the model does not perform well as an extractor because it has learned to rely on the DB record and alignment features (Sutton et al., 2006). Hence, we train a separate linear-chain CRF on the alignment-induced labels for evaluation as an extractor.

The extraction CRF (**ExtrCRF**) employs a fully-connected state machine with a unique state

[5] Our L-BFGS optimization procedure checks whether the approximate Hessian computed from cached gradient vectors is positive semi-definite. The optimization is restarted if this check fails.

per label $y \in \mathcal{Y}$ in the database schema. The CRF induces a conditional probability distribution over label sequences $\mathbf{y} = \langle y_1, \ldots, y_n \rangle$ and input text sequences $\mathbf{x} = \langle x_1, \ldots, x_n \rangle$ as

$$p_\Lambda(\mathbf{y}|\mathbf{x}) = \frac{\exp\left(\sum_{t=1}^{n} \Lambda^\top \vec{g}(y_{t-1}, y_t, \mathbf{x}, t)\right)}{Z_\Lambda(\mathbf{x})}. \quad (8)$$

In comparison to our earlier zero-order **AlignCRF** model, our **ExtrCRF** is a first-order model. All the feature functions in this model $g(y_{t-1}, y_t, \mathbf{x}, t)$ are a conjunction of the label pair (y_{t-1}, y_t) and input observational features. $Z_\Lambda(\mathbf{x})$ in the equation above is the partition function. Inference in the model is performed using the Viterbi algorithm.

Given expectation criteria $\mathcal{C}$ and data set $\mathcal{D} = \langle (\mathbf{x}_1^{(1)}, \mathbf{y}_1^{(1)}, \mathbf{x}_2^{(1)}), \ldots, (\mathbf{x}_1^{(K)}, \mathbf{y}_1^{(K)}, \mathbf{x}_2^{(K)}) \rangle$, we first estimate the parameters Θ of **AlignCRF** model as described in Section 3.2. Next, for all text sequences $\mathbf{x}_2^{(i)}, i = 1 \ldots K$ we compute the marginal probabilities of the labels $p_\Theta(y_t|\mathbf{x}_2^{(i)}), \forall t$ using Equation (3). To estimate parameters Λ we minimize the KL-divergence between $p_\Theta(\mathbf{y}|\mathbf{x}) = \prod_{t=1}^{n} p_\Theta(y_t|\mathbf{x})$ and $p_\Lambda(\mathbf{y}|\mathbf{x})$ for all sequences $\mathbf{x}$,

$$\begin{aligned} KL(p_\Theta \| p_\Lambda) &= \sum_{\mathbf{y}} p_\Theta(\mathbf{y}|\mathbf{x}) \log\left(\frac{p_\Theta(\mathbf{y}|\mathbf{x})}{p_\Lambda(\mathbf{y}|\mathbf{x})}\right) \\ &= H(p_\Theta(\mathbf{y}|\mathbf{x})) \\ &- \sum_{t, y_{t-1}, y_t} E_{p_\Theta(y_{t-1}, y_t)}[\Lambda^\top \vec{g}(y_{t-1}, y_t, \mathbf{x}, t)] \\ &+ \log(Z_\Lambda(\mathbf{x})). \quad (9) \end{aligned}$$

The gradient of the above equation is given by

$$\begin{aligned} \frac{\partial KL}{\partial \Lambda} &= \sum_{t, y_{t-1}, y_t} E_{p_\Lambda(y_{t-1}, y_t|\mathbf{x})}[\vec{g}(y_{t-1}, y_t, \mathbf{x}, t)] \\ &- E_{p_\Theta(y_{t-1}, y_t|\mathbf{x})}[\vec{g}(y_{t-1}, y_t, \mathbf{x}, t)]. \quad (10) \end{aligned}$$

Both the expectations can be computed using the Baum-Welch algorithm. The parameters Λ are estimated for a given data set $\mathcal{D}$ and learned parameters Θ by optimizing the objective

$$\begin{aligned} O(\Lambda; \mathcal{D}, \Theta) = \min_\Lambda \sum_{i=1}^{K} KL(p_\Theta(\mathbf{y}|\mathbf{x}_2^{(i)}) \| p_\Lambda(\mathbf{y}|\mathbf{x}_2^{(i)}) \\ + \|\Lambda\|^2/2. \end{aligned}$$

The objective is minimized using L-BFGS. Since the objective is convex we are guaranteed to obtain a global minima.

4 Experiments

In this section, we present details about the application of our method to citation extraction task.

Data set. We collected a set of 260 random records from the DBLP bibliographic database. The schema of DBLP has the following labels {*author, editor, address, title, booktitle, pages, year, journal, volume, number, month, url, ee, cdrom, school, publisher, note, isbn, chapter, series*}. The complexity of our alignment model depends on the number of schema labels and number of tokens in the DB record. We reduced the number of schema labels by: (1) mapping the labels *address, booktitle, journal* and *school* to *venue*, (2) mapping *month* and *year* to *date*, and (3) dropping the fields *url, ee, cdrom, note, isbn* and *chapter*, since they never appeared in citation texts. We also added the other label *O* for fields in text that are not represented in the database. Therefore, our final DB schema is {*author, title, date, venue, volume, number, pages, editor, publisher, series, O*}.

For each DBLP record we searched on the web for matching citation texts using the first author's last name and words in the title. Each citation text found is manually labeled for evaluation purposes. An example of a matching DBLP record-citation text pair is shown in Table 3. Our data set[6] contains 522 record-text pairs for 260 DBLP entries.

Features and Constraints. We use a variety of rich, non-independent features in our models to optimize system performance. The input features in our models are of the following two types:

(a) Extraction features in the **AlignCRF** model ($f(a_t, \mathbf{y}_1, \mathbf{x}_2, t)$) and **ExtrCRF** model ($g(y_{t-1}, y_t, \mathbf{x}, t)$) are conjunctions of assigned labels and observational tests on text sequence at time step t. The following observational tests are used: (1) regular expressions to detect tokens containing all characters (ALLCHAR), all digits (ALLDIGITS) or both digits and characters (ALPHADIGITS), (2) number of characters or digits in the token (NUMCHAR=3, NUMDIGITS=1), (3) domain-specific patterns for *date* and *pages*, (4) token identity, suffixes, prefixes and character n-grams, (5) presence of a token in lexicons such as "last names," "publisher names," "cities," (6) lexicon features within a window of 10, (7) regular

[6]The data set can be found at *http://www.cs.umass.edu/∼kedarb/dbie_cite_data.sgml*.

Table 3: Example of matching record-text pair found on the web.

expression features within a window of 10, and (8) token identity features within a window of 3.

(b) Alignment features in the **AlignCRF** model ($f(a_t, \mathbf{x}_1, \mathbf{x}_2, t)$) that operate on the aligned source token $\mathbf{x}_1[a_t]$ and target token $\mathbf{x}_2[t]$. Again the observational tests used for alignment are: (1) exact token match tests whether the source-target tokens are string identical, (2) approximate token match produces a binary feature after binning the Jaro-Winkler edit distance (Cohen et al., 2003) between the tokens, (3) substring token match tests whether one token is a substring of the other, (4) prefix token match returns true if the prefixes match for lengths $\{1, 2, 3, 4\}$, (5) suffix token match returns true if the prefixes match for lengths $\{1, 2, 3, 4\}$, and (6) exact and approximate token matches at offsets $\{-1, -1\}$ and $\{+1, +1\}$ around the alignment.

Thus, a conditional model lets us use these arbitrary helpful features that cannot be exploited tractably in a generative model.

As is common practice (Haghighi and Klein, 2006; Mann and McCallum, 2008), we simulate user-specified expectation criteria through statistics on manually labeled citation texts. For extraction criteria, we select for each label, the top N extraction features ordered by mutual information (MI) with that label. Also, we aggregate the alignment features of record tokens whose alignment with a target text token results in a correct label assignment. The top N alignment features that have maximum MI with this correct labeling are selected as alignment criteria. We bin target expectations of these criteria into 11 bins as $[0.05, 0.1, 0.2, 0.3, \ldots, 0.9, 0.95]$.[7] In our experiments, we set $N = 10$ and use a fixed weight $w = 10.0$ for all expectation criteria (no tuning of parameters was performed). Table 4 shows a sample of GE criteria used in our experiments.[8]

[7] Mann and McCallum (2008) note that GE criteria are robust to deviation of specified targets from actual expectations.

[8] A complete list of expectation criteria is available at *http://www.cs.umass.edu/∼kedarb/dbie_expts.txt*.

Table 4: Sample of expectation criteria used by our model.

Experimental Setup. Our experiments use a 3:1 split of the data for training and testing. We repeat the experiment 20 times with different random splits of the data. We train the **AlignCRF** model using the training data and the automatically created expectation criteria (Section 3.2). We evaluate our alignment model indirectly in terms of token labeling accuracy (i.e., percentage of correctly labeled tokens in test citation data) since we do not have annotated alignments. The alignment model is then used to train a **ExtrCRF** model as described in Section 3.3. Again, we use token labeling accuracy for evaluation. We also measure F1 performance as the harmonic mean of precision and recall for each label.

4.1 Alternate approaches

We compare our method against alternate approaches that either learn alignment or extraction models from training data.

Alignment approaches. We use GIZA++ (Och and Ney, 2003) to train generative directed alignment models: **HMM** and IBM **Model4** (Brown et al., 1993) from training record-text pairs. These models are currently being used in state-of-the-art machine translation systems. Alignments between matching DB records and text sequences are then used for labeling at test time.

Extraction approaches. The first alternative (**DB-CRF**) trains a linear-chain CRF for extraction on fields of the database entries only. Each field of the record is treated as a separate labeled text sequence. Given an unlabeled text sequence, it is segmented and labeled using the Viterbi algorithm. This method is an enhanced representative for (Agichtein and Ganti, 2004) in which a language model is trained for each column of the DB.

Another alternative technique constructs partially annotated text data using the matching records and a labeling function. The labeling function employs high-precision alignment rules to assign labels to text tokens using labeled record tokens. We use exact and approximate token matching rules to create a partially labeled sequence, skipping tokens that cannot be unambiguously labeled. In our experiments, we achieve a precision of 97% and a recall of 70% using these rules. Given a partially annotated citation text, we train a linear-chain CRF by maximizing the marginal likelihood of the observed labels. This marginal CRF training method (Bellare and McCallum, 2007) (**M-CRF**) was the previous state-of-the-art on this data set. Additionally, if a matching record is available for a test citation text, we can partially label tokens and use constrained Viterbi decoding with labeled positions fixed at their observed values (**M+R-CRF** approach).

Our third approach is similar to (Mann and McCallum, 2008). We create extraction expectation criteria from labeled text sequences in the training data and uses these criteria to learn a linear-chain CRF for extraction (**MM08**). The performance achieved by this approach is an upper bound on methods that: (1) use labeled training records to create extraction criteria, and, (2) only use extraction criteria without any alignment criteria.

Finally, we train a supervised linear-chain CRF (**GS-CRF**) using the labeled text sequences from the training set. This represents an upper bound on the performance that can be achieved on our task. All the extraction methods have access to the same features as the **ExtrCRF** model.

4.2 Results

Table 5 shows the results of various alignment algorithms applied to the record-text data set. Alignment methods use the matching record to perform labeling of a test citation text. The **AlignCRF** model outperforms the best generative alignment model **Model4** (IBM Model 4) with an error reduction of 63.8%. Our conjecture is that **Model4** is getting stuck in sub-optimal local maxima during EM training since our training set only contains hundreds of parallel record-text pairs. This problem may be alleviated by training on a large parallel corpus. Additionally, our alignment model is superior to **Model4** since it leverages rich non-independent features of input sequence pairs.

	HMM	**Model4**	**AlignCRF**

Table 5: Token-labeling accuracy and per-label F1 for different alignment methods. These methods all use matching DB records at test time. Bold-faced numbers indicate the best performing model. **HMM, Model4**: generative alignment models from GIZA++, **AlignCRF**: alignment model from this paper.

Table 6 shows the performance of various extraction methods. Except **M+R-CRF**, all extraction approaches, do not use any record information at test time. In comparison to the previous state-of-the-art **M-CRF**, the **ExtrCRF** method provides an error reduction of 35.1%. **ExtrCRF** also produces an error reduction of 21.7% compared to **M+R-CRF** without the use of matching records. These reductions are significant at level $p = 0.005$ using the two-tailed t-test. Training only on DB records is not helpful for extraction as we do not learn the transition structure[9] and additional context information[10] in text. This explains the low accuracy of the **DB-CRF** method. Furthermore, the **MM08** approach (Mann and McCallum, 2008) achieves low accuracy since it does not use any

[9] In general, the *editor* field follows the *title* field while the *author* field precedes it.

[10] The token "Vol." generally precedes the *volume* field in text. Similarly, tokens "pp" and "pages" occur before the *pages* field.

Table 6: Token-labeling accuracy and per-label F1 for different extraction methods. Except **M+R-CRF**†, all other approaches do not use any records at test time. Bold-faced numbers indicate the best performing model. **DB-CRF**: CRF trained on DB fields. **M+R-CRF**, **M-CRF**: CRFs trained from heuristic alignments. **ExtrCRF**: Extraction model presented in this paper. **GS-CRF**: CRF trained on human annotated citation texts.

alignment criteria during training. Hence, alignment information is crucial for obtaining high accuracy.

Note that we do not observe a decrease in performance of **ExtrCRF** over **AlignCRF** although we are not using the test records during decoding. This is because: (1) a first-order model in **ExtrCRF** improves performance compared to a zero-order model in **AlignCRF** and (2) the use of noisy DB records in the test set for alignment often increases extraction error.

Both our models have a high F1 value for the other label *O* because we provide our algorithm with constraints for the label *O*. In contrast, since there is no realization of the *O* field in the DB records, both **M-CRF** and **M+R-CRF** methods fail to label such tokens correctly. Our alignment model trained using expectation criteria achieves a performance of 92.7% close to gold-standard training (**GS-CRF**) (96.5%). Furthermore, **ExtrCRF** obtains an accuracy of 92.8% similar to **AlignCRF** without access to DB records due to better modeling of transition structure and context.

5 Related Work

Recent research in information extraction (IE) has focused on reducing the labeling effort needed to train supervised IE systems. For instance, Grenager et al. (2005) perform unsupervised HMM learning for field segmentation, and bias the model to prefer self-transitions and transitions on boundary tokens. Unfortunately, such unsupervised IE approaches do not attain performance close to state-of-the-art supervised methods. Semi-supervised approaches that learn a model with only a few constraints specifying prior knowledge have generated much interest. Haghighi and Klein (2006) assign each label in the model certain prototypical features and train a Markov random field for sequence tagging from these labeled features. In contrast, our method uses GE criteria (Mann and McCallum, 2008) – allowing soft-labeling of features with target expectation values – to train conditional models with complex and non-independent input features. Additionally, in comparison to previous methods, an information extractor trained from our record-text alignments achieves accuracy of 93% making it useful for real-world applications. Chang et al. (2007) use beam search for decoding unlabeled text with soft and hard constraints, and train a model with top-K decoded label sequences. However, this model requires large number of labeled examples (e.g., 300 annotated citations) to bootstrap itself. Active learning is another popular approach for reducing annotation effort. Settles and Craven (2008) provide a comparison of various active learning strategies for sequence labeling tasks. We have shown, however, that in domains where a database can provide significant supervision, one can bootstrap accurate extractors with very little human effort.

Another area of research, related to the task described in our paper, is learning extractors from database records. These records are also known as field books and reference sets in literature (Canisius and Sporleder, 2007; Michelson and Knoblock, 2008). Both Agichtein and Ganti (2004) and Canisius and Sporleder (2007) train a language model for each database column. The language modeling approach is sensitive to word re-orderings in text and other variability present in real-world text (e.g., abbreviation). We allow for word and field re-orderings through alignments and model complex transformations through feature functions. Michelson and Knoblock (2008) extract information from unstructured texts using a rule-based approach to align segments of text with fields in a DB record. Our probabilistic alignment approach is more robust and uses rich features of the alignment to obtain high performance.

Recently, Snyder and Barzilay (2007) and Liang et al. (2009) have explored record-text matching in domains with unstructured texts. Unlike a semi-structured text sequence obtained by noisily concatenating fields from a single record, an unstructured sequence may contain fields from multiple records embedded in large amounts of extraneous text. Hence, the problems of record-text matching and word alignment are significantly harder in unstructured domains. Snyder and Barzilay (2007) achieve a state-of-the-art performance of 80% F1 on matching multiple NFL database records to sentences in the news summary of a football game. Their algorithm is trained using supervised machine learning and learns alignments at the level of sentences and DB records. In contrast, this paper presents a semi-supervised learning algorithm for learning token-level alignments between records and texts. Liang et al. (2009) describe a model that simultaneously performs record-text matching and word alignment in unstructured domains. Their model is trained in an unsupervised fashion using EM. It may be possible to further improve their model performance by incorporating prior knowledge in the form of expectation criteria.

Traditionally, generative word alignment models have been trained on massive parallel corpora (Brown et al., 1993). Recently, discriminative alignment methods trained using annotated alignments on small parallel corpora have achieved superior performance. Taskar et al. (2005) train a discriminative alignment model from annotated alignments using a large-margin method. Labeled alignments are also used by Blunsom and Cohn (2006) to train a CRF word alignment model. Our method is trained using a small number of easily specified expectation criteria thus avoiding tedious and expensive human labeling of alignments. An alternate method of learning alignment models is proposed by McCallum et al. (2005) in which the training set consists of sequence pairs classified as match or mismatch. Alignments are learned to identify the class of a given sequence pair. However, this method relies on carefully selected negative examples to produce high-accuracy alignments. Our method produces good alignments as we directly encode prior knowledge about alignments.

6 Conclusion and Future Work

Information extraction is an important first step in data mining applications. Earlier approaches for learning reliable extractors have relied on manually annotated text corpora. This paper presents a novel approach for training extractors using alignments between texts and existing database records. Our approach achieves performance close to supervised training with very little supervision.

In the future, we plan to surpass supervised accuracy by applying our method to millions of parallel record-text pairs collected automatically using matching. We also want to explore the addition of Markov dependencies into our alignment model and other constraints such as monotonicity and one-to-one correspondence.

Nested Named Entity Recognition

Abstract

Many named entities contain other named entities inside them. Despite this fact, the field of named entity recognition has almost entirely ignored nested named entity recognition, but due to technological, rather than ideological reasons. In this paper, we present a new technique for recognizing nested named entities, by using a discriminative constituency parser. To train the model, we transform each sentence into a tree, with constituents for each named entity (and no other syntactic structure). We present results on both newspaper and biomedical corpora which contain nested named entities. In three out of four sets of experiments, our model outperforms a standard semi-CRF on the more traditional top-level entities. At the same time, we improve the overall F-score by up to 30% over the flat model, which is unable to recover any nested entities.

1 Introduction

Named entity recognition is the task of finding entities, such as people and organizations, in text. Frequently, entities are nested within each other, such as *Bank of China* and *University of Washington*, both *organizations* with nested *locations*. Nested entities are also common in biomedical data, where different biological entities of interest are often composed of one another. In the GENIA corpus (Ohta et al., 2002), which is labeled with entity types such as *protein* and *DNA*, roughly 17% of entities are embedded within another entity. In the AnCora corpus of Spanish and Catalan newspaper text (Martí et al., 2007), nearly half of the entities are embedded. However, work on named entity recognition (NER) has almost entirely ignored nested entities and instead chosen to focus on the outermost entities.

We believe this has largely been for practical, not ideological, reasons. Most corpus designers have chosen to skirt the issue entirely, and have annotated only the topmost entities. The widely used CoNLL (Sang and Meulder, 2003), MUC-6, and MUC-7 NER corpora, composed of American and British newswire, are all flatly annotated. The GENIA corpus contains nested entities, but the JNLPBA 2004 shared task (Collier et al., 2004), which utilized the corpus, removed all embedded entities for the evaluation. To our knowledge, the only shared task which has included nested entities is the SemEval 2007 Task 9 (Márquez et al., 2007b), which used a subset of the AnCora corpus. However, in that task all entities corresponded to particular parts of speech or noun phrases in the provided syntactic structure, and no participant directly addressed the nested nature of the data.

Another reason for the lack of focus on nested NER is technological. The NER task arose in the context of the MUC workshops, as small chunks which could be identified by finite state models or gazetteers. This then led to the widespread use of sequence models, first hidden Markov models, then conditional Markov models (Borthwick, 1999), and, more recently, linear chain conditional random fields (CRFs) (Lafferty et al., 2001). All of these models suffer from an inability to model nested entities.

In this paper we present a novel solution to the problem of nested named entity recognition. Our model explicitly represents the nested structure, allowing entities to be influenced not just by the labels of the words surrounding them, as in a CRF, but also by the entities contained in them, and in which they are contained. We represent each sentence as a parse tree, with the words as leaves, and with phrases corresponding to each entity (and a node which joins the entire sentence). Our trees look just like syntactic constituency trees, such as those in the Penn TreeBank (Marcus et al., 1993),

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 141–150,
Singapore, 6-7 August 2009.

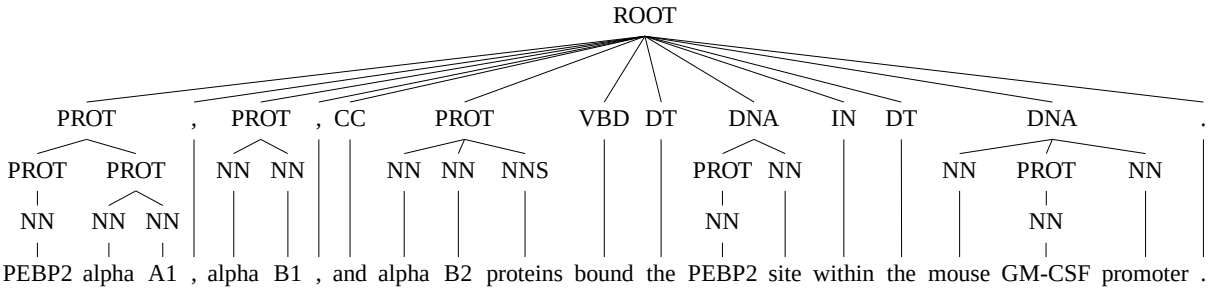

Figure 1: An example of our tree representation over nested named entities. The sentence is from the GENIA corpus. *PROT* is short for *PROTEIN*.

but they tend to be much flatter. This model allows us to include parts of speech in the tree, and therefore to jointly model the named entities and the part of speech tags. Once we have converted our sentences into parse trees, we train a discriminative constituency parser similar to that of (Finkel et al., 2008). We found that on top-level entities, our model does just as well as more conventional methods. When evaluating on *all* entities our model does well, with F-scores ranging from slightly worse than performance on top-level only, to substantially better than top-level only.

2 Related Work

There is a large body of work on named entity recognition, but very little of it addresses nested entities. Early work on the GENIA corpus (Kazama et al., 2002; Tsuruoka and Tsujii, 2003) only worked on the innermost entities. This was soon followed by several attempts at nested NER in GENIA (Shen et al., 2003; Zhang et al., 2004; Zhou et al., 2004) which built hidden Markov models over the innermost named entities, and then used a rule-based post-processing step to identify the named entities containing the innermost entities. Zhou (2006) used a more elaborate model for the innermost entities, but then used the same rule-based post-processing method on the output to identify non-innermost entities. Gu (2006) focused only on proteins and DNA, by building separate binary SVM classifiers for innermost and outermost entities for those two classes.

Several techniques for nested NER in GENIA where presented in (Alex et al., 2007). Their first approach was to layer CRFs, using the output of one as the input to the next. For inside-out layering, the first CRF would identify the innermost entities, the next layer would be over the words and the innermost entities to identify second-level entities, etc. For outside-in layering the first CRF would identify outermost entities, and then successive CRFs would identify increasingly nested entities. They also tried a cascaded approach, with separate CRFs for each entity type. The CRFs would be applied in a specified order, and then each CRF could utilize features derived from the output of previously applied CRFs. This technique has the problem that it cannot identify nested entities of the same type; this happens frequently in the data, such as the nested *proteins* at the beginning of the sentence in Figure 1. They also tried a joint labeling approach, where they trained a single CRF, but the label set was significantly expanded so that a single label would include all of the entities for a particular word. Their best results where from the cascaded approach.

Byrne (2007) took a different approach, on historical archive text. She modified the data by concatenating adjacent tokens (up to length six) into potential entities, and then labeled each concatenated string using the C&C tagger (Curran and Clark, 1999). When labeling a string, the "previous" string was the one-token-shorter string containing all but the last token of the current string. For single tokens the "previous" token was the longest concatenation starting one token earlier.

SemEval 2007 Task 9 (Márquez et al., 2007b) included a nested NER component, as well as noun sense disambiguation and semantic role labeling. However, the parts of speech and syntactic tree were given as part of the input, and named entities were specified as corresponding to noun phrases in the tree, or particular parts of speech. This restriction substantially changes the task. Two groups participated in the shared task, but only one (Márquez et al., 2007a) worked on the named entity component. They used a multi-label AdaBoost.MH algorithm, over phrases in the

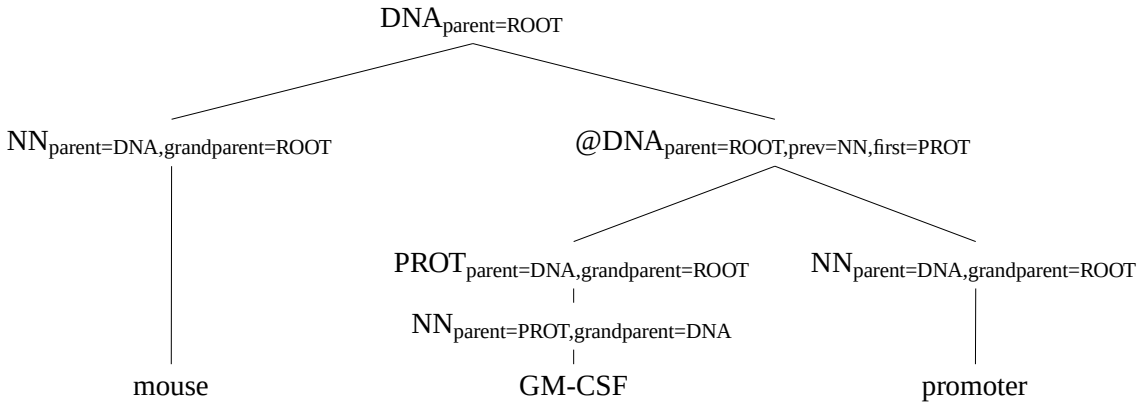

Figure 2: An example of a subtree after it has been annotated and binarized. Features are computed over this representation. An @ indicates a chart parser active state (incomplete constituent).

parse tree which, based on their labels, could potentially be entities.

Finally, McDonald et al. (2005) presented a technique for labeling potentially overlapping segments of text, based on a large margin, multilabel classification algorithm. Their method could be used for nested named entity recognition, but the experiments they performed were on joint (flat) NER and noun phrase chunking.

3 Nested Named Entity Recognition as Parsing

Our model is quite simple – we represent each sentence as a constituency tree, with each named entity corresponding to a phrase in the tree, along with a root node which connects the entire sentence. No additional syntactic structure is represented. We also model the parts of speech as preterminals, and the words themselves as the leaves. See Figure 1 for an example of a named entity tree. Each node is then annotated with both its parent and grandparent labels, which allows the model to learn how entities nest. We binarize our trees in a right-branching manner, and then build features over the labels, unary rules, and binary rules. We also use first-order horizontal Markovization, which allows us to retain some information about the previous node in the binarized rule. See Figure 2 for an example of an annotated and binarized subtree. Once each sentence has been converted into a tree, we train a discriminative constituency parser, based on (Finkel et al., 2008).

It is worth noting that if you use our model on data which does not have any nested entities, then it is precisely equivalent to a semi-CRF (Sarawagi and Cohen, 2004; Andrew, 2006), but with no length restriction on entities. Like a semi-CRF, we are able to define features over entire entities of arbitrary length, instead of just over a small, fixed window of words like a regular linear chain CRF.

We model part of speech tags jointly with the named entities, though the model also works without them. We determine the possible part of speech tags based on distributional similarity clusters. We used Alexander Clarke's software,[1] based on (Clark, 2003), to cluster the words, and then allow each word to be labeled with any part of speech tag seen in the data with any other word in the same cluster. Because the parts of speech are annotated with the parent (and grandparent) labels, they determine what, if any, entity types a word can be labeled with. Many words, such as verbs, cannot be labeled with any entities. We also limit our grammar based on the rules observed in the data. The rules whose children include part of speech tags restrict the possible pairs of adjacent tags. Interestingly, the restrictions imposed by this joint modeling (both observed word/tag pairs and observed rules) actually result in much faster inference (and therefore faster train and test times) than a model over named entities alone. This is different from most work on joint modeling of multiple levels of annotation, which usually results in significantly slower inference.

3.1 Discriminative Constituency Parsing

We train our nested NER model using the same technique as the discriminatively trained, conditional random field-based, CRF-CFG parser of (Finkel et al., 2008). The parser is similar to a

Table 1: The local and pairwise NER features used in all of our experiments. Consult the text for a full description of all features, which includes feature classes not in this table.

chart-based PCFG parser, except that instead of putting probabilities over rules, it puts *clique potentials* over local subtrees. These unnormalized potentials know what span (and split) the rule is over, and arbitrary features can be defined over the local subtree, the span/split and the words of the sentence. The inside-outside algorithm is run over the clique potentials to produce the partial derivatives and normalizing constant which are necessary for optimizing the log likelihood. Optimization is done by stochastic gradient descent.

The only real drawback to our model is runtime. The algorithm is $O(n^3)$ in sentence length. Training on all of GENIA took approximately 23 hours for the nested model and 16 hours for the semi-CRF. A semi-CRF *with* an entity length restriction, or a regular CRF, would both have been faster. At runtime, the nested model for GENIA tagged about 38 words per second, while the semi-CRF tagged 45 words per second. For comparison, a first-order linear chain CRF trained with similar features on the same data can tag about 4,000 words per second.

4 Features

When designing features, we first made ones similar to the features typically designed for a first-order CRF, and then added features which are not possible in a CRF, but are possible in our enhanced representation. This includes features over entire entities, features which directly model nested entities, and joint features over entities and parts of speech. When features are computed over each label, unary rule, and binary rule, the feature function is aware of the rule span and split.

Each word is labeled with its distributional similarity cluster (*distsim*), and a string indicating orthographic information (*shape*) (Finkel et al., 2005). Subscripts represent word position in the sentence. In addition to those below, we include features for each fully annotated label and rule.

Local named entity features. Local named entity features are over the label for a single word. They are equivalent to the local features in a linear chain CRF. However, unlike in a linear chain CRF, if a word belongs to multiple entities then the local features are computed for each entity. Local features are also computed for words not contained in any entity. Local features are in Table 1.

Pairwise named entity features. Pairwise features are over the labels for adjacent words, and are equivalent to the edge features in a linear chain CRF. They can occur when pairs of words have the same label, or over entity boundaries where the words have different labels. Like with the local features, if a pair of words are contained in, or straddle the border of, multiple entities, then the features are repeated for each. The pairwise features we use are shown in Table 1.

Embedded named entity features. Embedded named entity features occur in binary rules where one entity is the child of another entity. For our embedded features, we replicated the pairwise features, except that the embedded named entity was treated as one of the words, where the "word" (and other annotations) were indicative of the type of entity, and not the actual string that is the entity. For instance, in the subtree in Figure 2, we would compute $word_i + label_{i-1} + label_i$ as *PROT-DNA-DNA* for $i = 18$ (the index of the word *GM-CSF*). The normal pairwise feature at the same po-

sition would be *GM-CSF-DNA-DNA*.

Whole entity features. We had four whole entity features: the entire phrase; the preceding and following word; the preceding and following distributional similarity tags; and the preceding distributional similarity tag with the following word.

Local part of speech features. We used the same POS features as (Finkel et al., 2008).

Joint named entity and part of speech features. For the joint features we replicated the POS features, but included the parent of the POS, which either is the innermost entity type, or would indicate that the word is not in any entities.

5 Experiments

We performed two sets of experiments, the first set over biomedical data, and the second over Spanish and Catalan newspaper text. We designed our experiments to show that our model works just as well on outermost entities, the typical NER task, and also works well on nested entities.

5.1 GENIA Experiments

5.1.1 Data

We performed experiments on the GENIA v.3.02 corpus (Ohta et al., 2002). This corpus contains 2000 Medline abstracts (≈500k words), annotated with 36 different kinds of biological entities, and with parts of speech. Previous NER work using this corpus has employed 10-fold cross-validation for evaluation. We wanted to explore different model variations (e.g., level of Markovization, and different sets of distributional similarity clusterings) and feature sets, so we needed to set aside a development set. We split the data by putting the first 90% of sentences into the training set, and the remaining 10% into the test set. This is the exact same split used to evaluate part of speech tagging in (Tsuruoka et al., 2005). For development we used the first half of the data to train, and the next quarter of the data to test.[2] We made the same modifications to the label set as the organizers of the JNLPBA 2004 shared task (Collier et al., 2004). They collapsed all *DNA* subtypes into *DNA*; all *RNA* subtypes into *RNA*; all *protein* subtypes into *protein*; kept *cell line* and *cell type*; and removed all other entities. However, they also removed all embedded entities, while we kept them.

As discussed in Section 3, we annotated each word with a distributional similarity cluster. We used 200 clusters, trained using 200 million words from PubMed abstracts. During development, we found that fewer clusters resulted in slower infer-

[2]This split may seem strange: we had originally intended a 50/25/25 train/dev/test split, until we found the previously used 90/10 split.

ence with no improvement in performance.

5.1.2 Experimental Setup

We ran several sets of experiments, varying between all entities, or just top-level entities, for training and testing. As discussed in Section 3, if we train on just top-level entities then the model is equivalent to a semi-CRF. Semi-CRFs are state-of-the-art and provide a good baseline for performance on just the top-level entities. Semi-CRFs are strictly better than regular, linear chain CRFs, because they can use all of the features and strucutre of a linear chain CRF, but also utilize whole-entity features (Andrew, 2006). We also evaluated the semi-CRF model on all entities. This may seem like an unfair evaluation, because the semi-CRF has no way of recovering the nested entities, but we wanted to illustrate just how much information is lost when using a flat representation.

5.1.3 Results

Our named entity results when evaluating on all entities are shown in Table 2 and when evaluating on only top-level entities are shown in Table 3. Our nested model outperforms the flat semi-CRF on both top-level entities and all entities.

While not our main focus, we also evaluated our models on parts of speech. The model trained on just top level entities achieved POS accuracy of 97.37%, and the one trained on all entities achieved 97.25% accuracy. The GENIA tagger (Tsuruoka et al., 2005) achieves 98.49% accuracy using the same train/test split.

5.1.4 Additional JNLPBA 2004 Experiments

Because we could not compare our results on the NER portion of the GENIA corpus with any other work, we also evaluated on the JNLPBA corpus. This corpus was used in a shared task for the BioNLP workshop at Coling in 2004 (Collier et al., 2004). They used the entire GENIA corpus for training, and modified the label set as discussed in Section 5.1.1. They also removed all embedded entities, and kept only the top-level ones. They then annotated new data for the test set. This dataset has no nested entities, but because the training data is GENIA we can still train our model on the data annotated with nested entities, and then evaluate on their test data by ignoring all embedded entities found by our named entity recognizer.

Table 6: Named entity results on the Spanish portion of AnCora, evaluating on only top-level entities.

This experiment allows us to show that our named entity recognizer works well on top-level entities, by comparing it with prior work. Our model also produces part of speech tags, but the test data is not annotated with POS tags, so we cannot show POS tagging results on this dataset.

One difficulty we had with the JNLPBA experiments was with tokenization. The version of GENIA distributed for the shared task is tokenized differently from the original GENIA corpus, but we needed to train on the original corpus as it is the only version with nested entities. We tried our best to retokenize the original corpus to match the distributed data, but did not have complete success. It is worth noting that the data is actually tokenized in a manner which allows a small amount of "cheating." Normally, hyphenated words, such as *LPS-induced*, are tokenized as one word. However, if the portion of the word before the hyphen is in an entity, and the part after is not, such as *BCR-induced*, then the word is split into two tokens: *BCR* and *-induced*. Therefore, when a word starts with a hyphen it is a strong indicator that the prior word and it span the right boundary of an entity. Because the train and test data for the shared task do not contain nested entities, fewer words are split in this manner than in the original data. We did not intentionally exploit this fact in our feature design, but it is probable that some of our orthographic features "learned" this fact anyway. This probably harmed our results overall, because some hyphenated words, which straddled boundaries in nested entities and would have been split in the original corpus (and were split in our training data), were not split in the test data, prohibiting our model from properly identifying them.

For this experiment, we retrained our model on the entire, retokenized, GENIA corpus. We also retrained the distributional similarity model on the retokenized data. Once again, we trained one model on the nested data, and one on just the top-level entities, so that we can compare performance of both models on the top-level entities. Our full results are shown in Table 4, along with the current state-of-the-art (Zhou and Su, 2004). Besides the tokenization issues harming our performance, Zhou and Su (2004) also employed clever post-processing to improve their results.

5.2 AnCora Experiments

5.2.1 Data

We performed experiments on the NER portion of AnCora (Martí et al., 2007). This corpus has Spanish and Catalan portions, and we evaluated on both. The data is also annotated with parts of speech, parse trees, semantic roles and word

Table 8: Named entity results on the Catalan portion of AnCora, evaluating on only top-level entities.

senses. The corpus annotators made a distinction between *strong* and *weak* entities. They define *strong* named entities as "a word, a number, a date, or a string of words that refer to a single individual entity in the real world." If a strong NE contains multiple words, it is collapsed into a single token. *Weak* named entities, "consist of a noun phrase, being it simple or complex" and must contain a *strong* entity. Figure 3 shows an example from the corpus with both strong and weak entities. The entity types present are *person*, *location*, *organization*, *date*, *number*, and *other*. Weak entities are very prevalent; 47.1% of entities are embedded.

For Spanish, files starting with 7–9 were the test set, 5–6 were the development test set, and the remainder were the development train set. For Catalan, files starting with 8–9 were the test set, 6–7 were the development test set, and the remainder were the development train set. For both, the development train and test sets were combined to form the final train set. We removed sentences longer than 80 words. Spanish has 15,591 training sentences, and Catalan has 14,906.

5.2.2 Experimental Setup

The parts of speech provided in the data include detailed morphological information, using a similar annotation scheme to the Prague TreeBank (Hana and Hanová, 2002). There are around 250 possible tags, and experiments on the development data with the full tagset where unsuccessful. We removed all but the first two characters of each POS tag, resulting in a set of 57 tags which more closely resembles that of the Penn TreeBank (Marcus et al., 1993). All reported results use our modified version of the POS tag set.

We took only the words as input, none of the extra annotations. For both languages we trained a 200 cluster distributional similarity model over the words in the corpus. We performed the same set of experiments on AnCora as we did on GENIA.

5.2.3 Results and Discussion

The full results for Spanish when testing on all entities are shown in Table 5, and for only top-level entities are shown in Table 6. For part of speech tagging, the nested model achieved 95.93% accuracy, compared with 95.60% for the flatly trained model. The full results for Catalan when testing on all entities are shown in Table 7, and for only top-level entities are shown in Table 8. POS tagging results were even closer on Catalan: 96.62% for the nested model, and 96.59% for the flat model.

It is not surprising that the models trained on all entities do significantly better than the flatly trained models when testing on all entities. The

story is a little less clear when testing on just top-level entities. In this case, the nested model does 4.38% better than the flat model on the Spanish data, but 2.45% worse on the Catalan data. The overall picture is the same as for GENIA: modeling the nested entities does not, on average, reduce performance on the top-level entities, but a nested entity model does substantially better when evaluated on all entities.

6 Conclusions

We presented a discriminative parsing-based method for nested named entity recognition, which does well on both top-level and nested entities. The only real drawback to our method is that it is slower than common flat techniques. While most NER corpus designers have defenestrated embedded entities, we hope that in the future this will not continue, as large amounts of information are lost due to this design decision.

A Unified Model of Phrasal and Sentential Evidence for Information Extraction

Siddharth Patwardhan and **Ellen Riloff**
School of Computing
University of Utah
Salt Lake City, UT 84112
{sidd,riloff}@cs.utah.edu

Abstract

Information Extraction (IE) systems that extract role fillers for events typically look at the local context surrounding a phrase when deciding whether to extract it. Often, however, role fillers occur in clauses that are not directly linked to an event word. We present a new model for event extraction that jointly considers both the local context around a phrase along with the wider sentential context in a probabilistic framework. Our approach uses a *sentential event recognizer* and a *plausible role-filler recognizer* that is conditioned on event sentences. We evaluate our system on two IE data sets and show that our model performs well in comparison to existing IE systems that rely on local phrasal context.

1 Introduction

Information Extraction (IE) systems typically use extraction patterns (e.g., Soderland et al. (1995), Riloff (1996), Yangarber et al. (2000), Califf and Mooney (2003)) or classifiers (e.g., Freitag (1998), Freitag and McCallum (2000), Chieu et al. (2003), Bunescu and Mooney (2004)) to extract role fillers for events. Most IE systems consider only the immediate context surrounding a phrase when deciding whether to extract it. For tasks such as named entity recognition, immediate context is usually sufficient. But for more complex tasks, such as event extraction, a larger field of view is often needed to understand how facts tie together.

Most IE systems are designed to identify role fillers that appear as arguments to event verbs or nouns, either explicitly via syntactic relations or implicitly via proximity (e.g., *John murdered Tom* or *the murder of Tom by John*). But many facts are presented in clauses that do not contain event words, requiring discourse relations or deep structural analysis to associate the facts with event roles. For example, consider the sentences below:

Seven people *have died*

. . . and 30 were injured in India after terrorists launched an attack on the Taj Hotel.

. . . in Mexico City and its surrounding suburbs in a Swine Flu outbreak.

. . . after a tractor-trailer collided with a bus in Arkansas.

Two bridges *were destroyed*

. . . in Baghdad last night in a resurgence of bomb attacks in the capital city.

. . . and $50 million in damage was caused by a hurricane that hit Miami on Friday.

. . . to make way for modern, safer bridges that will be constructed early next year.

These examples illustrate a common phenomenon in text where information is not explicitly stated as filling an event role, but readers have no trouble making this inference. The role fillers above (***seven people***, ***two bridges***) occur as arguments to verbs that reveal state information (death, destruction) but are not event-specific (i.e., death and destruction can result from a wide variety of incident types). IE systems often fail to extract these role fillers because these systems do not recognize the immediate context as being relevant to the specific type of event that they are looking for.

We propose a new model for information extraction that incorporates both phrasal and sentential evidence in a unified framework. Our unified probabilistic model, called GLACIER, consists of two components: a model for *sentential event recognition* and a model for recognizing *plausible role fillers*. The Sentential Event Recognizer offers a probabilistic assessment of whether a sentence is discussing a domain-relevant event. The

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 151–160,
Singapore, 6-7 August 2009.

Plausible Role-Filler Recognizer is then conditioned to identify phrases as role fillers based upon the assumption that the surrounding context is discussing a relevant event. This unified probabilistic model allows the two components to jointly make decisions based upon both the local evidence surrounding each phrase and the "peripheral vision" afforded by the sentential event recognizer.

This paper is organized as follows. Section 2 positions our research with respect to related work. Section 3 presents our unified probabilistic model for information extraction. Section 4 shows experimental results on two IE data sets, and Section 5 discusses directions for future work.

2 Related Work

Many event extraction systems rely heavily on the local context around words or phrases that are candidates for extraction. Some systems use extraction patterns (Soderland et al., 1995; Riloff, 1996; Yangarber et al., 2000; Califf and Mooney, 2003), which represent the immediate contexts surrounding candidate extractions. Similarly, classifier-based approaches (Freitag, 1998; Freitag and McCallum, 2000; Chieu et al., 2003; Bunescu and Mooney, 2004) rely on features in the immediate context of the candidate extractions. Our work seeks to incorporate additional context into IE.

Indeed, several recent approaches have shown the need for global information to improve IE performance. Maslennikov and Chua (2007) use discourse trees and local syntactic dependencies in a pattern-based framework to incorporate wider context. Finkel et al. (2005) and Ji and Grishman (2008) incorporate global information by enforcing event role or label consistency over a document or across related documents. In contrast, our approach simply creates a richer IE model for individual extractions by expanding the "field of view" to include the surrounding sentence.

The two components of the unified model presented in this paper are somewhat similar to our previous work (Patwardhan and Riloff, 2007), where we employ a relevant region identification phase prior to pattern-based extraction. In that work we adopted a pipeline paradigm, where a classifier identifies relevant sentences and only those sentences are fed to the extraction module. Our unified probabilistic model described in this paper does not draw a hard line between relevant and irrelevant sentences, but gently balances the influence of both local and sentential contexts through probability estimates.

3 A Unified IE Model that Combines Phrasal and Sentential Evidence

We introduce a probabilistic model for event-based IE that balances the influence of two kinds of contextual information. Our goal is to create a model that has the flexibility to make extraction decisions based upon strong evidence from the local context, or strong evidence from the wider context coupled with a more general local context. For example, some phrases explicitly refer to an event, so they almost certainly warrant extraction regardless of the wider context (e.g., *terrorists launched an attack*).[1] In contrast, some phrases are potentially relevant but too general to warrant extraction on their own (e.g., *people died* could be the result of different incident types). If we are confident that the sentence discusses an event of interest, however, then such phrases could be reliably extracted.

Our unified model for IE (GLACIER) combines two types of contextual information by incorporating it into a probabilistic framework. To determine whether a noun phrase instance NP_i should be extracted as a filler for an event role, GLACIER computes the joint probability that NP_i:

(1) appears in an event sentence, and
(2) is a legitimate filler for the event role.

Thus, GLACIER is designed for noun phrase extraction and, mathematically, its decisions are based on the following joint probability:

$$P(EvSent(S_{NP_i}), PlausFillr(NP_i))$$

where S_{NP_i} is the sentence containing noun phrase NP_i. This probability estimate is based on contextual features F appearing within S_{NP_i} and in the local context of NP_i. Including F in the joint probability, and applying the product rule, we can split our probability into two components:

$$\begin{aligned} P(EvSent(S_{NP_i}), PlausFillr(NP_i)|F) = \\ P(EvSent(S_{NP_i})|F) \\ * \quad P(PlausFillr(NP_i)|EvSent(S_{NP_i}), F) \end{aligned}$$

These two probability components, in the expression above, form the basis of the two modules in

[1] There are always exceptions of course, such as hypothetical statements, but they are relatively uncommon.

our IE system – the *sentential event recognizer* and the *plausible role-filler recognizer*. In arriving at a decision to extract a noun phrase, our unified model for IE uses these modules to estimate the two probabilities based on the set of contextual features F. Note that having these two probability components allows the system to gently balance the influence from the sentential and phrasal contexts, without having to make hard decisions about sentence relevance or phrases in isolation.

In this system, the sentential event recognizer is embodied in the probability component $P(EvSent(S_{NP_i})|F)$. This is essentially the probability of a sentence describing a relevant event. Similarly, the plausible role-filler recognizer is embodied by the probability $P(PlausFillr(NP_i)|EvSent(S_{NP_i}), F)$. This component, therefore, estimates the probability that a noun phrase fills a specific event role, *assuming that the noun phrase occurs in an event sentence*. Many different techniques could be used to produce these probability estimates. In the rest of this section, we present the specific models that we used for each of these components.

3.1 Plausible Role-Filler Recognizer

The plausible role-filler recognizer is similar to most traditional IE systems, where the goal is to determine whether a noun phrase can be a legitimate filler for a specific type of event role based on its local context. Pattern-based approaches match the context surrounding a phrase using lexico-syntactic patterns or rules. However, most of these approaches do not produce probability estimates for the extractions. Classifier-based approaches use machine learning classifiers to make extraction decisions, based on features associated with the local context. Any classifier that can generate probability estimates, or similar confidence values, could be plugged into our model.

In our work, we use a Naïve Bayes classifier as our plausible role-filler recognizer. The probabilities are computed using a generative Naïve Bayes framework, based on local contextual features surrounding a noun phrase. These clues include lexical matches, semantic features, and syntactic relations, and will be described in more detail in Section 3.3. The Naïve Bayes (NB) plausible role-filler recognizer is defined as follows:

$$P(PlausFillr(NP_i)|EvSent(S_{NP_i}), F) = \frac{1}{Z} P(PlausFillr(NP_i)|EvSent(S_{NP_i})) * \prod_{f_i \in F} P(f_i|PlausFillr(NP_i), EvSent(S_{NP_i}))$$

where F is the set of local contextual features and Z is the normalizing constant. The prior $P(PlausFillr(NP_i)|EvSent(S_{NP_i}))$ is estimated from the fraction of role fillers in the training data. The product term in the equation is the likelihood, which makes the simplifying assumption that all of the features in F are independent of one another. It is important to note that these probabilities are conditioned on the noun phrase NP_i appearing in an event sentence.

Most IE systems need to extract several different types of role fillers for each event. For instance, to extract information about terrorist incidents a system may extract the names of perpetrators, victims, targets, and weapons. We create a separate IE model for each type of event role. To construct a unified IE model for an event role, we must specifically create a plausible role-filler recognizer for that event role, but we can use a single sentential event recognizer for all of the role filler types.

3.2 Sentential Event Recognizer

The task at hand for the sentential event recognizer is to analyze features in a sentence and estimate the probability that the sentence is discussing a relevant event. This is very similar to the task performed by text classification systems, with some minor differences. Firstly, we are dealing with the classification of sentences, as opposed to entire documents. Secondly, we need to generate a probability estimate of the "class", and not just a class label. Like the plausible role-filler recognizer, here too we employ machine learning classifiers to estimate the desired probabilities.

3.2.1 Naïve Bayes Event Recognizer

Since Naïve Bayes classifiers estimate class probabilities, we employ such a classifier to create a sentential event recognizer:

$$P(EvSent(S_{NP_i})|F) = \frac{1}{Z} P(EvSent(S_{NP_i})) * \prod_{f_i \in F} P(f_i|EvSent(S_{NP_i}))$$

where Z is the normalizing constant and F is the set of contextual features in the sentence. The

prior $P(EvSent_{S(NP_i)})$ is obtained from the ratio of event and non-event sentences in the training data. The product term in the equation is the likelihood, which makes the simplifying assumption that the features in F are independent of one another. The features used by the model will be described in Section 3.3.

A known issue with Naïve Bayes classifiers is that, even though their classification accuracy is often quite reasonable, their probability estimates are often poor (Domingos and Pazzani, 1996; Zadrozny and Elkan, 2001; Manning et al., 2008). The problem is that these classifiers tend to overestimate the probability of the predicted class, resulting in a situation where most probability estimates from the classifier tend to be either extremely close to 0.0 or extremely close to 1.0. We observed this problem in our classifier too, so we decided to explore an additional model to estimate probabilities for the sentential event recognizer. This second model, based on SVMs, is described next.

3.2.2 SVM Event Recognizer

Given the all-or-nothing nature of the probability estimates that we observed from the Naïve Bayes model, we decided to try using a Support Vector Machine (SVM) (Vapnik, 1995; Joachims, 1998) classifier as an alternative to Naïve Bayes. One of the issues with doing this is that SVMs are not probabilistic classifiers. SVMs make classification decisions using on a *decision boundary* defined by *support vectors* identified during training. A decision function is applied to unseen test examples to determine which side of the decision boundary those examples lie. While the values obtained from the decision function only indicate class assignments for the examples, we used these values to produce confidence scores for our sentential event recognizer.

To produce a confidence score from the SVM classifier, we take the values generated by the decision function for each test instance and normalize them based on the minimum and maximum values produced across all of the test instances. This normalization process produces values between 0 and 1 that we use as a rough indicator of the confidence in the SVM's classification. We observed that we could effect a consistent recall/precision trade-off by using these values as thresholds for classification decisions, which suggests that this approach worked reasonably well for our task.

3.3 Contextual Features

We used a variety of contextual features in both components of our system. The plausible role-filler recognizer uses the following types of features for each candidate noun phrase NP_i: *lexical head* of NP_i, *semantic class* of NP_i's lexical head, *named entity tags* associated with NP_i and *lexico-syntactic patterns* that represent the local context surrounding NP_i. The feature set is automatically generated from the texts. Each feature is assigned a binary value for each instance, indicating either the presence or absence of the feature.

The *named-entity* features are generated by the freely available Stanford NER tagger (Finkel et al., 2005). We use the pre-trained NER model that comes with the software to identify person, organization and location names. The syntactic and semantic features are generated by the Sundance/AutoSlog system (Riloff and Phillips, 2004). We use the Sundance shallow parser to identify lexical heads, and use its semantic dictionaries to assign semantic features to words. The AutoSlog pattern generator (Riloff, 1996) is used to create the *lexico-syntactic pattern* features that capture local context around each noun phrase.

Our training sets produce a very large number of features, which initially bogged down our classifiers. Consequently, we reduced the size of the feature set by discarding all features that appeared four times or less in the training set.

Our sentential event recognizer uses the same contextual features as the plausible role-filler recognizer, except that features are generated for every NP in the sentence. In addition, it uses three types of sentence-level features: *sentence length*, *bag of words*, and *verb tense*, which are also binary features. We have two binary *sentence length* features indicating that the sentence is long (greater than 35 words) or is short (shorter than 5 words). Additionally, all of the words in each sentence in the training data are generated as *bag of words* features for the sentential model. Finally, we generate *verb tense* features from all verbs appearing in each sentence. Here too we apply a frequency cutoff and eliminate all features that appear four times or less in the training data.

4 IE Evaluation

4.1 Data Sets

We evaluated the performance of our IE system on two data sets: the MUC-4 terrorism corpus (Sund-

heim, 1992), and a ProMed disease outbreaks corpus (Phillips and Riloff, 2007; Patwardhan and Riloff, 2007). The MUC-4 data set is a standard IE benchmark collection of news stories about terrorist events. It contains 1700 documents divided into 1300 development (DEV) texts, and four test sets of 100 texts each (TST1, TST2, TST3, and TST4). Unless otherwise stated, our experiments adopted the same training/test split used in previous research: the 1300 DEV texts for training, 200 texts (TST1+TST2) for tuning, and 200 texts (TST3+TST4) as the blind test set. We evaluated our system on five MUC-4 string roles: *perpetrator individuals*, *perpetrator organizations*, *physical targets*, *victims*, and *weapons*.

The ProMed corpus consists of 120 documents obtained from ProMed-mail[2], a freely accessible global electronic reporting system for outbreaks of diseases. These 120 documents are paired with corresponding answer key templates. Unless otherwise noted, all of our experiments on this data set used 5-fold cross validation. We extracted two types of event roles: *diseases* and *victims*[3].

Unlike some other IE data sets, many of the texts in these collections do not describe a relevant event. Only about half of the MUC-4 articles describe a specific terrorist incident[4], and only about 80% of the ProMed articles describe a disease outbreak. The answer keys for the irrelevant documents are therefore empty. IE systems are especially susceptible to false hits when they can be given texts that contain no relevant events.

The complete IE task involves the creation of answer key templates, one template per incident (many documents in our data sets describe multiple events). Our work focuses on accurately extracting the facts from the text and not on template generation per se (e.g., we are not concerned with coreference resolution or which extraction belongs in which template). Consequently, our experiments evaluate the accuracy of the extractions individually. We used *head noun* scoring, where an extraction is considered to be correct if its head noun matches the head noun in the answer key.[5]

[2]http://www.promedmail.org

[3]The "victims" can be people, animals, or plants.

[4]With respect to the definition of terrorist incidents in the MUC-4 guidelines (Sundheim, 1992).

[5]Pronouns were discarded from both the system responses and the answer keys since we do not perform coreference resolution. Duplicate extractions (e.g., the same string extracted multiple times from the same document) were conflated before being scored, so they count as just one hit or one miss.

4.2 Baselines

We generated three baselines to use as comparisons with our IE system. As our first baseline, we used AutoSlog-TS (Riloff, 1996), which is a weakly-supervised, pattern-based IE system available as part of the Sundance/AutoSlog software package (Riloff and Phillips, 2004). Our previous work in event-based IE (Patwardhan and Riloff, 2007) also used a pattern-based approach that applied *semantic affinity* patterns to relevant regions in text. We use this system as our second baseline. As a third baseline, we trained a Naïve Bayes IE classifier that is analogous to the plausible role-filler recognizer in our unified IE model, except that this baseline system is not conditioned on the assumption of having an event sentence. Consequently, this baseline NB classifier is akin to a traditional supervised learning-based IE system that uses only local contextual features to make extraction decisions. Formally, the baseline NB classifier uses the formula:

$$P(PlausFillr(NP_i)|F) = \frac{1}{Z}P(PlausFillr(NP_i)) * \prod_{f_i \in F} P(f_i|PlausFillr(NP_i))$$

where F is the set of local features, $P(PlausFillr(NP_i))$ is the prior probability, and Z is the normalizing constant. We used the Weka (Witten and Frank, 2005) implementation of Naïve Bayes for this baseline NB system.

New Jersey, February, 26. An outbreak of Ebola has been confirmed in Mercer County, New Jersey. Five teenage boys appear to have contracted the deadly virus from an unknown source. The CDC is investigating the cases and is taking measures to prevent the spread...

Disease:	Ebola
Victims:	Five teenage boys

Figure 1: A *Disease Outbreak* Event Template

Both the MUC-4 and ProMed data sets have separate answer keys rather than annotated source documents. Figure 1 shows an example of a document and its corresponding answer key template. To train the baseline NB system, we identify all instances of each answer key string in the source document and consider every instance a positive training example. This produces noisy training data, however, because some instances occur in

Table 2: Baseline Results on ProMed

undesirable contexts. For example, if the string "man" appears in an answer key as a victim, one instance of "man" may refer to the actual victim in an event sentence, while another instance of "man" may occur in a non-event context (e.g., background information) or may refer to a completely different person.

We report three evaluation metrics in our experiments: precision (P), recall (R), and F-score (F), where recall and precision are equally weighted. For the Naïve Bayes classifier, the natural threshold for distinguishing between positive and negative classes is 0.5, but we also evaluated this classifier with thresholds of 0.7 and 0.9 to see if we could effect a recall/precision trade-off. Tables 1 and 2 present the results of our three baseline systems. The NB classifier performs comparably to AutoSlog-TS and Semantic Affinity on most event roles, although a threshold of 0.90 is needed to reach comparable performance on ProMed. The relatively low numbers across the board indicate that these corpora are challenging, but these results suggest that our plausible role-filler recognizer is competitive with other existing IE systems. In Section 4.4 we will show how our unified IE model compares to these baselines. But before that (in the next section) we evaluate the quality of the second component of our IE system: the sentential event recognizer.

4.3 Sentential Event Recognizer Models

The sentential event recognizer is one of the core contributions of this research, so in this section we evaluate it by itself, before we employ it within the unified framework. The purpose of the sentential event recognizer is to determine whether a sentence is discussing a domain-relevant event. For our data sets, the classifier must decide whether a sentence is discussing a terrorist incident (MUC-4) or a disease outbreak (ProMed). Ideally, we want such a classifier to operate independently from the answer keys and the extraction task per se. For example, a terrorism IE system could be designed to extract only perpetrators and victims of terrorist events, or it could be designed to extract only targets and locations. The job of the sentential event recognizer remains the same: to identify sentences that discuss a terrorist event. How to train and evaluate such a system is a difficult question. In this section, we present two approaches that we explored to generate the training data: (a) using the IE answer keys, and (b) using human judgements.

4.3.1 Sentence Annotation via Answer Keys

We have argued that the *event relevance* of a sentence should not be tied to a specific set of event roles. However, the IE answer keys can be used to identify some sentences that describe an event, because they contain an answer string. So we can map the answer strings back to sentences in the source documents to automatically generate event sentence annotations.[6] These annotations will be noisy, though, because an answer string can appear in a non-event sentence, and some event sentences may not contain any answer strings. The alternative, however, is sentence annotations by humans, which (as we will discuss in Section 4.3.2) is challenging.

4.3.2 Sentence Annotation via Human Judgements

For many sentences there is a clear consensus among people that an event is being discussed. For example, most readers would agree that sentence (1) below is describing a terrorist event, while sen-

[6] A similar strategy was used in previous work (Patwardhan and Riloff, 2007) to generate a test set for the evaluation of a relevant region classifier.

Table 4: Sentential Event Recognizer Results for MUC-4 using 1300 Documents for Training

tence (2) is not. However it is difficult to draw a clear line. Sentence (3), for example, describes an action taken in response to a terrorist event. Is this a terrorist event sentence? Precisely how to define an *event sentence* is not obvious.

> (1) *Al Qaeda operatives launched an attack on the Madrid subway system.*
>
> (2) *Madrid has a population of about 3.2 million people.*
>
> (3) *City officials stepped up security in response to the attacks.*

We tackled this issue by creating detailed annotation guidelines to define the notion of an event sentence, and conducting a human annotation study. The guidelines delineated a general time frame for the beginning and end of an event, and constrained the task to focus on specific incidents that were reported in the IE answer key. We gave the annotators a brief description (e.g., *murder in Peru*) of each event that had a filled answer key in the data set. They only labeled sentences that discussed those particular events.

We employed two human judges, who annotated 120 documents from the ProMed test set, and 100 documents from the MUC-4 test set. We asked both judges to label 30 of the same documents from each data set so that we could compute inter-annotator agreement. The annotators had an agreement of 0.72 Cohen's κ on the ProMed data, and 0.77 Cohen's κ on the MUC-4 data. Given the difficulty of this task, we were satisfied that this task is reasonably well-defined and the annotations are of good quality.

4.3.3 Event Recognizer Results

We evaluated the two sentential event recognizer models described in Section 3.2 in two ways: (1) using the answer key sentence annotations for training/testing, and (2) using the human annotations for training/testing. Table 3 shows the results for all combinations of training/testing data. Since we only have human annotations for 100 MUC-4 texts and 120 ProMed texts, we performed 5-fold cross-validation on these documents. For our classifiers, we used the Weka (Witten and Frank, 2005) implementation of Naïve Bayes and the SVMLight (Joachims, 1998) implementation of the SVM. For each classifier we report overall accuracy, and precision, recall and F-scores with respect to both the positive and negative classes (event vs. non-event sentences).

The rows labeled *Ans* show the results for models trained via answer keys, and the rows labeled *Hum* show the results for the models trained with human annotations. The left side of the table shows the results using the answer key annotations for evaluation, and the right side of the table shows the results using the human annotations for evaluation. One expects classifiers to perform best when they are trained and tested on the same type of data, and our results bear this out – the classifiers that were trained and tested on the same kind of annotations do best. The boldfaced numbers represent the best accuracies achieved for each domain. As we would expect, the classifiers that are both trained and tested with human annotations (*Hum*) show the best performance, with the Naïve Bayes achieving the best accuracy of 85% on the

Table 5: Unified IE Model on MUC-4

MUC-4 texts, and the SVM achieving the best accuracy of 79% on the ProMed texts.

The recall and precision for non-event sentences is much higher than for event sentences. This classifier is forced to draw a hard line between the event and non-event sentences, which is a difficult task even for people. One of the advantages of our unified IE model, which will be described in the next section, is that it does not require hard decisions but instead uses a probabilistic estimate of how "event-ish" a sentence is.

Table 3 showed that models trained on human annotations outperform models trained on answer key annotations. But with the MUC-4 data, we have the luxury of 1300 training documents with answer keys, while we only have 100 documents with human annotations. Even though the answer key annotations are noisier, we have 13 times as much training data.

So we trained another sentential event recognizer using the entire MUC-4 training set. These results are shown in Table 4. Observe that using this larger (albeit noisy) training data does not appear to affect the Naïve Bayes model very much. Compared with the model trained on 100 manually annotated documents, its accuracy decreases by 2% from 85% to 83%. The SVM model, on the other hand, achieves an 89% accuracy when trained with the larger MUC-4 training data, compared to 84% accuracy for the model trained from the 100 manually labeled documents. Consequently, the sentential event recognizer models used in our unified IE framework (described in Section 4.4) are trained with this 1300 document training set.

4.4 Evaluation of the Unified IE Model

We now evaluate the performance of our unified IE model, GLACIER, which allows a plausible role-filler recognizer and a sentential event recognizer to make joint decisions about phrase extractions. Tables 5 and 6 present the results of the unified

	Disease			Victim

NB/SVM .50	.38	.54	.44	.42	.47	**.44**

Table 6: Unified IE Model on ProMed

IE model on the MUC-4 and ProMed data sets. The NB/NB systems use Naïve Bayes models for both components, while the NB/SVM systems use a Naïve Bayes model for the plausible role-filler recognizer and an SVM for the sentential event recognizer. As with our baseline system, we obtain good results using a threshold of 0.90 for our NB/NB model (i.e., only NPs with probability $\geq$ 0.90 are extracted). For our NB/SVM models, we evaluated using the default threshold (0.50) but observed that recall was sometimes low. So we also use a threshold of 0.40, which produces superior results. Here too, we used the Weka (Witten and Frank, 2005) implementation of the Naïve Bayes model and the SVMLight (Joachims, 1998) implementation of the SVM.

For the MUC-4 data, our unified IE model using the SVM (0.40) outperforms all 3 baselines on three roles (**PerpInd, Victim, Weapon**) and outperforms 2 of the 3 baselines on the **Target** role. When GLACIER outperforms the other systems it is often by a wide margin: the F-score for **PerpInd** jumped from 0.43 for the best baseline (Sem Affinity) to 0.54 for GLACIER, and the F-scores for **Victim** and **Weapon** each improved by 5% over the best baseline. These gains came from both increased recall and increased precision, demonstrating that GLACIER extracts some information that was missed by the other systems and is also less prone to false hits.

Only the **PerpOrg** role shows inferior performance. Organizations perpetrating a terrorist

event are often discussed later in a document, far removed from the main event description. For example, a statement that *Al Qaeda* is believed to be responsible for an attack would typically appear after the event description. As a result, the sentential event recognizer tends to generate low probabilities for such sentences. We believe that addressing this issue would require the use of discourse relations or the use of even larger context sizes. We intend to explore these avenues of research in future work.

On the ProMed data, GLACIER produces results that are similar to the baselines for the **Victim** role, but it outperforms the baselines for the **Disease** role. We find that for this domain, the unified IE model with the Naïve Bayes sentential event recognizer is superior to the unified IE model with the SVM classifier. For the **Disease** role, the F-score jumped 6%, from 0.43 for the best baseline systems (AutoSlog-TS and the NB baseline) to 0.49 for $\text{GLACIER}_{\text{NB/NB}}$. In contrast to the MUC-4 data, this improvement was mostly due to an increase in precision (up to 0.41), indicating that our unified IE model was effective at eliminating many false hits. For the **Victim** role, the performance of the unified model is comparable to the baselines. On this event role, the F-score of $\text{GLACIER}_{\text{NB/NB}}$ (0.44) matches that of the best baseline system (Sem Affinity, with 0.44). However, note that $\text{GLACIER}_{\text{NB/NB}}$ can achieve a 5% gain in recall over this baseline, at the cost of a 3% precision loss.

4.5 Specific Examples

Figure 2 presents some specific examples of extractions that are failed to be extracted by the baseline models, but are correctly identified by GLACIER because of its use of sentential evidence. Observe that in each of these examples, GLACIER correctly extracts the underlined phrases, in spite of the inconclusive evidence in the local contexts around them. In the last sentence in Figure 2, for example, GLACIER correctly makes the inference that the policemen in the bus (which was traveling on the bridge) are likely the victims of the terrorist event. Thus, we see that our system manages to balance the influence of the two probability components to make extraction decisions that would be impossible to make by relying only on the local phrasal context. In addition, the sentential event recognizer can also help improve precision by preventing extractions from non-event sentences.

Figure 2: Examples of GLACIER Extractions

5 Conclusions

We presented a unified model for IE that balances the influence of sentential context with local contextual evidence to improve the performance of event-based IE. Our experimental results showed that using sentential contexts indeed produced better results on two IE data sets. Our current model uses supervised learning, so one direction for future work is to adapt the model for weakly supervised learning. We also plan to incorporate discourse features and investigate even wider contexts to capture broader discourse effects.

Review Sentiment Scoring via a Parse-and-Paraphrase Paradigm

Abstract

This paper presents a parse-and-paraphrase paradigm to assess the degrees of sentiment for product reviews. Sentiment identification has been well studied; however, most previous work provides binary polarities only (positive and negative), and the polarity of sentiment is simply reversed when a negation is detected. The extraction of lexical features such as unigram/bigram also complicates the sentiment classification task, as linguistic structure such as implicit long-distance dependency is often disregarded. In this paper, we propose an approach to extracting adverb-adjective-noun phrases based on clause structure obtained by parsing sentences into a hierarchical representation. We also propose a robust general solution for modeling the contribution of adverbials and negation to the score for degree of sentiment. In an application involving extracting aspect-based pros and cons from restaurant reviews, we obtained a 45% relative improvement in recall through the use of parsing methods, while also improving precision.

1 Introduction

Online product reviews have provided an extensive collection of free-style texts as well as product ratings prepared by general users, which in return provide grassroots contributions to users interested in a particular product or service as assistance. Yet, valuable as they are, free-style reviews contain much noisy data and are tedious to read through in order to reach an overall conclusion. Thus, we conducted this study to automatically process and evaluate product reviews in order to generate both numerical evaluation and textual summaries of users' opinions, with the ultimate goal of adding value to real systems such as a restaurant-guide dialogue system.

Sentiment summarization has been well studied in the past decade (Turney, 2002; Pang et al., 2002; Dave et al., 2003; Hu and Liu, 2004a, 2004b; Carenini et al., 2006; Liu et al., 2007). The polarity of users' sentiments in each segment of review texts is extracted, and the polarities of individual sentiments are aggregated among all the sentences/segments of texts to give a numerical scaling on sentiment orientation.

Most of the work done for sentiment analysis so far has employed shallow parsing features such as part-of-speech tagging. Frequent adjectives and nouns/noun phrases are extracted as opinion words and representative product features. However, the linguistic structure of the sentence is usually not taken into consideration. High level linguistic features, if well utilized and accurately extracted, can provide much insight into the semantic meaning of user opinions and contribute to the task of sentiment identification.

Furthermore, in addition to adjectives and nouns, adverbials and negation also play an important role in determining the degree of the orientation level. For example, "very good" and "good" certainly express different degrees of positive sentiment. Also, in previous studies, when negative expressions are identified, the polarity of sentiment in the associated segment of text is simply reversed. However, semantic expressions are quite different from the absolute opposite values in mathematics. For example, "not bad" does not express the opposite meaning of "bad", which would be highly positive. Simply reversing the polarity of sentiment on the appearance of negations may result in inaccurate interpretation of sentiment expressions. Thus, a system which attempts to quantify sentiment while ignoring adverbials is missing a significant component of the sentiment score, especially if the adverbial is a negative word.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 161–169,
Singapore, 6-7 August 2009.

Another challenging aspect of negation is proper scoping of the negative reference over the right constituent, which we argue, can be handled quite well with careful linguistic analysis. Take the sentence "*I don't think the place is very clean*" as example. A linguistic approach associating long-distance elements with semantic relations can identify that the negation "not" scopes over the complement clause, thus extracting "not very clean" instead of "very clean".

Our goal in modeling adverbials is to investigate whether a simple linear correction model can capture the polarity contribution of all adverbials. Furthermore, is it also appropriate to adjust for multiple adverbs, including negation, via a linear *additive* model? I.e., can "not very good" be modeled as *not(very(good))*? The fact that "not very good" seems to be *less* negative than "not good" suggests that such an algorithm might work well. From these derivations we have developed a model which treats negations in the exact same way as modifying adverbs, via an accumulative linear offset model. This yields a very generic and straightforward solution to modeling the strength of sentiment expression.

In this paper we utilize a parse-and-paraphrase paradigm to identify semantically related phrases in review texts, taking quantifiers (e.g., modifying adverbs) and qualifiers (e.g., negations) into special consideration. The approach makes use of a lexicalized probabilistic syntactic grammar to identify and extract sets of *adverb-adjective-noun* phrases that match review-related patterns. Such patterns are constructed based on well-formed linguistic structure; thus, relevant phrases can be extracted reliably.

We also propose a cumulative linear offset model to calculate the degree of sentiment for joint adjectives and quantifiers/qualifiers. The proposed sentiment prediction model takes modifying adverbs and negations as universal scales on strength of sentiment, and conducts cumulative calculation on the degree of sentiment for the associated adjective. With this model, we can provide not only qualitative textual summarization such as "good food" and "bad service", but also a numerical scoring of sentiment, i.e., "how good the food is" and "how bad the service is."

2 Related Work

There have been many studies on sentiment classification and opinion summarization (Pang and Lee, 2004, 2005; Gamon et al., 2005; Popescu and Etzioni, 2005; Liu et al., 2005; Zhuang et al., 2006; Kim and Hovy, 2006). Specifically, aspect rating as an interesting topic has also been widely studied (Titov and McDonald, 2008a; Snyder and Barzilay, 2007; Goldberg and Zhu, 2006). Recently, Baccianella et. al. (2009) conducted a study on multi-facet rating of product reviews with special emphasis on how to generate vectorial representations of the text by means of POS tagging, sentiment analysis, and feature selection for ordinal regression learning. Titov and McDonald (2008b) proposed a joint model of text and aspect ratings which utilizes a modified LDA topic model to build topics that are representative of ratable aspects, and builds a set of sentiment predictors. Branavan et al. (2008) proposed a method for leveraging unstructured annotations in product reviews to infer semantic document properties, by clustering user annotations into semantic properties and tying the induced clusters to hidden topics in the text.

3 System Overview

Our review summarization task is to extract sets of descriptor-topic pairs (e.g., "excellent service") from a set of reviews (e.g., for a particular restaurant), and to cluster the extracted phrases into representative aspects on a set of dimensions (e.g., "food", "service" and "atmosphere"). Driven by this motivation, we propose a three-stage system that automatically processes reviews. A block diagram is given in Figure 1.

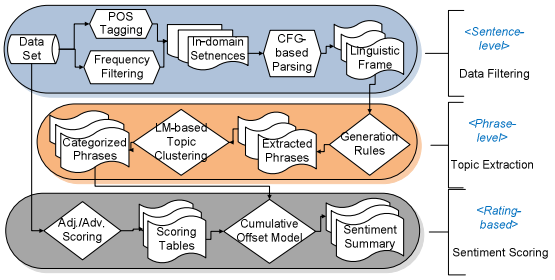

Figure 1. Framework of review processing.

The first stage is *sentence-level data filtering*. Review data published by general users is often in free-style, and a large fraction of the data is either ill-formed or not relevant to the task. We classify these as *out of domain* sentences. To filter out such noisy data, we collect unigram statistics on all the relevant words in the corpus, and select high frequency adjectives and nouns. Any sentence that contains none of the high-frequency nouns or adjectives is rejected from further analysis. The remaining *in-domain* sentences are subjected to the second stage, *parse*

analysis and semantic understanding, for topic extraction.

From the parsable sentences we extract descriptor-topic phrase patterns based on a carefully-designed generation grammar. We then apply *LM* (*language model) based topic clustering* to group the extracted phrases into representative aspects. The third stage scores the *degree of sentiment* for adjectives, as well as the *strength of sentiment* for modifying adverbs and negations, which further refine the degree of sentiment of the associated adjectives. We then run a *linear additive model* to assign a combined sentiment score for each extracted phrase.

The rest of the paper is structured as follows: In Section 4, we explain the linguistic analysis. In Section 5, we describe the cumulative model for assessing the degree of sentiment. Section 6 provides a systematic evaluation, conducted on real data in the restaurant review domain harvested from the Web. Section 7 provides a discussion analyzing the results. Section 8 summarizes the paper as well as pointing to future work.

4 Linguistic Analysis

4.1 Parse-and-Paraphrase

Our linguistic analysis is based on a parse-and-paraphrase paradigm. Instead of the flat structure of a surface string, the parser provides a hierarchical representation, which we call a *linguistic frame* (Xu et al., 2008). It preserves linguistic structure by encoding different layers of semantic dependencies. The grammar captures syntactic structure through a set of carefully constructed context free grammar rules, and employs a feature-passing mechanism to enforce long distance constraints. The grammar is lexicalized, and uses a statistical model to rank order competing hypotheses. It knows explicitly about 9,000 words, with all unknown words being interpreted as nouns. The grammar probability model was trained automatically on the corpus of review sentences.

To produce the phrases, a set of generation rules is carefully constructed to only extract sets of related adverbs, adjectives and nouns. The adjective-noun relationships are captured from the following linguistic patterns: (1) all adjectives attached directly to a noun in a noun phrase, (2) adjectives embedded in a relative clause modifying a noun, and (3) adjectives related to nouns in a subject-predicate relationship in a clause. These patterns are compatible, i.e., if a clause contains both a modifying adjective and a predicate adjective related to the same noun, two adjective-noun pairs are generated by different patterns. As in, "The efficient waitress was nonetheless very courteous." It is a "parse-and-paraphrase-like" paradigm: the paraphrase tries to preserve the original words intact, while reordering them and/or duplicating them into multiple NP units. Since they are based on syntactic structure, the generation rules can also be applied in any other domain involving opinion mining.

An example linguistic frame is shown in Figure 2, which encodes the sentence "*The caesar with salmon or chicken is really quite good.*" In this example, for the adjective "good", the nearby noun "chicken" would be associated with it if only proximity is considered. From the linguistic frame, however, we can easily associate "caesar" with "good" by extracting the head of the topic sub-frame and the head of the predicate sub-frame, which are encoded in the same layer (root layer) of the linguistic frame. Also, we can tell from the predicate sub-frame that there is an adverb "*quite*" modifying the head word "*good*". The linguistic frame also encodes an adverb "*really*" in the upstairs layer. A well-constructed generation grammar can create customized *adverb-adjective-noun* phrases such as "quite good caesar" or "really quite good caesar".

```
{c cstatement
 :topic {q caesar
         :quantifier "def"
         :pred {p with :topic {q salmon
                               :pred {p conjunction
                                      :or {q chicken }}}}
 :adv "really"
 :pred {p adj_complement
        :pred {p adjective
               :adv "quite"
               :pred {p quality :topic "good" }}}}
```

Figure 2. Linguistic frame for "*The caesar with salmon or chicken is really quite good.*"

Interpreting negation in English is not straightforward, and it is often impossible to do correctly without a deep linguistic analysis. Xuehui Wu (2005) wrote: "The scope of negation is a complex linguistic phenomenon. It is easy to perceive but hard to be defined from a syntactic point of view. Misunderstanding or ambiguity may occur when the negative scope is not understood clearly and correctly." The majority rule for negation is that it scopes over the remainder of its containing clause, and this works well for most cases. For example, Figure 3 shows

the linguistic frame for the sentence "*Their menu was a good one that didn't try to do too much.*"

```
{c cstatement
 :topic {q menu   :poss "their" } }
 :complement {q pronoun   :name "one"
        :adj_clause {c cstatement
                :conjn "that"
                :negate "not"
                :pred {p try :to_clause  {p do
                        :topic {q object
                        :adv "too"
                        :quant "much" }}}}
 :pred {p adjective
        :pred {p quality :topic "good" }}}
```

Figure 3. Linguistic frame for "*Their menu was a good one that didn't try to do too much.*"

Traditional approaches which do not consider the linguistic structure would treat the appearance of "*not*" as a negation and simply reverse the sentiment of the sentence to negative polarity, which is wrong as the sentence actually expresses positive opinion for the topic "menu". In our approach, the negation "*not*" is identified as under the sub-frame of the complement clause, instead of in the same or higher layer of the adjective sub-frame; thus it is considered as unrelated to the adjective "good". In this way we can successfully predict the scope of the reference of the negation over the correct constituent of a sentence and create proper association between negation and its modified words.

4.2 LM-based Topic Clustering

To categorize the extracted phrases into representative aspects, we automatically group the identified topics into a set of clusters based on LM probabilities. The LM-based algorithm assumes that topics which are semantically related have high probability of co-occurring with similar descriptive words. For example, "delicious" might co-occur frequently with both "pizza" and "dessert". By examining the distribution of bigram probability of these topics with corresponding descriptive words, we can group "pizza" and "dessert" into the same cluster of "food".

We select a small set of the most common topics, i.e., topics with the highest frequency counts, and put them into an initial set *I*. Then, for each candidate topic t_c outside set *I*, we calculate its probability given each topic t_i within the initial set *I*, given by:

$$P(t_c|\, t_i) = \sum_{a\in A} P(t_c|a) \cdot P(a|t_i)$$
$$= \sum_{a\in A} \frac{P(a,t_c)}{P(a)} \cdot \frac{P(a,t_i)}{P(t_i)}$$
$$= \frac{1}{P(t_i)} \sum_{a\in A} \frac{1}{P(a)} \cdot P(a,t_c) \cdot P(a,t_i) \quad (1)$$

where *A* represents the set of all the adjectives in the corpus. For each candidate topic t_c, we choose the cluster of the initial topic t_i with which it has the highest probability score.

There are also cases where a meaningful adjective occurs in the absence of an associated topic, e.g., "It is quite *expensive*." We call such cases the "*widow-adjective*" case. Without hard-coded ontology matching, it is difficult to identify "expensive" as a price-related expression. To discover such cases and associate them with related topics, we propose a "*surrogate topic*" matching approach based on bigram probability.

As aforementioned, the linguistic frame organizes all adjectives into separate clauses. Thus, we create a "surrogate topic" category in the linguistic frames for widow-adjective cases, which makes it easy to detect descriptors that are affiliated with uninformative topics like the pronoun "it". We then have it generate phrases such as "expensive surrogate_topic" and use bigram probability statistics to automatically map each sufficiently strongly associated adjective to its most common topic among our major classes, e.g., mapping "expensive" with its surrogate topic "price". Therefore, we can generate sets of additional phrases in which the topic is "hallucinated" from the widow-adjective.

5 Assessment of Sentiment Strength

5.1 Problem Formulation

Given the sets of adverb-adjective-noun phrases extracted by linguistic analysis, our goal is to assign a score for the degree of sentiment to each phrase and calculate an average rating for each aspect. An example summary is given in Table 1.

Table 1. Example of review summary.

Aspect	Extracted phrases	Rating
Atmosphere	very nice ambiance, outdoor patio	4.8
Food	not bad meal, quite authentic food	4.1
Place	not great place, very smoky restaurant	2.8
Price	so high bill, high cost, not cheap price	2.2

To calculate the numerical degree of sentiment, there are three major problems to solve: 1) how to associate *numerical scores* with *textual sentiment*; 2) whether to calculate sentiment scores for adjectives and adverbs *jointly* or *separately*; 3)

whether to treat negations as *special cases* or in the *same way* as modifying adverbs.

There have been studies on building sentiment lexicons to define the strength of sentiment of words. Esuli and Sebastiani (2006) constructed a lexical resource, SentiWordNet, a WordNet-like lexicon emphasizing sentiment orientation of words and providing numerical scores of how objective, positive and negative these words are. However, lexicon-based methods can be tedious and inefficient and may not be accurate due to the complex cross-relations in dictionaries like WordNet. Instead, our primary approach to sentiment scoring is to make use of collective data such as user ratings. In product reviews collected from online forums, the format of a review entry often consists of three parts: pros/cons, free-style text and user rating. We assume that user rating is normally consistent with the tone of the review text published by the same user. By associating user ratings with each phrase extracted from review texts, we can easily associate numerical scores with textual sentiment.

A simple strategy of rating assignment is to take each extracted adverb-adjective pair as a composite unit. However, this method is likely to lead to a large number of rare combinations, thus suffering from sparse data problems. Therefore, an interesting question to ask is whether it is feasible to assign to each adverb a perturbation score, which adjusts the score of the associated adjective up or down by a fixed scalar value. This approach thus hypothesizes that "very expensive" is as much worse than "expensive" as "very romantic" is better than "romantic". This allows us to pool all instances of a given adverb regardless of which adjective it is associated with, in order to compute the absolute value of the perturbation score for that adverb. Therefore, we consider adverbs and adjectives separately when calculating the sentiment score, treating each modifying adverb as a universal quantifier which consistently scales up/down the strength of sentiment for the adjectives it modifies.

Furthermore, instead of treating negation as a special case, the universal model works for all adverbials. The model hypothesizes that "not bad" is as much better than "bad" as "not good" is worse than "good", i.e., negations push positive/negative adjectives to the other side of sentiment polarity by a *universal scale*. This again, allows us to pool all instances of a given negation and compute the absolute value of the perturbation score for that negation, in the same way as dealing with modifying adverbs.

5.2 Linear Additive Model

For each adjective, we average all its ratings given by:

$$Score(adj) = \frac{\sum_{i \in P} \frac{N}{n_{r_i}} \cdot r_i}{\sum_{r_i} \frac{N}{n_{r_i}}} \qquad (2)$$

where P represents the set of appearances of adjective adj, r_i represents the associated user rating in each appearance of adj, N represents the number of entities (e.g., restaurants) in the entire data set, and n_{r_i} represents the number of entities with rating r_i. The score is averaged over all the appearances, weighted by the frequency count of each category of rating to remove bias towards any category.

As for adverbs, using a slightly modified version of equation (2), we can get a rating table for all *adverb-adjective* pairs. For each adverb *adv*, we get a list of all its possible combinations with adjectives. Then, for each *adj* in the list, we calculate the distance between the rating of *adv-adj* and the rating of the *adj* alone. We then aggregate the distances among all the pairs of *adv-adj* and *adj* in the list, weighted by the frequency count of each *adv-adj* pair:

$$Score(adv) = \sum_{t \in A} \frac{count(adv, adj_t)}{\sum_{j \in A} count(adv, adj_j)} \cdot Pol(adj_t) \cdot (r(adv, adj_t) - r(adj_t)) \qquad (3)$$

where $count(adv,\ adj_t)$ represents the count of the combination $adv - adj_t$, A represents the set of adjectives that co-occur with adv, $r(adv, adj_t)$ represents the sentiment rating of the combination $adv - adj_t$, and $r(adj_t)$ represents the sentiment rating of the adjective adj_t alone. $Pol(adj_t)$ represents the polarity of adj_t, assigned as *1* if adj_t is positive, and *-1* if negative.

Specifically, negations are well handled by the same scoring strategy, treated exactly the same as modifying adverbs, except that they get such strong negative scores that the sentiment of the associated adjectives is pushed to the other side of the polarity scale.

After obtaining the strength rating for adverbs and the sentiment rating for adjectives, the next step is to assign the strength of sentiment to each phrase (negation-adverb-adjective-noun) extracted by linguistic analysis, as given by:

$$Score\left(neg\left(adv(adj)\right)\right) = r(adj) + Pol(adj) \cdot r(adv) + Pol(adj) \cdot r(neg) \qquad (4)$$

where $r(adj)$ represents the rating of adjective adj, $r(adv)$ represents the rating of adverb adv, and $r(neg)$ represents the rating of negation neg. $Pol(adj)$ represents the polarity of adj, assigned as *1* if adj is positive, and *-1* if negative. Thus, if adj is positive, we assign a combined rating $r(adj) + r(adv)$ to this phrase. If it is negative, we assign $r(adj) - r(adv)$. Specifically, if it is a negation case, we further assign a linear offset $r(neg)$ if adj is positive or $-r(neg)$ if adj is negative. For example, given the ratings <good: 4.5>, <bad: 1.5>, <very: 0.5> and <not: -3.0>, we would assign "5.0" to "very good" (*score(very(good))=4.5+0.5*), "1.0" to "very bad" (*score(very(bad))=1.5-0.5*), and "2.0" to "not very good" (s*core(not(very(good)))= 4.5+0.5-3.0*). The corresponding sequence of different degrees of sentiment is: "*very good*: 5.0" > "*good*: 4.5" > "*not very good*: 2.0" > "*bad*: 1.5" > "*very bad*: 1.0".

6 Experiments

In this section we present a systematic evaluation of the proposed approaches conducted on real data. We crawled a data collection of 137,569 reviews on 24,043 restaurants in 9 cities in the U.S. from an online restaurant evaluation website[1]. Most of the reviews have both pros/cons and free-style text. For the purpose of evaluation, we take those reviews containing pros/cons as the experimental set, which is 72.7% (99,147 reviews) of the original set.

6.1 Topic Extraction

Based on the experimental set, we first filtered out-of-domain sentences based on frequency count, leaving a set of 857,466 in-domain sentences (67.5%). This set was then subjected to parse analysis; 78.6% of them are parsable.

Given the parsing results in the format of linguistic frame, we used a set of language generation rules to extract relevant adverb-adjective-noun phrases. We then selected the most frequent 6 topics that represented appropriate dimensions for the restaurant domain ("place", "food", "service", "price", "atmosphere" and "portion") as the initial set, and clustered the extracted topic mentions into different aspect categories by creating a set of topic mappings with the LM-based clustering method. Phrases not belonging to any category are filtered out.

[1] http://www.citysearch.com

To evaluate the performance of the proposed approach (LING) to topic extraction, we compare it with a baseline method similar to (Hu and Liu, 2004a, 2004b; Liu et al., 2005). We performed part-of-speech tagging on both parsable and unparsable sentences, extracted each pair of noun and adjective that has the smallest proximity, and filtered out those with low frequency counts. Adverbs and negation words that are adjacent to the identified adjectives were also extracted along with the adjective-noun pairs. We call this the "neighbor baseline" (NB).

The proposed method is unable to make use of the non-parsable sentences, which make up over 20% of the data. Hence, it seems plausible to utilize a back-off mechanism for these sentences via a combined system (COMB) incorporating NB only for the sentences that fail to parse.

In considering how to construct the "ground truth" set of pros and cons for particular aspects, our goal was to minimize error as much as possible without requiring exorbitant amounts of manual labeling. We also wanted to assure that the methods were equally fair to both systems (LING and NB). To these ends, we decided to pool together all of the topic mappings and surrogate topic hallucinations obtained automatically from both systems, and then to manually edit the resulting list to eliminate any that were deemed unreasonable. We then applied these edited mappings in an automatic procedure to the adjective-noun pairs in the user-provided pros and cons of all the restaurant reviews. The resulting aspect-categorized phrase lists are taken as the ground truth. Each system then used its own (unedited) set of mappings in processing the associated review texts.

We also needed an algorithm to decide on a particular set of reviews for consideration, again, with the goal of omitting bias towards either of the two systems. We decided to retain as the evaluation set all reviews which obtained at least one topic extraction from both systems. Thus the two systems processed exactly the same data with exactly the same definitions of "ground truth". Performance was evaluated on this set of 62,588 reviews in terms of recall (percentage of topics in the ground truth that are also identified from the review body) and precision (percentage of extracted topics that are also in the ground truth). These measures are computed separately for each review, and then averaged over all reviews.

As shown in Table 2, without clustering, the LING approach gets 4.6% higher recall than the

NB baseline. And the recall from the COMB approach is 3.9% higher than that from the LING approach and 8.5% higher than that from the NB baseline. With topic clustering, the COMB approach also gets the highest recall, with a 4.9% and 17.5% increase from the LING approach and the NB baseline respectively. The precision is quite close among the different approaches, around 60%. Table 2 also shows that the topic clustering approach increases the recall by 4.8% for the NB baseline, 12.8% for the LING approach, and 13.8% for the COMB approach.

Table 2. Experimental results of topic extraction by the NB baseline, the proposed LING approach and a combined system (COMB).

	No Clustering		
	NB	**LING**	**COMB**
Recall	39.6%	44.2%	48.1%
Precision	60.2%	60.0%	59.8%
	With Clustering		
	NB	**LING**	**COMB**
Recall	44.4%	57.0%	61.9%
Precision	56.8%	61.1%	60.8%

6.2 Sentiment Scoring

To score the degree of sentiment for each extracted phrase, we built a table of sentiment score (<*adjective*: *score*>) for adjectives and a table of strength score (<*adverb*: *score*>) for adverbs. The pros/cons often contain short and well-structured phrases, and have better parsing quality than the long and complex sentences in free-style texts; pros/cons also have clear sentiment orientations. Thus, we use pros/cons to score the sentiment of adjectives, which requires strong polarity association. To obtain reliable ratings, we associate the adjectives in the "*pros*" of review entries which have a user rating 4 or 5, and associate the adjectives in the "*cons*" of review entries with user ratings 1 or 2 (the scale of user rating is 1 to 5). Reviews with rating 3 are on the boundary of sentiment, so we associate both sides with the overall rating. On the other hand, the frequencies of adverbs in free-style texts are much higher than those in pros/cons, as pros/cons mostly contain *adjective-noun* patterns. Thus, we use free-style texts instead of pros/cons to score the strength of adverbs.

Partial results of the sentiment scoring are shown in Tables 3 and 4. As shown in Table 3, the polarity of sentiment as well as the degree of polarity of an adjective can be distinguished by its score. The higher the sentiment score is, the more positive the adjective is.

Table 3. Sentiment scoring for selected adjectives.

Adjective	**Rating**	**Adjective**	**Rating**
Excellent	5.0	Awesome	4.8
Easy	4.1	Great	4.4
Good	3.9	Limited	3.4
Inattentive	2.75	Overpriced	2.3
Rude	1.69	Horrible	1.3

Table 4 gives the scores of strength for most common adverbs. The higher the strength score is, the more the adverb scales up/down the degree of sentiment of the adjective it modifies. While "not" gets a strong negative score, some adverbs such as "a little" (-0.65) and "a bit" (-0.83) also get negative scores, indicating slightly less sentiment for the associated adjectives.

Table 4. Strength scoring for selected adverbs.

Adverb	**Rating**	**Adverb**	**Rating**
Super	0.58	Fairly	0.13
Extremely	0.54	Pretty	0.07
Incredibly	0.49	A little	-0.65
Very	0.44	A bit	-0.83
Really	0.39	Not	-3.10

To evaluate the performance of sentiment scoring, we randomly selected a subset of 1,000 adjective-noun phrases and asked two annotators to independently rate the sentiment of each phrase on a scale of 1 to 5. We compared the sentiment scoring between our system and the annotations in a measurement of mean distance:

$$distance = \frac{1}{|S|}\sum_{p \in S} |r_{ip} - r_{ap}| \quad (5)$$

where S represents the set of phrases, p represents each phrase in the set S, r_{ip} represents the rating on phrase p from our sentiment scoring system, and r_{ap} represents the annotated rating on phrase p. As shown in Table 5, the obtained mean distance between the scoring from our approach and that from each annotation set is 0.46 and 0.43 respectively, based on the absolute rating scale from 1 to 5. This shows that the scoring of sentiment from our system is quite close to human annotation. The kappa agreement between the two annotation sets is 0.68, indicating high consistency between the annotators. The reliability of these results gives us sufficient confidence to make use of the scores of sentiments for summarization.

To examine the prediction of sentiment polarity, for each annotation set, we pooled the phrases with rating 4/5 into "positive", rating 1/2 into "negative", and rating 3 into "neutral". Then we rounded up the sentiment scores from our system to integers and pooled the scores into three polar-

ity sets ("positive", "negative" and "neutral") in the same way. As shown in Table 5, the obtained kappa agreement between the result from our system and that from each annotation set is 0.55 and 0.60 respectively. This shows reasonably high agreement on the polarity of sentiment between our system and human evaluation.

Table 5. Comparison of sentiment scoring between the proposed approach and two annotation sets.

	Annotation 1	**Annotation 2**
Mean distance	0.46	0.43
Kappa agreement	0.55	0.60

Table 6. Experimental results of topic extraction based on sentiment polarity matching.

	No Clustering		
	NB	**LING**	**COMB**
Recall	34.5%	38.9%	42.2%
Precision	53.8%	54.0%	53.3%
	With Clustering		
	NB	**LING**	**COMB**
Recall	37.4%	49.7%	54.1%
Precision	48.5%	52.9%	51.4%

To evaluate the combination of topic extraction and sentiment identification, we repeated the topic extraction experiments presented in Table 2, but this time requiring as well a correct polarity assignment to obtain a match with the pros/cons ground truth. As shown in Table 6, the COMB approach gets the highest recall both with and without topic clustering, and the recall from the LING approach is higher than that from the NB baseline in both cases as well, indicating the superiority of the proposed approach. The precision is stable among the different approaches, consistent with the case without the consideration of sentiment polarity.

7 Discussion

It is surprising that the parse-and-paraphrase method performs so well, despite the fact that it utilizes less than 80% of the data (parsable set). In this section, we will discuss two experiments that were done to tease apart the contributions of different variables. In both experiments, we compared the change in relative improvement in recall between NB and LING, relative to the values in Table 6, in the with-clustering condition. In the table, LING obtains a score of 49.7% for recall, which is a 33% relative increase from the score for NB (37.4%). Three distinct factors could play a role in the improvement: the widow-adjective topic hallucinations, the topic mapping for clustering, and the extracted phrases themselves. An experiment involving omitting topic hallucinations from widow adjectives determined that these account for 12% of the relative increase. To evaluate the contribution of clustering, we replaced the mapping tables used by both systems with the edited one used by the ground truth computation. Thus, both systems made use of the same mapping table, removing this variable from consideration. This improved the performance of both systems (NB and LING), but resulted in a decrease of LING's relative improvement by 17%. This implies that LING's mapping table is superior. Since both systems use the same sentiment scores for adjectives and adverbs, the remainder of the difference (71%) must be due simply to higher quality extracted phrases.

We suspected that over-generated phrases (the 40% of phrases that find no mappings in the pros/cons) might not really be a problem. To test this hypothesis, we selected 100 reviews for their high density of extracted phrases, and manually evaluated all the over-generated phrases. We found that over 80% were well formed, correct, and informative. Therefore, a lower precision here does not necessarily mean poor performance, but instead shows that the pros/cons provided by users are often incomplete. By extracting summaries from review texts we can recover additional valuable information.

8 Conclusions & Future Work

This paper presents a parse-and-paraphrase approach to assessing the degree of sentiment for product reviews. A general purpose context free grammar is employed to parse review sentences, and semantic understanding methods are developed to extract representative negation-adverb-adjective-noun phrases based on well-defined semantic rules. A language modeling-based method is proposed to cluster topics into respective categories. We also introduced in this paper a cumulative linear offset model for supporting the assessment of the strength of sentiment in adjectives and quantifiers/qualifiers (including negations) on a numerical scale. We demonstrated that the parse-and-paraphrase method can perform substantially better than a neighbor baseline on topic extraction from reviews even with less data. The future work focuses in two directions: (1) building a relational database from the summaries and ratings and using it to enhance users' experiences in a multimodal spoken dialogue system; and (2) applying our techniques to other domains to demonstrate generality.

Abstract

This work investigates design choices in modeling a discourse scheme for improving opinion polarity classification. For this, two diverse global inference paradigms are used: a supervised collective classification framework and an unsupervised optimization framework. Both approaches perform substantially better than baseline approaches, establishing the efficacy of the methods and the underlying discourse scheme. We also present quantitative and qualitative analyses showing how the improvements are achieved.

1 Introduction

The importance of discourse in opinion analysis is being increasingly recognized (Polanyi and Zaenen, 2006). Motivated by the need to enable discourse-based opinion analysis, previous research (Asher et al., 2008; Somasundaran et al., 2008) developed discourse schemes and created manually annotated corpora. However, it was not known whether and how well these linguistic ideas and schemes can be translated into effective computational implementations.

In this paper, we first investigate ways in which an opinion discourse scheme can be computationally modeled, and then how it can be utilized to improve polarity classification. Specifically, the discourse scheme we use is from Somasundaran et al. (2008), which was developed to support a global, interdependent polarity interpretation. To achieve discourse-based global inference, we explore two different frameworks. The first is a supervised framework that learns interdependent opinion interpretations from training data. The second is an unsupervised optimization framework which uses constraints to express the ideas of coherent opinion interpretation embodied in the scheme. For the supervised framework, we use Iterative Collective Classification (ICA), which facilitates machine learning using relational information. The unsupervised optimization is implemented as an Integer Linear Programming (ILP) problem. Via our implementations, we aim to empirically test if discourse-based approaches to opinion analysis are useful.

Our results show that both of our implementations achieve significantly better accuracies in polarity classification than classifiers using local information alone. This confirms the hypothesis that the discourse-based scheme is useful, and also shows that both of our design choices are effective. We also find that there is a difference in the way ICA and ILP achieve improvements, and a simple hybrid approach, which incorporates the strengths of both, is able to achieve significant overall improvements over both. Our analyses show that even when our discourse-based methods bootstrap from noisy classifications, they can achieve good improvements.

The rest of this paper is organized as follows: we discuss related work in Section 2 and the discourse scheme in Section 3. We present our discourse-based implementations in Section 4, experiments in Section 5, discussions in Section 6 and conclusions in Section 7.

2 Related Work

Previous work on polarity disambiguation has used contextual clues and reversal words (Wilson et al., 2005; Kennedy and Inkpen, 2006; Kanayama and Nasukawa, 2006; Devitt and Ahmad, 2007; Sadamitsu et al., 2008). However, these do not capture discourse-level relations.

Researchers, such as (Polanyi and Zaenen, 2006), have discussed how the discourse structure can influence opinion interpretation; and previous work, such as (Asher et al., 2008; Somasundaran et al., 2008), have developed annota-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 170–179,
Singapore, 6-7 August 2009.

tion schemes for interpreting opinions with discourse relations. However, they do not empirically demonstrate how automatic methods can use their ideas to improve polarity classification. In this work, we demonstrate concrete ways in which a discourse-based scheme can be modeled using global inference paradigms.

Joint models have been previously explored for other NLP problems (Haghighi et al., 2005; Moschitti et al., 2006; Moschitti, 2009). Our global inference model focuses on opinion polarity recognition task.

The biggest difference between this work and previous work in opinion analysis that use global inference methods is in the type of linguistic relations used to achieve the global inference. Some of the work is not related to discourse at all (e.g., lexical similarities (Takamura et al., 2007), morphosyntactic similarities (Popescu and Etzioni, 2005) and word-based measures like TF-IDF (Goldberg and Zhu, 2006)). Others use sentence cohesion (Pang and Lee, 2004), agreement/disagreement between speakers (Thomas et al., 2006; Bansal et al., 2008), or structural adjacency. In contrast, our work focuses on discourse-based relations for global inference. Another difference from the above work is that our work is over multi-party conversations.

Previous work on emotion and subjectivity detection in multi-party conversations has explored using prosodic information (Neiberg et al., 2006), combining linguistic and acoustic information (Raaijmakers et al., 2008) and combining lexical and dialog information (Somasundaran et al., 2007). Our work is focused on harnessing discourse-based knowledge and on interdependent inference.

There are several collective classification frameworks, including (Neville and Jensen, 2000; Lu and Getoor, 2003; Taskar et al., 2004; Richardson and Domingos, 2006; Bilgic et al., 2007). In this paper, we use an approach by (Lu and Getoor, 2003) which iteratively predicts class values using local and relational features. ILP has been used on other NLP tasks, e.g., (Denis and Baldridge, 2007; Choi et al., 2006; Roth and Yih, 2004). In this work, we employ ILP for modeling discourse constraints for polarity classification.

3 Discourse Scheme and Data

The scheme in Somasundaran et al. (2008) has been developed and annotated over the AMI meeting corpus (Carletta et al., 2005).[1] This scheme annotates opinions, their polarities (positive, negative, neutral) and their targets (a target is what the opinion is about). The targets of opinions are related via two types of relations: the *same* relation, which relates targets referring to the same entity or proposition, and the *alternative* relation, which relates targets referring to mutually exclusive options in the context of the discourse. Additionally, the scheme relates opinions via two types of *frame* relations: the *reinforcing* and *non-reinforcing* relations. The frame relations represent discourse scenarios: reinforcing relations exist between opinions when they contribute to the same overall stance, while non-reinforcing relations exist between opinions that show ambivalence.

The opinion annotations are text-span based, while in this work, we use Dialog Act (DA) based segmentation of meetings.[2] As the DAs are our units of classification, we map opinion annotations to the DA units as follows. If a DA unit contains an opinion annotation, the label is transferred upwards to the containing DA. When a DA contains multiple opinion annotations, each with a different polarity, one of them is randomly chosen as the label for the DA. The discourse relations existing between opinions are also transferred upwards, between the DAs containing each of these annotations. We recreate an example from Somasundaran et al. (2008) using DA segmentation in Example 1. Here, the speaker has a positive opinion towards the rubbery material for the TV remote.

(1) DA-1: ... this kind of rubbery material,
DA-2: *it's* a **bit more bouncy**,
DA-3: like you said they get chucked around a lot.
DA-4: A **bit more durable** and *that* can also be **ergonomic** and
DA-5: *it* kind of feels **a bit different from all the other remote controls**.

In the example, the individual opinion expressions (shown in bold) are essentially regarding the same thing – the rubbery material. Thus, the explicit targets (shown in *italics*), *it's*, *that*, and *it*, and the implicit target of **a bit more durable** are all linked

[1] The AMI corpus contains a set of scenario-based meetings where participants have to design a new TV remote prototype.

[2] DA segmentation is provided with the AMI corpus.

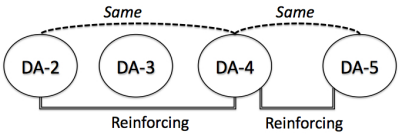

Figure 1: Discourse Relations between DA segments for Example 1.

with *same* target relations. Also, notice that the opinions reinforce a particular stance, i.e., a pro-rubbery-material stance. Thus, the scheme links the opinions via reinforcing relations. Figure 1 illustrates the corresponding discourse relations between the containing DA units.

4 Implementing the Discourse Model

The hypothesis in using discourse information for polarity classification is that the global discourse view will improve upon a classification with only a local view. Thus, we implement a local classifier to bootstrap the classification process, and then implement classifiers that use discourse information from the scheme annotations, over it. We explore two approaches for implementing our discourse-based classifier. The first is ICA, where discourse relations and the neighborhood information brought in by these relations are incorporated as features into the learner. The second approach is ILP optimization, which tries to maximize the class distributions predicted by the local classifier, subject to constraints imposed by discourse relations. Both classifiers thus accommodate preferences of the local classifier and for coherence with discourse neighbors.

4.1 Local Classifier

A supervised local classifier, *Local*, is used to provide the classifications to bootstrap the discourse-based classifiers.[3] It is important to make Local as reliable as possible; otherwise, the discourse relations will propagate misclassifications. Thus, we build Local using a variety of knowledge sources that have been shown to be useful for opinion analysis in previous work. Specifically, we construct features using polarity lexicons (used by (Wilson et al., 2005)), DA tags (used by (Somasundaran et al., 2007)) and unigrams (used by many researchers, e.g., (Pang and Lee, 2004)).

Note that, as our discourse-based classifiers attempt to improve upon the local classifications, Local is also a baseline for our experiments.

4.2 Iterative Collective Classification

We use a variant of ICA (Lu and Getoor, 2003; Neville and Jensen, 2000), which is a collective classification algorithm shown to perform consistently well over a wide variety of relational data.

Algorithm 1 ICA Algorithm

```
for each instance i do {bootstrapping}
   Compute polarity for i using local attributes
end for
repeat {iterative}
   Generate ordering I over all instances
   for each i in I do
      Compute polarity for i using local and relational attributes
   end for
until Stopping criterion is met
```

ICA uses two classifiers: a local classifier and a *relational classifier*. The local classifier is trained to predict the DA labels using only the local features. We use Local, described in Section 4.1, for this purpose. The relational classifier is trained using the local features, and an additional set of features commonly referred to as *relational features*. The value of a relational feature, for a given DA, depends on the polarity of the discourse neighbors of that DA. Thus, the relational features incorporate discourse and neighbor information; that is, they incorporate the information about the frame and target relations in conjunction with the polarity of the discourse neighbors. Intuitively, our motivation for this approach can be explained using Example 1. Here, in interpreting the ambiguous opinion **a bit different** as being positive, we use the knowledge that it participates in a reinforcing discourse, and that all its neighbors (e.g., **ergonomic**, **durable**) are positive opinions regarding the same thing. On the other hand, if it had been a non-reinforcing discourse, then the polarity of **a bit different**, when viewed with respect to the other opinions, could have been interpreted as negative.

Table 1 lists the relational features we defined for our experiments where each row represents a

[3]Local is supervised, as previous work has shown that supervised methods are effective in opinion analysis. Even though this makes the final end-to-end system with the ILP implementation semi-supervised, note that the discourse-based ILP part is itself unsupervised.

Percent of neighbors with polarity type a related via frame relation f'
Percent of neighbors with polarity type a related via target relation t'
Percent of neighbors with polarity type a related via frame relation f and target relation t
Percent of neighbors with polarity type a and same speaker related via frame relation f'
Percent of neighbors with polarity type a and same speaker related via target relation t'
Percent of neighbors with polarity type a related via a frame relation or target relation
Percent of neighbors with polarity type a related via a reinforcing frame relation or *same* target relation
Percent of neighbors with polarity type a related via a non-reinforcing frame relation or alt target relation
Most common polarity type of neighbors related via a *same* target relation
Most common polarity type of neighbors related via a reinforcing frame relation and *same* target relation

Table 1: Relational features: $a \in$ {non-neutral (i.e., positive or negative), positive, negative}, $t \in$ {same, alt}, $f \in$ {reinforcing, non-reinforcing}, $t' \in$ {same or alt, same, alt}, $f' \in$ {reinforcing or non-reinforcing, reinforcing, non-reinforcing}

set of features. Features are generated for all combinations of a, t, t', f and f' for each row. For example, one of the features in the first row is *Percent of neighbors with polarity type positive, that are related via a reinforcing frame relation*. Thus, each feature for the relational classifier identifies neighbors for a given instance via a specific relation (f, t, f' or t', obtained from the scheme annotations) and factors in their polarity values (a, obtained from the classifier predictions from the previous round). This adds a total of 59 relational features to the already existing local features.

ICA has two main phases: the bootstrapping and iterative phases. In the bootstrapping phase, the polarity of each instance is initialized to the most likely value given only the local classifier and its features. In the iterative phase, we create a random ordering of all the instances and, in turn, apply the relational classifier to each instance where the relational features, for a given instance, are computed using the most recent polarity assignments of its neighbors. We repeat this until some stopping criterion is met. For our experiments, we use a fixed number of 30 iterations, which has been found to be sufficient in most data sets for ICA to converge to a solution.

The pseudocode for the algorithm is shown in Algorithm 1.

4.3 Integer Linear Programming

First, we explain the intuition behind viewing discourse relations as enforcing constraints on polarity interpretation. Then, we explain how the constraints are encoded in the optimization problem.

4.3.1 Discourse Constraints on Polarity

The discourse relations between opinions can provide coherence constraints on the way their polarity is interpreted. Consider a discourse scenario in which a speaker expresses multiple opinions regarding the same thing, and is reinforcing his stance in the process (as in Example 1). The set of individual polarity assignments that is most coherent with this global scenario is the one where all the opinions have the same (*equal*) polarity. On the other hand, a pair of individual polarity assignments most consistent with a discourse scenario where a speaker reinforces his stance via opinions towards alternative options, is one with opinions having mutually *opposite* polarity. For instance, in the utterance "Shapes **should** be *curved*, **nothing** *square-like*", the speaker reinforces his pro-curved stance via his opinions about the alternative shapes: *curved* and *square-like*. And, we see that the first opinion is positive and the second is negative. Table 2 lists the discourse relations (target and frame relation combinations) found in the corpus, and the likely polarity interpretation for the related instances.

Target relation + Frame relation	Polarity
same+reinforcing	equal (e)
same+non-reinforcing	opposite (o)
alternative+reinforcing	opposite (o)
alternative+non-reinforcing	equal (e)

Table 2: Discourse relations and their polarity constraints on the related instances.

4.3.2 Optimization Problem

For each DA instance i in a dataset, the local classifier provides a class distribution $[p_i, q_i, r_i]$, where p_i, q_i and r_i correspond to the probabilities that i belongs to positive, negative and neutral categories, respectively. The optimization problem is formulated as an ILP minimization of the objective function in Equation 1.

$$-1 \times \sum_i (p_i x_i + q_i y_i + r_i z_i) + \sum_{i,j} \epsilon_{ij} + \sum_{i,j} \delta_{ij} \quad (1)$$

where the x_i, y_i and z_i are binary *class variables* corresponding to positive, negative and neutral classes, respectively. When a class variable is 1, the corresponding class is chosen. Variables ϵ_{ij} and δ_{ij} are binary *slack variables* that correspond to the discourse constraints between two distinct DA instances i and j. When a given slack variable is 1, the corresponding discourse constraint is violated. Note that the objective function tries to achieve two goals. The first part ($\sum_i p_i x_i + q_i y_i + r_i z_i$) is a maximization that tries to choose a classification for the instances that maximizes the probabilities provided by the local classifier. The second part ($\sum_{i,j} \epsilon_{ij} + \sum_{i,j} \delta_{ij}$) is a minimization that tries to minimize the number of slack variables used, that is, minimize the number of discourse constraints violated.

Constraints in Equations 2 and 3 listed below impose binary constraints on the variables. The constraint in Equation 4 ensures that, for each instance i, only one class variable is set to 1.

$$x_i \in \{0,1\}, y_i \in \{0,1\}, z_i \in \{0,1\}\ ,\ \forall i \quad (2)$$

$$\epsilon_{ij} \in \{0,1\}, \delta_{ij} \in \{0,1\}\ ,\ \forall i \neq j \quad (3)$$

$$x_i + y_i + z_i = 1\ ,\ \forall i \quad (4)$$

We pair distinct DA instances i and j as ij, and if there exists a discourse relation between them, they can be subject to the corresponding polarity constraints listed in Table 2. For this, we define two binary discourse-constraint constants: the *equal-polarity* constant, e_{ij} and the *opposite-polarity* constant, o_{ij}. If a given DA pair ij is related by either a same+reinforcing relation or an alternative+non-reinforcing relation (rows 1, 4 of Table 2), then $e_{ij} = 1$; otherwise it is zero. Similarly, if it is related by either a same+non-reinforcing relation or an alternative+reinforcing relation (rows 2, 3 of Table 2), then $o_{ij} = 1$. Both e_{ij} and o_{ij} are zero if the instance pair is unrelated in the discourse.

For each DA instance pair ij, equal-polarity constraints are applied to the polarity variables of i (x_i, y_i) and j (x_j, y_j) via the following equations:

$$|x_i - x_j| \leq 1 - e_{ij} + \epsilon_{ij}\ ,\ \forall i \neq j \quad (5)$$

$$|y_i - y_j| \leq 1 - e_{ij} + \epsilon_{ij}\ ,\ \forall i \neq j \quad (6)$$

$$-(x_i + y_i) \leq -l_i\ ,\ \forall i \quad (7)$$

When $e_{ij} = 1$, the Equation 5 constrains x_i and x_j to be of the same value (both zero or both one). Similarly, Equation 6 constrains y_i and y_j to be of the same value. Via these equations, we ensure that the instances i and j do not have the opposite polarity when $e_{ij} = 1$. However, notice that, if we use just Equations 5 and 6, the optimization can converge to the same, non-polar (neutral) category. To guide the convergence to the same polar (positive or negative) category, we use Equation 7. Here $l_i = 1$ if the instance i participates in one or more discourse relations. When $e_{ij} = 0$, x_i and x_j (and y_i and y_j), can take on assignments independently of one another. Notice that both constraints 5 and 6 are relaxed when $\epsilon_{ij} = 1$; thus, x_i and x_j (or y_i and y_j) can take on values independently of one another, even if $e_{ij} = 1$.

Next, the opposite-polarity constraints are applied via the following equations:

$$|x_i + x_j - 1| \leq 1 - o_{ij} + \delta_{ij}\ ,\ \forall i \neq j \quad (8)$$

$$|y_i + y_j - 1| \leq 1 - o_{ij} + \delta_{ij}\ ,\ \forall i \neq j \quad (9)$$

In the above equations, when $o_{ij} = 1$, x_i and x_j (and y_i and y_j) take on opposite values; for example, if $x_i = 1$ then $x_j = 0$ and vice versa. When $o_{ij} = 0$, the variable assignments are independent of one another. This set of constraints is relaxed when $\delta_{ij} = 1$.

In general, in our ILP formulation, notice that if an instance does not have a discourse relation to any other instance in the data, its classification is unaffected by the optimization. Also, as the underlying discourse scheme poses constraints only on the interpretation of the polarity of the related instances, discourse constraints are applied only to the polarity variables x and y, and not to the neutral class variable, z. Finally, even though slack variables are used, we discourage the ILP system from indiscriminately setting the slack variables to 1 by making them a part of the objective function that is minimized.

5 Experiments

In this work, we are particularly interested in improvements due to discourse-based methods. Thus, we report performance under three conditions: over only those instances that are related via discourse relations (*Connected*), over instances not related via discourse relations (*Singletons*), and over all instances (*All*).

The annotated data consists of 7 scenario-based, multi-party meetings from the AMI meeting corpus. We filter out very small DAs (DAs with fewer than 3 tokens, punctuation included). This gives

us a total of 4606 DA instances, of which 1935 (42%) have opinion annotations. For our experiments, the DAs with no opinion annotations as well as those with neutral opinions are considered as neutral. Table 3 shows the class distributions in the data for the three conditions.

	Pos	Neg	Neutral	Total
Connected	643	343	81	1067
Singleton	553	233	2753	3539
All	1196	576	2834	4606

Table 3: Class distribution over connected, single and all instances.

5.1 Classifiers

Our first baseline, *Base*, is a simple distribution-based classifier that classifies the test data based on the overall distribution of the classes in the training data. However, in Table 3, the class distribution is different for the Connected and Singleton conditions. We incorporate this in a smarter baseline, *Base-2*, which constructs separate distributions for connected instances and singletons. Thus, given a test instance, depending on whether it is connected, Base-2 uses the corresponding distribution to make its prediction.

The third baseline is the supervised classifier, *Local*, described in Section 4.1. It is implemented using the SVM classifiers from the Weka toolkit (Witten and Frank, 2002).[4] Our supervised discourse-based classifier, ICA from Section 4.2, also uses a similar SVM implementation for its relational classifier. We implement our ILP approach from Section 4.3 using the optimization toolbox from Mathworks (http://www.mathworks.com) and GNU Linear Programming Kit.

We observed that the ILP system performs better than the ICA system on instances that are connected, while ICA performs better on singletons. Thus, we also implemented a simple hybrid classifier (HYB), which selects the ICA prediction for classification of singletons and the ILP prediction for classification of connected instances.

5.2 Results

We performed 7-fold cross validation experiments, where six meetings are used for training and the seventh is used for testing the supervised classifiers (Base, Base-2, Local and ICA). In the case of ILP, the optimization is applied to the output of Local for each test fold. Table 4 reports the accuracies of the classifiers, averaged over 7 folds.

First, we observe that Base performs poorly over connected instances, but performs considerably better over singletons. This is expected as the overall majority class is neutral and the singletons are more likely to be neutral. Base-2, which incorporates the differentiated distributions, performs substantially better than Base. Local achieves an overall performance improvement over Base and Base-2 by 23 percentage points and 9 percentage points, respectively. In general, Local outperforms Base for all three conditions ($p < 0.001$), and Base-2 for the Singleton and All conditions ($p < 0.001$). This overall improvement in Local's accuracy corroborates the utility of the lexical, unigram and DA based features for polarity detection in this corpus.

Turning to the discourse-based classifiers, ICA, ILP and HYB, all of these perform better than Base and Base-2 for all conditions. ICA improves over Local by 9 percentage points for Connected, 3 points for Singleton and 4 points for All. ILP's improvement over Local for Connected and All is even more substantial: 28 percentage points and 6 points, respectively. Notice that ILP has the same performance as Local for Singletons, as the discourse constraints are not applied over unconnected instances. Finally, HYB significantly outperforms Local under all conditions. The significance levels of the improvements over Local are highlighted in Table 4. These improvements also signify that the underlying discourse scheme is effective, and adaptable to different implementations.

Interestingly, ICA and ILP improve over Local in different ways. While ILP sharply improves the performance over the connected instances, ICA shows relatively modest improvements over both connected and singletons. ICA's improvement over singletons is interesting because it indicates that, even though the features in Table 1 are focused on discourse relations, ICA utilizes them to learn the classification of singletons too.

Comparing our discourse-based approaches, ILP does significantly better than ICA over connected instances ($p < 0.001$), while ICA does significantly better than ILP over singletons ($p <$

[4]We use the SMO implementation, which, when used with the logistic regression, has an output that can be viewed as a posterior probability distribution.

	Base	Base-2	Local	ICA	ILP	HYB
Connected	24.4	47.56	46.66	**55.64**	**75.07**	**75.07**
Singleton	51.72	63.23	75.73	78.72	75.73	78.72
All	45.34	59.46	68.72	**73.31**	**75.35**	**77.72**

Table 4: Accuracies of the classifiers measured over Connected, Singleton and All instances. Performance significantly better than Local are indicated in **bold** for $p < 0.001$ and underline for $p < 0.01$.

0.01). However, there is no significant difference between ICA and ILP for the All condition. The HYB classifier outperforms ILP for the Singleton condition ($p < 0.01$) and ICA for the Connected condition ($p < 0.001$). Interestingly, over all instances (the All condition), HYB also performs significantly better than *both* ICA ($p < 0.001$) and ILP ($p < 0.01$).

5.3 Analysis

Amongst our two approaches, ILP performs better, and hence we further analyze its behavior to understand how the improvements are achieved. Table 5 reports the performance of ILP and Local for the precision, recall and f-measure metrics (averaged over 7 test folds), measured separately for each of the opinion categories. The most prominent improvement by ILP is observed for the recall of the polar categories under the Connected condition: 40 percentage points for the positive class, and 29 percentage points for the negative class. The gain in recall is not accompanied by a significant loss in precision. This results in an improvement in f-measure for the polar categories (24 points for positive and 16 points for negative). Also note that, by virtue of the constraint in Equation 7, ILP does not classify any connected instance as neutral; thus the precision is NaN, recall is 0 and the f-meaure is NaN. This is indicated as * in the Table.

The improvement of ILP for the All condition, for the polar classes, follows a similar trend for recall (18 to 21 point improvement) and f-measure (9 to 13 point improvement). In addition to this, the ILP has an *overall improvement in precision over Local*. This may seem counterintuitive, as in Table 5, ILP's precision for connected nodes is similar to, or lower than, that of Local. This is explained by the fact that, while going from connected to overall conditions, Local's polar predictions increase by threefold (565 to 1482), but its *correct* polar predictions increase by only twofold (430 to 801). Thus, the ratio of change in the total polar predictions to the correct polar predictions is $3 : 2$. On the other hand, while polar predictions by ILP increase by only twofold (1067 to 1984), its *correct* polar predictions increase by 1.5 times (804 to 1175). Here, the ratio of change in the total polar predictions to the correct polar predictions is $4 : 3$, a smaller ratio.

Gold	Local			
	Pos	Neg	Neut	Total
Pos	551	113	532	1196
Neg	121	250	205	576
Neut	312	135	2387	2834
Total	984	498	3124	4606
Gold	ILP			
	Pos	Neg	Neut	Total
Pos	817	157	222	1196
Neg	147	358	71	576
Neut	358	147	2329	2834
Total	1322	662	2622	4606

Table 6: Contingency table over all instances.

The contingency table (Table 6) shows how Local and ILP compare against the gold standard annotations. Notice here, that even though ILP makes more polar guesses as compared to Local, a greater proportion of the ILP guesses are correct. The number of non-diagonal elements are much smaller for ILP, resulting in the accuracy improvements seen in Table 4.

6 Examples and Discussion

The results in Table 4 show that Local, which provides the classifications for bootstrapping ICA and ILP, predicts an incorrect class for more than 50% of the connected instances. Methods starting with noisy starting points are in danger of propagating the errors and hence worsening the performance. Interestingly, in spite of starting with so many bad classifications, ILP is able to achieve a large performance improvement. We discovered that, given a set of connected instances, even when Local has only one correct guess, ILP is able to use this to rectify the related instances. We illustrate this situation in Figure 2, which reproduces the connected DAs for Example 1. It shows the classifications

	Positive		Negative		Neutral	
	Local	ILP	Local	ILP	Local	ILP
Connected-Prec	78.1	78.2	71.9	69.8	12.1	
Connected-Recall	45.3	**86.3**	44.1	**73.4**	62.8	*
Connected-F1	56.8	**81.5**	54.0	**70.7**	18.5	
All-Prec	56.2	**61.3**	52.3	*54.6*	76.3	**88.3**
All-Recall	46.6	**67.7**	44.3	**62.5**	83.9	81.5
All-F1	50.4	**64.0**	46.0	**57.1**	79.6	84.6

Table 5: Precision, Recall, Fmeasure for each Polarity category. Performance significantly better than Local are indicated in **bold** ($p < 0.001$), underline ($p < 0.01$) and *italics* ($p < 0.05$). The * denotes that ILP does not retrieve any connected node as neutral.

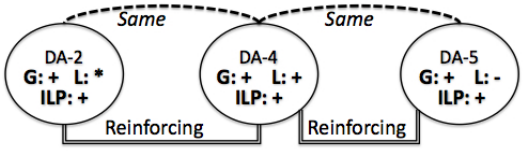

Figure 2: Discourse Relations and Classifications for Example 1.

for each DA from the gold standard (G), the Local classifier (L) and the ILP classifier (ILP). Observe that Local predicts the correct positive class (+) for only DA-4 (the DA containing **bit more durable** and **ergonomic**). Notice that these are clear cases of positive evaluation. It incorrectly predicts the polarity of DA-2 (containing **bit more bouncy**) as neutral (*), and DA-5 (containing **a bit different from all the other remote controls**) as negative (-). DA-2 and DA-5 exemplify the fact that polarity classification is a complex and difficult problem: being bouncy is a positive evaluation in this particular discourse context, and may not be so elsewhere. Thus, naturally, lexicons and unigram-based learning would fail to capture this positive evaluation. Similarly, "being different" could be deemed negative in other discourse contexts. However, ILP is able to arrive at the correct predictions for all the instances. As the DA-4 is connected to both DA-2 and DA-5 via a discourse relation that enforces an equal-polarity constraint (same+reinforcing relation of row 1, Table 2), both of the misclassifications are rectified. Presumably, the incorrect predictions made by Local are low confidence estimates, while the predictions of the correct cases have high confidence, which makes it possible for ILP to make the corrections.

We also observed the propagation of the correct classification for other types of discourse relations, for more complex types of connectivity, and also for conditions where an instance is not directly connected to the correctly predicted instance. The meeting snippet below (Example 2) and its corresponding DA relations (Figure 3) illustrate this. This example is a reinforcing discourse where the speaker is arguing for the number keypad, which is an alternative to the scrolling option. Thus, he argues against the scrolling, and argues for entering the number (which is a capability of the number keypad).

(2) D-1: I reckon you're **gonna have to have** a *number keypad* anyway for the amount of channels these days,
D-2: You **wouldn't want to** just have to *scroll through* all the channels to get to the one you want
D-3: You **wanna** *enter just the number of it* , if you know it
D-4: I reckon **we're gonna have to have** a *number keypad* anyway

In Figure 3, we see that, DA-2 is connected via an alternative+reinforcing discourse relation to each of its neighbors DA-1 and DA-3, which encourages the optimization to choose a class for it that is opposite to DA-1 and DA-3. Notice also, that even though Local predicts only DA-4 correctly, this correct classification finally influences the correct choice for all the instances, including the remotely connected DA-2.

7 Conclusions and Future Work

This work focuses on the first step to ascertain whether discourse relations are useful for improving opinion polarity classification, whether they can be modeled and what modeling choices can be used. To this end, we explored two distinct paradigms: the supervised ICA and the unsupervised ILP. We showed that both of our approaches are effective in exploiting discourse relations to

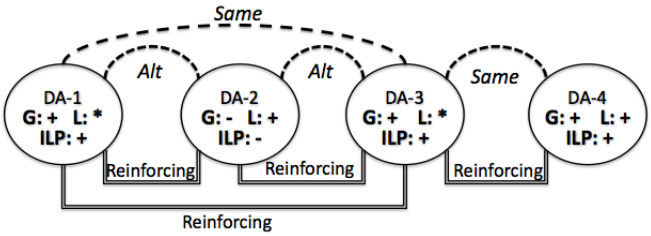

Figure 3: Discourse Relations and Classifications for Example 2.

significantly improve polarity classification. We found that there is a difference in how ICA and ILP achieve improvements, and that combining the two in a hybrid approach can lead to further overall improvement. Quantitatively, we showed that our approach is able to achieve a large increase in recall of the polar categories without harming the precision, which results in the performance improvements. Qualitatively, we illustrated how, even if the bootstrapping process is noisy, the optimization and discourse constraints effectively rectify the misclassifications. The improvements of our diverse global inference approaches indicate that discourse information can be adapted in different ways to augment and improve existing opinion analysis techniques.

The automation of the discourse-relation recognition is the next step in this research. The behavior of ICA and ILP can change, depending on the automation of discourse level recognition. The implementation and comparison of the two methods under full automation is the focus of our future work.

Abstract

This paper studies sentiment analysis of conditional sentences. The aim is to determine whether opinions expressed on different topics in a conditional sentence are positive, negative or neutral. Conditional sentences are one of the commonly used language constructs in text. In a typical document, there are around 8% of such sentences. Due to the condition clause, sentiments expressed in a conditional sentence can be hard to determine. For example, in the sentence, *if your Nokia phone is not good, buy this great Samsung phone*, the author is positive about "*Samsung phone"* but does not express an opinion on "*Nokia phone"* (although the owner of the "*Nokia phone*" may be negative about it). However, if the sentence does not have "*if*", the first clause is clearly negative. Although "*if*" commonly signifies a conditional sentence, there are many other words and constructs that can express conditions. This paper first presents a linguistic analysis of such sentences, and then builds some supervised learning models to determine if sentiments expressed on different topics in a conditional sentence are positive, negative or neutral. Experimental results on conditional sentences from 5 diverse domains are given to demonstrate the effectiveness of the proposed approach.

1 Introduction

Sentiment analysis (also called opinion mining) has been an active research area in recent years. There are many research directions, e.g., sentiment classification (classifying an opinion document as positive or negative) (e.g., Pang, Lee and Vaithyanathan, 2002; Turney, 2002), subjectivity classification (determining whether a sentence is subjective or objective, and its associated opinion) (Wiebe and Wilson, 2002; Yu and Hatzivassiloglou, 2003; Wilson et al, 2004; Kim and Hovy, 2004; Riloff and Wiebe, 2005), feature/topic-based sentiment analysis (assigning positive or negative sentiments to topics or product features) (Hu and Liu 2004; Popescu and Etzioni, 2005; Carenini et al., 2005; Ku et al., 2006; Kobayashi, Inui and Matsumoto, 2007; Titov and McDonald. 2008). Formal definitions of different aspects of the sentiment analysis problem and discussions of major research directions and algorithms can be found in (Liu, 2006; Liu, 2009). A comprehensive survey of the field can be found in (Pang and Lee, 2008).

Our work is in the area of topic/feature-based sentiment analysis or opinion mining (Hu and Liu, 2004). The existing research focuses on solving the general problem. However, we argue that it is unlikely to have a one-technique-fit-all solution because different types of sentences express sentiments/opinions in different ways. A divide-and-conquer approach is needed, e.g., focused studies on different types of sentences. This paper focuses on one type of sentences, i.e., conditional sentences, which have some unique characteristics that make it hard to determine the orientation of sentiments on topics/features in such sentences. By *sentiment orientation*, we mean positive, negative or neutral opinions. By *topic*, we mean the target on which an opinion has been expressed. In the product domain, a topic is usually a *product feature* (i.e., a component or attribute). For example, in the sentence, *I do not like the sound quality, but love the design of this MP3 player*, the product features (topics) are "*sound quality*" and "*design*" of the MP3 player as opinions have been expressed on them. The sentiment is positive on "*design*" but negative on "*sound quality*".

Conditional sentences are sentences that describe implications or hypothetical situations and their consequences. In the English language, a variety of conditional connectives can be used to form these sentences. A conditional sentence contains two clauses: the condition clause and

* This work was done when Bing Liu was on sabbatical leave at Northwestern University.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 180–189,
Singapore, 6-7 August 2009.

the consequent clause, that are dependent on each other. Their relationship has significant implications on whether the sentence describes an opinion. One simple observation is that sentiment words (also known as opinion words) (e.g., *great*, *beautiful*, *bad*) alone cannot distinguish an opinion sentence from a non-opinion one. A conditional sentence may contain many sentiment words or phrases, but express no opinion.

Example 1: *If someone makes a beautiful and reliable car, I will buy it* expresses no sentiment towards any particular car, although "*beautiful*" and "*reliable*" are positive sentiment words.

This, however, does not mean that a conditional sentence cannot express opinions/sentiments.

Example 2: *If your Nokia phone is not good, buy this great Samsung phone* is positive about the "*Samsung phone*" but does not express an opinion on the "*Nokia phone*" (although the owner of the "*Nokia phone*" may be negative about it). Clearly, if the sentence does not have "*if*", the first clause is negative. Hence, a method for determining sentiments in normal sentences will not work for conditional sentences. The examples below further illustrate the point.

In many cases, both the condition and consequent together determine the opinion.

Example 3: *If you are looking for a phone with good voice quality, don't buy this Nokia phone* is negative about the "*voice quality*" of the "Nokia phone", although there is a positive sentiment word "*good*" in the conditional clause modifying "*voice quality*". However, in the following example, the opinion is just the opposite.

Example 4: *If you want a phone with good voice quality, buy this Nokia phone* is positive about the "*voice quality*" of the "Nokia phone".

As we can see, sentiment analysis of conditional sentences is a challenging problem.

One may ask whether there is a large percentage of conditional sentences to warrant a focused study. Indeed, there is a fairly large proportion of such sentences in evaluative text. They can have a major impact on the sentiment analysis accuracy. Table 1 shows the percentage of conditional sentences (sentences containing the words *if*, *unless*, *assuming*, etc) and also the total number of sentences from which we computed the percentage in several user-forums. The figures definitely suggest that there is considerable benefit to be gained by developing techniques that can analyze conditional sentences.

Table 1: Percent of conditional sentences

Source	% of cond. (total #. of sent.)
Cellphone	8.6 (47711)
Automobile	5.0 (8113)
LCD TV	9.92 (258078)
Audio Systems	8.1 (5702)
Medicine	8.29 (160259)

To the best of our knowledge, there is no focused study on conditional sentences. This paper makes such an attempt. Specifically, we determine whether a conditional sentence (which is also called a *conditional* in the linguistic literature) expresses positive, negative or neutral opinions on some topics/features. Since our focus is on studying how conditions and consequents affect sentiments, we assume that *topics* are given, which are *product attributes* since our data sets are user comments on different products.

Our study is conducted from two perspectives. We start with the linguistic angle to gain a good understanding of existing work on different types of conditionals. As conditionals can be expressed with other words or phrases than *if*, we will study how they behave compared to *if*. We will also show that the distribution of these conditionals based on our data sets.

With the linguistic knowledge, we perform a computational study using machine learning. A set of features for learning is designed to capture the essential determining information. Note that the features here are data attributes used in learning rather than product attributes or features. Three classification strategies are designed to study how to best perform the classification task due to the complex situation of two clauses and their interactions in conditional sentences. These three classification strategies are *clause-based*, *consequent-based* and *whole-sentence-based*. Clause-based classification classifies each clause separately and then combines their results. Consequent-based classification only uses consequents for classification as it is observed that in conditional sentences, it is often the consequents that decide the opinion. Whole-sentence-based classification treats the entire sentence as a whole in classification. Experimental results on conditional sentences from diverse domains demonstrate the effectiveness of these classification models. The results indicate that the whole-sentence-based classifier performs the best.

Since this paper only studies conditional sentences, a natural question is whether the proposed technique can be easily integrated into an overall sentiment analysis or opinion mining system. The answer is yes because a large proportion of conditional sentences can be detected using conditional connectives. Keyword search is

thus sufficient to identify such sentences for special handling using the proposed approach. There are, however, some subtle conditionals which do not use normal conditional connectives and will need an additional module to identify them, but such sentences are very rare as Table 2 indicates.

2 The Problem Statement

The paper follows the *feature-based sentiment analysis* model in (Hu and Liu 2004; Popescu and Etzioni, 2005). We are particularly interested in sentiments on products and services, which are called objects or entities. Each object is described by its *parts* and *attributes*, which are collectively called *features* in (Hu and Liu, 2004; Liu, 2006). For example, in the sentence, *If this camera has great picture quality, I will buy it*, "*picture quality*" is a feature of the camera. For formal definitions of objects and features, please refer to (Liu, 2006; Liu, 2009). In this paper, we use the term *topic* to mean *feature* as the feature here can confuse with the feature used in machine learning. The term topic has also been used by some researchers (e.g., Kim and Hovy, 2004; Stoyanov and Cardie, 2008).

Our objective is to predict the sentiment orientation (positive, negative or neutral) on each topic that has been commented on in a sentence.

The problem of automatically identifying features or topics being spoken about in a sentence has been studied in (Hu and Liu, 2004; Popescu and Etzioni, 2005; Stoyanov and Cardie, 2008). In this work, we do not attempt to identify such topics automatically. Instead, we assume that they are given because our objective is to study how the interaction of the condition and consequent clauses affects sentiments. For this purpose, we manually identify all the topics.

3 Conditional Sentences

This section presents the linguistic perspective of conditional sentences.

Table 2: Percentage of sentences with some main conditional connectives

Conditional Connective	% of sentences
If	6.42
Unless	0.32
Even if	0.17
Until	0.10
As (so) long as	0.09
Assuming/supposing	0.04
In case	0.04
Only if	0.03

3.1 Conditional Connectives

A large majority of conditional sentences are introduced by the subordinating conjunction *If*. However, there are also many other conditional connectives, e.g., *even if*, *unless*, *in case*, *assuming*/*supposing*, *as long as*, etc. Table 2 shows the distribution of conditional sentences with various connectives in our data. Detailed linguistic discussions of them are beyond the scope of this paper. Interested readers, please refer to (Declerck and Reed, 2001). Below, we briefly discuss some important ones and their interpretations.

If: This is the most commonly used conditional connective. In addition to its own usage, it can also be used to replace other conditional connectives, except some semantically richer connectives (Declerck and Reed, 2001). Most (but not all) conditional sentences can be logically expressed in the form 'If *P* then *Q*', where *P* is the condition clause and *Q* is the consequent clause. For practical purposes, we can automatically segment the condition and consequent clauses using simple rules generated by observing grammatical and linguistic patterns.

Unless: Most conditional sentences containing *unless* can be replaced with equivalent sentences with an *if* and a *not*. For example, the sentence *Unless you need clarity, buy the cheaper model* can be expressed with *If you don't need clarity, buy the cheaper model*.

Even if: Linguistic theories claim that *even if* is a special case of a conditional which may not always imply an if-then relationship (Gauker 2005). However, in our datasets, we have observed that the usage of *even if* almost always translates into a conditional. Replacing *even if* by *if* will yield a sentence that is semantically similar enough for the purpose of sentiment analysis.

Only if, provided/providing that, on condition that: Conditionals involving these phrases typically express a necessary condition, e.g., *I will buy this camera only if they can reduce the price*. In such sentences, *only* usually does not affect whether the sentence is opinionated or not.

In case: Conditional sentences containing *in case* usually describe a precaution (*I will close the window in case it rains*), prevention (*I wore sunglasses in case I was recognized*), or a relevance conditional (*In case you need a car, you can rent one*). Identifying the conditional and consequent clauses is not straightforward in many cases. Further, in these instances, replacing *in case* with *if* may not convey the intended meaning of the conditional. We have ignored these cases in

our analysis as we believe that they need a separate study, and also such sentences are rare.

As (so) long as: Sentences with these connectives behave similarly to *if* and can usually be replaced with *if*.

Assuming/Supposing: These are a category of conditionals that behave quite differently. The participles *supposing* and *assuming* create conditional sentences where the conditional clause and the consequent clause can be syntactically independent. It is quite difficult to distinguish those conditional sentences which contain an explicit consequent clause and fit within our analysis framework. In our data, most of such sentences have no consequent, thus representing assumptions rather than opinions. We omit these sentences in our study (they are also rare).

3.2 Types of Conditionals

There are extensive studies of conditional sentences (also known as *conditionals*) in linguistics. Various theories have led to a number of classification systems. Popular types of conditionals include *actualization conditionals, inferential conditionals*, *implicative conditionals*, etc (Declerck and Reed, 2001). However, these classifications are mainly based on semantic meanings which are difficult to recognize by a computer program. To build classification models, we instead exploit *canonical tense patterns* of conditionals, which are often used in pedagogic grammar books. They are defined based on tense and are associated with general meanings. However, as described in (Declerck and Reed, 2001), their meanings are much more complex and numerous than their associated general meanings. However, the advantage of this classification is that different types can be detected easily because they depend on tense which can be produced by a part-of-speech tagger. As we will see in Section 5, canonical tense patterns help sentiment classification significantly. Below, we introduce the four canonical tense patterns.

Zero Conditional: This conditional form is used to describe universal statements like facts, rules and certainties. In a zero conditional, both the condition and consequent clauses are in the simple present tense. An example of such sentences is: *If you heat water, it boils*.

First Conditional: Conditional sentences of this type are also called potential or indicative conditionals. They are used to express a hypothetical situation that is probably true, but the truth of which is unverified. In the first conditional, the condition is in the simple present tense, and the consequent can be either in past tense or present tense, usually with a modal auxiliary verb preceding the main verb, e.g., *If the acceleration is good, I will buy it.*

Second Conditional: This is usually used to describe less probable situations, for stating preferences and imaginary events. The condition clause of a second conditional sentence is in the past subjunctive (past tense), and the consequent clause contains a conditional verb modifier (like *would*, *should*, *might*), in addition to the main verb, e.g., *If the cell phone was robust, I would consider buying it.*

Third conditional: This is usually used to describe contrary-to-fact (impossible) past events. The past perfect tense is used in the condition clause, and the consequent clause is in the present perfect tense, e.g., *If I had bought the a767, I would have hated it.*

Based on the above definitions, we have developed approximate part-of-speech (POS) tags [1] for the condition and the consequent of each pattern (Table 3), which do not cover all sentences, but overall they cover a majority of the sentences. For those not covered cases, the problem is mainly due to incomplete sentences and wrong grammars, which are typical for informal writings in forum postings and blogs. For example, the sentence, *Great car if you need powerful acceleration*, does not fall into any category, but it actually means *It is a great car if you need powerful acceleration*, which is a zero conditional. To handle such sentences, we designed a set of rules to assign them some default types:

If condition contains VB/VBP/VBZ → 0 conditional
If consequent contains VB/VBP/VBS → 0 conditional
If condition contains VBG → 1st conditional
If condition contains VBD → 2nd conditional
If conditional contains VBN → 3rd conditional.

Table 3: Tenses for identifying conditional types

Type	Linguistic Rule	Condition POS tags	Consequent POS tags
0	If + simple present → simple present	VB/VBP/VBZ	VB/VBP/ VBZ
1	If + simple present → will + bare infinitive	VB/VBP/VBZ /VBG	MD + VB
2	If + past tense → would + infinitive	VBD	MD + VB
3	If + past perfect → present perfect	VBD+VBN	MD + VBD

[1] The list of Part-Of-Speech (POS) tags can be found at: http://www.ling.upenn.edu/courses/Fall_2003/ling001/penn_treebank_pos.html

By using these rules, we can increase the sentence coverage from 73% to 95%.

4 Sentiment Analysis of Conditionals

We now describe our computational study. We take a machine learning approach to predict sentiment orientations. Below, we first describe features used and then classification strategies.

4.1 Feature construction

I. *Sentiment words/phrases and their locations*: Sentiment words are words used to express positive or negative opinions, which are instrumental for sentiment classification for obvious reasons. We obtained a list of over 6500 sentiment words gathered from various sources. The bulk of it is from http://www.cs.pitt.edu/mpqa. We also added some of our own. Our list is mainly from the work in (Hu and Liu, 2004; Ding, Liu and Yu, 2008). In addition to words, there are phrases that describe opinions. We have identified a set of such phrases. Although obtaining these phrases was time-consuming, it was only a one-time effort. We will make this list available as a community resource. It is possible that there is a better automated method for finding such phrases, such as the methods in (Kanayama and Nasukawa, 2006; Breck, Choi and Cardie, 2007). However, automatically generating sentiment phrases has not been the focus of this work as our objective is to study how the two clauses interact to determine opinions given the sentiment words and phrases are known. Our list of phrases is by no means complete and we will continue to expand it in the future.

   For each sentence, we also identify whether it contains sentiment words/phrases in its condition or consequent clause. It was observed that the presence of a sentiment word/phrase in the consequent clause has more effect on the sentiment of a sentence.

II. *POS tags of sentiment words*: Sentiment words may be used in several contexts, not all of which may correspond to an opinion. For example, *I trust Motorola* and *He has a trust fund* both contain the word *trust*. But only the former contains an opinion. In such cases, the POS tags can provide useful information.

III. *Words indicating no opinion*: Similar to how sentiment words are related to opinions, there are also a number of words which imply the opposite. Words like *wondering*, *thinking*, *debating* are used when the user is posing a question or expressing doubts. Thus such phrases usually do not contribute an opinion, especially if they are in the vicinity of the *if* connective. We search a window of 3 words on either side of *if* to determine if there is any such word. We have compiled a list of these words as well and use it in our experiments.

IV. *Tense patterns*: These are the canonical tense patterns in Section 3.2. They are used to generate a set of features. We identify the first verb in both the condition and consequent clauses by searching for the relevant POS tags in Table 3. We also search for the words preceding the main verb to find modal auxiliary verbs, which are also used as features.

V. *Special characters*: The presence or absence of '?' and '!'.

VI. *Conditional connectives*: The conditional connective used in the sentence (*if*, *even if*, *unless*, *only if*, etc) is also taken as a feature.

VII. *Length of condition and consequent clauses*: Using simple linguistic and punctuation rules, we automatically segment a sentence into condition and consequent clauses. The numbers of words in the condition and consequent clauses are then used as features. We observed that when the condition clause is short, it usually has no impact on whether the sentence expresses an opinion.

VIII. *Negation words*: The use of negation words like *not, don't*, *never*, etc, often alter the sentiment orientation of a sentence. For example, the addition of *not* before a sentiment word can change the orientation of a sentence from positive to negative. We consider a window of 3-6 words before an opinion word, and search for these kinds of words.

The following two features are singled out for easy reference later. They are only used in one classification strategy. The first feature is an indicator, and the second feature has a parameter (which will be evaluated separately).

(1). *Topic location*: This feature indicates whether the topic is in the conditional clause or the consequent clause.

(2). *Opinion weight*: This feature considers only sentiment words in the vicinity of the topic, since they are more likely to influence the opinion on the topic. A window size is used to control what we mean by vicinity. The following formula is used to assign a weight to each sentiment word, which is inversely proportional to the distance (D_{op}) of the sentiment word to the topic mention. Sentiment

value is +1 for a positive word and -1 for a negative word. *Sentwords* are the set of known sentiment words and phrases.

$$weight = \sum_{op} \frac{\pm 1}{D_{op}}, \forall op \in \{sentwords\}$$

4.2 Classification Strategies

Since we are interested in topic-based sentiment analysis, how to perform classification becomes an interesting issue. Due to the two clauses, it may not be sufficient to classify the whole sentence as positive or negative as in the same sentence, some topics may be positive and some may be negative. We propose three strategies.

Clause-based classification: Since there are two clauses in a conditional sentence, in this case we build two classifiers, one for the condition and one for the consequent.

Condition classifier: This method classifies the condition clause as expressing positive, negative or neutral opinion.

Training data: Each training sentence is represented as a feature vector. Its class is positive, negative or neutral depending on whether the conditional clause is positive, negative or neutral while considering both clauses.

Testing: For each test sentence, the resulting classifier predicts the opinion of the condition clause.

Topic class prediction: To predict the opinion on a topic, if the topic is in the condition clause, it takes the predicted class of the clause.

Consequent classifier: This classifier classifies the consequent clause as expressing positive, negative or neutral opinion.

Training data: Each training sentence is represented as a feature vector. Its class is positive, negative or neutral depending on whether the consequent clause is positive, negative or neutral while considering both clauses.

Testing: For each test sentence, the resulting classifier predicts the opinion of the consequent clause.

Topic class prediction: To predict the opinion on a topic, if the topic is in the consequent clause, it takes the predicted class of the clause.

The combination of these two classifiers is called the *clause-based classifier*. It works as follows: If a topic is in the conditional clause, the condition classifier is used, and if a topic is in the consequent clause, the consequent classifier is used.

Consequent-based classification: It is observed that in most cases, the condition clause contains no opinion whereas the consequent clause reflects the sentiment of the entire sentence. Thus, this method uses (in a different way) only the above consequent classifier. If it classifies the consequent of a testing conditional sentence as positive, all the topics in the whole sentence are assigned the positive orientation, and likewise for negative and neutral.

Whole-sentence-based classification: In this case, a single classifier is built to predict the opinion on each topic in a sentence.

Training data: In addition to the normal features, the two features (1) and (2) in Section 4.1 are used for this classifier. If a sentence contains multiple topics, multiple training instances of the same sentence are created in the training data. Each instance represents one specific topic. The class of the instance depends on whether the opinion on the topic is positive, negative or neutral.

Testing: For each topic in each test sentence, the resulting classifier predicts its opinion.

Topic class prediction: This is not needed as the prediction has been done in testing.

5 Results and Discussions

5.1 Data sets

Our data consists of conditional sentences from 5 different user forums: Cellphone, Automobile, LCD TV, Audio systems and Medicine. We obtained user postings from these forums and extracted the conditional sentences. We then manually annotated 1378 sentences from this corpus. We also annotated the conditional and consequent clauses and identified the topics (or product features) being commented upon, and their sentiment orientations. In our annotation, we observed that sentences with no sentiment words or phrases almost never express opinions, i.e., only around 3% of them express opinions. There are around 26% sentences containing no sentiment words or phrases in our data. To make the problem challenging, we restrict our attention to only those sentences that contain at least one sentiment word or phrase. We have annotated topics from around 900 such sentences. Table 4 shows the class distributions of this data. At the clause level (topics are not considered), we observe that conditional clauses contain few opinions. At the topic-level, 43.5% of the topics have positive opinions, 26.4% of the topics have negative opinions, and the rest have no opinions.

Table 4: Distribution of classes

	Positive	Negative	Neutral
Condition	6.9%	6.7%	86.4%
Consequent	49.3%	16.5%	34%
Topic-level	43.5%	26.4%	29.9%

For the annotation of data, we assume that topics are known. One student annotated the topics first. Then two students annotated the sentiments on the topics. If a student found that a topic annotation is wrong, he will let us know. Some mistakes and missing topics were found but there were mainly due to oversights rather than disagreements. The agreement on sentiment annotations were computed using the Kappa score. We achieved the Kappa score of 0.63, which indicates strong agreements. The conflicting cases were then solved through discussion to reach consensus. We did not find anything that the annotators absolutely disagree with each other.

5.2 Experimental results

We now present the results for different combinations of features and classification strategies. For model building, we used Support Vector Machines (SVM), and the LIBSVM implementation (Chang and Lin, 2001) with a Gaussian kernel, which produces the best results. All the results are obtained via 10-fold cross validation.

Two-class classification: We first discuss the results for a simpler version of the problem that involves only sentences with positive or negative orientations on some topics (at least one of the clauses must have a positive/negative opinion on a topic). Neutral sentences are not used (~28% of the total). The results of all three classifiers are given in Table 5. The feature sets have been described in Section 4.1. For all the experiments below, features (1) and (2) are only used by the whole-sentence-based classifier, but not used by the other two classifiers for obvious reasons.

{I+II}: This setting uses sentiment words and phrases, their positions and POS tags as features (we used Brill's POS tagger). This can be seen as the baseline. We observe that both the consequent-based and whole-sentence-based classifiers perform dramatically better than the clause-based classifier. The consequent-based classifier and the whole-sentence-based classifier perform similarly (with the latter being slightly better). The precision, recall, and F-score are computed as the average of the two classes.

{I+II+III}: In this setting, the list of special non-sentiment related words is added to the feature set. All three classifiers improve slightly.

{I+II+III+IV}: This setting includes all the canonical tense based features. We see marked improvements for the consequent-based and whole-sentence-based classifiers both in term of accuracy and F-score, which are statistically significant compared to those of {I+II+III} at the 95% confidence level based on paired t-test.

All: When all the features are used, the results of all the classifiers improve further.

Two main observations worth mentioning:

1. Both the consequent-based and whole-sentence-based classifiers outperform the clause-based classifier dramatically. This confirms our observation that the consequent usually plays the key role in determining the sentiment of the sentence. This is further reinforced by the fact that the consequent-based classifier actually performs similarly to the whole-sentence-based classifier. The condition clause seems to give no help.
2. The second observation is that the linguistic knowledge of canonical tense patterns helps significantly. This shows that the linguistic knowledge is very useful.

We also noticed that many misclassifications are caused by grammatical errors, use of slang phrases and improper punctuations, which are typical of postings on the Web. Due to language irregularities (e.g., wrong grammar, missing punctuations, sarcasm, exclamations), the POS tagger makes many mistakes as well causing some errors in the tense based features.

Three-class classification: We now move to the more difficult and realistic case of three classes: positive, negative and neutral (no-opinion). Table 6 shows the results. The trend is similar except that the whole-sentence-based classifier now performs markedly better than the consequent-based classifier. We believe that this is because the neutral class needs information from both the condition and consequent clauses. This is evident from the fact that there is little or no improvement after {I+II} for the consequent-based classifier. We also observe that the accuracies and F-scores for the three-class classification are lower than those for the two-class classification. This is understandable due to the difficulty of determining whether a sentence has opinion or not. Again, statistical test shows that the canonical tense-based features help significantly.

As mentioned in Section 4.1, the whole-sentence-based classifier only considers those sentiment words in the vicinity of the topic under

Table 5: Two-class classification – positive and negative

	Clause-based classifier				***Consequent-based classifier***				***Whole-sentence-based classifier***			
	Acc.	Prec.	Rec.	**F**	Acc.	Prec.	Rec.	**F**	Acc.	Prec.	Rec.	**F**

All	43.2	46.1	38.9	**42.2**	73.3	77.0	72.7	**74.8**	72.3	77.8	73.6	**75.6**

Table 6: Three-class classification – positive, negative and neutral (no opinion)

	Clause-based classifier				***Consequent-based classifier***				***Whole-sentence-based classifier***			
	Acc.	Prec.	Rec.	**F**	Acc.	Prec.	Rec.	**F**	Acc.	Prec.	Rec.	**F**
I+II (senti. words+POS)	45.2	41.3	35.1	**37.9**	54.6	57.7	52.9	**55.2**	59.1	58.1	56.4	**57.2**
I+II+III (+ non-senti. words)	46.9	42.8	37.8	**40.1**	55.3	60.0	51.3	**55.3**	61.4	60.1	60.8	**60.4**
I+II+III+IV (+ tenses)	50.3	48.7	40.9	**44.5**	57.3	64.0	50.0	**56.1**	64.6	63.3	63.9	**63.6**
All	53.3	49.8	44.1	**46.8**	58.7	64.5	50.1	**56.4**	67.8	66.9	65.1	**66.0**

Table 7: Accuracy of the whole-sentence-based classifier with varying window sizes (*n*)

Window size	1	2	3	4	5	6	7	**8**	9	10
Accuracy	66.1	62.6	64.1	64.8	65.3	65.7	66.3	**67.3**	66.9	66.8

investigation. For this, we search a window of *n* words on either side of the topic mention. To study the effect of varying *n*, we performed an experiment with various values of the window size and measured the overall accuracy for each case. Table 7 shows how the accuracy changes as we increase the window size. We found that a window size of 6-10 yielded good accuracies. This is because lower values of *n* lead to loss of information regarding sentiment words as some sentiment words could be far from the topic. We finally used 8, which gave the best results.

We also investigated ways of using the negation word in the sentence to correctly predict the sentiment. One method is to use the negation word as a feature, as described in Section 4.1. Another technique is to reverse the orientation of the prediction for those sentences which contain negation words. We found that the former technique yielded better results. The results reported so far are based on the former approach.

6 Related Work

There are several research directions in sentiment analysis (or opinion mining). One of the main directions is sentiment classification, which classifies the whole opinion document (e.g., a product review) as positive or negative (e.g., Pang et al, 2002; Turney, 2002; Dave et al, 2003; Ng et al. 2006; McDonald et al, 2007). It is clearly different from our work as we are interested in conditional sentences.

Another important direction is classifying sentences as subjective or objective, and classifying subjective sentences or clauses as positive or negative (Wiebe et al, 1999; Wiebe and Wilson, 2002, Yu and Hatzivassiloglou, 2003; Wilson et al, 2004; Kim and Hovy, 2004; Riloff and Wiebe, 2005; Gamon et al 2005; McDonald et al, 2007). Although these works deal with sentences, they aim to solve the general problem. This paper argues that there is unlikely a one-technique-fit-all solution, and advocates dealing with specific types of sentences differently by exploiting their unique characteristics. Conditional sentences are the focus of this paper. To the best of our knowledge, there is no focused study on them.

Several researchers also studied feature/topic-based sentiment analysis (e.g., Hu and Liu, 2004; Popescu and Etzioni, 2005; Ku et al, 2006; Carenini et al, 2006; Mei et al, 2007; Ding, Liu and Yu, 2008; Titov and R. McDonald, 2008; Stoyanov and Cardie, 2008; Lu and Zhai, 2008). Their objective is to extract topics or product features in sentences and determine whether the sentiments expressed on them are positive or negative. Again, no focused study has been made to handle conditional sentences. Effectively handling of conditional sentences can help their effort significantly.

In this work, we used many sentiment words and phrases. These words and phrases are usually compiled using different approaches (Hatzivassiloglou and McKeown, 1997; Kaji and Kitsuregawa, 2006; Kanayama and Nasukawa, 2006; Esuli and Sebastiani, 2006; Breck et al, 2007; Ding, Liu and Yu. 2008; Qiu et al, 2009). There are several existing lists produced by researchers. We used the one from the MPQA corpus (http://www.cs.pitt.edu/mpqa) with added phrases of our own from (Ding, Liu and Yu. 2008). In our work, we also assume that the topics are known. (Hu and Liu, 2004; Popescu and Etzioni, 2005; Kobayashi, Inui and Matsumoto, 2007; Stoyanov and Cardie, 2008) have studied topic/feature extraction.

One existing focused study is on comparative and superlative sentences (Jindal and Liu, 2006; Bos and Nissim, 2006; Fiszman et al, 2007; Ganapathibhotla and Liu, 2008). Their work identifies comparative sentences, extracts comparative relations in the sentences and analyzes comparative opinions (Ganapathibhotla and Liu, 2008). An example comparative sentence is "*Honda looks better than Toyota*". As we can see, comparative sentences are entirely different from conditional sentences. Thus, their methods cannot be directly applied to conditional sentences.

7 Conclusion

To perform sentiment analysis accurately, we argue that a divide-and-conquer approach is needed, i.e., focused study on each type of sentences. It is unlikely that there is a one-size-fit-all solution. This paper studied one type, i.e., conditional sentences, which have some unique characteristics that need special handling. Our study was carried out from both the linguistic and computational perspectives. In the linguistic study, we focused on canonical tense patterns, which have been showed useful in classification. In the computational study, we built SVM models to automatically predict whether opinions on topics are positive, negative or neutral. Experimental results have shown the effectiveness of the models.

In our future work, we will further improve the classification accuracy and study related problems, e.g., identifying topics/features. Although there are some special conditional sentences that do not use easily recognizable conditional connectives and identifying them are useful, such sentences are very rare and spending time and effort on them may not be cost-effective at the moment.

Abstract

This paper investigates a new task, *subjectivity word sense disambiguation (SWSD)*, which is to automatically determine which word instances in a corpus are being used with subjective senses, and which are being used with objective senses. We provide empirical evidence that SWSD is more feasible than full word sense disambiguation, and that it can be exploited to improve the performance of contextual subjectivity and sentiment analysis systems.

1 Introduction

The automatic extraction of opinions, emotions, and sentiments in text (*subjectivity analysis*) to support applications such as product review mining, summarization, question answering, and information extraction is an active area of research in NLP.

Many approaches to opinion, sentiment, and subjectivity analysis rely on lexicons of words that may be used to express subjectivity. Examples of such words are the following (in bold):

(1) He is a **disease** to every team he has gone to.
Converting to SMF is a **headache**.
The concert left me **cold**.
That guy is such a **pain**.

Knowing the meaning (and thus subjectivity) of these words would help a system recognize the negative sentiments in these sentences.

Most subjectivity lexicons are compiled as lists of keywords, rather than word meanings (senses). However, many keywords have both subjective and objective senses. False hits – subjectivity clues used with objective senses – are a significant source of error in subjectivity and sentiment analysis. For example, even though the following sentence contains all of the negative keywords above, it is nevertheless objective, as they are all false hits:

(2) Early symptoms of the **disease** include severe **headaches**, red eyes, fevers and **cold** chills, body **pain**, and vomiting.

To tackle this source of error, we define a new task, *subjectivity word sense disambiguation (SWSD)*, which is to automatically determine which word instances in a corpus are being used with subjective senses, and which are being used with objective senses. We hypothesize that SWSD is more feasible than full word sense disambiguation, because it is more coarse grained – often, the exact sense need not be pinpointed. We also hypothesize that SWSD can be exploited to improve the performance of contextual subjectivity analysis systems via sense-aware classification.

The paper consists of two parts. In the first part, we build and evaluate a targeted supervised SWSD system that aims to disambiguate members of a subjectivity lexicon. It labels clue instances as having a subjective sense or an objective sense in context. The system relies on common machine learning features for word sense disambiguation (WSD). The performance is substantially above both baseline and the performance of full WSD on the same data, suggesting that the task is feasible, and that subjectivity provides a natural coarse-grained grouping of senses.

The second part demonstrates the promise of SWSD for contextual subjectivity analysis. First, we show that subjectivity sense ambiguity is highly prevalent in the MPQA opinion-annotated corpus (Wiebe et al., 2005; Wilson, 2008), thus establishing the potential benefit of performing SWSD. Then, we exploit SWSD to improve performance on several subjectivity analysis tasks, from subjective/objective sentence-level classification to positive/negative/neutral expression-level classification. To our knowledge, this is the

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 190–199,
Singapore, 6-7 August 2009.

first attempt to explicitly use sense-level subjectivity tags in contextual subjectivity and sentiment analysis.

2 Background

We adopt the definitions of *subjective* and *objective* from (Wiebe et al., 2005; Wiebe and Mihalcea, 2006; Wilson, 2008). Subjective expressions are words and phrases being used to express mental and emotional states, such as speculations, evaluations, sentiments, and beliefs. A general covering term for such states is *private state* (Quirk et al., 1985), an internal state that cannot be directly observed or verified by others. (Wiebe and Mihalcea, 2006) give the following examples:

(3) His **alarm** grew.
He **absorbed** the information quickly.
UCC/Disciples leaders **roundly condemned** the Iranian President's **verbal assault** on Israel.
What's the catch?

Polarity (also called *semantic orientation*) is also important to NLP applications. In review mining, for example, we want to know whether an opinion about a product is positive or negative. Nonetheless, as argued by (Wiebe and Mihalcea, 2006; Su and Markert, 2008), there are also motivations for a separate subjective/objective (*S/O*) classification.

First, expressions may be subjective but not have any particular polarity. An example given by (Wilson et al., 2005a) is *Jerome says the hospital* **feels** *no different than a hospital in the states.* An NLP application system may want to find a wide range of private states attributed to a person, such as their motivations, thoughts, and speculations, in addition to their positive and negative sentiments. Second, benefits for sentiment analysis can be realized by decomposing the problem into *S*/*O* (or neutral versus polar) and polarity classification (Yu and Hatzivassiloglou, 2003; Pang and Lee, 2004; Wilson et al., 2005a; Kim and Hovy, 2006). We will see further evidence of this in Section 4.2.3 in this paper.

The contextual subjectivity analysis experiments in Section 4 include both *S*/*O* and polarity classifications. The data used in those experiments is from the MPQA Corpus (Wiebe et al., 2005; Wilson, 2008),[1] which consists of texts from the world press annotated for subjective expressions. In the MPQA Corpus, subjective expressions of varying lengths are marked, from single words to long phrases. In addition, other properties are annotated, including polarity.

For SWSD, we need the notions of subjective and objective *senses* of words in a dictionary. We adopt the definitions from (Wiebe and Mihalcea, 2006), who describe the annotation scheme as follows. Classifying a sense as *S* means that, when the sense is used in a text or conversation, one expects it to express subjectivity, and also that the phrase or sentence containing it expresses subjectivity. As noted in (Wiebe and Mihalcea, 2006), sentences containing objective senses may not be objective. Thus, objective senses are defined as follows: Classifying a sense as *O* means that, when the sense is used in a text or conversation, one does not expect it to express subjectivity and, if the phrase or sentence containing it is subjective, the subjectivity is due to something else. Finally, classifying a sense as *B* means it covers both subjective and objective usages.

The following subjective examples are given in (Wiebe and Mihalcea, 2006):

His **alarm** grew.
alarm, dismay, consternation – (fear resulting from the awareness of danger)
=> fear, fearfulness, fright – (an emotion experienced in anticipation of some specific pain or danger (usually accompanied by a desire to flee or fight))

What's the **catch**?
catch – (a hidden drawback; "it sounds good but what's the catch?")
=> drawback – (the quality of being a hindrance; "he pointed out all the drawbacks to my plan")

They give the following objective examples:

The **alarm** went off.
alarm, warning device, alarm system – (a device that signals the occurrence of some undesirable event)
=> device – (an instrumentality invented for a particular purpose; "the device is small enough to wear on your wrist"; "a device intended to conserve water")

He sold his **catch** at the market.
catch, haul – (the quantity that was caught; "the catch was only 10 fish")
=> indefinite quantity – (an estimated quantity)

Wiebe and Mihalcea performed an agreement study and report that good agreement (κ=0.74) can be achieved between human annotators labeling the subjectivity of senses. For a similar task, (Su and Markert, 2008) also report good agreement (κ=0.79).

3 Subjectivity Word Sense Disambiguation

3.1 Task Definition and Method

We now turn to SWSD, and our method for performing it.

Note that SWSD is midway between pure dictionary classification and pure contextual interpretation. For SWSD, the context of the word is considered in order to *perform* the task, but the subjectivity is determined solely by the dictionary. In contrast, full contextual interpretation can deviate from a sense's subjectivity label in the dictionary. As noted above, words used with objective senses may appear in subjective expressions. For example, an SWSD system would label the following examples of alarm as *S*, *O* and *O*, respectively. On the other hand, a sentence-level subjectivity classifier would label the sentences as *S*, *S*, and *O*, respectively.

(4) His **alarm** grew.
Will someone shut that darn **alarm** off?
The **alarm** went off.

We use a supervised approach to SWSD. We train a different classifier for each lexicon entry for which we have training data. Thus, our approach is like targeted WSD (in contrast to all-words WSD), with two labels: *S* and *O*.

We borrow machine learning features which have been successfully used in WSD. Specifically, given an ambiguous target word, we use the following features from (Mihalcea, 2002):

CW : the target word itself
CP : POS of the target word
CF : surrounding context of 3 words and their POS
HNP : the head of the noun phrase to which the target word belongs
NB : the first noun before the target word
VB : the first verb before the target word
NA : the first noun after the target word
VA : the first verb after the target word
SK : at most 10 context words occurring at least 5 times; determined for each sense

3.2 Lexicon and Data

Our target words are members of a subjectivity lexicon, because, since they are in such a lexicon, we know they have subjective usages. Specifically, we use the lexicon of (Wilson et al., 2005b; Wilson, 2008).[2] The entries have been divided into those that are strongly subjective (*strongsubj*) and those that are weakly subjective (*weaksubj*), reflecting their reliability as subjectivity clues. The sources of the entries in the lexicon are identified in (Wilson, 2008). In the second part of this paper, we evaluate systems against the MPQA corpus. Wilson also uses this corpus for her evaluations. To enable this, entries were added to the lexicon independently from the MPQA corpus (that is, none of the entries were derived using the MPQA corpus).

The training and test data for SWSD consists of word instances in a corpus labeled as *S* or *O*, indicating whether they are used with a subjective or objective sense. Because we do not have data labeled with the *S*/*O* coarse-grained senses and we did not want to undertake the annotation effort at this stage, we created an annotated corpus by combining two types of sense annotations: (1) labels of senses within a dictionary as *S* or *O* (i.e., subjectivity sense labels), and (2) sense tags of word instances in a corpus (i.e., sense-tagged data). The subjectivity sense labels are used to collapse the sense labels in the sense-tagged data into the two new senses, *S* and *O*.

Our sense-tagged data are the lexical sample corpora (training and test data) from SENSEVAL1 (Kilgarriff and Palmer, 2000), SENSEVAL2 (Preiss and Yarowsky, 2001), and SENSEVAL3 (Mihalcea and Edmonds, 2004). We selected all of the SENSEVAL words that are also in the subjectivity lexicon, and labeled their dictionary senses as *S*, *O*, or *B* according to the annotation scheme described above in Section 2. We did this subjectivity sense labeling according to the sense inventory of the underlying corpus (Hector for SENSEVAL1; WordNet1.7 for SENSEVAL2; and WordNet1.7.1 for SENSEVAL3).

Among the words, we found that 11 are not ambiguous - either they have only *S* or only *O* senses (in the corresponding sense inventory), or the senses of their instances in the SENSEVAL data are all *S* or all *O*. So as not to inflate our results, we removed those 11 from the data, leaving 39 words. In addition, we excluded the senses labeled *B* (a total of 10 senses). This leaves a total of 372 senses: 9 words (64 senses) from SENSEVAL1, 18 words (201 senses) from SENSEVAL2, and 12 words (107 senses) from SENSEVAL3.

Table 1: Overall SWSD results (micro averages). *Base* is majority-class baseline; *Acc* is accuracy; *SP*, *SR*, and *SF* are subjective precision, recall and F-measure; similarly for *OP*, *OR*, and *OF*. *IB* is absolute improvement in Acc over Base; *EB* is percent error reduction in Acc.

3.3 SWSD Experiments

In this section, we evaluate our SWSD system, and compare its performance to an WSD system on the same data.

Note that, although generally in the SENSEVAL datasets, training and test data are provided separately, a few target words from SENSEVAL1 do not have both training and testing data. Thus, we opted to combine the training and test data into one dataset, and then perform 10-fold cross validation experiments.

For our classifier, we use the SVM classifier from the Weka package (Witten and Frank., 2005) with its default settings.

We were interested in how well the system would perform on more and less ambiguous words. Thus, we split the words into three subsets according to their majority-class baselines, and report separate results: *S1* (9 words), *S2* (18 words), and *S3* (12 words) have majority-class baselines in the intervals [50%,70%) , [70%,90%), and [90%,100%), respectively.

Table 1 contains the results, giving the overall results (micro averages), as well as results for the subsets *S1*, *S2*, and *S3*.

The improvement for SWSD over baseline is especially high for the less skewed set, *S1*. This is very encouraging because these words are the more ambiguous words, and thus are the ones that most need SWSD (assuming the SENSEVAL priors are similar to the priors in the corpus). The average error reduction over baseline for *S1* words is 54.2%. Even for the more skewed sets *S2* and *S3*, reductions are 32.8% and 28.0%, respectively, with an overall reduction of 41.8%.

To compare SWSD with WSD, we re-ran the 10-fold cross validation experiments, but this time using the original sense labels, rather than *S* and *O*. The (micro-averaged) accuracy is 67.9%, much lower than the overall accuracy for SWSD (88.3%).

The positive results provide evidence that SWSD is a feasible variant of WSD, and that the *S*/*O* sense groupings are natural ones, since the system is able to learn to distinguish between them with high accuracy. There is also potential for improvement by using a richer feature set, including subjectivity features.

4 Opinion Analysis with Subjectivity Word Sense Disambiguation

In this section, we explore the promise of SWSD for contextual subjectivity analysis. First, we provide evidence that a subjectivity lexicon can have substantial coverage of the subjective expressions in a corpus, yet still be responsible for significant subjectivity sense ambiguity in that corpus. Then, we exploit SWSD in several contextual opinion analysis systems, comparing the performance of sense-aware and non-sense-aware versions. They are all variations of components of the OpinionFinder opinion recognition system.[3]

4.1 Coverage and Ambiguity of Lexicon Entries in the MPQA Corpus

In this section, we consider the distribution of lexicon entries in the MPQA corpus.

The lexicon covers a substantial subset of the subjective expressions in the corpus: 67.1% of the subjective expressions contain one or more lexicon entries.

On the other hand, fully 42.9% of the instances of the lexicon entries in the MPQA corpus are not in subjective expressions. An instance that is not in a subjective expression is, by definition, being used with an objective sense. Thus, these instances are false hits of subjectivity clues. As mentioned above, the entries in the lexicon have been pre-classified as either more (*strongsubj*) or less (*weaksubj*) reliable. We see this difference reflected in their degree of ambiguity – 53% of the

[3] Available at http://www.cs.pitt.edu/opin

weaksubj instances are false hits, while only 22% of the *strongsubj* instances are.

The high coverage of the lexicon demonstrates its potential usefulness for opinion analysis systems, while its degree of ambiguity, in the form of false hits in a subjectivity annotated corpus, shows the potential benefit to opinion analysis of performing SWSD.

As mentioned above, our experiments involve only lexicon entries that are covered by the SENSEVAL data, as we did not perform manual sense tagging for this work. We have hope to expand the system's coverage in the future, as more word-sense tagged data is produced (e.g., ONTONOTES (Hovy et al., 2006)). We also have evidence that a moderate amount of manual annotation would be worth the effort. For example, let us order the lexicon entries from highest to lowest by frequency in the MPQA corpus. The top 20 are responsible for 25% of all false hits in the corpus; the top 40 are responsible for 34%; and the top 80 are responsible for 44%. If the SWSD system could be trained for these words, the potential impact on reducing false hits could be substantial, especially considering the good performance of the SWSD system on the more ambiguous words. Note that we do not want to simply discard these clues. The top 20 cover 9.4% of all subjective expressions; the top 40 cover 15.4%; and the top 80 cover 29.5%. Note that SWSD only needs the data annotated with the coarse-grained binary labels, which should be less time consuming to produce than full word sense tags.

4.2 Contextual Classification

We found in Section 3.3 that SWSD is a feasible task and then in Section 4.1 that there is a great deal of subjectivity sense ambiguity in a standard subjectivity-annotated corpus (MPQA). We now turn to exploiting the results of SWSD to automatically recognize subjectivity and sentiment in the MPQA corpus.

A motivation for using the MPQA data is that many types of classifiers have been evaluated on it, and we can directly test the effect of SWSD on these classifiers.

Note that, for the SWSD experiments, the number of words does not limit the amount of data, as SENSEVAL provides data for each word. However, the only parts of the MPQA corpus for which SWSD could affect performance is the subset containing instances of the words in the SWSD system's coverage. Thus, for the classifiers in this section, the data used is the *SenMPQA* dataset, which consists of the sentences in the MPQA Corpus that contain at least one instance of the 39 keywords. There are 689 such sentences (containing, in total, 723 instances of the 39 keywords).

Even though this dataset is smaller than the one used above, it gives us enough data to draw conclusions according to McNemar's test for statistical significance.

4.2.1 Rule-based Classifier

We first apply SWSD to the rule-based classifier from (Riloff and Wiebe, 2003). The classifier, which is a sentence-level *S/O* classifier, has low subjective and objective recall but high subjective and objective precision. It is useful for creating training data for subsequent processing by applying it to large amounts of unannotated data.

The classifier is a good candidate for directly measuring the effects of SWSD on contextual subjectivity analysis, because it classifies sentences only by looking for the presence of subjectivity keywords. Performance will improve if false hits can be ignored.

The classifier labels a sentence as *S* if it contains two or more *strongsubj* clues. On the other hand, it considers three conditions to classify a sentence as *O*: there are no *strongsubj* clues in the current sentence, there are together at most one *strongsubj* clue in the previous and next sentence, and there are together at most 2 *weaksubj* clues in the current, previous, and next sentence. A sentence that is not labeled *S* or *O* is labeled *unknown*.

The rule-based classifier is made sense aware by making it blind to the target word instances labeled *O* by the SWSD system, as these represent false hits of subjectivity keywords. We compare this sense-aware method (*SE*), with the original classifier (O_{RB}), in order to see if SWSD would improve performance. We also built another modified rule-based classifier *RE* to demonstrate the effect of randomly ignoring subjectivity keywords. *RE* ignores a keyword instance randomly with a probability of 0.429, the expected value of false hits in the MPQA corpus. The results are listed in Table 2.

The rule-based classifier looks for the presence of the keywords to find subjective sentences and for the absence of the keywords to find objective sentences. It is obvious that a variant working on

	Acc	OP	OR	OF	SP	SR	SF
O_{RB}	27.0	50.0	4.1	7.6	92.7	36.0	51.8
SE	28.3	62.1	9.3	16.1	92.7	35.8	51.6
RE	27.6	48.4	7.7	13.3	92.6	35.4	51.2

Table 2: Effect of SWSD on the rule-based classifiers.

fewer keyword instances than O_{RB} will always have the same or higher objective recall and the same or lower subjective recall than O_{RB}. That is the case for both *SE* and *RE*. The real benefit we see is in objective precision, which is substantially higher for *SE* than O_{RB}. For our experiments, *OP* gives a better idea of the impact of SWSD, because most of the keyword instances SWSD disambiguates are *weaksubj* clues, and *weaksubj* keywords figure more prominently in objective classification. On the other hand, *RE* has both lower *OP* and *SP* than O_{RB}. Note that accuracy for all three systems is low, because all *unknown* predictions are counted as incorrect.

These findings suggest that SWSD performs well on disambiguating keyword instances in the MPQA corpus,[4] and demonstrates a positive impact of SWSD on sentence-level subjectivity classification.

4.2.2 Subjective/Objective Classifier

We now move to more fine-grained expression-level subjectivity classification. Since sentences often contain multiple subjective expressions, expression-level classification is more informative than sentence-level classification.

The classifier in this section is an implementation of the *neutral/polar* supervised classifier of (Wilson et al., 2005a) (using the same features), except that the classes are *S*/*O* rather than *neutral/polar*. These classifiers label instances of lexicon entries. The gold standard is defined on the MPQA Corpus as follows: If an instance is in a subjective expression, it is contextually *S*. If the instance is in an objective expression, it is contextually *O*. We evaluate the system on the 723 clue instances in the SenMPQA dataset.

We incorporate SWSD information into the contextual subjectivity classifier in a straightforward fashion: outputs are modified according to simple, intuitive rules.

[4]which we cannot evaluate directly, as the MPQA corpus is not sense tagged.

Our strategy is defined by the relation between sense subjectivity and contextual subjectivity and involves two rules, *R1* and *R2*.

We know that a keyword instance used with a *S* sense must be in a subjective expression. *R1* is to simply trust SWSD: If the contextual classifier labels an instance as *O*, but SWSD determines that it has an *S* sense, then *R1* flips the contextual classifier's label to *S*.

Things are not as simple in the case of *O* senses, since they may appear in both subjective and objective expressions. We will state *R2*, and then explain it: If the contextual classifier labels an instance as *S*, but (1) SWSD determines that it has an *O* sense, (2) the contextual classifier's confidence is low, and (3) there is no other subjective keyword in the same expression, then *R2* flips the contextual classifier's label to *O*. First, consider confidence: though a keyword with an *O* sense may appear in either subjective or objective expressions, it is more likely to appear in an objective expression. We assume that this is reflected to some extent in the contextual classifier's confidence. Second, if a keyword with an *O* sense appears in a subjective expression, then the subjectivity is not due to that keyword but rather due to something else. Thus, the presence of another lexicon entry "explains away" the presence of the *O* sense in the subjective expression, and we do not want SWSD to overrule the contextual classifier. Only when the contextual classifier isn't certain and only when there isn't another keyword does *R2* flip the label to *O*.

Our definition of low confidence is in terms of the label weights assigned by BoosTexter (Schapire and Singer, 2000), which is the underlying machine learning algorithm of the classifier. We use the difference between the largest label weight and the second largest label weight as a measure of confidence, as suggested in the BoosTexter documentation. The threshold we use is 0.0008.[5]

We apply the contextual classifier and the SWSD system to the data, and compare the performance of the original system ($O_{S/O}$) and three sense-aware variants: one using only *R1*, one us-

[5]As will be noted below, we experimented with three thresholds for the classifier in Section 4.2.3, with no significant difference in accuracy. Here, we simply adopt 0.0008, without further experimentation. In addition, we did not experiment with other conditions than those incorporated in the two rules in this section and the two rules in Section 4.2.3 below.

	Acc	OP	OR	OF	SP	SR	SF
$O_{S/O}$	75.4	68.0	62.9	65.4	79.2	82.7	80.9
R1	77.7	75.5	58.8	66.1	78.6	88.8	83.4
R2	79.0	67.3	83.9	74.7	89.0	76.1	82.0
R1R2	81.3	72.5	79.8	75.9	87.4	82.2	84.8

Table 3: Effect of SWSD on the subjective/objective classifier

ing only *R2*, and one using both (*R1R2*). The results are in Table 3. The *R1* variant shows an improvement of 2.3 points in accuracy (a 9.4% error reduction). The *R2* variant shows an improvement of 3.6 points in accuracy (a 14.6% error reduction). Applying both rules (*R1R2*) gives an improvement of 5.9 percentage points in accuracy (a 24% error reduction).

In our case, a paired t-test is not appropriate to measure statistical significance, as we are not doing multiple runs. Thus, we apply McNemar's test, which is a non-parametric method for algorithms that can be executed only once, meaning training once and testing once (Dietterich, 1998). For *R1*, the improvement in accuracy is statistically significant at the $p < .05$ level. For *R2* and *R1R2*, the improvement in accuracy is statistically significant at the $p < .01$ level. Moreover, in all cases, we see improvement in both objective and subjective F-measure.

4.2.3 Contextual Polarity Classifier

We now apply SWSD to contextual polarity classification (positive/negative/neutral), in the hope that avoiding false hits of subjectivity keywords will also lead to performance improvement in contextual sentiment analysis.

We use an implementation of the classifier of (Wilson et al., 2005a). This classifier labels instances of lexicon entries. The gold standard is defined on the MPQA Corpus as follows: If an instance is in a positive subjective expression, it is contextually positive (*Ps*); if in a negative subjective expression, it is contextually negative (*Ng*); and if it is in an objective expression or a neutral subjective expression, then it is contextually *N(eutral)*. As above, we evaluate the system on the keyword instances in the SenMPQA dataset.

Wilson et al. use a two step approach. The first step classifies keyword instances as being in a polar (positive or negative) or a neutral context. The first step is performed by the neutral/polar classifier mentioned above in Section 4.2.2. The second step decides the contextual polarity (positive or negative) of the instances classified as polar in the first step, and is performed by a separate classifier.

To make a sense-aware version of the system, we use rules to change some of the answers of the neutral/polar classifier.

Unfortunately, we cannot simply trust SWSD when it labels a keyword as an *S* sense, because an *S* sense might be in a *N(eutral)* expression (since there are neutral subjective expressions). But, an *S* sense is more likely to appear in a *P(olar)* expression. Thus, we consider confidence (rule *R3*): If the contextual classifier labels an instance as *N*, but SWSD determines it has an *S* sense and the contextual classifier's confidence is low,[6] then *R3* flips the contextual classifier's label to *P*.

Rule *R4* is analogous to *R2* in the previous section: If the contextual classifier labels an instance as *P*, but (1) SWSD determines that it has an *O* sense, (2) the contextual classifier's confidence is low, and (3) there is no other subjective keyword in the same expression, then *R2* flips the contextual classifier's label to *N*.

We compare the performance of the original neutral/polar classifier ($O_{N/P}$) and sense-aware variants using *R3* and *R4*. The results are in Table 4. This time, the table does not include a combined method, because only *R4* improves performance. This is consistent with the finding in (Wilson et al., 2005a) that most errors are caused by subjectivity keywords with non-neutral prior polarity appearing in phrases with neutral contextual polarity. *R4* targets these cases. It is promising to see that SWSD provides enough information to fix some of them. There is a 2.6 point improvement in accuracy (a 12.4% error reduction). The improvement in accuracy is statistically significant at the $p < .01$ level with McNemar's test. The improvement in accuracy is accompanied by improvements in both neutral and polar F-measure.

We wanted to see if the improvements in the

[6] As in the previous section, low confidence is defined in terms of the difference between the largest label weight and the second largest label weight assigned by BoosTexter. We tried three thresholds, 0.0007, 0.0008, and 0.0009, resulting in only a slight difference in accuracy: 0.0007 and 0.0009 both give 81.5 accuracy compared to 81.6 accuracy for 0.0008. We report results using 0.0008, though the accuracy using the other thresholds is statistically significantly better than the accuracy of the original classifier at the same level.

	Acc	NP	NR	NF	NgP	NgR	NgF	PsP	PsR	PsF
$O_{Ps/Ng/N}$	77.6	80.9	94.6	87.2	60.4	29.4	39.5	52.2	32.4	40.0
R4	80.6	81.2	98.7	89.1	82.1	29.4	43.2	68.6	32.4	44.0

Table 5: Effect of SWSD on the contextual polarity classifier

	Acc	NP	NR	NF	PP	PR	PF
$O_{N/P}$	79.0	81.5	92.5	86.7	65.8	40.7	50.3
R3	70.0	83.7	73.8	78.4	44.4	59.3	50.8
R4	81.6	81.7	96.8	88.6	81.1	38.6	52.3

Table 4: Effect of SWSD on the neutral/polar classifier

first step of Wilson et al's system can be propagated to their second step, yielding an overall improvement in positive /negative/neutral (*Ps*/*Ng*/*N*) classification.

The sense-aware variant of the overall two-part system is the same as the original except that we apply *R4* to the output of the first step (flipping some of the neutral/polar classifier's *P* labels to *N*). Thus, since the second step in Wilson et al.'s classifier processes only those instances labeled *P* in the first step, in the sense-aware system, fewer instances are passed from the first to the second step.

Table 5 reports results for the original system ($O_{Ps/Ng/N}$) and the sense-aware variant (*R4*). These results are for the entire SenMPQA dataset, not just those labeled *P* in the first step.

The accuracy improves 3 percentage points (a 13.4% error reduction). The improvement in accuracy is statistically significant at the $p < .01$ level with McNemar's test. We see the real benefit when we look at the precision of the positive and negative classes. Negative precision goes from 60.4 to 82.1 and positive precision goes from 52.2 to 68.6, with no loss in recall. This is evidence that the SWSD system is doing a good job of removing some false hits of subjectivity clues that harm the original version of the system.

5 Comparisons to Previous Work

Several researchers exploit lexical resources for contextual subjectivity and sentiment analysis. These systems typically look for the presence of subjective or sentiment-bearing words in the text. They may rely only on this information (e.g., (Turney, 2002; Whitelaw et al., 2005; Riloff and Wiebe, 2003)), or they may combine it with additional information as well (e.g., (Yu and Hatzivassiloglou, 2003; Kim and Hovy, 2004; Bloom et al., 2007; Wilson et al., 2005a)). We apply SWSD to some of those systems to show the effect of SWSD on contextual subjectivity and sentiment analysis.

Another set of related work is on subjectivity and polarity labeling of word senses (e.g. (Esuli and Sebastiani, 2006; Andreevskaia and Bergler, 2006; Wiebe and Mihalcea, 2006; Su and Markert, 2008)). They label senses of words in a dictionary. In comparison, we label senses of word instances in a corpus.

Moreover, our work extends findings in (Wiebe and Mihalcea, 2006) and (Su and Markert, 2008). (Wiebe and Mihalcea, 2006) demonstrates that subjectivity is a property that can be associated with word senses. We show that it is a natural grouping of word senses and that it provides a principled way for clustering senses. They also demonstrate that subjectivity helps with WSD. We show that a coarse-grained WSD variant (SWSD) helps with subjectivity and sentiment analysis. Both (Wiebe and Mihalcea, 2006) and (Su and Markert, 2008) show that even reliable subjectivity clues have objective senses. We demonstrate that this ambiguity is also prevalent in a corpus.

Several researchers (e.g., (Palmer et al., 2004; Navigli, 2006; Snow et al., 2007; Hovy et al., 2006)) work on reducing the granularity of sense inventories for WSD. They aim for a more coarse-grained sense inventory to overcome performance shortcomings related to fine-grained sense distinctions. Our work is similar in the sense that we reduce all senses of a word to two senses (*S*/*O*). The difference is the criterion driving the grouping. Related work concentrates on syntactic and semantic similarity between senses to group them. In contrast, our grouping is driven by subjectivity with a specific application area in mind, namely subjectivity and sentiment analysis.

6 Conclusions and Future Work

We introduced the task of subjectivity word sense disambiguation (SWSD), and evaluated a supervised method inspired by research in WSD. The

system achieves high accuracy, especially on highly ambiguous words, and substantially outperforms WSD on the same data. The positive results provide evidence that SWSD is a feasible variant of WSD, and that the *S*/*O* sense groupings are natural ones.

We also explored the promise of SWSD for contextual subjectivity analysis. We showed that a subjectivity lexicon can have substantial coverage of the subjective expressions in the corpus, yet still be responsible for significant sense ambiguity. This demonstrates the potential benefit to opinion analysis of performing SWSD. We then exploit SWSD in several contextual opinion analysis systems, including positive/negative/neutral sentiment classification. Improvements in performance were realized for all of the systems.

We plan several future directions which promise to further increase the impact of SWSD on subjectivity and sentiment analysis. We will manually annotate a moderate number of strategically chosen words, namely frequent ones which are highly ambiguous. In addition, we will add features to the SWSD system reflecting the subjectivity of the surrounding context. Finally, there are more sophisticated strategies to explore for improving subjectivity and sentiment analysis via SWSD than the simple, intuitive rules we began with in this paper.

Non-Projective Parsing for Statistical Machine Translation

Xavier Carreras **Michael Collins**
MIT CSAIL, Cambridge, MA 02139, USA
{carreras,mcollins}@csail.mit.edu

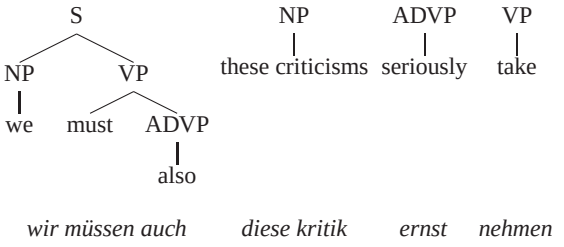
Abstract

We describe a novel approach for syntax-based statistical MT, which builds on a variant of tree adjoining grammar (TAG). Inspired by work in discriminative dependency parsing, the key idea in our approach is to allow highly flexible reordering operations during parsing, in combination with a discriminative model that can condition on rich features of the source-language string. Experiments on translation from German to English show improvements over phrase-based systems, both in terms of BLEU scores and in human evaluations.

1 Introduction

Syntax-based models for statistical machine translation (SMT) have recently shown impressive results; many such approaches are based on either synchronous grammars (e.g., (Chiang, 2005)), or tree transducers (e.g., (Marcu et al., 2006)). This paper describes an alternative approach for syntax-based SMT, which directly leverages methods from non-projective dependency parsing. The key idea in our approach is to allow highly flexible reordering operations, in combination with a discriminative model that can condition on rich features of the source-language input string.

Our approach builds on a variant of tree adjoining grammar (TAG; (Joshi and Schabes, 1997)) (specifically, the formalism of (Carreras et al., 2008)). The models we describe make use of phrasal entries augmented with subtrees that provide syntactic information in the target language. As one example, when translating the sentence *wir müssen auch diese kritik ernst nehmen* from German into English, the following sequence of syntactic phrasal entries might be used (we show each English syntactic fragment above its associated German sub-string):



TAG parsing operations are then used to combine these fragments into a full parse tree, giving the final English translation *we must also take these criticisms seriously*.

Some key aspects of our approach are as follows:

• We impose no constraints on entries in the phrasal lexicon. The method thereby retains the full set of lexical entries of phrase-based systems (e.g., (Koehn et al., 2003)).[1]

• The model allows a straightforward integration of lexicalized syntactic language models—for example the models of (Charniak, 2001)—in addition to a surface language model.

• The operations used to combine tree fragments into a complete parse tree are significant generalizations of standard parsing operations found in TAG; specifically, they are modified to be highly flexible, potentially allowing any possible permutation (reordering) of the initial fragments.

As one example of the type of parsing operations that we will consider, we might allow the tree fragments shown above for *these criticisms* and *take* to be combined to form a new structure with the sub-string *take these criticisms*. This step in the derivation is necessary to achieve the correct English word order, and is novel in a couple of respects: first, *these criticisms* is initially seen to the left of *take*, but after the adjunction this order is reversed; second, and more unusually, the treelet for *seriously* has been skipped over, with the result that the German words translated at this point (*diese*, *kritik*, and *nehmen*) form a non-contiguous sequence. More generally, we will allow any two

[1] Note that in the above example each English phrase consists of a completely connected syntactic structure; this is not, however, a required constraint, see section 3.2 for discussion.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 200–209,
Singapore, 6-7 August 2009.

tree fragments to be combined during the translation process, irrespective of the reorderings which are introduced, or the non-projectivity of the parsing operations that are required.

The use of flexible parsing operations raises two challenges that will be a major focus of this paper. First, these operations will allow the model to capture complex reordering phenomena, but will in addition introduce many spurious possibilities. Inspired by work in discriminative dependency parsing (e.g., (McDonald et al., 2005)), we add probabilistic constraints to the model through a discriminative model that links lexical dependencies in the target language to features of the source language string. We also investigate hard constraints on the dependency structures that are created during parsing. Second, there is a need to develop efficient decoding algorithms for the models. We describe approximate search methods that involve a significant extension of decoding algorithms originally developed for phrase-based translation systems.

Experiments on translation from German to English show a 0.5% improvement in BLEU score over a phrase-based system. Human evaluations show that the syntax-based system gives a significant improvement over the phrase-based system. The discriminative dependency model gives a 1.5% BLEU point improvement over a basic model that does not condition on the source language string; the hard constraints on dependency structures give a 0.8% BLEU improvement.

2 Relationship to Previous Work

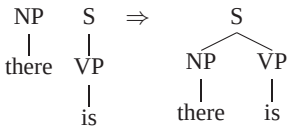
A number of syntax-based translation systems have framed translation as a parsing problem, where search for the most probable translation is achieved using algorithms that are generalizations of conventional parsing methods. Early examples of this work include (Alshawi, 1996; Wu, 1997); more recent models include (Yamada and Knight, 2001; Eisner, 2003; Melamed, 2004; Zhang and Gildea, 2005; Chiang, 2005; Quirk et al., 2005; Marcu et al., 2006; Zollmann and Venugopal, 2006; Nesson et al., 2006; Cherry, 2008; Mi et al., 2008; Shen et al., 2008). The majority of these methods make use of synchronous grammars, or tree transducers, which operate over parse trees in the source and/or target languages. Reordering rules are typically specified through rotations or transductions stated at the level of context-free rules, or larger fragments, within parse trees. These rules can be learned automatically from corpora.

A critical difference in our work is to allow arbitrary reorderings of the source language sentence (as in phrase-based systems), through the use of flexible parsing operations. Rather than stating reordering rules at the level of source or target language parse trees, we capture reordering phenomena using a discriminative dependency model. Other factors that distinguish us from previous work are the use of all phrases proposed by a phrase-based system, and the use of a dependency language model that also incorporates constituent information (although see (Charniak et al., 2003; Shen et al., 2008) for related approaches).

3 A Syntactic Translation Model

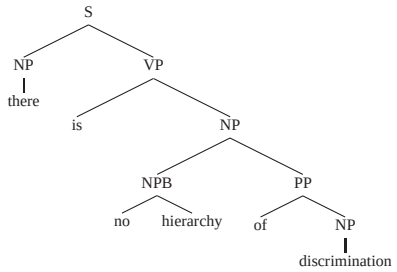
3.1 Background

Our work builds on the variant of tree adjoining grammar (TAG) introduced by (Carreras et al., 2008). In this formalism the basic units in the grammar are spines, which associate tree fragments with lexical items. These spines can be combined using a *sister-adjunction* operation (Rambow et al., 1995), to form larger pieces of structure.[2] For example, we might have the following operation:



In this case the spine for *there* has sister-adjoined into the S node in the spine for *is*; we refer to the spine for *there* as being the modifier spine, and the spine for *is* being the head spine. There are close connections to dependency formalisms: in particular in this operation we see a lexical dependency between the modifier word *there* and the head word *is*. It is possible to define syntactic language models, similar to (Charniak, 2001), which associate probabilities with these dependencies, roughly speaking of the form $P(w_m, s_m | w_h, s_h, pos, \sigma)$, where w_m and s_m are the identities of the modifier word and spine, w_h and s_h are the identities of the head word and spine, pos is the position in the head spine that is being adjoined into, and σ is some additional state (e.g., state that tracks previous modifiers that have adjoined into the same spine).

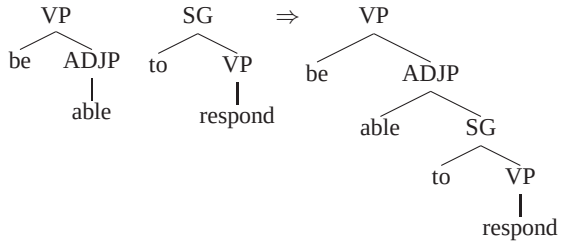
[2] We also make use of the r-adjunction operation defined in (Carreras et al., 2008), which, together with sister-adjunction, allows us to model the full range of structures found in the Penn treebank.



es gibt keine hierarchie der diskriminierung

Figure 1: A training example consisting of an English (target language) tree and a German (source language) sentence.

In this paper we will also consider *treelets*, which are a generalization of spines, and which allow lexical entries that include more than one word. These treelets can again be combined using a sister-adjunction operation. As an example, consider the following operation:



In this case the treelet for *to respond* sister-adjoins into the treelet for *be able*. This operation introduces a bi-lexical dependency between the modifier word *to* and the head word *able*.

3.2 S-phrases

This section describes how phrase entries from phrase-based translation systems can be modified to include associated English syntactic structures. These syntactic phrase-entries (from here on referred to as "s-phrases") will form the basis of the translation models that we describe.

We extract s-phrases from training examples consisting of a source-language string paired with a target-language parse tree. For example, consider the training example in figure 1. We assume some method that enumerates a set of possible *phrase entries* for each training example: each phrase entry is a pair $\langle (i,j),(k,l) \rangle$ specifying that source-language words $f_i \ldots f_j$ correspond to target-language words $e_k \ldots e_l$ in the example. For example, one phrase entry for the example might be $\langle (1,2),(1,2) \rangle$, representing the pair $\langle$*es gibt* $\Rightarrow$ *there is*$\rangle$. In our experiments we use standard methods in phrase-based systems (Koehn et al., 2003) to define the set of phrase entries for each sentence in training data.

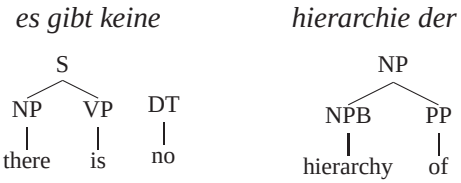


Figure 2: Example syntactic phrase entries. We show German sub-strings above their associated sequence of treelets.[4]

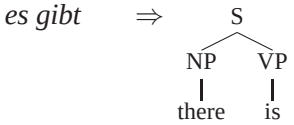
For each phrase entry, we add syntactic information to the English string. To continue our example, the resulting entry would be as follows:



To give a more formal description of how syntactic structures are derived for phrases, first note that each parse tree t is mapped to a TAG derivation using the method described in (Carreras et al., 2008). This procedure uses the head finding rules of (Collins, 1997). The resulting derivation consists of a TAG spine for each word seen in the sentence, together with a set of adjunction operations which each involve a modifier spine and a head spine. Given an English string $\mathbf{e} = e_1 \ldots e_n$, with an associated parse tree t, the syntactic structure associated with a substring $e_k \ldots e_l$ (e.g., *there is*) is then defined as follows:

• For each word in the English sub-string, include its associated TAG spine in t.

• In addition, include any adjunction operations in t where both the head and modifier word are in the sub-string $e_j \ldots e_k$.

In the above example, the resulting structure (i.e., the structure for *there is*) is a single treelet. In other cases, however, we may get a sequence of treelets, which are disconnected from each other. For example, another likely phrase-entry for this training example is $\langle$*es gibt keine* $\Rightarrow$ *there is no*$\rangle$ resulting in the first lexical entry in figure 2, which has two treelets. Allowing s-phrases with multiple treelets ensures that all phrases used by phrase-based systems can be used within our approach.

As a final step, we add additional *alignment* information to each s-phrase. Consider an s-phrase which contains source-language words $f_1 \ldots f_n$ paired with target-language words $e_1 \ldots e_m$. The alignment information is a vector $\langle (a_1,b_1) \ldots (a_m,b_m) \rangle$ that specifies for each word e_i its alignment to words $f_{a_i} \ldots f_{b_i}$ in the source language. For example, for the phrase en-

try $\langle$*es gibt* $\Rightarrow$ *there is*$\rangle$ a correct alignment would be $\langle(1,1),(2,2)\rangle$, specifying that *there* is aligned to *es*, and *is* is aligned to *gibt* (note that in many, but not all, cases $a_i = b_i$, i.e., a target language word is aligned to a single source language word).

The alignment information in s-phrases will be useful in tying syntactic dependencies created in the target language to positions in the source language string. In particular, we will consider discriminative models (analogous to models for dependency parsing, e.g., see (McDonald et al., 2005)) that estimate the probability of target-language dependencies conditioned on properties of the source-language string. Alignments may be derived in a number of ways; in our method we directly use phrase entries proposed by a phrase-based system. Specifically, for each target word e_i in a phrase entry $\langle f_1 \ldots f_n, e_1 \ldots e_m \rangle$ for a training example, we find the smallest[5] phrase entry in the same training example that includes e_i on the target side, and is a subset of $f_1 \ldots f_n$ on the source side; the word e_i is then aligned to the subset of source language words in this "minimal" phrase.

In conclusion, s-phrases are defined as follows:

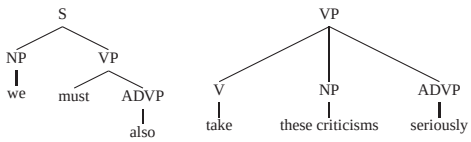
Definition 1 *An s-phrase is a 4-tuple $\langle f, e, t, a \rangle$ where: f is a sequence of foreign words; e is a sequence of English words; t is a sequence of treelets specifying a TAG spine for each English word, and potentially some adjunctions between these spines; and a is an alignment. For an s-phrase q we will sometimes refer to the 4 elements of q as $f(q)$, $e(q)$, $t(q)$ and $a(q)$.*

3.3 The Model

We now introduce a model that makes use of s-phrases, and which is flexible in the reorderings that it allows. To provide some intuition, and some motivation for the use of reordering operations, figure 3 gives several examples of German strings which have different word orders from English.

The crucial idea will be to use TAG adjunction operations to combine treelets to form a complete parse tree, but with a complete relaxation on the order in which the treelets are combined. For example, consider again the example given in the introduction to this paper. In the first step of a derivation that builds on these treelets, the treelet for *these criticisms* might adjoin into the treelet for *take*, giving the following new sequence:

In the next derivation step *seriously* is adjoined to the right of *take*, giving the following treelets:



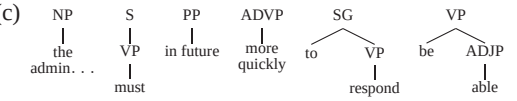
In the final step the second treelet adjoins into the VP above *must*, giving a parse tree for the string *we must also take these criticisms seriously*, and completing the translation.

Formally, given an input sentence $\mathbf{f}$, a derivation d is a pair $\langle \mathbf{q}, \pi \rangle$ where:

- $\mathbf{q} = q_1 \ldots q_n$ is a sequence of s-phrases such that $\mathbf{f} = f(q_1) \oplus f(q_2) \oplus \ldots \oplus f(q_n)$ (where $u \oplus v$ denotes the concatenation of strings u and v).
- π is a set of adjunction operations that connects the sequence of treelets contained in $\langle t(q_1), t(q_2), \ldots, t(q_n) \rangle$ into a parse tree in the target language. The operations allow a complete relaxation of word order, potentially allowing any of the $n!$ possible orderings of the n s-phrases. We make use of both sister-adjunction and r-adjunction operations, as defined in (Carreras et al., 2008).[6]

1(a) [die verwaltung] [muss] [künftig] [schneller] [reagieren] [können] 1(b) the administration must be able to respond more quickly in future

1(c)



2(a) [meiner ansicht nach] [darf] [der erweiterungsprozess] [nicht] [unnötig] [verzögert] [werden] 2(b) in my opinion the expansion process should not be delayed unnecessarily

2(c)

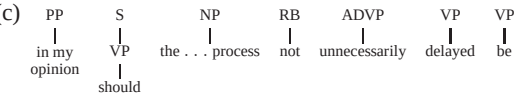


Figure 3: Examples of translations. In each example (a) is the original German string, with a possible segmentation marked with "[" and "]"; (b) is a translation for (a); and (c) is a sequence of phrase entries, including syntactic structures, for the segmentation given in (a).

[5] The "size" of a phrase entry is defined to be $n_s + n_t$ where n_s is the number of source language words in the phrase, n_t is the number of target language words.

[6] In principle we allow any treelet to adjoin into any other treelet—for example there are no hard, grammar-based constraints ruling out the combination of certain pairs of non-terminals. Note however that in some cases operations will have probability 0 under the syntactic language model introduced later in this section.

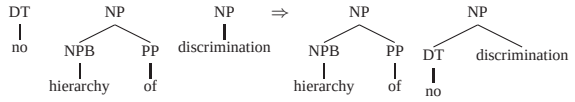

Figure 4: A spurious derivation step. The treelets arise from *[keine] [hierarchie der] [diskriminierung]*.

Given a derivation $d = \langle \mathbf{q}, \pi \rangle$, we define $e(d)$ to be the target-language string defined by the derivation, and $t(d)$ to be the complete target-language parse tree created by the derivation. The most likely derivation for a foreign sentence $\mathbf{f}$ is $\arg\max_{d \in G(\mathbf{f})} score(d)$, where $G(\mathbf{f})$ is the set of possible derivations for $\mathbf{f}$, and the score for a derivation is defined as[7]

$$\begin{aligned} score(d) &= score_{LM}(e(d)) + score_{SYN}(t(d)) \\ &+ score_R(d) + \sum_{j=1}^{n} score_P(q_j) \end{aligned} \quad (1)$$

The components of the model are as follows:

- $score_{LM}(e(d))$ is the log probability of the English string under a trigram language model.
- $score_{SYN}(t(d))$ is the log probability of the English parse tree under a syntactic language model, similar to (Charniak, 2001), that associates probabilities with lexical dependencies.
- $score_R(d)$ will be used to score the parsing operations in π, based on the source-language string and the alignments in the s-phrases. This part of the model is described extensively in section 4.1 of this paper.
- $score_P(q)$ is the score for an s-phrase q. This score is a log-linear combination of various features, including features that are commonly found in phrase-based systems: for example $\log P(f(q)|e(q))$, $\log P(e(q)|f(q))$, and lexical translation probabilities. In addition, we include a feature $\log P(t(q)|f(q), e(q))$, which captures the probability of the phrase in question having the syntactic structure $t(q)$.

Note that a model that includes the terms $score_{LM}(e(d))$ and $\sum_{j=1}^{n} score_P(q_j)$ alone would essentially be a basic phrase-based model (with no distortion terms). The terms $score_{SYN}(t(d))$ and $score_R(d)$ add syntactic information to this basic model.

A key motivation for this model is the flexibility of the reordering operations that it allows. However, the approach raises two major challenges:

[7] In practice, MERT training (Och, 2003) will be used to train relative weights for the different model components.

Constraints on reorderings. Relaxing the operations in the parsing model will allow complex reorderings to be captured, but will also introduce many spurious possibilities. As one example, consider the derivation step shown in figure 4. This step may receive a high probability from a syntactic or surface language model—*no discrimination* is a quite plausible `NP` in English—but it should be ruled out for other reasons, for example because it does not respect the dependencies in the original German (i.e., *keine*/no is not a modifier to *diskriminierung*/discrimination in the German string). The challenge will be to develop either hard constraints which rule out spurious derivation steps such as these, or soft constraints, encapsulated in $score_R(d)$, which penalize them.

Efficient search. Exact search for the derivation which maximizes the score in Eq. 1 cannot be accomplished efficiently using dynamic programming (as in phrase-based systems, it is easy to show that the decoding problem is NP-complete). Approximate search methods will be needed.

The next two sections of this paper describe solutions to these two challenges.

4 Constraints on Reorderings

4.1 A Discriminative Dependency Model

We now describe the model $score_R$ introduced in the previous section. Recall that π specifies k adjunction operations that are used to build a full parse tree, where $k \geq n$ is the number of treelets within the sequence of s-phrases $\mathbf{q} = \langle q_1 \ldots q_n \rangle$.

Each of the k adjunction operations creates a dependency between a modifier word w_m within a phrase q_m, and a head word w_h within a phrase q_h. For example, in the example in section 3.3 where *these criticisms* was combined with *take*, the modifier word is *criticisms* and the head word is *take*. The modifier and head words have TAG spines s_m and s_h respectively. In addition we can define (a_m, b_m) to be the start and end indices of the words in the foreign string to which the word w_m is aligned; this information can be recovered because the s-phrase q_m contains alignment information for all target words in the phrase, including w_m. Similarly, we can define (a_h, b_h) to be alignment information for the head word w_h. Finally, we can define ρ to be a binary flag specifying whether or not the adjunction operation involves reordering (in the *take criticism* example, this flag is set to `true`, because the order in En-

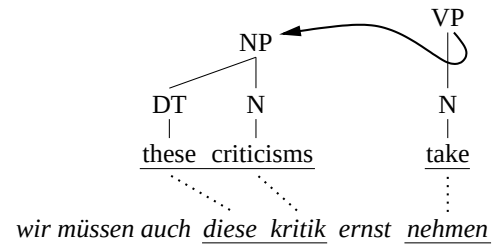

Figure 5: An adjunction operation that involves the modifier *criticisms* and the head *take*. The phrases involved are underlined; the dotted lines show alignments within s-phrases between English words and positions in the German string. The Γ-dependency in this case includes the head and modifier words, together with their spines, and their alignments to positions in the German string (*kritik* and *nehmen*).

glish is reversed from that in German). This leads to the following definition:

Definition 2 *Given a derivation $d = \langle \mathbf{q}, \pi \rangle$, we define $\Gamma(d)$ to be the set of* Γ-dependencies *in d. Each* Γ*-dependency is a tuple $\langle w_m, s_m, a_m, b_m, w_h, s_h, a_h, b_h, \rho \rangle$ of elements as described above.*

Figure 5 gives an illustration of how an adjunction creates one such Γ-dependency.

The model is then defined as

$$score_R(d) = \sum_{\gamma \in \Gamma(d)} score_r(\gamma, \mathbf{f})$$

where $score_r(\gamma, \mathbf{f})$ is a score associated with the Γ-dependency γ. This score can potentially be sensitive to any information in γ or the source-language string $\mathbf{f}$; in particular, note that the alignment indices (a_m, b_m) and (a_h, b_h) essentially anchor the target-language dependency to positions in the source-language string, allowing the score for the dependency to be based on features that have been widely used in discriminative dependency parsing, for example features based on the proximity of the two positions in the source-language string, the part-of-speech tags in the surrounding context, and so on. These features have been shown to be powerful in the context of regular dependency parsing, and our intent is to leverage them in the translation problem.

In our model, we define $score_r$ as follows. We estimate a model $P(y|\gamma, \mathbf{f})$ where $y \in \{-1, +1\}$, and $y = +1$ indicates that a dependency does exist between w_m and w_h, and $y = -1$ indicates that a dependency does not exist. We then define

$$score_r(\gamma, \mathbf{f}) = \log P(+1|\gamma, \mathbf{f})$$

To estimate $P(y|\gamma, \mathbf{f})$, we first extract a set of labeled training examples of the form $\langle y_i, \gamma_i, \mathbf{f}_i \rangle$ for $i = 1 \ldots N$ from our training data as follows: for each pair of target-language words (w_m, w_h) seen in the training data, we can extract associated spines (s_m, s_h) from the relevant parse tree, and also extract a label y indicating whether or not a head-modifier dependency is seen between the two words in the parse tree. Given an s-phrase in the training example that includes w_m, we can extract alignment information (a_m, b_m) from the s-phrase; we can extract similar information (a_h, b_h) for w_h. The end result is a training example of the form $\langle y, \gamma, \mathbf{f} \rangle$.[8] We then estimate $P(y|\gamma, \mathbf{f})$ using a simple backed-off model that takes into account the identity of the two spines, the value for the flag r, the distance between (a_m, b_m) and (a_h, b_h), and part-of-speech information in the source language.

4.2 Contiguity of π-Constituents

We now describe a second type of constraint, which limits the amount of non-projectivity in derivations. Consider again the k adjunction operations in π, which are used to connect treelets into a full parse tree. Each adjunction operation involves a head treelet that *dominates* a modifier treelet. Thus for any treelet t, we can consider its *descendants*, that is, the entire set of treelets that are directly or indirectly dominated by t. We define a *π-constituent* for treelet t to be the subset of source-language words dominated by t and its descendants. We then introduce the following constraint on π-constituents:

Definition 3 *(π-constituent constraint.) A* π*-constituent is* contiguous *iff it consists of a contiguous sequence of words in the source language. A derivation π satisfies the π-constituent constraint iff all π-constituents that it contains are contiguous.*

In this paper we constrain all derivations to satisfy the π-constituent constraint (future work may consider probabilistic versions of the constraint).

The intuition behind the constraint deserves more discussion. The constraint specifies that the modifiers to each treelet can appear in any order around the treelet, with arbitrary reorderings or non-projective operations. However, once a treelet has taken all its modifiers, the resulting π-constituent must form a contiguous sub-sequence

[8] To be precise, there may be multiple (or even zero) s-phrases which include w_m or w_h, and these s-phrases may include conflicting alignment information. Given n_m different alignments seen for w_m, and n_h different alignments seen for w_h, we create $n_m \times n_h$ training examples, which include all possible combinations of alignments.

of the source-language string. As one set of examples, consider the translations in figure 3, and the example given in the introduction. These examples involve reordering of arguments and adjuncts within clauses, a very common case of reordering in translation from German to English. The reorderings in these translations are quite flexible, but in all cases satisfy the π-constituent constraint.

As an illustration of a derivation that violates the constraint, consider again the derivation step shown in figure 4. This step has formed a partial hypothesis, *no discrimination*, which corresponds to the German words *keine* and *diskriminierung*, which do not form a contiguous sub-string in the German. Consider now a complete derivation, which derives the string *there is hierarchy of no discrimination*, and which includes the π-constituent *no discrimination* shown in the figure (i.e., where the treelet *discrimination* takes *no* as its only modifier). This derivation will violate the π-constituent constraint.[9]

5 Decoding

We now describe decoding algorithms for the syntactic models: we first describe inference rules that are used to combine pieces of structure, and then describe heuristic search algorithms that use these inference rules. Throughout this section, for brevity and simplicity, we describe algorithms that apply under the assumption that each s-phrase has a single associated treelet. The generalization to the case where an s-phrase may have multiple treelets is discussed in section 5.3.

5.1 Inference Rules

Parsing operations for the TAG grammars described in (Carreras et al., 2008) are based on the dynamic programming algorithms in (Eisner, 2000). A critical idea in dynamic programming algorithms such as these is to associate constituents in a chart with *spans* of the input sentence, and to introduce inference rules that combine constituents into larger pieces of structure. The crucial step in generalizing these algorithms to the non-projective case, and to translation, will be to make use of *bit-strings* that keep track of which words in the German have already been translated in a chart entry. To return to the example from the introduction, again assume that the selected s-phrases

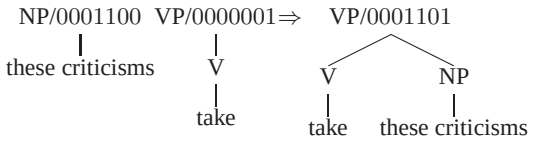
[9]Note, however, that the derivation step show in figure 4 will be considered in the search, because if *discrimination* takes additional modifiers, and thereby forms a π-constituent that dominates a contiguous sub-string in the German, then the resulting derivation will be valid.

0. Data structures: $\mathcal{Q}_i$ for $i = 1 \ldots n$ is a set of hypotheses for each length i, $\mathcal{S}$ is a set of chart entries
1. $\mathcal{S} \leftarrow \emptyset$
2. Initialize $\mathcal{Q}_1 \ldots \mathcal{Q}_n$ with basic chart entries derived from phrase entries
3. **For** $i = 1 \ldots n$
4. **For** any $A \in \text{BEAM}(\mathcal{Q}_i)$
5. **If** $\mathcal{S}$ contains a chart entry with the same signature as A, and which has a higher inside score,
6. **continue**
7. **Else**
8. Add A to $\mathcal{S}$
9. For any chart entry C that can be derived from A together with another chart entry $B \in \mathcal{S}$, add C to the set $\mathcal{Q}_j$ where $j = \text{length}(C)$
10. **Return** $\mathcal{Q}_n$, a set of items of length n

Figure 6: A beam search algorithm. A dynamic-programming *signature* consists of the regular dynamic-programming state for the parsing algorithm, together with the span (bit-string) associated with a constituent.

segment the German input into *[wir müssen auch] [diese kritik] [ernst] [nehmen]*, and the treelets are as shown in the introduction. Each of these treelets will form a basic entry in the chart, and will have an associated bit-string indicating which German words have been translated by that entry.

These basic chart entries can then be combined to form larger pieces of structure. For example, the following inferential step is possible:



We have shown the bit-string representation for each consituent: for example, the new constituent has the bit-string 0001101 representing the fact that the non-contiguous sub-strings *diese kritik* and *nehmen* have been translated at this point. Any two constituents can be combined, providing that the logical AND of their bit-strings is all 0's.

Inference steps such as that shown above will have an associated score corresponding to the TAG adjunction that is involved: in our models, both $score_{SYN}$ and $score_R$ will contribute to this score. In addition, we add state—specifically, word bigrams at the start and end of constituents—that allows trigram language model scores to be calculated as constituents are combined.

5.2 Approximate Search

There are 2^n possible bit-strings for a sentence of length n, hence the search space is of exponential size; approximate algorithms are therefore required in search for the highest scoring derivation. Figure 6 shows a beam search algorithm which makes use of the inference rules described in the

previous section. The algorithm stores sets $\mathcal{Q}_i$ for $i = 1 \ldots n$, where n is the source-language sentence length; each set $\mathcal{Q}_i$ stores hypotheses of length i (i.e., hypotheses with an associated bit-string with i ones). These sets are initialized with basic entries derived from s-phrases.

The function BEAM($\mathcal{Q}_i$) returns all items within $\mathcal{Q}_i$ that have a high enough score to fall within a beam (more details for BEAM are given below). At each iteration (step 4), each item in turn is taken from BEAM($\mathcal{Q}_i$) and added to a chart; the inference rules described in the previous section are used to derive new items which are added to the appropriate set $\mathcal{Q}_j$, where $j > i$.

We have found the definition of BEAM($\mathcal{Q}_i$) to be critical to the success of the method. As a first step, each item in $\mathcal{Q}_i$ receives a score that is a sum of an inside score (the cost of all derivation steps used to create the item) and a future score (an estimate of the cost to complete the translation). The future score is based on the source-language words that are still to be translated—this can be directly inferred from the item's bit-string—this is similar to the use of future scores in Pharoah (Koehn et al., 2003), and in fact we use Pharoah's future scores in our model. We then give the following definition, where N is a parameter (the beam size):

Definition 4 *(BEAM) Given $\mathcal{Q}_i$, define $\mathcal{Q}_{i,j}$ for $j = 1 \ldots n$ to be the subset of items in $\mathcal{Q}_i$ which have their j'th bit equal to one (i.e., have the j'th source language word translated). Define $\mathcal{Q}'_{i,j}$ to be the N highest scoring elements in $\mathcal{Q}_{i,j}$. Then BEAM($\mathcal{Q}_i$) $= \cup_{j=1}^{n} \mathcal{Q}'_{i,j}$.*

To motivate this definition, note that a naive method would simply define BEAM($\mathcal{Q}_i$) to be the N highest scoring elements of $\mathcal{Q}_i$. This definition, however, assumes that constituents which form translations of different parts of a sentence have scores that can be compared—an assumption that would be true if the future scores were highly accurate, but which quickly breaks down when future scores are inaccurate. In contrast, the definition above ensures that the top N analyses for each of the n source language words are stored at each stage, and hence that all parts of the source sentence are well represented. In experiments, the naive approach was essentially a failure, with parsing of some sentences either failing or being hopelessly inefficient, depending on the choice of N. In contrast, definition 4 gives good results.

System	BLEU score
Syntax-based	25.2
Syntax (no $Score_R$)	23.7 (-1.5)
Syntax (no π-c constraint)	24.4 (-0.8)

Table 1: Development set results showing the effect of removing $Score_R$ or the π-constituent constraint.

5.3 Allowing Multiple Treelets per s-Phrase

The decoding algorithms that we have described apply in the case where each s-phrase has a single treelet. The extension of these algorithms to the case where a phrase may have multiple treelets (e.g., see figure 2) is straightforward, but for brevity the details are omitted. The basic idea is to extend bit-string representations with a record of "pending" treelets which have not yet been included in a derivation. It is also possible to enforce the π-constituent constraint during decoding, as well as a constraint that ensures that reordering operations do not "break apart" English sub-strings within s-phrases that have multiple treelets (for example, for the s-phrase in figure 2, we ensure that *there is no* remains as a contiguous sequence of words in any translation using this s-phrase).

6 Experiments

We trained the syntax-based system on 751,088 German-English translations from the Europarl corpus (Koehn, 2005). A syntactic language model was also trained on the English sentences in the training data. We used Pharoah (Koehn et al., 2003) as a baseline system for comparison; the s-phrases used in our system include all phrases, with the same scores, as those used by Pharoah, allowing a direct comparison. For efficiency reasons we report results on sentences of length 30 words or less.[10] The syntax-based method gives a BLEU (Papineni et al., 2002) score of 25.04, a 0.46 BLEU point gain over Pharoah. This result was found to be significant ($p = 0.021$) under the paired bootstrap resampling method of Koehn (2004), and is close to significant ($p = 0.058$) under the sign test of Collins et al. (2005).

Table 1 shows results for the full syntax-based system, and also results for the system with the discriminative dependency scores (see section 4.1) and the π-contituent constraint removed from the system. In both cases we see a clear impact of these components of the model, with 1.5 and 0.8 BLEU point decrements respectively.

[10] Both Pharoah and our system have weights trained using MERT (Och, 2003) on sentences of length 30 words or less, to ensure that training and test conditions are matched.

Figure 7: Examples where both annotators judged the syntactic system to give an improved translation when compared to the baseline system. 51 out of 200 translations fall into this category. These examples were chosen at random from these 51 examples. **R** is the human (reference) translation; **S** is the translation from the syntax-based system; **P** is the output from the baseline (phrase-based) system.

	Syntax	PB	=	Total
Syntax	51	3	7	61
PB	1	25	11	37
=	21	14	67	102
Total	73	42	85	200

Table 2: Human annotator judgements. Rows show results for annotator 1, and columns for annotator 2. *Syntax* and *PB* show the number of cases where an annotator respectively preferred/dispreferred the syntax-based system. $=$ gives counts of translations judged to be equal in quality.

In addition, we obtained human evaluations on 200 sentences chosen at random from the test data, using two annotators. For each example, the reference translation was presented to the annotator, followed by translations from the syntax-based and phrase-based systems (in a random order). For each example, each annotator could either decide that the two translations were of equal quality, or that one translation was better than the other. Table 2 shows results of this evaluation. Both annotators show a clear preference for the syntax-based system: for annotator 1, 73 translations are judged to be better for the syntax-based system, with 42 translations being worse; for annotator 2, 61 translations are improved with 37 being worse; both annotators' results are statistically significant with $p < 0.05$ under the sign test. Figure 7 shows some translation examples where the syntax-based system was judged to give an improvement.

7 Conclusions and Future Work

We have described a translation model that makes use of flexible parsing operations, critical ideas being the definition of s-phrases, Γ-dependencies, the π-constituent constraint, and an approximate search algorithm. A key area for future work will be further development of the discriminative dependency model (section 4.1). The model of $score_r(\gamma, \mathbf{f})$ that we have described in this paper is relatively simple; in general, however, there is the potential for $score_r$ to link target language dependencies to arbitrary properties of the source language string $\mathbf{f}$ (recall that γ contains a head and modifier spine in the target language, along with positions in the source-language string to which these spines are aligned). For example, we might introduce features that: a) condition dependencies created in the target language on dependency relations between their aligned words in the source language; b) condition target-language dependencies on whether they are aligned to words that are in the same clause or segment in the source language string; or, c) condition the grammatical roles of nouns in the target language on grammatical roles of aligned words in the source language. These features should improve translation quality by giving a tighter link between syntax in the source and target languages, and would be easily incorporated in the approach we have described.

Acknowledgments We would like to thank Ryan McDonald for conversations that were influential in this work, and Meg Aycinena Lippow and Ben Snyder for translation judgments. Extending Statistical Machine Translation with Discriminative and Trigger-Based Lexicon Models

Abstract

In this work, we propose two extensions of standard word lexicons in statistical machine translation: A discriminative word lexicon that uses sentence-level source information to predict the target words and a trigger-based lexicon model that extends IBM model 1 with a second trigger, allowing for a more fine-grained lexical choice of target words. The models capture dependencies that go beyond the scope of conventional SMT models such as phrase- and language models. We show that the models improve translation quality by 1% in BLEU over a competitive baseline on a large-scale task.

1 Introduction

Lexical dependencies modeled in standard phrase-based SMT are rather local. Even though the decision about the best translation is made on sentence level, phrase models and word lexicons usually do not take context beyond the phrase boundaries into account. This is especially problematic since the average source phrase length used during decoding is small. When translating Chinese to English, e.g., it is typically close to only two words.

The target language model is the only model that uses lexical context across phrase boundaries. It is a very important feature in the log-linear setup of today's phrase-based decoders. However, its context is typically limited to three to six words and it is not informed about the source sentence. In the presented models, we explicitly take advantage of sentence-level dependencies including the source side and make non-local predictions for the target words. This is an important aspect when translating from languages like German and Chinese where long-distance dependencies are common. In Chinese, for example, tenses are often encoded by indicator words and particles whose position is relatively free in the sentence. In German, prefixes of verbs can be moved over long distances towards the end of the sentence.

In this work, we propose two models that can be categorized as extensions of standard word lexicons: A discriminative word lexicon that uses global, i.e. sentence-level source information to predict the target words using a statistical classifier and a trigger-based lexicon model that extends the well-known IBM model 1 (Brown et al., 1993) with a second trigger, allowing for a more fine-grained lexical choice of target words. The log-linear framework of the discriminative word lexicon offers a high degree of flexibility in the selection of features. Other sources of information such as syntax or morphology can be easily integrated.

The trigger-based lexicon model, or simply triplet model since it is based on word triplets, is not trained discriminatively but uses the classical maximum likelihood approach (MLE) instead. We train the triplets iteratively on a training corpus using the Expectation-Maximization (EM) algorithm. We will present how both models allow for a representation of topic-related sentence-level information which puts them close to word sense disambiguation (WSD) approaches. As will be shown later, the experiments indicate that these models help to ensure translation of content words that are often omitted by the baseline system. This is a common problem in Chinese-English translation. Furthermore, the models are often capable to produce a better lexical choice of content words.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 210–218,
Singapore, 6-7 August 2009.

The structure of the paper is as follows: In Section 2, we will address related work and briefly pin down how our models differentiate from previous work. Section 3 will describe the discriminative lexical selection model and the triplet model in more detail, explain the training procedures and show how the models are integrated into the decoder. The experimental setup and results will be given in Section 4. A more detailed discussion will be presented in Section 5. In the end, we conclude our findings and give an outlook for further research in Section 6.

2 Related Work

Several word lexicon models have emerged in the context of multilingual natural language processing. Some of them were used as a machine translation system or as a part of one such system. There are three major types of models: Heuristic models as in (Melamed, 2000), generative models as the IBM models (Brown et al., 1993) and discriminative models (Varea et al., 2001; Bangalore et al., 2006).

Similar to this work, the authors of (Varea et al., 2001) try to incorporate a maximum entropy lexicon model into an SMT system. They use the words and word classes from the local context as features and show improvements with n-best rescoring.

The models in this paper are also related to word sense disambiguation (WSD). For example, (Chan et al., 2007) trained a discriminative model for WSD using local but also across-sentence unigram collocations of words in order to refine phrase pair selection dynamically by incorporating scores from the WSD classifier. They showed improvements in translation quality in a hierarchical phrase-based translation system. Another WSD approach incorporating context-dependent phrasal translation lexicons is given in (Carpuat and Wu, 2007) and has been evaluated on several translation tasks. Our model differs from the latter in three ways. First, our approach models word selection of the target sentence based on global sentence-level features of the source sentence. Second, instead of disambiguating phrase senses as in (Carpuat and Wu, 2007), we model word selection independently of the phrases used in the MT models. Finally, the training is done in a different way as will be presented in Sections 3.1.1 and 3.2.1.

Recently, full translation models using discriminative training criteria emerged as well. They are designed to generate a translation for a given source sentence and not only score or disambiguate hypotheses given by a translation system. In (Ittycheriah and Roukos, 2007), the model can predict 1-to-many translations with gaps and uses words, morphologic and syntactic features from the local context.

The authors of (Venkatapathy and Bangalore, 2007) propose three different models. The first one is a global lexical selection model which includes all words of the source sentence as features, regardless of their position. Using these features, the system predicts the words that should be included in the target sentence. Sentence structure is then reconstructed using permutations of the generated bag of target words. We will also use this type of features in our model.

One of the simplest models in the context of lexical triggers is the IBM model 1 (Brown et al., 1993) which captures lexical dependencies between source and target words. It can be seen as a lexicon containing correspondents of translations of source and target words in a very broad sense since the pairs are trained on the full sentence level. The trigger-based lexicon model used in this work follows the training procedure introduced in (Hasan et al., 2008) and is integrated directly in the decoder instead of being applied in n-best list reranking. The model is very close to the IBM model 1 and can be seen as an extension of it by taking another word into the conditioning part, i.e. the triggering items. Thus, instead of $p(f|e)$, it models $p(f|e, e')$. Furthermore, since the second trigger can come from any part of the sentence, there is a link to long-range monolingual triggers as presented in (Tillmann and Ney, 1997) where a trigger language model was trained using the EM algorithm and helped to reduce perplexities and word error rates in a speech recognition experiment. In (Rosenfeld, 1996), another approach was chosen to model monolingual triggers using a maximum-entropy based framework. Again, this adapted LM could improve speech recognition performance significantly.

A comparison of a variant of the trigger-based lexicon model applied in decoding and n-best list reranking can be found in (Hasan and Ney, 2009). In order to reduce the number of overall triplets, the authors use the word alignments for fixing the

first trigger to the aligned target word. In general, this constraint performs slightly worse than the unconstrained variant used in this work, but allows for faster training and decoding.

3 Extended Lexicon Models

In this section, we present the extended lexicon models, how they are trained and integrated into the phrase-based decoder.

3.1 Discriminative Lexicon Model

Discriminative models have been shown to outperform generative models on many natural language processing tasks. For machine translation, however, the adaptation of these methods is difficult due to the large space of possible translations and the size of the training data that has to be used to achieve significant improvements.

In this section, we propose a discriminative word lexicon model that follows (Bangalore et al., 2007) and integrate it into the standard phrase-based machine translation approach.

The core of our model is a classifier that predicts target words, given the words of the source sentence. The structure of source as well as target sentence is neglected in this model. We do not make any assumptions about the location of the words in the sentence. This is useful in many cases, as words and morphology can depend on information given at other positions in the sentence. An example would be the character 了 in Chinese that indicates a completed or past action and does not need to appear close to the verb.

We model the probability of the set of target words in a sentence $\mathbf{e}$ given the set of source words $\mathbf{f}$. For each word in the target vocabulary, we can calculate a probability for being or not being included in the set. The probability of the whole set then is the product over the entire target vocabulary $\mathbf{V_E}$:

$$P(\mathbf{e}|\mathbf{f}) = \prod_{e \in \mathbf{e}} P(e^+|\mathbf{f}) \cdot \prod_{e \in \mathbf{V_E} \setminus \mathbf{e}} P(e^-|\mathbf{f}) \quad (1)$$

For notational simplicity, we use the event e^+ when the target word e is included in the target sentence and e^- if not. We model the individual factors $p(e|\mathbf{f})$ of the probability in Eq. 1 as a log-linear model using the source words from $\mathbf{f}$ as binary features

$$\phi(f, \mathbf{f}) = \begin{cases} 1 & \text{if } f \in \mathbf{f} \\ 0 & \text{else} \end{cases} \quad (2)$$

and feature weights $\lambda_{f,\cdot}$:

$$P(e^+|\mathbf{f}) = \frac{\exp\left(\sum_{f \in \mathbf{f}} \lambda_{f,e^+} \, \phi(f, \mathbf{f})\right)}{\sum_{e \in \{e^+, e^-\}} \exp\left(\sum_{f \in \mathbf{f}} \lambda_{f,e} \, \phi(f, \mathbf{f})\right)} \quad (3)$$

Subsequently, we will call this model discriminative word lexicon (DWL).

Modeling the lexicon on sets and not on sequences has two reasons. Phrase-based MT along with n-gram language models is strong at predicting sequences but only uses information from a local context. By using global features and predicting words in a non-local fashion, we can augment the strong local decisions from the phrase-based systems with sentence-level information.

For practical reasons, translating from a set to a set simplifies the parallelization of the training procedure. The classifiers for the target words can be trained separately as explained in the following section.

3.1.1 Training

Common classification tasks have a relatively small number of classes. In our case, the number of classes is the size of the target vocabulary. For large translation tasks, this is in the range of a hundred thousand classes. It is far from what conventional out-of-the-box classifiers can handle.

The discriminative word lexicon model has the convenient property that we can train a separate model for each target word making parallelization straightforward. Discussions about possible classifiers and the choice of regularization can be found in (Bangalore et al., 2007). We used the freely available MegaM Toolkit[1] for training, which implements the L-BFGS method (Byrd et al., 1995). Regularization is done using Gaussian priors. We performed 100 iterations of the training algorithm for each word in the target vocabulary. This results in a large number of classifiers to be trained. For the Arabic-English data (cf. Section 4), the training took an average of 38 seconds per word. No feature cutoff was used.

3.1.2 Decoding

In search, we compute the model probabilities as an additional model in the log-linear model combination of the phrase-based translation approach. To reduce the memory footprint and startup time of the decoding process, we reduced the number of

[1] http://www.cs.utah.edu/~hal/megam/

parameters by keeping only large values $\lambda_{f,e}$ since smaller values tend to have less effect on the overall probability. In experiments we determined that we could safely reduce the size of the final model by a factor of ten without losing predictive power. In search, we compute the model probabilities as an additional model in the log-linear combination. When scoring hypotheses from the phrase-based system, we see the translation hypothesis as the set of target words that are predicted. Words from the target vocabulary which are not included in the hypothesis are not part of the set. During the search process, however, we also have to score incomplete hypotheses where we do not know which words will not be included. This problem is circumvented by rewriting Eq. 1 as

$$P(\mathbf{e}|\mathbf{f}) = \prod_{e \in \mathbf{V_E}} P(e^-|\mathbf{f}) \cdot \prod_{e \in \mathbf{e}} \frac{P(e^+|\mathbf{f})}{P(e^-|\mathbf{f})}.$$

The first product is constant given a source sentence and therefore does not affect the search. Using the model assumption from Eq. 3, we can further simplify the computation and compute the model score entirely in log-space which is numerically stable even for large vocabularies. Experiments showed that using only the first factor of Eq. 1 is sufficient to obtain good results.

In comparison with the translation model from (Bangalore et al., 2007) where a threshold on the probability is used to determine which words are included in the target sentence, our approach relies on the phrase model to generate translation candidates. This has several advantages: The length of the translation is determined by the phrase model. Words occurring multiple times in the translation do not have to be explicitly modeled. In (Bangalore et al., 2007), repeated target words are treated as distinct classes.

The main advantage of the integration being done in a way as presented here is that the phrase model and the discriminative word lexicon model are complementary in the way they model the translation. While the phrase model is good in predicting translations in a local context, the discriminative word lexicon model is able to predict global aspects of the sentence like tense or vocabulary changes in questions. While the phrase model is closely tied to the structure of word and phrase alignments, the discriminative word lexicon model completely disregards the structure in source and target sentences.

3.2 Trigger-based Lexicon Model

The triplets of the trigger-based lexicon model, i.e. $p(e|f, f')$, are composed of two words in the source language triggering one target language word. We chose this inverse direction since it can be integrated directly into the decoder and, thus, does not rely on a two-pass approach using reranking, as it is the case for (Hasan et al., 2008). The triggers can originate from words of the whole source sentence, also crossing phrase boundaries of the conventional bilingual phrase pairs. The model is symmetric though, meaning that the order of the triggers is not relevant, i.e. $(f, f' \rightarrow e) = (f', f \rightarrow e)$. Nevertheless, the model is able to capture long-distance effects such as verb splits or adjustments to lexical choice of the target word given the topic-triggers of the source sentence. In training, we determine the probability of a target sentence e_1^I given the source sentence f_1^J within the model by

$$\begin{aligned} p(e_1^I|f_1^J) &= \prod_{i=1}^{I} p(e_i|f_1^J) \\ &= \prod_{i=1}^{I} \frac{2}{J(J+1)} \sum_{j=0}^{J} \sum_{j'=j+1}^{J} p(e_i|f_j, f_{j'}), \quad (4) \end{aligned}$$

where f_0 denotes the empty word and, thus, for $f_j = \varepsilon$, allows for modeling the conventional (inverse) IBM model 1 lexical probabilities as well. Since the second trigger $f_{j'}$ always starts right of the current first trigger, the model is symmetric and does not need to look at all trigger pairs. Eq. 4 is used in the iterative EM training on all sentence pairs of the training data which is described in more detail in the following.

3.2.1 Training

For training the trigger-based lexicon model, we apply the Expectation-Maximization (EM) algorithm (Dempster et al., 1977). The goal is to maximize the log-likelihood F_{trip} of this model for a given bilingual training corpus $\{(f_1^{J_n}, e_1^{I_n})\}_1^N$ consisting of N sentence pairs:

$$F_{trip} := \sum_{n=1}^{N} \log p(e_1^{I_n}|f_1^{J_n}),$$

where I_n and J_n are the lengths of the n-th target and source sentence, respectively. An auxiliary function $Q(\mu; \bar{\mu})$ is defined based on F_{trip}

where $\bar{\mu}$ is the updated estimate within an iteration which is to be derived from the current estimate μ. Here, μ stands for the entire set of model parameters, i.e. the set of all $\{\alpha(e|f, f')\}$ with the constraint $\sum_e \alpha(e|f, f') = 1$. The accumulators $\alpha(\cdot)$ are therefore iteratively trained on the training data by using the current estimate, i.e. deriving the expected value (E-step), and maximizing their likelihood afterwards to reestimate the distribution. Thus, the perplexity of the training data is reduced in each iteration.

3.2.2 Decoding

In search, we can apply this model directly when scoring bilingual phrase pairs. Given a trained model for $p(e|f, f')$, we compute the feature score $h_{trip}(\cdot)$ of a phrase pair $(\tilde{e}, \tilde{f})$ as

$$h_{trip}(\tilde{e}, \tilde{f}, f_0^J) = - \sum_i \log \Big(\frac{2}{J \cdot (J+1)} \sum_j \sum_{j'>j} p(\tilde{e}_i | f_j, f_{j'}) \Big), \quad (5)$$

where i moves over all target words in the phrase $\tilde{e}$, the second sum selects all source sentence words f_0^J including the empty word, and $j' > j$ incorporates the rest of the source sentence right of the first trigger. We take negative log-probabilities and normalize to obtain the final score (representing costs) for the given phrase pair. Note that in search, we can only use this direction, $p(e|f, f')$, since the whole source sentence is available for triggering effects whereas not all target words have been generated so far, as it would be necessary for the standard direction, $p(f|e, e')$.

Due to the enormous number of triplets, we trained the model on a subset of the overall training data. The subcorpus, mainly consisting of newswire articles, contained 1.4M sentence pairs with 32.3M running words on the English side. We trained two versions of the triplet lexicon, one using 4 EM iterations and another one that was trained for 10 EM iterations. Due to trimming of triplets with small probabilities after each iteration, the version based on 10 iterations was slightly smaller, having 164 million triplets but also performed slightly worse. Thus, for the experiments, we used the version based on 4 iterations which contained 291 million triplets.

Note that decoding with this model can be quite efficient if caching is applied. Since the given source sentence does not change, we have to calculate $p(e|f, f')$ for each e only once and can retrieve the probabilities from the cache for consecutive scorings of the same target word e. This significantly speeds up the decoding process.

4 Experimental Evaluation

In this section we evaluate our lexicon models on the GALE Chinese-English task for newswire and web text translation and additionally on the official NIST 2008 task for both Chinese-English and Arabic-English. The baseline system was built using a state-of-the art phrase-based MT system (Zens and Ney, 2008). We use the standard set of models with phrase translation probabilities for source-to-target and target-to-source direction, smoothing with lexical weights, a word and phrase penalty, distance-based and lexicalized reordering and a 5-gram (GALE) or 6-gram (NIST) target language model.

We used training data provided by the Linguistic Data Consortium (LDC) consisting of 9.1M parallel Chinese-English sentence pairs of various domains for GALE (cf. Table 1) and smaller amounts of data for the NIST systems (cf. Table 2). The DWL and Triplet models were integrated into the decoder as presented in Section 3.

For the GALE development and test set, we separated the newswire and web text parts and did separate parameter tuning for each genre using the corresponding development set which consists of 485 sentences for newswire texts and 533 sentences of web text. The test set has 480 sentences for newswire and 490 sentences for web text. For NIST, we tuned on the official 2006 eval set and used the 2008 evaluation set as a blind test set.

DWL+Trip.	27.9	63.56	43.0	49.15

Table 4: Results on the test sets for the NIST 2008 Chinese-English and Arabic-English task (case-insensitive evaluation).

4.1 Translation Results

The translation results on the two GALE test sets are shown in Table 3 for newswire and web text. Both the discriminative word lexicon and the triplet lexicon can individually improve the baseline by approximately +0.6–0.9% BLEU and -0.5–0.8% TER. For the combination of both lexicons on the newswire setting, we observe only a slight improvement on BLEU but also an additional boost in TER reduction, arriving at +1% BLEU and -1.2% TER. For web text, the findings are similar: The combination of the discriminative and trigger-based lexicons yields +1% BLEU and decreases TER by -0.5%.

We compared these results against an inverse IBM model 1 but the results were inconclusive which is consistent with the results presented in (Och et al., 2004) where no improvements were achieved using $p(e|f)$. In our case, inverse IBM1 improves results by 0.2–0.4% BLEU on the development set but does not show the same trend on the test sets. Furthermore, combining IBM1 with DWL or Triplets often even degraded the translation results, e.g. only 32.8% BLEU was achieved on newswire for a combination of the IBM1, DWL and Triplet model. In contrast, combinations of the DWL and Triplet model did not degrade performance and could benefit from each other.

In addition to the automatic scoring, we also did a randomized subjective evaluation where the hypotheses of the baseline was compared against the hypotheses generated using the discriminative word lexicon and triplet models. We evaluated 200 sentences from newswire and web text. In 80% of the evaluated sentences, the improved models were judged equal or better than the baseline.

We tested the presented lexicon models also on another large-scale system, i.e. NIST, for two language pairs, namely Chinese-English and Arabic-English. Interestingly, the results obtained for Arabic-English are similar to the findings for Chinese-English, as can be seen in Table 4. The overall improvements for this language pair are +1% BLEU and -1.4% TER. In contrast to the GALE Chinese-English task, the triplet lexicon model for the Arabic-English language pair performs slightly better than the discriminative word lexicon.

These results strengthen the claim that the presented models are capable of improving lexical choice of the MT system. In the next section, we discuss the observed effects and analyze our results in more detail.

5 Discussion

In terms of automatic evaluation measures, the results indicate that it is helpful to incorporate the extended lexicon models into the search process. In this section, we will analyze some more details of the models and take a look at the lexical choice they make and what differentiates them from the baseline models. In Table 5, we picked an example sentence from the GALE newswire test set and show the different hypotheses produced by our system. As can be seen, the baseline does not produce the present participle of the verb *restore* which makes the sentence somewhat hard to understand. Both the discriminative and the trigger-based lexicon approach are capable of generating this missing information, i.e. the correct use of *restoring*. Figure 1 gives an example how discontinuous triggers affect the word choice on the target side. Two cases are depicted where high probabilities of triplets including *emergency* and *restoring* on the target side influence the overall hypothesis selection. The non-local modeling advantages of the triplet model can be observed as well: The

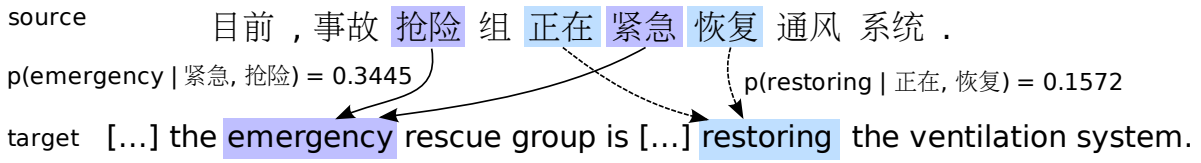

Figure 1: Triggering effect for the example sentence using the triplet lexicon model. The Chinese source sentence is shown in its segmented form. Two triplets are highlighted that have high probability and favor the target words *emergency* and *restoring*.

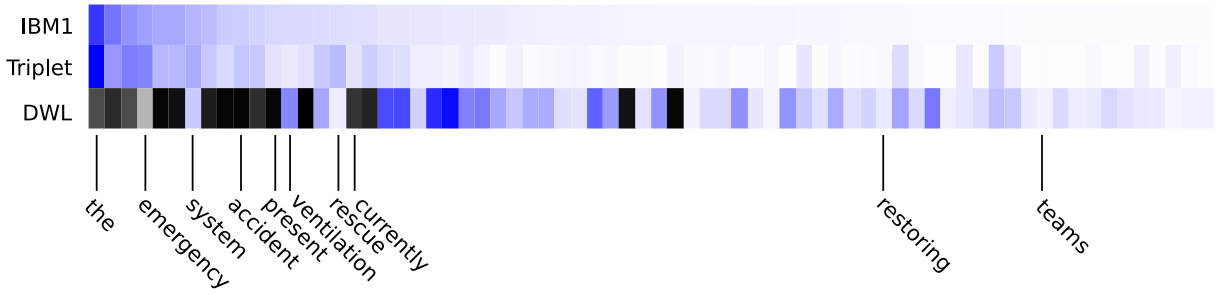

Figure 2: Ranking of words for the example sentence for IBM1, Triplet and DWL model. Ranks are sorted at IBM1, darker colors indicate higher probabilities within the model.

triggering events do not need to be located next to each other or within a given phrase pair. They move across the whole source sentence, thus allowing for capturing of long-range dependencies.

Table 6 shows the top ten content words that are predicted by the two models, discriminative word lexicon and triplet lexicon model. IBM model 1 ranks are indicated by subscripts in the column of the triplet model. Although the triplet model is similar to IBM1, we observe differences in the word lists. Comparing this to the visualization of the probability distribution for the example sentence, cf. Figure 2, we argue that, although the IBM1 and Triplet distributions look similar, the triplet model is sharper and favors words such as the ones in Table 6, resulting in different word choice in the translation process. In contrast, the DWL approach gives more distinct probabilities, selecting content words that are not chosen by the other models.

Table 7 shows an example from the web text test set. Here, the baseline hypothesis contains an incorrect word, *anna*, which might have been mistaken for the name *ying*. Interestingly, the hypotheses of the DWL lexicon and the combination of DWL and Triplet contain the correct content word *remarks*. The triplet model makes an error by selecting *music*, an artifact that might come from words that co-occur frequently with the corresponding Chinese verb *to listen*, i.e. 听 , in the data. Although the TER score of the baseline is better than the one for the alternative models for this particular example, we still think that the observed effects show how our models help producing different hypotheses that might lead to subjectively better translations.

An Arabic-English translation example is shown in Table 8. Here, the term *incidents of murder in apartments* was chosen over the baseline's *killings inside the flats*. Both translations are understandable and the difference in the wording is only based on synonyms. The translation using the discriminative and trigger-based lexicons better matches the reference translation and, thus, reflects a better lexical choice of the content words.

6 Conclusion

We have presented two lexicon models that use global source sentence context and are capable of predicting context-specific target words. The models have been directly integrated into the decoder and have shown to improve the translation quality of a state-of-the-art phrase-based machine translation system. The first model was a discriminative word lexicon that uses sentence-level features to predict if a word from the target vocabulary should be included in the translation or not. The second model was a trigger-based lexi-

con that uses triplets to model long-range dependencies in the data. The source word triggers can move across the whole sentence and capture the topic of the sentence and incorporate more fine-grained lexical choice of the target words within the decoder.

Overall improvements are up to +1% in BLEU and -1.5% in TER on large-scale systems for Chinese-English and Arabic-English. Compared to the inverse IBM model 1 which did not yield consistent improvements, the presented models are valuable additional features in a phrase-based statistical machine translation system. We will test this setup for other language pairs and expect that languages like German where long-distance effects are common can benefit from these extended lexicon models.

In future work, we plan to extend the discriminative word lexicon model in two directions: extending context to the document level and feature engineering. For the trigger-based model, we plan to investigate more model variants. It might be interesting to look at cross-lingual trigger models such as $p(f|e, f')$ or constrained variants like $p(f|e, e')$ with $pos(e') < pos(e)$, i.e. the second trigger coming from the left context within a sentence which has already been generated. extensions could be integrated directly in search as well and would enable the system to combine both directions (standard and inverse) to some extent which was previously shown to help when applying the standard direction $p(f|e, e')$ as an additional reranking step, cf. (Hasan and Ney, 2009).

Abstract

We present a machine translation framework that can incorporate arbitrary features of both input and output sentences. The core of the approach is a novel decoder based on lattice parsing with quasi-synchronous grammar (Smith and Eisner, 2006), a syntactic formalism that does not require source and target trees to be isomorphic. Using generic approximate dynamic programming techniques, this decoder can handle "non-local" features. Similar approximate inference techniques support efficient parameter estimation with hidden variables. We use the decoder to conduct controlled experiments on a German-to-English translation task, to compare lexical phrase, syntax, and combined models, and to measure effects of various restrictions on non-isomorphism.

1 Introduction

We have seen rapid recent progress in machine translation through the use of rich features and the development of improved decoding algorithms, often based on grammatical formalisms.[1] If we view MT as a machine learning problem, features and formalisms imply structural independence assumptions, which are in turn exploited by efficient inference algorithms, including decoders (Koehn et al., 2003; Yamada and Knight, 2001). Hence a tension is visible in the many recent research efforts aiming to decode with "non-local" features (Chiang, 2007; Huang and Chiang, 2007).

Lopez (2009) recently argued for a separation between features/formalisms (and the independence assumptions they imply) from inference algorithms in MT; this separation is widely appreciated in machine learning. Here we take first steps toward such a "universal" decoder, making the following contributions:

Arbitrary feature model (§2): We define a single, direct log-linear translation model (Papineni et al., 1997; Och and Ney, 2002) that encodes most popular MT features and can be used to encode *any* features on source and target sentences, dependency trees, and alignments. The trees are optional and can be easily removed, allowing simulation of "string-to-tree," "tree-to-string," "tree-to-tree," and "phrase-based" models, among many others. We follow the widespread use of log-linear modeling for direct translation modeling; the novelty is in the use of richer feature sets than have been previously used in a single model.

Decoding as QG parsing (§3–4): We present a novel decoder based on lattice parsing with quasi-synchronous grammar (QG; Smith and Eisner, 2006).[2] Further, we exploit generic approximate inference techniques to incorporate arbitrary "non-local" features in the dynamic programming algorithm (Chiang, 2007; Gimpel and Smith, 2009).

Parameter estimation (§5): We exploit similar approximate inference methods in regularized pseudolikelihood estimation (Besag, 1975) with hidden variables to discriminatively and efficiently train our model. Because we start with *inference* (the key subroutine in training), many other learning algorithms are possible.

Experimental platform (§6): The flexibility of our model/decoder permits carefully controlled experiments. We compare lexical phrase and dependency syntax features, as well as a novel com-

[1] Informally, features are "parts" of a parallel sentence pair and/or their mutual derivation structure (trees, alignments, etc.). Features are often implied by a choice of formalism.

[2] To date, QG has been used for word alignment (Smith and Eisner, 2006), adaptation and projection in parsing (Smith and Eisner, 2009), and various monolingual recognition and scoring tasks (Wang et al., 2007; Das and Smith, 2009); this paper represents its first application to MT.

Singapore, 6-7 August 2009.

Σ, T	source and target language vocabularies, respectively
$\text{Trans} : \Sigma \cup \{\text{NULL}\} \rightarrow 2^{\text{T}}$	function mapping each source word to target words to which it may translate
$\boldsymbol{s} = \langle s_0, \ldots, s_n \rangle \in \Sigma^n$	source language sentence (s_0 is the NULL word)
$\boldsymbol{t} = \langle t_1, \ldots, t_m \rangle \in \text{T}^m$	target language sentence, translation of $\boldsymbol{s}$
$\tau_{\boldsymbol{s}} : \{1, \ldots, n\} \rightarrow \{0, \ldots, n\}$	dependency tree of $\boldsymbol{s}$, where $\tau_{\boldsymbol{s}}(i)$ is the index of the parent of s_i (0 is the root, \$)
$\tau_{\boldsymbol{t}} : \{1, \ldots, m\} \rightarrow \{0, \ldots, m\}$	dependency tree of $\boldsymbol{t}$, where $\tau_{\boldsymbol{t}}(i)$ is the index of the parent of t_i (0 is the root, \$)
$\boldsymbol{a} : \{1, \ldots, m\} \rightarrow 2^{\{1,\ldots,n\}}$	alignments from words in $\boldsymbol{t}$ to words in $\boldsymbol{s}$; $\emptyset$ denotes alignment to NULL
$\boldsymbol{\theta}$	parameters of the model
$\boldsymbol{g}_{trans}(\boldsymbol{s}, \boldsymbol{a}, \boldsymbol{t})$	*lexical translation features (§2.1):*
$\boldsymbol{f}_{lex}(s, t)$	word-to-word translation features for translating s as t
$\boldsymbol{f}_{phr}(\boldsymbol{s}_i^j, \boldsymbol{t}_k^\ell)$	phrase-to-phrase translation features for translating $\boldsymbol{s}_i^j$ as $\boldsymbol{t}_k^\ell$
$\boldsymbol{g}_{lm}(\boldsymbol{t})$	*language model features (§2.2):*
$\boldsymbol{f}_N(\boldsymbol{t}_{j-N+1}^j)$	N-gram probabilities
$\boldsymbol{g}_{syn}(\boldsymbol{t}, \tau_{\boldsymbol{t}})$	*target syntactic features (§2.3):*
$\boldsymbol{f}_{att}(t, j, t', k)$	syntactic features for attaching target word t' at position k to target word t at position j
$\boldsymbol{f}_{val}(t, j, I)$	syntactic valence features with word t at position j having children $I \subseteq \{1, \ldots, m\}$
$\boldsymbol{g}_{reor}(\boldsymbol{s}, \tau_{\boldsymbol{s}}, \boldsymbol{a}, \boldsymbol{t}, \tau_{\boldsymbol{t}})$	*reordering features (§2.4):*
$\boldsymbol{f}_{dist}(i, j)$	distortion features for a source word at position i aligned to a target word at position j
$\boldsymbol{g}_{tree^2}(\tau_{\boldsymbol{s}}, \boldsymbol{a}, \tau_{\boldsymbol{t}})$	*tree-to-tree syntactic features (§3):*
$\boldsymbol{f}_{qg}(i, i', j, k)$	configuration features for source pair $s_i/s_{i'}$ being aligned to target pair t_j/t_k
$\boldsymbol{g}_{cov}(\boldsymbol{a})$	*coverage features (§4.2)*
$\boldsymbol{f}_{\boldsymbol{s}\,cov}(\boldsymbol{a})$, $\boldsymbol{f}_{z\text{th}}(\boldsymbol{a})$, $\boldsymbol{f}_{\boldsymbol{s}\,unc}(\boldsymbol{a})$	counters for "covering" each $\boldsymbol{s}$ word each time, the zth time, and leaving it "uncovered"

Table 1: Key notation. Feature factorings are elaborated in Tab. 2.

bination of the two. We quantify the effects of our approximate inference. We explore the effects of various ways of restricting syntactic non-isomorphism between source and target trees through the QG. We do not report state-of-the-art performance, but these experiments reveal interesting trends that will inform continued research.

2 Model

(Table 1 explains notation.) Given a sentence $\boldsymbol{s}$ and its parse tree $\tau_{\boldsymbol{s}}$, we formulate the translation problem as finding the target sentence $\boldsymbol{t}^*$ (along with its parse tree $\tau_{\boldsymbol{t}}^*$ and alignment $\boldsymbol{a}^*$ to the source tree) such that[3]

$$\langle \boldsymbol{t}^*, \tau_{\boldsymbol{t}}^*, \boldsymbol{a}^* \rangle = \underset{\langle \boldsymbol{t}, \tau_{\boldsymbol{t}}, \boldsymbol{a} \rangle}{\text{argmax}}\ p(\boldsymbol{t}, \tau_{\boldsymbol{t}}, \boldsymbol{a} \mid \boldsymbol{s}, \tau_{\boldsymbol{s}}) \quad (1)$$

In order to include overlapping features and permit hidden variables during training, we use a single globally-normalized conditional log-linear model. That is, $p(\boldsymbol{t}, \tau_{\boldsymbol{t}}, \boldsymbol{a} \mid \boldsymbol{s}, \tau_{\boldsymbol{s}}) =$

$$\frac{\exp\{\boldsymbol{\theta}^\top \boldsymbol{g}(\boldsymbol{s}, \tau_{\boldsymbol{s}}, \boldsymbol{a}, \boldsymbol{t}, \tau_{\boldsymbol{t}})\}}{\sum_{\boldsymbol{a}', \boldsymbol{t}', \tau_{\boldsymbol{t}}'} \exp\{\boldsymbol{\theta}^\top \boldsymbol{g}(\boldsymbol{s}, \tau_{\boldsymbol{s}}, \boldsymbol{a}', \boldsymbol{t}', \tau_{\boldsymbol{t}}')\}} \quad (2)$$

where the $\boldsymbol{g}$ are arbitrary feature functions and the $\boldsymbol{\theta}$ are feature weights. If one or both parse trees or the word alignments are unavailable, they can be ignored or marginalized out as hidden variables.

In a log-linear model over structured objects, the choice of feature functions $\boldsymbol{g}$ has a huge effect on the feasibility of inference, including decoding. Typically these feature functions are chosen to *factor* into local parts of the overall structure. We next define some key features used in current MT systems, explaining how they factor. We will use subscripts on $\boldsymbol{g}$ to denote different groups of features, which may depend on subsets of the structures $\boldsymbol{t}$, $\tau_{\boldsymbol{t}}$, $\boldsymbol{a}$, $\boldsymbol{s}$, and $\tau_{\boldsymbol{s}}$. When these features factor into parts, we will use $\boldsymbol{f}$ to denote the factored vectors, so that if $\boldsymbol{x}$ is an object that breaks into parts $\{x_i\}_i$, then $\boldsymbol{g}(\boldsymbol{x}) = \sum_i \boldsymbol{f}(x_i)$.[4]

2.1 Lexical Translations

Classical lexical translation features depend on $\boldsymbol{s}$ and $\boldsymbol{t}$ and the alignment $\boldsymbol{a}$ between them. The simplest are word-to-word features, estimated as the conditional probabilities $p(t \mid s)$ and $p(s \mid t)$ for $s \in \Sigma$ and $t \in \text{T}$. Phrase-to-phrase features generalize these, estimated as $p(\boldsymbol{t}' \mid \boldsymbol{s}')$ and $p(\boldsymbol{s}' \mid \boldsymbol{t}')$ where $\boldsymbol{s}'$ (respectively, $\boldsymbol{t}'$) is a substring of $\boldsymbol{s}$ ($\boldsymbol{t}$).

A major difference between the phrase features used in this work and those used elsewhere is that we do not assume that phrases segment into disjoint parts of the source and target sentences

[3] We assume in this work that $\boldsymbol{s}$ is parsed. In principle, we might include source-side parsing as part of decoding.

[4] There are two conventional definitions of feature functions. One is to let the range of these functions be *conditional probability* estimates (Och and Ney, 2002). These estimates are usually heuristic and inconsistent (Koehn et al., 2003). An alternative is to instantiate features for different structural patterns (Liang et al., 2006; Blunsom et al., 2008). This offers more expressive power but may require much more training data to avoid overfitting. For this reason, and to keep training fast, we opt for the former convention, though our decoder can handle both, and the factorings we describe are agnostic about this choice.

(Koehn et al., 2003); they can overlap.[5] Additionally, since phrase features can be any function of words and alignments, we permit features that consider phrase pairs in which a target word outside the target phrase aligns to a source word inside the source phrase, as well as phrase pairs with gaps (Chiang, 2005; Ittycheriah and Roukos, 2007).

Lexical translation features factor as in Eq. 3 (Tab. 2). We score all phrase pairs in a sentence pair that pair a target phrase with the smallest source phrase that contains all of the alignments in the target phrase; if $\bigcup_{k:i\leq k\leq j} \boldsymbol{a}(k) = \emptyset$, no phrase feature fires for $\boldsymbol{t}_i^j$.

2.2 N-gram Language Model

N-gram language models have become standard in machine translation systems. For bigrams and trigrams (used in this paper), the factoring is in Eq. 4 (Tab. 2).

2.3 Target Syntax

There have been many features proposed that consider source- and target-language syntax during translation. Syntax-based MT systems often use features on grammar rules, frequently maximum likelihood estimates of conditional probabilities in a probabilistic grammar, but other syntactic features are possible. For example, Quirk et al. (2005) use features involving phrases and source-side dependency trees and Mi et al. (2008) use features from a forest of parses of the source sentence. There is also substantial work in the use of target-side syntax (Galley et al., 2006; Marcu et al., 2006; Shen et al., 2008). In addition, researchers have recently added syntactic features to phrase-based and hierarchical phrase-based models (Gimpel and Smith, 2008; Haque et al., 2009; Chiang et al., 2008).

In this work, we focus on syntactic features of target-side dependency trees, $\tau_{\boldsymbol{t}}$, along with the words $\boldsymbol{t}$. These include attachment features that relate a word to its syntactic parent, and valence features. They factor as in Eq. 5 (Tab. 2). Features that consider only target-side syntax and words without considering $\boldsymbol{s}$ can be seen as "syntactic language model" features (Shen et al., 2008).

[5] Segmentation might be modeled as a hidden variable in future work.

$$\boldsymbol{g}_{trans}(\boldsymbol{s},\boldsymbol{a},\boldsymbol{t}) = \sum_{j=1}^{m}\sum_{i\in\boldsymbol{a}(j)} \boldsymbol{f}_{lex}(s_i,t_j) + \sum_{i,j:1\leq i<j\leq m} \boldsymbol{f}_{phr}(\boldsymbol{s}_{first(i,j)}^{last(i,j)},\boldsymbol{t}_i^j) \quad (3)$$

$$\boldsymbol{g}_{lm}(\boldsymbol{t}) = \sum_{N\in\{2,3\}}\sum_{j=1}^{m+1} \boldsymbol{f}_N(\boldsymbol{t}_{j-N+1}^j) \quad (4)$$

$$\boldsymbol{g}_{syn}(\boldsymbol{t},\tau_{\boldsymbol{t}}) = \sum_{j=1}^{m} \boldsymbol{f}_{att}(t_j,j,t_{\tau_{\boldsymbol{t}}(j)},\tau_{\boldsymbol{t}}(j)) + \boldsymbol{f}_{val}(t_j,j,\tau_{\boldsymbol{t}}^{-1}(j)) \quad (5)$$

$$\boldsymbol{g}_{reor}(\boldsymbol{s},\tau_{\boldsymbol{s}},\boldsymbol{a},\boldsymbol{t},\tau_{\boldsymbol{t}}) = \sum_{j=1}^{m}\sum_{i\in\boldsymbol{a}(j)} \boldsymbol{f}_{dist}(i,j) \quad (6)$$

$$\boldsymbol{g}_{tree^2}(\tau_{\boldsymbol{s}},\boldsymbol{a},\tau_{\boldsymbol{t}}) = \sum_{j=1}^{m} \boldsymbol{f}_{qg}(\boldsymbol{a}(j),\boldsymbol{a}(\tau_{\boldsymbol{t}}(j)),j,\tau_{\boldsymbol{t}}(j)) \quad (7)$$

Table 2: Factoring of global feature collections $\boldsymbol{g}$ into $\boldsymbol{f}$. $\boldsymbol{x}_i^j$ denotes $\langle x_i,\ldots x_j\rangle$ in sequence $\boldsymbol{x} = \langle x_1,\ldots\rangle$. $first(i,j) = \min_{k:i\leq k\leq j}(\min(\boldsymbol{a}(k)))$ and $last(i,j) = \max_{k:i\leq k\leq j}(\max(\boldsymbol{a}(k)))$.

2.4 Reordering

Reordering features take many forms in MT. In phrase-based systems, reordering is accomplished both within phrase pairs (local reordering) as well as through distance-based distortion models (Koehn et al., 2003) and lexicalized reordering models (Koehn et al., 2007). In syntax-based systems, reordering is typically parameterized by grammar rules. For generality we permit these features to "see" all structures and denote them $\boldsymbol{g}_{reor}(\boldsymbol{s},\tau_{\boldsymbol{s}},\boldsymbol{a},\boldsymbol{t},\tau_{\boldsymbol{t}})$. Eq. 6 (Tab. 2) shows a factoring of reordering features based on absolute positions of aligned words.

We turn next to the "backbone" model for our decoder; the formalism and the properties of its decoding algorithm will inspire two additional sets of features.

3 Quasi-Synchronous Grammars

A *quasi-synchronous dependency grammar* (QDG; Smith and Eisner, 2006) specifies a conditional model $p(\boldsymbol{t},\tau_{\boldsymbol{t}},\boldsymbol{a} \mid \boldsymbol{s},\tau_{\boldsymbol{s}})$. Given a source sentence $\boldsymbol{s}$ and its parse $\tau_{\boldsymbol{s}}$, a QDG induces a probabilistic monolingual dependency grammar over sentences "inspired" by the source sentence and tree. We denote this grammar by $G_{\boldsymbol{s},\tau_{\boldsymbol{s}}}$; its (weighted) language is the set of translations of $\boldsymbol{s}$. Each word generated by $G_{\boldsymbol{s},\tau_{\boldsymbol{s}}}$ is annotated with a "sense," which consists of zero or more words from $\boldsymbol{s}$. The senses imply an alignment ($\boldsymbol{a}$) between words in $\boldsymbol{t}$ and words in $\boldsymbol{s}$, or equivalently, between nodes in $\tau_{\boldsymbol{t}}$ and nodes in $\tau_{\boldsymbol{s}}$. In principle, any portion of $\tau_{\boldsymbol{t}}$ may align to any portion of $\tau_{\boldsymbol{s}}$, but in practice we often make restrictions on the alignments to simplify computation. Smith and Eisner, for example, restricted $|\boldsymbol{a}(j)|$ for all words

t_j to be at most one, so that each target word aligned to at most one source word, which we also do here.[6]

Which translations are possible depends heavily on the *configurations* that the QDG permits. Formally, for a parent-child pair $\langle t_{\tau_{\boldsymbol{t}}(j)}, t_j \rangle$ in $\tau_{\boldsymbol{t}}$, we consider the relationship between $\boldsymbol{a}(\tau_{\boldsymbol{t}}(j))$ and $\boldsymbol{a}(j)$, the source-side words to which $t_{\tau_{\boldsymbol{t}}(j)}$ and t_j align. If, for example, we require that, for all j, $\boldsymbol{a}(\tau_{\boldsymbol{t}}(j)) = \tau_{\boldsymbol{s}}(\boldsymbol{a}(j))$ or $\boldsymbol{a}(j) = 0$, and that the root of $\tau_{\boldsymbol{t}}$ must align to the root of $\tau_{\boldsymbol{s}}$ or to NULL, then strict isomorphism must hold between $\tau_{\boldsymbol{s}}$ and $\tau_{\boldsymbol{t}}$, and we have implemented a synchronous CF dependency grammar (Alshawi et al., 2000; Ding and Palmer, 2005). Smith and Eisner (2006) grouped all possible configurations into eight classes and explored the effects of permitting different sets of classes in word alignment. ("$\boldsymbol{a}(\tau_{\boldsymbol{t}}(j)) = \tau_{\boldsymbol{s}}(\boldsymbol{a}(j))$" corresponds to their "parent-child" configuration; see Fig. 3 in Smith and Eisner (2006) for illustrations of the rest.) More generally, we can define *features* on tree pairs that factor into these local configurations, as shown in Eq. 7 (Tab. 2).

Note that the QDG instantiates the model in Eq. 2. Of the features discussed in §2, $\boldsymbol{f}_{lex}$, $\boldsymbol{f}_{att}$, $\boldsymbol{f}_{val}$, and $\boldsymbol{f}_{dist}$ can be easily incorporated into the QDG as described while respecting the independence assumptions implied by the configuration features. The others ($\boldsymbol{f}_{phr}$, $\boldsymbol{f}_2$, and $\boldsymbol{f}_3$) are *nonlocal*, or involve parts of the structure that, from the QDG's perspective, are conditionally independent given intervening material. Note that "nonlocality" is relative to a choice of formalism; in §2 we did not commit to any formalism, so it is only now that we can describe phrase and N-gram features as non-local. Non-local features will present a challenge for decoding and training (§4.3).

4 Decoding

Given a sentence $\boldsymbol{s}$ and its parse $\tau_{\boldsymbol{s}}$, at decoding time we seek the target sentence $\boldsymbol{t}^*$, the target tree $\tau_{\boldsymbol{t}}^*$, and the alignments $\boldsymbol{a}^*$ that are most probable, as defined in Eq. 1.[7] (In §5 we will consider k-best and all-translations variations on this problem.) As usual, the normalization constant is not required for decoding; it suffices to solve:

$$\langle \boldsymbol{t}^*, \tau_{\boldsymbol{t}}^*, \boldsymbol{a}^* \rangle = \operatorname*{argmax}_{\langle \boldsymbol{t}, \tau_{\boldsymbol{t}}, \boldsymbol{a} \rangle} \boldsymbol{\theta}^\top \boldsymbol{g}(\boldsymbol{s}, \tau_{\boldsymbol{s}}, \boldsymbol{a}, \boldsymbol{t}, \tau_{\boldsymbol{t}}) \quad (8)$$

For a QDG model, the decoding problem has not been addressed before. It equates to finding the most probable derivation under the $\boldsymbol{s}/\tau_{\boldsymbol{s}}$-specific grammar $G_{\boldsymbol{s},\tau_{\boldsymbol{s}}}$. We solve this by lattice parsing, assuming that an upper bound on m (the length of $\boldsymbol{t}$) is known. The advantage offered by this approach (like most other grammar-based translation approaches) is that decoding becomes *dynamic programming* (DP), a technique that is both widely understood in NLP and for which practical, efficient, generic techniques exist. A major advantage of DP is that, with small modifications, *summing* over structures is also possible with "inside" DP algorithms. We will exploit this in training (§5). Efficient summing opens up many possibilities for training $\boldsymbol{\theta}$, such as likelihood and pseudo-likelihood, and provides principled ways to handle hidden variables during learning.

4.1 Translation as Monolingual Parsing

We decode by performing lattice parsing on a lattice encoding the set of possible translations. The lattice is a weighted "sausage" lattice that permits sentences up to some maximum length ℓ; ℓ is derived from the source sentence length. Let the states be numbered 0 to ℓ; states from $\lfloor \rho\ell \rfloor$ to ℓ are final states (for some $\rho \in (0, 1)$). For every position between consecutive states $j-1$ and j ($0 < j \leq \ell$), and for every word s_i in $\boldsymbol{s}$, and for every word $t \in \mathrm{Trans}(s_i)$, we instantiate an arc annotated with t and i. The weight of such an arc is $\exp\{\boldsymbol{\theta}^\top \boldsymbol{f}\}$, where $\boldsymbol{f}$ is the sum of feature functions that fire when s_i translates as t in target position j (e.g., $\boldsymbol{f}_{lex}(s_i, t)$ and $\boldsymbol{f}_{dist}(i, j)$).

Given the lattice and $G_{\boldsymbol{s},\tau_{\boldsymbol{s}}}$, lattice parsing is a straightforward generalization of standard context-free dependency parsing DP algorithms (Eisner, 1997). This decoder accounts for $\boldsymbol{f}_{lex}$, $\boldsymbol{f}_{att}$, $\boldsymbol{f}_{val}$, $\boldsymbol{f}_{dist}$, and $\boldsymbol{f}_{qg}$ as local features.

Figure 1 gives an example, showing a German sentence and dependency tree from an automatic parser, an English reference, and a lattice representing possible translations. In each bundle, the arcs are listed in decreasing order according to weight and for clarity only the first five are shown. The output of the decoder consists of lattice arcs

[6] I.e., from here on, $\boldsymbol{a} : \{1, \ldots, m\} \to \{0, \ldots, n\}$ where 0 denotes alignment to NULL.

[7] Arguably, we seek $\operatorname{argmax}_{\boldsymbol{t}} p(\boldsymbol{t} \mid \boldsymbol{s})$, marginalizing out everything else. Approximate solutions have been proposed for that problem in several settings (Blunsom and Osborne, 2008; Sun and Tsujii, 2009); we leave their combination with our approach to future work.

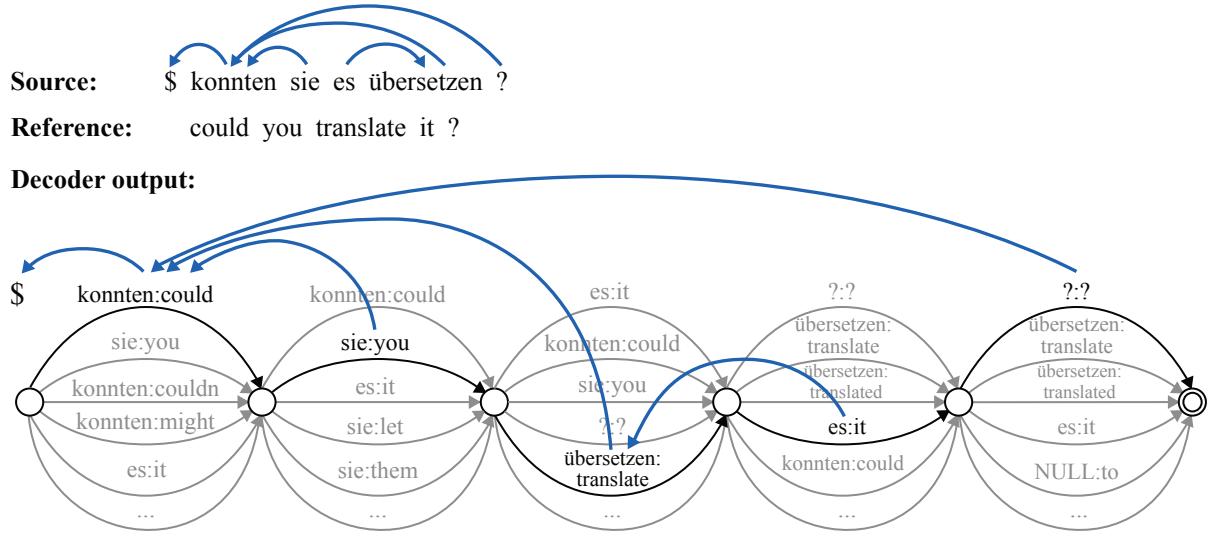

Figure 1: Decoding as lattice parsing, with the highest-scoring translation denoted by black lattice arcs (others are grayed out) and thicker blue arcs forming a dependency tree over them.

selected at each position and a dependency tree over them.

4.2 Source-Side Coverage Features

Most MT decoders enforce a notion of "coverage" of the source sentence during translation: all parts of $\boldsymbol{s}$ should be aligned to some part of $\boldsymbol{t}$ (alignment to NULL incurs an explicit cost). Phrase-based systems such as Moses (Koehn et al., 2007) explicitly search for the highest-scoring string in which all source words are translated. Systems based on synchronous grammars proceed by parsing the source sentence with the synchronous grammar, ensuring that every phrase and word has an analogue in $\tau_{\boldsymbol{t}}$ (or a deliberate choice is made by the decoder to translate it to NULL). In such systems, we do not need to use features to implement source-side coverage, as it is assumed as a hard constraint always respected by the decoder.

Our QDG decoder has no way to enforce coverage; it does not track any kind of state in $\tau_{\boldsymbol{s}}$ apart from a single recently aligned word. This is a problem with other direct translation models, such as IBM model 1 used as a direct model rather than a channel model (Brown et al., 1993). This sacrifice is the result of our choice to use a conditional model (§2).

The solution is to introduce a set of *coverage* features $\boldsymbol{g}_{cov}(\boldsymbol{a})$. Here, these include:

- A counter for the number of times each source word is covered: $\boldsymbol{f}_{\boldsymbol{s}cov}(\boldsymbol{a}) = \sum_{i=1}^{n} |\boldsymbol{a}^{-1}(i)|$.
- Features that fire once when a source word is covered the zth time ($z \in \{2, 3, 4\}$) and fire again all subsequent times it is covered; these are denoted $\boldsymbol{f}_{2\text{nd}}$, $\boldsymbol{f}_{3\text{rd}}$, and $\boldsymbol{f}_{4\text{th}}$.
- A counter of uncovered source words: $\boldsymbol{f}_{\boldsymbol{s}unc}(\boldsymbol{a}) = \sum_{i=1}^{n} \delta(|\boldsymbol{a}^{-1}(i)|, 0)$.

Of these, only $\boldsymbol{f}_{\boldsymbol{s}cov}$ is local.

4.3 Non-Local Features

The lattice QDG parsing decoder incorporates many of the features we have discussed, but not all of them. Phrase lexicon features $\boldsymbol{f}_{phr}$, language model features $\boldsymbol{f}_N$ for $N > 1$, and most coverage features are non-local with respect to our QDG. Recently Chiang (2007) introduced "cube pruning" as an approximate decoding method that extends a DP decoder with the ability to incorporate features that break the Markovian independence assumptions DP exploits. Techniques like cube pruning can be used to include the non-local features in our decoder.[8]

5 Training

Training requires us to learn values for the parameters $\boldsymbol{\theta}$ in Eq. 2. Given T training examples of the form $\langle \boldsymbol{t}^{(i)}, \tau_{\boldsymbol{t}}^{(i)}, \boldsymbol{s}^{(i)}, \tau_{\boldsymbol{s}}^{(i)} \rangle$, for $i = 1, ..., T$, maximum likelihood estimation for this model consists of solving Eq. 9 (Tab. 3).[9] Note that the

[8] A full discussion is omitted for space, but in fact we use "cube decoding," a slightly less approximate, slightly more expensive method that is more closely related to the approximate inference methods we use for training, discussed in §5.

[9] In practice, we regularize by including a term $-c\|\boldsymbol{\theta}\|_2^2$.

$$\mathrm{LL}(\boldsymbol{\theta}) = \sum_{i=1}^{T} \log p(\boldsymbol{t}^{(i)}, \tau_{\boldsymbol{t}}^{(i)} \mid \boldsymbol{s}^{(i)}, \tau_{\boldsymbol{s}}^{(i)}) = \sum_{i=1}^{T} \log \frac{\sum_{\boldsymbol{a}} \exp\{\boldsymbol{\theta}^\top \boldsymbol{g}(\boldsymbol{s}^{(i)}, \tau_{\boldsymbol{s}}^{(i)}, \boldsymbol{a}, \boldsymbol{t}^{(i)}, \tau_{\boldsymbol{t}}^{(i)})\}}{\sum_{\boldsymbol{t}, \tau_{\boldsymbol{t}}, \boldsymbol{a}} \exp\{\boldsymbol{\theta}^\top \boldsymbol{g}(\boldsymbol{s}^{(i)}, \tau_{\boldsymbol{s}}^{(i)}, \boldsymbol{a}, \boldsymbol{t}, \tau_{\boldsymbol{t}})\}} = \sum_{i=1}^{T} \log \frac{\text{“numerator”}}{\text{“denominator”}} \quad (9)$$

$$\mathrm{PL}(\boldsymbol{\theta}) = \sum_{i=1}^{T} \log\Big(\sum_{\boldsymbol{a}} p(\boldsymbol{t}^{(i)}, \boldsymbol{a} \mid \tau_{\boldsymbol{t}}^{(i)}, \boldsymbol{s}^{(i)}, \tau_{\boldsymbol{s}}^{(i)})\Big) + \sum_{i=1}^{T} \log\Big(\sum_{\boldsymbol{a}} p(\tau_{\boldsymbol{t}}^{(i)}, \boldsymbol{a} \mid \boldsymbol{t}^{(i)}, \boldsymbol{s}^{(i)}, \tau_{\boldsymbol{s}}^{(i)})\Big) \quad (10)$$

$$\begin{array}{l}\text{“denominator” of}\\ \text{term 1 in Eq. 10}\end{array} = \sum_{i=0}^{n} \sum_{t' \in \mathrm{Trans}(s_i)} S(\tau_{\boldsymbol{t}}^{-1}(0), i, t') \times \exp\Big\{\boldsymbol{\theta}^\top \big(\boldsymbol{f}_{lex}(s_i, t') + \boldsymbol{f}_{att}(\$, 0, t', k) + \boldsymbol{f}_{qg}(0, i, 0, k)\big)\Big\} \quad (11)$$

$$S(j, i, t) = \prod_{k \in \tau_{\boldsymbol{t}}^{-1}(j)} \sum_{i'=0}^{n} \sum_{t' \in \mathrm{Trans}(s_{i'})} S(k, i', t') \times \exp\left\{\boldsymbol{\theta}^\top \begin{pmatrix} \boldsymbol{f}_{lex}(s_{i'}, t') + \boldsymbol{f}_{att}(t, j, t', k) + \\ \boldsymbol{f}_{val}(t, j, \tau_{\boldsymbol{t}}^{-1}(j)) + \boldsymbol{f}_{qg}(i, i', j, k) \end{pmatrix}\right\} \quad (12)$$

$$S(j, i, t) = \exp\Big\{\boldsymbol{\theta}^\top \big(\boldsymbol{f}_{val}(t, j, \tau_{\boldsymbol{t}}^{-1}(j))\big)\Big\} \quad \text{if } \tau_{\boldsymbol{t}}^{-1}(j) = \emptyset \quad (13)$$

Table 3: Eq. 9: Log-likelihood. Eq. 10: Pseudolikelihood. In both cases we maximize w.r.t. $\boldsymbol{\theta}$. Eqs. 11–13: Recursive DP equations for summing over $\boldsymbol{t}$ and $\boldsymbol{a}$.

alignments are treated as a hidden variable to be marginalized out.[10] Optimization problems of this form are by now widely known in NLP (Koo and Collins, 2005), and have recently been used for machine translation as well (Blunsom et al., 2008). Such problems are typically solved using variations of gradient ascent; in our experiments, we will use an online method called stochastic gradient ascent (SGA). This requires us to calculate the function's gradient (vector of first derivatives) with respect to $\boldsymbol{\theta}$.[11]

Computing the numerator in Eq. 9 involves summing over all possible alignments; with QDG and a hard bound of 1 on $|\boldsymbol{a}(j)|$ for all j, a fast "inside" DP solution is known (Smith and Eisner, 2006; Wang et al., 2007). It runs in $O(mn^2)$ time and $O(mn)$ space.

Computing the denominator in Eq. 9 requires summing over all word sequences and dependency trees for the target language sentence and all word alignments between the sentences. With a maximum length imposed, this is tractable using the "inside" version of the maximizing DP algorithm of Sec. 4, but it is prohibitively expensive. We therefore optimize *pseudo-likelihood* instead, making the following approximation (Besag, 1975):

$$p(\boldsymbol{t}, \tau_{\boldsymbol{t}} \mid \boldsymbol{s}, \tau_{\boldsymbol{s}}) \approx p(\boldsymbol{t} \mid \tau_{\boldsymbol{t}}, \boldsymbol{s}, \tau_{\boldsymbol{s}}) \times p(\tau_{\boldsymbol{t}} \mid \boldsymbol{t}, \boldsymbol{s}, \tau_{\boldsymbol{s}})$$

Plugging this into Eq. 9, we arrive at Eq. 10 (Tab. 3). The two parenthesized terms in Eq. 10 each have their own numerators and denominators (not shown). The numerators are identical to each other and to that in Eq. 9. The denominators are much more manageable than in Eq. 9, never requiring summation over more than two structures at a time. We must sum over target word sequences and word alignments (with fixed $\tau_{\boldsymbol{t}}$), and separately over target trees and word alignments (with fixed $\boldsymbol{t}$).

5.1 Summing over $\boldsymbol{t}$ and $\boldsymbol{a}$

The summation over target word sequences and alignments given fixed $\tau_{\boldsymbol{t}}$ bears a resemblance to the inside algorithm, except that the tree structure is fixed (Pereira and Schabes, 1992). Let $S(j, i, t)$ denote the sum of all translations rooted at position j in $\tau_{\boldsymbol{t}}$ such that $\boldsymbol{a}(j) = i$ and $t_j = t$.

Tab. 3 gives the equations for this DP: Eq. 11 is the quantity of interest, Eq. 12 is the recursion, and Eq. 13 shows the base cases for leaves of $\tau_{\boldsymbol{t}}$.

Letting $q = \max_{0 \le i \le n} |\mathrm{Trans}(s_i)|$, this algorithm runs in $O(mn^2q^2)$ time and $O(mnq)$ space. For efficiency we place a hard upper bound on q during training (details in §6).

5.2 Summing over $\tau_{\boldsymbol{t}}$ and $\boldsymbol{a}$

For the summation over dependency trees and alignments given fixed $\boldsymbol{t}$, required for $p(\tau_{\boldsymbol{t}} \mid \boldsymbol{t}, \boldsymbol{s}, \tau_{\boldsymbol{s}})$, we perform "inside" lattice parsing with $G_{\boldsymbol{s}, \tau_{\boldsymbol{s}}}$. The technique is the summing variant of the decoding method in §4, except for each state j,

[10] Alignments could be supplied by automatic word alignment algorithms. We chose to leave them hidden so that we could make the best use of our parsed training data when configuration constraints are imposed, since it is not always possible to reconcile automatic word alignments with automatic parses.

[11] When the function's value is computed by "inside" DP, the corresponding "outside" algorithm can be used to obtain the gradient. Because outside algorithms can be automatically derived from inside ones, we discuss only inside algorithms in this paper; see Eisner et al. (2005).

the sausage lattice only includes arcs from $j-1$ to j that are labeled with the known target word t_j. If a is the number of arcs in the lattice, which is $O(mn)$, this algorithm runs in $O(a^3)$ time and requires $O(a^2)$ space. Because we use a hard upper bound on $|\mathrm{Trans}(s)|$ for all $s \in \Sigma$, this summation is much faster in practice than the one over words and alignments.

5.3 Handling Non-Local Features

So far, all of our algorithms have exploited DP, disallowing any *non-local* features (e.g., $\boldsymbol{f}_{phr}$, $\boldsymbol{f}_N$ for $N > 1$, $\boldsymbol{f}_{\mathrm{zth}}$, $\boldsymbol{f}_{\boldsymbol{s}unc}$). We recently proposed "cube summing," an approximate technique that permits the use of non-local features for inside DP algorithms (Gimpel and Smith, 2009). Cube summing is based on a slightly less greedy variation of cube *pruning* (Chiang, 2007) that maintains k-best lists of derivations for each DP chart item. Cube summing augments the k-best list with a residual term that sums over remaining structures not in the k-best list, albeit without their non-local features. Using the machinery of cube summing, it is straightforward to include the desired non-local features in the summations required for pseudo-likelihood, as well as to compute their approximate gradients.

Our approach permits an alternative to minimum error-rate training (MERT; Och, 2003); it is discriminative but handles latent structure and regularization in more principled ways. The pseudo-likelihood calculations for a sentence pair, taken together, are faster than (k-best) decoding, making SGA's inner loop faster than MERT's inner loop.

6 Experiments

Our decoding framework allows us to perform many experiments with the same feature representation and inference algorithms, including combining and comparing phrase-based and syntax-based features and examining how isomorphism constraints of synchronous formalisms affect translation output.

6.1 Data and Evaluation

We use the German-English portion of the Basic Travel Expression Corpus (BTEC). The corpus has approximately 100K sentence pairs. We filter sentences of length more than 15 words, which only removes 6% of the data. We end up with a training set of 82,299 sentences, a development set of 934 sentences, and a test set of 500 sentences. We evaluate translation output using case-insensitive BLEU (Papineni et al., 2001), as provided by NIST, and METEOR (Banerjee and Lavie, 2005), version 0.6, with Porter stemming and WordNet synonym matching.

6.2 Features

Our base system uses features as discussed in §2. To obtain lexical translation features $\boldsymbol{g}_{trans}(\boldsymbol{s}, \boldsymbol{a}, \boldsymbol{t})$, we use the Moses pipeline (Koehn et al., 2007). We perform word alignment using GIZA++ (Och and Ney, 2003), symmetrize the alignments using the "grow-diag-final-and" heuristic, and extract phrases up to length 3. We define $\boldsymbol{f}_{lex}$ by the lexical probabilities $p(t \mid s)$ and $p(s \mid t)$ estimated from the symmetrized alignments. After discarding phrase pairs with only one target-side word (since we only allow a target word to align to at most one source word), we define $\boldsymbol{f}_{phr}$ by 8 features: $\{2, 3\}$ target words $\times$ phrase conditional and "lexical smoothing" probabilities $\times$ two conditional directions.

Bigram and trigam language model features, $\boldsymbol{f}_2$ and $\boldsymbol{f}_3$, are estimated using the SRI toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing (Chen and Goodman, 1998).

For our target-language syntactic features $\boldsymbol{g}_{syn}$, we use features similar to lexicalized CFG events (Collins, 1999), specifically following the dependency model of Klein and Manning (2004). These include probabilities associated with individual attachments ($\boldsymbol{f}_{att}$) and child-generation valence probabilities ($\boldsymbol{f}_{val}$). These probabilities are estimated on the training corpus parsed using the Stanford factored parser (Klein and Manning, 2003). The same probabilities are also included using 50 hard word classes derived from the parallel corpus using the GIZA++ `mkcls` utility (Och and Ney, 2003). In total, there are 7 lexical and 7 word-class syntax features.

For reordering, we use a single absolute distortion feature $\boldsymbol{f}_{dist}(i, j)$ that returns $|i-j|$ whenever $\boldsymbol{a}(j) = i$ and $i, j > 0$. (Unlike the other feature functions, which returned probabilities, this feature function returns a nonnegative integer.)

The tree-to-tree syntactic features $\boldsymbol{g}_{tree^2}$ in our model are binary features $\boldsymbol{f}_{qg}$ that fire for particular QG configurations. We use one feature for each of the configurations in (Smith and Eisner, 2006), adding 7 additional features that score configura-

Phrase features:	Syntactic Features:		
	(base)	$+\boldsymbol{f}_{att} \cup \boldsymbol{f}_{val}$ (target)	$+\boldsymbol{f}_{qg}$ (tree-to-tree)
(base)	0.3727	0.4458	0.4424
$+\boldsymbol{f}_{phr}$	0.4682	0.4971	0.5142

Table 4: Feature set comparison (BLEU).

tions involving root words and NULL-alignments more finely. There are 14 features in this category.

Coverage features $\boldsymbol{g}_{cov}$ are as described in §4.2.

In all, 46 feature weights are learned.

6.3 Experimental Procedure

Our model permits training the system on the full set of parallel data, but we instead use the parallel data to estimate feature functions and learn $\boldsymbol{\theta}$ on the development set.[12] We trained using three iterations of SGA over the development data with a batch size of 1 and a fixed step size of 0.01. We used ℓ_2 regularization with a fixed, untuned coefficient of 0.1. Cube summing used a 10-best list for training and a 7-best list for decoding unless otherwise specified.

To obtain the translation lexicon (Trans) we first included the top three target words t for each s using $p(s \mid t) \times p(t \mid s)$ to score target words. For any training sentence $\langle \boldsymbol{s}, \boldsymbol{t} \rangle$ and t_j for which $t_j \notin \bigcup_{i=1}^{n} \text{Trans}(s_i)$, we added t_j to $\text{Trans}(s_i)$ for $i = \text{argmax}_{i' \in I}\, p(s_{i'}|t_j) \times p(t_j|s_{i'})$, where $I = \{i : 0 \leq i \leq n \wedge |\text{Trans}(s_i)| < q_i\}$. We used $q_0 = 10$ and $q_{>0} = 5$, restricting $|\text{Trans}(\text{NULL})| \leq 10$ and $|\text{Trans}(s)| \leq 5$ for any $s \in \Sigma$. This made 191 of the development sentences unreachable by the model, leaving 743 sentences for learning $\boldsymbol{\theta}$.

During decoding, we generated lattices with all $t \in \text{Trans}(s_i)$ for $0 \leq i \leq n$, for every position. We used $\rho = 0.9$, causing states within 90% of the source sentence length to be final states. Between each pair of consecutive states, we pruned edges that fell outside a beam of 70% of the sum of edge weights (see §4.1; edge weights use $\boldsymbol{f}_{lex}$, $\boldsymbol{f}_{dist}$, and $\boldsymbol{f}_{\boldsymbol{s}cov}$) of all edges between those two states.

6.4 Feature Set Comparison

Our first set of experiments compares feature sets commonly used in phrase- and syntax-based translation. In particular, we compare the effects of combining phrase features and syntactic features. The base model contains $\boldsymbol{f}_{lex}$, $\boldsymbol{g}_{lm}$, $\boldsymbol{g}_{reor}$, and $\boldsymbol{g}_{cov}$. The results are shown in Table 4. The second row contains scores when adding in the eight $\boldsymbol{f}_{phr}$ features. The second column shows scores when adding the 14 target syntax features ($\boldsymbol{f}_{att}$ and $\boldsymbol{f}_{val}$), and the third column adds to them the 14 additional tree-to-tree features ($\boldsymbol{f}_{qg}$). We find large gains in BLEU by adding more features, and find that gains obtained through phrase features and syntactic features are partially additive, suggesting that these feature sets are making complementary contributions to translation quality.

6.5 Varying k During Decoding

For models without syntactic features, we constrained the decoder to produce dependency trees in which every word's parent is immediately to its right and ignored syntactic features while scoring structures. This causes decoding to proceed left-to-right in the lattice, the way phrase-based decoders operate. Since these models do not search over trees, they are substantially faster during decoding than those that use syntactic features and do not require any pruning of the lattice. Therefore, we explored varying the value of k used during k-best cube decoding; results are shown in Fig. 2. Scores improve when we increase k up to 10, but not much beyond, and there is still a substantial gap (2.5 BLEU) between using phrase features with $k = 20$ and using all features with $k = 5$. Models without syntax perform poorly when using a very small k, due to their reliance on non-local language model and phrase features. By contrast, models with syntactic features, which are local in our decoder, perform relatively well even with $k = 1$.

6.6 QG Configuration Comparison

We next compare different constraints on isomorphism between the source and target dependency

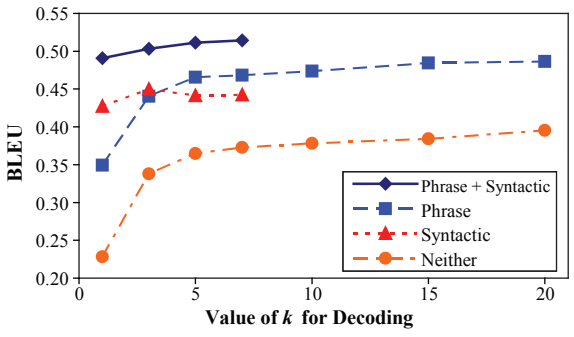

Figure 2: Comparison of size of k-best list for cube decoding with various feature sets.

[12] We made this choice both for similarity to standard MT systems and a more rapid experiment cycle.

QDG Configurations	BLEU	METEOR
synchronous	0.4008	0.6949
+ nulls, root-any	0.4108	0.6931
+ child-parent, same node	0.4337	0.6815
+ sibling	0.4881	0.7216
+ grandparent/child	0.5015	0.7365
+ c-command	0.5156	0.7441
+ other	0.5142	0.7472

Table 5: QG configuration comparison. The name of each configuration, following Smith and Eisner (2006), refers to the relationship between $\boldsymbol{a}(\tau_{\boldsymbol{t}}(j))$ and $\boldsymbol{a}(j)$ in $\tau_{\boldsymbol{s}}$.

trees. To do this, we impose harsh penalties on some QDG configurations (§3) by fixing their feature weights to -1000. Hence they are permitted only when absolutely necessary in training and rarely in decoding.[13] Each model uses all phrase and syntactic features; they differ only in the sets of configurations which have fixed negative weights.

Tab. 5 shows experimental results. The base "synchronous" model permits parent-child ($\boldsymbol{a}(\tau_{\boldsymbol{t}}(j)) = \tau_{\boldsymbol{s}}(\boldsymbol{a}(j))$), any configuration where $\boldsymbol{a}(j) = 0$, including both words being linked to NULL, and requires the root word in $\tau_{\boldsymbol{t}}$ to be linked to the root word in $\tau_{\boldsymbol{s}}$ or to NULL(5 of our 14 configurations). The second row allows any configuration involving NULL, including those where t_j aligns to a non-NULL word in $\boldsymbol{s}$ and its parent aligns to NULL, and allows the root in $\tau_{\boldsymbol{t}}$ to be linked to any word in $\tau_{\boldsymbol{s}}$. Each subsequent row adds additional configurations (i.e., trains its θ rather than fixing it to -1000). In general, we see large improvements as we permit more configurations, and the largest jump occurs when we add the "sibling" configuration ($\tau_{\boldsymbol{s}}(\boldsymbol{a}(\tau_{\boldsymbol{t}}(j))) = \tau_{\boldsymbol{s}}(\boldsymbol{a}(j))$). The BLEU score does not increase, however, when we permit all configurations in the final row of the table, and the METEOR score increases only slightly. While allowing certain categories of non-isomorphism clearly seems helpful, permitting arbitrary violations does not appear to be necessary for this dataset.

6.7 Discussion

We note that these results are not state-of-the-art on this dataset (on this task, Moses/MERT achieves 0.6838 BLEU and 0.8523 METEOR with maximum phrase length 3).[14] Our aim has been to illustrate how a single model can provide a controlled experimental framework for comparisons of features, of inference methods, and of constraints. Our findings show that phrase features and dependency syntax produce complementary improvements to translation quality, that tree-to-tree configurations (a new feature in MT) are helpful for translation, and that substantial gains can be obtained by permitting certain types of non-isomorphism. We have validated cube summing and decoding as practical methods for approximate inference.

Our framework permits exploration of alternative objectives, alternative approximate inference techniques, additional hidden variables (e.g., Moses' phrase segmentation variable), and, of course, additional feature representations. The system is publicly available at `www.ark.cs.cmu.edu/Quipu`.

7 Conclusion

We presented feature-rich MT using a principled probabilistic framework that separates features from inference. Our novel decoder is based on efficient DP-based QG lattice parsing extended to handle "non-local" features using generic techniques that also support efficient parameter estimation. Controlled experiments permitted with this system show interesting trends in the use of syntactic features and constraints.

Improved Word Alignment with Statistics and Linguistic Heuristics

ulf@isi.edu

Abstract

We present a method to align words in a bitext that combines elements of a traditional statistical approach with linguistic knowledge. We demonstrate this approach for Arabic-English, using an alignment lexicon produced by a statistical word aligner, as well as linguistic resources ranging from an English parser to heuristic alignment rules for function words. These linguistic heuristics have been generalized from a development corpus of 100 parallel sentences. Our aligner, UALIGN, outperforms both the commonly used GIZA++ aligner and the state-of-the-art LEAF aligner on F-measure and produces superior scores in end-to-end statistical machine translation, +1.3 BLEU points over GIZA++, and +0.7 over LEAF.

1 Introduction

Word alignment is a critical component in training statistical machine translation systems and has received a significant amount of research, for example, (Brown et al., 1993; Ittycheriah and Roukos, 2005; Fraser and Marcu, 2007), including work leveraging syntactic parse trees, e.g., (Cherry and Lin, 2006; DeNero and Klein, 2007; Fossum et al., 2008). Word alignment is also a required first step in other algorithms such as for learning sub-sentential phrase pairs (Lavie et al., 2008) or the generation of parallel treebanks (Zhechev and Way, 2002).

Yet word alignment precision remains surprisingly low, under 80% for state-of-the-art aligners on not closely related language pairs.

Consider the following Arabic/English sentence pair with alignments built by the statistical word aligner LEAF:

Bitext Arabic: وفاز التايلاندى بارادورن سريشافان على الاسترالى جايسون ستولتنبرغ 4 - 6 و 4 - 6 ,والتشيكى ييرى فانيك على الالمانى لارش بورغسمولر 4 - 6 و 4 - 6

Gloss: Won(1) Thai Paradorn Srichaphan(1) on/to(2) Australian Jason(2) Stoltenberg(3) 6(4) - 4(5) and(3) 6(4) - 4(5), and Czech Jiří(7) Vaněk(7) on/to German(6) Lars Burgsmüller 6(4) - 4 and(3) 6(4) - 4

Bitext English: Thailand 's(1) *Baradorn Srichfan*(1) beat(2) Australian *Gayson*(1) *Stultenberg*(3) 6(4) - *6*(4) 6(4) - 4(5) , Czech player(1) *Pierre*(1) *Vanic*(7) beat(6) Germany(6) 's Lars Burgsmuller 6 - 4 6 - 4

In the example above, words with the same index in the gloss for Arabic and the English are aligned to each other, alignment errors are underlined, translation errors are in *italics*. For example, the Arabic words for *won* and *Srichaphan* are aligned with the English words *'s*, *Srichfan*, *Gayson*, *player* and *Pierre*.

As reflected in the example above, typical alignment problems include

- words that change sentence position between languages, such as verbs, which in Arabic are often sentence-initial (e.g. *won/beat* in the example above)
- function words without a clear and explicit equivalent in the other language (e.g. the Arabic و/*and* in the example above)
- lack of robustness with respect to poor translations (e.g. *Gayson Stultenberg* instead of *Jason Stoltenberg*) or bad sentence alignment.

We believe we can overcome such problems with the increased use of linguistically based

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 229–237,
Singapore, 6-7 August 2009.

heuristics. We can model typical word order differences between English and Arabic using English parse trees and a few Arabic-specific phrase reordering heuristics. We can narrow the space of possible alignment candidates for function words using English parse trees and a few heuristics for each type of function word.

These heuristics have been developed using a development corpus of 100 parallel sentences. The heuristics are generalizations based on patterns of misaligned words, misaligned with respect to a Gold Standard alignment for that development corpus.

The following sections describe how our word aligner works, first how relatively reliable content words are aligned, and then how function words and any remaining content words are aligned, with a brief discussion of an interesting issue relating to the Gold Standard we used. Finally we present evaluations on word alignment accuracy as well as the impact on end-to-end machine translation quality.

2 Phase I: Content Words

We divide the alignment process into two phases: first, we align relatively reliable content words, which in phase II we then use as a skeleton to align function words and remaining content words.

Function words such as English *a, ah, all, am, an, and, any, are, as, at, ...* are common words that often do not have an explicit equivalent word or words in the other side of the bitext. In our system, we use a list of 96 English and 110 Arabic function words with those characteristics. For the purposes of our algorithm, a word is a function word if and only if it is on the function word list for its language. A content word then is defined as a word that is neither a function word nor punctuation.

The approach for aligning content words in phase I is as follows: First, we score each combination of an Arabic content word and English content word in an aligned sentence and align those pairs that pass a threshold, typically generating too many alignments. Second, we compute a more comprehensive score that also takes into consideration matching alignments in the context around each alignment. Third, we eliminate inferior alignments that are incompatible with higher-scoring alignments.

The score in the first step is *pointwise mutual information* (PMI). The key resource to compute this PMI is an alignment lexicon generated beforehand by a statistical word alignment system from a large bitext. An alignment lexicon is a list of triples, each consisting of an English word, an Arabic word, and how often they have been aligned for a given bitext. Additional counts on how often each English and Arabic word occurs allow us use this alignment lexicon to compute PMI(e,f) = $\log \frac{p(e,f)}{p(e) \cdot p(f)}$. We align those Arabic and English content words that have a PMI > 0 and a minimum alignment lexicon count (≥ 10 initially). Using the alignment lexicon generated by a statistical word aligner to compute PMIs is the principal statistical component in our system. We explored alternative metrics such as the dice-coefficient that was used by other researchers in earlier alignment work, but found PMI to work better for our system.

In a second step, we lay a window of size 5 around each aligned pair of Arabic and English words (counting only content words) and then add to the PMI score of the link itself the PMI scores of other links within that window, with a distance weight of $\frac{1}{distance+1}$. This yields a new score that takes into account whether a link is supported by context.

In the third step, we check for overgenerated links, comparing links that share an Arabic or an English word. If a word on one side of the bitext is linked to multiple *adjacent* words on the other, we leave them alone, as one word in one language often corresponds to multiple words in the other. However, if a word on one side is linked to non-adjacent words on the other side, this flags an incompatibility, and we remove those links that have inferior context-sensitive scores. This removal is done one link at a time, with the lowest relative scores first.

We boost the process we just described in a few ways. In the first alignment step, we also include as alignment candidates any content words that are string-identical on each side, such as ASCII numbers and ASCII words. We finally also include as alignment candidates those word pairs that are transliterations of each other to cover rare proper names (Hermjakob et al., 2008), which is important for language pairs that don't share the same alphabet such as Arabic and English.

2.1 Reordering Using an English Parser

We use a refined notion of context window that models word order differences between Arabic and English. Traversing a parse tree for English, we identify sub-trees for which the order in Arabic can be substantially different. In Arabic, for example, the verb is often sentence-initial. So for trees or subtrees identified by the parser as sentences, we generate an alternative reordering of its subtrees where the verb has been moved to the front. Similarly, in a noun phrase, we generate an alternative order where adjectives are moved to the right of the noun they modify.

For example, consider the sentence *John bought a new car* . We can reorder its parse tree both at the sentence level: *(bought) (John) (a new car) (.)* as well as at its object NP level: *(a) (car) (new)*. If fully enumerated, this would yield these four reordering alternatives:

1. John bought a new car .
2. John bought a car new .
3. bought John a new car .
4. bought John a car new .

We don't actually explicitly enumerate all variants but keep all reordering alternatives in a reordering forest, since the number of fully expanded reorderings grows exponentially with the number of phrases with reordering(s). At the beginning of Phase I, we compute from this reordering forest a minimum distance matrix, which, for specific instances of the words *John* and *car* would record a minimum distance of 1 (based on reordering 4, skipping the function word *a*).

For the example sentence at the beginning of the paper we would get reorderings including the following:

Engl. orig.: thailand 's baradorn srichfan beat ...
A reordering: beat thailand 's baradorn srichfan ...
Arabic (gloss): won thai paradorn srichaphan ...

In the above reordered English alternative, *beat* and *thailand* are next to each other, so their minimum distance is 1, which means that a link between English *thailand* and Arabic *thai* now strongly boosts the context-sensitive score between English *beat* and Arabic *won*.

2.2 Morphological Variation

Another challenge to content word alignment is morphological variation which can create data sparsity in the alignment lexicon. For example, in a given bitext sentence, the Arabic word *AlAwDAE* might be translated as *situational*, for which there might be no support in the alignment lexicon. However the PMI between *AlAwDAE* and *situation* might be sufficiently high. Additionally, there is another Arabic word, *AlHAlAt*, which often translates as both *situation* and *situational*.

To take advantage of such constellations, we built morphological variation lists for both Arabic and English, lists that for a given head word such as *situational* lists variants such as *situation*, and *situations*.

We built these lists in a one-time process by identifying superficially similar words, i.e. those that vary only with respect to an ending or a prefix, and then semantically validating such candidates using a pivot word in the other language such as *AlHAlAt* that has sufficiently strong alignment lexicon co-alignment counts with both *situation* and *situational*. The alignment lexicon co-alignment count of an Arabic word w_{ar} and an English word w_{en} is considered strong enough, if it is at least 2.0 and at least 0.001 times as high as the highest co-alignment count of w_{ar} with any English word; words shorter than four letters are excluded from consideration. So because *situation* and *situational* are superficially similar **and** they are both have a strong alignment count with *AlHAlAt* in the alignment lexicon, *situation* is added to the English morphological variation list as a variant of *situational* and vice versa.

Exploring whether we can align *situational* and *AlAwDAE* in the bitext, we find that *situational* is a morphological variant of *situation* (based on our morphological variation list for English); next we find that based on the alignment lexicon, there is a positive PMI between *situation* and *AlAwDAE*, which completes the chain between *situational* and *AlAwDAE*, so we include them as an alignment candidate after all. The PMI of such a morphological-variation-based candidate is weighted by a 'penalty' factor of 0.5 when compared with the PMI of any competing alignment candidate without such morphological-variation step.

Similarly, the English pivot word *situations* can be used to semantically validate the similarity between Arabic *AlAwDAE* and *AwDAE* for our Arabic morphological variation list. The resulting Arabic morphological variation list has entries for 193,263 Arabic words with an average of 4.2 variants each; our English morphological variation list has 57,846 entries with 2.8 variants

each.

At the end of phase I, most content words will be aligned with relatively high precision. Since function words often do not have an explicit equivalent word or words in the other side of a bitext, they can not be aligned as reliably as content words based on bilingual PMI.[1] Note that due to data sparsity, some content words will remained unaligned in phase I and will subsequently be aligned in phase II as explained in section 3.3.

3 Phase II: Function Words

In Phase II, we align function words, punctuation, and some remaining content words. Function words can be classified into three categories: monovalent, divalent and independent. Monovalent function words modify one head; they include articles (which modify nouns), possessive pronouns, demonstrative adjectives and auxiliary verbs. Divalent function words connect two words or phrases; they include conjunctions and prepositions. Independent function words include non-possessive pronouns and copula (e.g. *is* as a main verb). Each of these types of function words is aligned according to its own heuristics.

In this section we present three representative examples, one for articles (monovalent), one for prepositions (divalent), as well as a structural heuristic.

3.1 Example: Articles

Monovalent function words have the simplest heuristics. Recall that Arabic does not have articles (only a definite prefix *Al-* added to one or more words in a definite noun phrase), so there is usually no explicit equivalent of the English article on the Arabic side.

For an English article, our system identifies the English head word that it modifies based on the English parse tree, and then aligns it with the same Arabic word(s) which that head word is aligned with.

3.2 Example: Prepositions

Divalent function words are much more interesting. In many cases, an English preposition corresponds to an explicit Arabic preposition in basically the same position. Alignment in that case is straightforward. However, some Arabic prepositions and even more English prepositions do not have an explicit counterpart on the other side. We call such prepositions *orphan prepositions*. The English preposition *of* is almost always orphaned in this way.

The decision how to align such an orphan preposition is not trivial. Consider the bitext *island of Basilan/jzyrp bAsylAn*, a typical (NP1 (P NP2)) construction on the English side. Should we co-align the preposition *of* with the head of NP1 or the head of NP2? In English syntax, the preposition is grouped with NP2, but a preposition is often better "motivated" by NP1. We therefore decided to use the English parse tree to identify the heads of both NP1 and NP2, identify the Arabic words aligned to these heads as candidates, and then align the preposition to the Arabic candidate word with which it has the highest bilingual PMI. It turns out that in most cases this will be the candidate on the "left". For the example at the top of this paragraph, *of* will be aligned with *jzyrp* ("island"), which is actually desirable for MT, as it facilitates subsequent rule extraction of type "island of X/jzyrp X". We refer to this orphan preposition alignment style as *MT-style*.

According to the gold standard alignment guidelines used for the LDC Gold Standard however, an orphan preposition should always be aligned to the "right", to *bAsylAn* in the example above. We therefore implemented an alternative *GS-style* (for "Gold Standard") to be able to later evaluate the impact of these alternatives alignment styles.

The question whether GIZA or LEAF alignments will indeed give meaningful scores to support the *MT-style* attachments will be answered by the MT experiments described in section 4.3.

Here is a more complex example with Arabic (A), its gloss (G) and English (E):

Arabic: الاحد اغارت الطائرات الاميركية على منطقة جوار
Gloss: sunday attacked aircraft american on/to area jiwar
Engl.: on sunday american aircraft attacked the area of jiwar

For the Arabic orphan preposition على/*ElY* ("on/to"), our system identifies two candidates based on the English parse tree: *attacked* and *area*. Based on a higher mutual information, our system then aligns Arabic *ElY* ("on/to") with English *attacked*, which results in the English word *attacked* now being aligned to both Arabic *attacked* and the

[1] It is this lack of reliability that is the defining characteristic of our function words, differentiating them from the concept of marker words used in EBMT chunking (Way and Gough, 2002).

Arabic *on/to*, even though they are not adjacent. In the Gold Standard, Arabic *on/to* is aligned with English *area*, and LEAF aligns it with English *on* (yes, the one preceding Sunday). This is apparently very tempting as Arabic *on/to* is often translated as English *on*, but here it is incorrect, and our system avoids this tempting alignment because it is ruled out linguistically.

Note that in some cases, such as sentence-initial prepositional phrases, there is only one candidate; occasionally, when relevant content words remain unaligned, no candidate can be identified, in which case the orphan preposition remains unaligned as well.

3.3 Example: Adjectives

It is not uncommon that content words that we would like to be aligned are not supported by the alignment lexicon, due to general data sparsity or maybe a somewhat unorthodox translation. In those cases we can use structure and word order knowledge to make reasonable alignments anyway.

Consider an English noun phase ADJ-E NOUN-E and the corresponding Arabic NOUN-A ADJ-A. If the nouns are already aligned, but the adjectives are not yet aligned, we can use the English parse tree to identify ADJ-E as a modifier to NOUN-E, and, aware that adjectives in Arabic post-modify their nouns, identify the corresponding Arabic word based on structure and word order alone. This can be done the other way around as well (link nouns based on already aligned adjectives) and other elements of other phrases as well.

As more and more function words and remaining content words get aligned, heuristics that weren't applicable before may now apply to the remaining unaligned words, so we perform four passes through a sentence pair to align unaligned words using heuristics. We found that an additional fifth pass did not yield any further improvements.

4 Experiments

We evaluated our word aligner in terms of both alignment accuracy and its impact on an end-to-end machine translation system.

4.1 Alignment Experiments

We evaluated our word aligner against a Gold Standard distributed by LDC. The human alignments of the sentences in this Gold Standard are based on the 2006 GALE Guidelines for Arabic Word Alignment Annotation.

Both the 100-sentence development set and the separate 837-sentence test set are Arabic newswire sentences from LDC2006E86. The test set includes only sentences for which our English parser (Soricut and Marcu, 2003) could produce a parse tree, which effectively excluded a few very long sentences.

In the first set of experiments, we compare two settings of our UALIGN system with other aligners, GIZA++ (Union) (Och and Ney, 2003) and LEAF (with 2 iterations) (Fraser and Marcu, 2007). The GIZA++ aligner is based on IBM Model 4 (Brown et al., 1993). We chose GIZA Union for our comparison, because it led to a higher BLEU score for our overall MT system than other GIZA variants such as GIZA Intersect and Grow-Diag. The two settings of our system vary in the style on how to align orphan prepositions. Besides precision, recall and (balanced) F-measure, we also include an F-measure variant strongly biased towards recall (α=0.1), which (Fraser and Marcu, 2007) found to be best to tune their LEAF aligner for maximum MT accuracy. GIZA++ and LEAF alignments are based on a parallel training corpus of 6.6 million sentence pairs, incl. the LDC2006E86 set mentioned above.

Aligner	Prec.	Recall	F-0.5	F-0.1
GIZA	26.9	84.3	40.8	69.5
LEAF	73.3	79.7	76.4	79.0
UALIGN MT-style	82.5	80.0	81.2	80.2
UALIGN GS-style	84.0	82.9	83.5	83.0

Table 1: Alignment precision, recall, F-measure (α=0.5), F-measure(α=0.1) for different aligners; with UALIGN using LEAF alignment lexicon.

Our aligner outperforms both GIZA and LEAF on all metrics. Not surprisingly, the GS-style alignments, which align "orphan" prepositions according to Gold Standard guidelines, yield higher scores than MT-style alignments. And interestingly by a remarkably high margin.

In a second set of experiments, we measure the impact of using different input alignment lexicon used by our aligner on alignment accuracy. In one case UALIGN uses as input the alignment lexicon produced by LEAF, in the other the alignment lexicon produced by GIZA. All experiments in table 2

are for UALIGN.

Style	A-Lexicon	Prec.	Recall	F-0.5	F-0.1
MT	from LEAF	82.5	80.0	81.2	80.2
MT	from GIZA	80.8	79.2	80.0	79.4
GS	from LEAF	84.0	82.9	83.5	83.0
GS	from GIZA	82.1	81.8	82.0	81.9

Table 2: Alignment precision, recall, F-measure (α=0.5), F-measure(α=0.1), all of UALIGN, for different alignment styles, different input alignment lexicons.

As LEAF clearly outperforms GIZA on F-0.1 (79.0 vs. 69.5, see table 1), the alignment lexicon based on LEAF is better, so it is not surprising that when we use an alignment lexicon based on GIZA, all metrics degrade, and consistently so for both alignment styles. However the drop in F-0.1 of about 1 point (80.2 $\rightarrow$ 79.4 and 83.0 $\rightarrow$ 81.9) is much smaller than the differences between the underlying aligners themselves. Our aligner therefore degrades quite gracefully for a worse alignment lexicon.

Aligner	Arabic aligned	Engl. aligned
GIZA Union	100%	100%
LEAF	99.99%	97.25%
UALIGN	92.10%	91.55%
Gold Standard	95.37%	95.86%

Table 3: Percentages of Arabic and English words aligned

Table 3 shows how much LEAF and UALIGN differ in the percentage of Arabic and English words aligned (correctly or incorrectly). LEAF is much more aggressive in making alignments, aligning almost every Arabic word. Our aligner still leaves some 8% of all words in a sentence unaligned (an opportunity for further improvements). For comparison, in the Gold Standard, 4-5% of all words in our test corpus are left unaligned.

4.2 Impact of Sub-Components

To better understand the impact of several alignment system sub-components, we ran a number of experiments disabling individual sub-components and then comparing the resulting alignment scores with those of the full system. We also measured alignment scores running Phase II with 0 to 5 passes. The test set was the same as in section 4.1.

System	Prec.	Recall	F-0.1
Full system (FS)	84.0	82.9	83.0
FS w/o morph.variation	84.0	82.4	82.5
FS w/o Engl. tree reord.	83.8	82.7	82.8
FS w/o string identity	84.0	82.8	82.9
FS w/o name translit.	84.0	82.8	82.9
System after Phase I	90.6	44.5	46.8
+ Phase II w/ 1 pass	87.6	77.1	78.0
+ Phase II w/ 2 passes	85.8	80.3	80.8
+ Phase II w/ 3 passes	84.2	82.7	82.8
+ Phase II w/ 4 passes	84.0	82.9	83.0
+ Phase II w/ 5 passes	84.0	82.9	83.0

Table 4: Impact of sub-components on alignment precision, recall, F-measure, with GS-style attachments, based on the LEAF alignment lexicon.

Special sub-components of Phase I include adding link candidates for ASCII-string-identical words and transliterated names (see last paragraph before section 2.1), reordering using an English parser (section 2.1) and morphological variation (section 2.2). Each of these sub-components provides a small boost to F-0.1, ranging from +0.1 to +0.5. The second part of the table shows alignment scores before and after each pass of Phase II. Our full system includes 4 passes; an additional 5th pass did not yield any further improvements. Note that during Phase II, precision drops. This is a reflection of (1) our strategy to first align relatively reliable content words in Phase I, followed by less reliable function words and remaining content words, and (2) the challenges of building reliable Gold Standard alignments for function words and non-literal translations.

4.3 MT Experiments

The ultimate test for a word aligner is to measure its impact on an end-to-end machine translation system. For this we aligned 170,863 pairs of Arabic/English newswire sentences from LDC, trained a state-of-the-art syntax-based statistical machine translation system (Galley et al., 2006) on these sentences and alignments, and measured BLEU scores (Papineni et al., 2002) on a separate set of 1298 newswire test sentences. Besides swapping in a new set of alignments for the same set of training sentences, and automatically retuning the parameters of the translation system for each set of alignments, no other changes or adjustments were made to the existing MT system.

In the first set of experiments, we compare two settings of our UALIGN system with other aligners, again GIZA++ (Union) and LEAF (with 2 iterations). The two settings vary in the alignment lexicon that the UALIGN aligner uses as input.

Aligner	BLEU
GIZA	47.4
LEAF	48.0
UALIGN using GIZA alignment-lexicon	48.4
UALIGN using LEAF alignment-lexicon	48.7

Table 5: BLEU scores in end-to-end statistical MT system based on different aligners. Both UALIGN variants use MT-style alignments.

With a BLEU score of 48.7, UALIGN using a LEAF alignment-lexicon is significantly better than both GIZA (+1.3) and LEAF (+0.7). This and other significance assertions in this paper are based on paired bootstrap resampling tests with 95% confidence. UALIGN using a GIZA alignment-lexicon significantly outperforms GIZA itself (+1.0).

In a second experiment, we measured the impact of the two alignment styles on BLEU. Recall that for GS-style alignments, orphan prepositions are always co-aligned to the right, following Gold Standard annotation guidelines, whereas for MT-style alignments, mutual information is used to decide whether to align orphan prepositions to the left or to the right.

Aligner	BLEU
LEAF	48.0
UALIGN with GS-style alignments	48.0
UALIGN with MT-style alignments	48.7

Table 6: BLEU scores in end-to-end statistical MT system based on different alignment styles for orphan prepositions. Both UALIGN variants use a LEAF alignment lexicon.

While the GS-style alignments yielded a 2.8 point higher F-0.1 score (83.0 vs. 80.2), the MT-style alignments result in a significantly better BLEU score (48.7 vs. 48.0). This shows that (1) a seemingly small difference in alignment styles can have a remarkably high impact on both BLEU scores and alignment accuracy as measured against a Gold Standard, and that (2) optimizing alignment accuracy against an alignment Gold Standard does **not** necessarily optimize BLEU in end-to-end MT. The latter has been observed by other researchers before, but these results additionally suggest that the gold-standard annotation style might itself have to shoulder part of the blame.

4.4 Corpus Noise Robustness

In a small random "sanity check" sample from the 170,863 training sentences for the MT experiment, we found cases where the sentence in one language contained much more material than the sentence in the other language. Consider, for example the following sentence pair (with spurious material underlined):

Arabic:
لكن ايضا هناك بند اخر ينص على انه اذا لم ينشا الفندق ،

Gloss: but also there-is clause another stipulates on/to that if not established the-hotel ,

English: but , also there is another clause that stipulates that if the hotel is not established , then the government shall be compensated .

Both LEAF and UALIGN correctly align the English "*but , also ... not established ,*" with the Arabic side. LEAF further aligns all words in the spurious English "*then the government shall be compensated .*" with seemingly random material on the Arabic side, whereas UALIGN leaves these spurious words completely unaligned. It would be reasonable to speculate that this behavior, observed in several cases, may be contributing to the good BLEU scores.

5 Discussion

Building on existing statistical aligners, our new word aligner significantly outperforms the best word aligner to date in both alignment error rate and BLEU score.

We have developed an approach to word alignment that combines a statistical component with linguistic heuristics. It is novel in that it goes beyond generic resources such as parsers, adding heuristics to explicitly model word order differences and function word alignment.

The approach has numerous benefits. Our system produces superior results both on alignment accuracy and end-to-end machine translation quality. Alignments have a high precision. The system is fast (about 0.7 seconds per sentence), and sentences are aligned individually so that a large corpus can easily be aligned on several computers in

parallel. All alignment links are tagged with additional information, such as which phase and/or heuristic created them, yielding extensive explanatory power to the developer for easy understanding on how the system arrived at a given alignment. Our approach needs and uses a parser for only one side (English) and not for the other (Arabic).

On the other hand, some of the components of this aligner are language-specific, such as word order heuristics, the list of specific function words, and morphological variation lists. While these parts of the system need to be adapted for new languages, the overall architecture and types of heuristics and function words are language-independent. Chinese for example has different specific types of function words such as aspect markers and measure words. But these fall into the existing category of monovalent function words and will be treated according the same principles as other monovalent function words (section 3.1). Similarly, Japanese postpositions would be treated like other divalent function words (such as Arabic or English prepositions). The author and developer has a basic knowledge of Arabic in general, and an intermediate knowledge of Arabic grammar, which means that no intimate knowledge of Arabic was required to develop the language-specific components. This same author and developer recently started to adapt UALIGN to Chinese-English word alignment.

The alignment rate is still somewhat low. We plan to increase it by enlarging our development set beyond 100 sentences and adding further heuristics, as well as generalizing the output word alignment structure to allow alignments of words to larger constituents in a tree, and to explicitly assert that some words are not covered by the other side of a bitext to model poor translations and poor sentence alignments.

Acknowledgment

This research was supported under DARPA Contract No. HR0011-06-C-0022. The author would like to thank Kevin Knight and the anonymous reviewers for their helpful suggestions, and Steve DeNeefe for running the end-to-end MT evaluations.

Abstract

Combining information extraction systems yields significantly higher quality resources than each system in isolation. In this paper, we generalize such a mixing of sources and features in a framework called *Ensemble Semantics*. We show very large gains in entity extraction by combining state-of-the-art distributional and pattern-based systems with a large set of features from a webcrawl, query logs, and Wikipedia. Experimental results on a web-scale extraction of actors, athletes and musicians show significantly higher mean average precision scores (29% gain) compared with the current state of the art.

1 Introduction

Mounting evidence shows that combining information sources and information extraction algorithms leads to improvements in several tasks such as fact extraction (Paşca et al., 2006), open-domain IE (Talukdar et al., 2008), and entailment rule acquisition (Mirkin et al., 2006). In this paper, we show large gains in entity extraction by combining state-of-the-art distributional and pattern-based systems with a large set of features from a 600 million document webcrawl, one year of query logs, and a snapshot of Wikipedia. Further, we generalize such a mixing of sources and features in a framework called *Ensemble Semantics*.

Distributional and pattern-based extraction algorithms capture aspects of paradigmatic and syntagmatic dimensions of semantics, respectively, and are believed to be quite complementary. Paşca et al. (2006) showed that filtering facts, extracted by a pattern-based system, according to their arguments' distributional similarity with seed facts yielded large precision gains. Mirkin et al. (2006) showed similar gains on the task of acquiring lexical entailment rules by exploring a supervised combination of distributional and pattern-based algorithms using an ML-based SVM classifier.

This paper builds on the above work, by studying the impact of various sources of features external to distributional and pattern-based algorithms, on the task of entity extraction. Mirkin et al.'s results are corroborated on this task and large and significant gains over this baseline are obtained by incorporating 402 features from a webcrawl, query logs and Wikipedia. We extracted candidate entities for the classes *Actors*, *Athletes* and *Musicians* from a webcrawl using a variant of Paşca et al.'s (2006) pattern-based engine and Pantel et al.'s (2009) distributional extraction system. A gradient boosted decision tree is used to learn a regression function over the feature space for ranking the candidate entities. Experimental results show 29% gains (19% nominal) in mean average precision over Mirkin et al.'s method and 34% gains (22% nominal) in mean average precision over an unsupervised baseline similar to Paşca et al.'s method. Below we summarize the contributions of this paper:

- We explore the hypothesis that although distributional and pattern-based algorithms are complementary, they do not exhaust the semantic space; other sources of evidence can be leveraged to better combine them;
- We model the mixing of knowledge sources and features in a novel and general information extraction framework called *Ensemble Semantics*; and
- Experiments over an entity extraction task show that our model achieves large and significant gains over state-of-the-art extractors. A detailed analysis of feature correlations and interactions shows that query log and webcrawl features yield the highest gains, but easily accessible Wikipedia features also improve over current state-of-the-art systems.

Singapore, 6-7 August 2009.

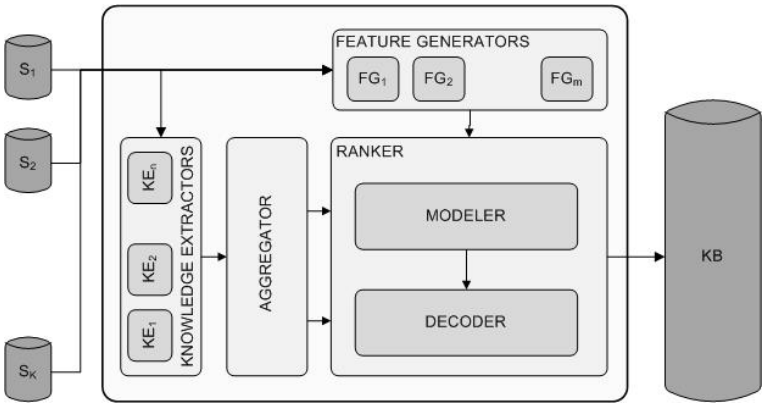

Figure 1: The *Ensemble Semantics* framework for information extraction.

The remainder of this paper is organized as follows. In the next section, we present our Ensemble Semantics framework and outline how various information extraction systems can be cast into the framework. Section 3 then presents our entity extraction system as an instance of Ensemble Semantics, comparing and contrasting it with previous information extraction systems. Our experimental methodology and analysis is described in Section 4 and shows empirical evidence that our extractor significantly outperforms prior art. Finally, Section 5 concludes with a discussion and future work.

2 Ensemble Semantics

Ensemble Semantics (ES) is a general framework for modeling information extraction algorithms that combine multiple sources of information and multiple extractors. The ES framework allows to:

- Represent multiple sources of knowledge and multiple extractors of that knowledge;
- Represent multiple sources of features;
- Integrate both rule-based and ML-based knowledge ranking algorithms; and
- Model previous information extraction systems (i.e., backwards compatibility).

2.1 ES Framework

ES can be instantiated to extract various types of knowledge such as entities, facts, and lexical entailment rules. It can also be used to better understand the commonalities and differences between existing information extraction systems.

After presenting the framework in the next section, Section 2.2 shows how previous information extraction algorithms can be cast into ES. In Section 3 we describe our novel entity extraction algorithm based on ES.

The ES framework is illustrated in Figure 1. It decomposes the process of information extraction into the following components:

Sources (S): textual repositories of information, either structured (e.g., a database such as DBpedia), semi-structured (e.g., Wikipedia Infoboxes or HTML tables) or unstructured (e.g., news articles or a webcrawl).

Knowledge Extractors (KE): algorithms responsible for extracting candidate instances such as entities or facts. Examples include fact extraction systems such as (Cafarella et al., 2005) and entity extraction systems such as (Paşca, 2007).

Feature Generators (FG): methods that extract evidence (features) of knowledge in order to decide which candidate instances extracted from KEs are correct. Examples include capitalization features for named entity extractors, and the distributional similarity matrix used in (Paşca et al., 2006) for filtering facts.

Aggregator (A). A module collecting and assembling the instances coming from the different extractors. This module keeps the *footprint* of each instance, i.e. the number and the type of the KEs that extracted the instance. This information can be used by the Ranker module to build a ranking strategy, as described below.

Ranker (R): a module for ranking the knowledge instances returned from KEs using the features generated by FGs. Ranking algorithms may be rule-based (e.g., the one using a threshold on distributional similarity in (Paşca et al., 2006)) or ML-based (e.g., the SVM model in (Mirkin et al., 2006) for combining pattern-based and distributional features).

The Ranker is composed of two sub-modules: the Modeler and the Decoder. The *Modeler* is responsible for creating the model which ranks the candidate instances. The *Decoder* collects the candidate instances from the Aggregator, and applies the model to produce the final ranking.

In rule-based systems, the Modeler corresponds to a set of manually crafted or automatically induced rules operating on the features (e.g. a combination of thresholds). In ML-based systems, it is an actual machine learning algorithm, that takes as input a set of labeled training instances, and builds the model according to their features. Training instances can be obtained as a subset of those collected by the Aggregator, or from some external resource. In many cases, training instances are manually labeled by human experts, through a long and costly editorial process.

Information sources (S) serve as inputs to the system. Some sources will serve as sources for knowledge extractors to generate candidate instances, some will serve as sources for feature generators to generate features or evidence of knowledge, and some will serve as both.

2.2 Related Work

To date, most information extraction systems rely on a model composed of a single source S, a single extractor KE and a single feature generator FG. For example, many classic relation extraction systems (Hearst, 1992; Riloff and Jones, 1999; Pantel and Pennacchiotti, 2006; Paşca et al., 2006) are based on a single pattern-based extractor KE, which is seeded with a set of patterns or instances for a given relation (e.g. the pattern *'X starred in Y'* for the *act-in* relation). The extractor then iteratively extracts new instances until a stop condition is met. The resulting extractor scores are proposed by FG as a feature. The *Ranker* simply consists of a sorting function on the feature from FG.

Systems such as the above that do not consist of multiple sources, knowledge extractors or feature generators are not considered Ensemble Semantics models, even though they can be cast into the framework. Recently, some researchers have explored more complex systems, having multiple sources, extractors and feature generators. Below we show examples and describe how they map as Ensemble Semantics systems. We use this characterization to clearly outline how our proposed entity extraction system, proposed in Section 3, differs from previous work.

Talukdar et al. (2008) present a weakly-supervised system for extracting large sets of class-instance pairs using two knowledge extractors: a pattern-based extractor supported by distributional evidence, which harvests candidate pairs from a Web corpus; and a table extractor that harvests candidates from Web tables. The *Ranker* uses graph random walks to combine the information of the two extractors and output the final list. The authors show large improvements in coverage with little precision loss.

Mirkin et al. (2006) introduce a machine learning system for extracting lists of lexical entailments (e.g. 'government' → 'organization'). They rely on two knowledge extractors, operating on a same large textual source: a pattern-based extractor, leveraging the Hearst (1992) *is-a* patterns; and a distributional extractor applied to a set of entailment seeds. Candidate instances are passed to an SVM *Ranker*, which uses features stemming from the two extractors, to decide which instances are output in the final list. The authors report a +9% increase in F-measure over a rule-based system that takes the union of the instances extracted by the two modules.

Other examples include the system for taxonomic-relation extraction by Cimiano et al. (2005), using a pool of feature generators based on pattern-based, distributional and WordNet techniques; and Paşca and Van Durme's (2008) system that uses a Web corpus and query logs to extract semantic classes and their attributes.

Similarly to these methods, our proposed entity extractor (Section 3) utilizes multiple sources and extractors. A key difference of our method lies in the Feature Generator module. We propose several generators resulting in 402 features extracted from Web pages, query logs and Wikipedia articles. The use of these features results in dramatic performance improvements, reported in Section 4.

3 ES for Entity Extraction

Entity extraction is a fundamental task in NLP responsible for extracting instances of semantic classes (e.g., *'Brad Pitt'* and *'Tom Hanks'* are instances of the class *Actors*). It forms a building block for various NLP tasks such as ontology learning (Cimiano and Staab, 2004) and co-reference resolution (Mc Carthy and Lehn-

Family	*Type*		*Features*
Web (w)	Frequency	(wF)	term frequency; document frequency; term frequency as noun phrase
	Pattern	(wP)	confidence score returned by KE_{pat}; pmi with the 100 most reliable patterns used by KE_{pat}
	Distributional	(wD)	distributional similarity with the centroid in KE_{dis}; distributional similarities with each seed in $\mathcal{S}$
	Termness	(wT)	ratio between term frequency as noun phrase and term frequency; pmi between internal tokens of the instance; capitalization ratio
Query log (q)	Frequency	(qF)	number of queries matching the instance; number of queries containing the instance
	Co-occurrence	(qC)	query log pmi with any seed in $\mathcal{S}$
	Pattern	(qP)	pmi with a set of trigger words $\mathcal{T}$ (i.e., the 10 words in the query logs with highest pmi with $\mathcal{S}$)
	Distributional	(qD)	distributional similarity with $\mathcal{S}$ (vector coordinates consist of the instance's pmi with the words in $\mathcal{T}$)
	Termness	(qT)	ratio between the two frequency features F
Web table (t)	Frequency	(tF)	table frequency
	Co-occurrence	(tC)	table pmi with $\mathcal{S}$; table pmi with any seed in $\mathcal{S}$
Wikipedia (k)	Frequency	(kF)	term frequency
	Co-occurrence	(kC)	pmi with any seed in $\mathcal{S}$
	Distributional	(kD)	distributional similarity with $\mathcal{S}$

Table 1: Feature space describing each candidate instance ($\mathcal{S}$ indicates the set of seeds for a given class).

ert, 2005). Search engines such as Yahoo, Live, and Google collect large sets of entities (Paşca, 2007; Chaudhuri et al., 2009) to better interpret queries (Tan and Peng, 2006), to improve query suggestions (Cao et al., 2008) and to understand query intents (Hu et al., 2009). Entity extraction differs from the similar task of named entity extraction, in that classes are more fine-grained and possibly overlapping.

Below, we propose a new method for entity extraction built on the ES framework (Section 3.1). Then, we comment on related work in entity extraction (Section 3.2).

3.1 ES Entity Extraction Model

In this section, we propose a novel entity extraction model following the Ensemble Semantics framework presented in Section 2. The sources of our systems can come from any textual corpus. In our experiments (described in Section 4.1), we extracted entities from a large crawl of the Web, and generated features from this crawl as well as query logs and Wikipedia.

3.1.1 Knowledge extractors

Our system relies on two knowledge extractors: one pattern-based and the other distributional.

Pattern-based extractor (KE_{pat}). We reimplemented Paşca et al.'s (2006) state-of-the-art web-scale fact extractor, which, given seed instances of a binary relation, finds instances of that relation. We extract entities of a class, such as *Actors*, by instantiating typical relations involving that class such as *act-in(Actor, Movie)*. We instantiate such relations instead of the classical *is-a* patterns since these have been shown to bring in too many false positives, see (Pantel and Pennacchiotti, 2006) for a discussion of such generic patterns. The extractor's confidence score for each instance is used by the *Ranker* to score the entities being extracted. Section 4.1 lists the system parameters we used in our experiments.

Distributional extractor (KE_{dis}). We use Pantel et al.'s (2009) distributional entity extractor. For each noun in our source corpus, we build a context vector consisting of the noun chunks preceding and following the target noun, scored using pointwise mutual information (pmi). Given a small set of seed entities $\mathcal{S}$ of a class, the extractor computes the centroid of the seeds' context vectors as a geometric mean, and then returns all nouns whose similarity with the centroid exceeds a threshold τ (using the cosine measure between the context vectors). Full algorithmic details are presented in (Pantel et al., 2009). Section 4.1 lists the threshold and text preprocessing algorithms used in our experiments.

The *Aggregator* simply takes a union of the entities discovered by the two extractors.

3.1.2 Feature generators

Our model includes four feature generators, which compute a total of 402 features (full set described in Table 1). Each generator extracts from a specific source a *feature family*, as follows:

- *Web (w)*: a body of 600 million documents

crawled from the Web at Yahoo! in 2008;

- *Query logs (q)*: one year of web search queries issued to the Yahoo! search engine;
- *Web tables*: all HTML inner tables extracted from the above *Web* source; and
- *Wikipedia*: an official Wikipedia dump from February 2008, consisting of about 2 million articles.

Feature families are further subclassified into five types: *frequency (F)* (frequency-based features); *co-occurrence (C)* (features capturing first order co-occurrences between an instance and class seeds); *distributional (D)* (features based on the distributional similarity between an instance and class seeds); *pattern (P)* (features indicating class-specific lexical pattern matches); and *termness (T)* (features used to distinguish well-formed terms such as *'Brad Pitt'* from ill-formed ones such as *'with Brad Pitt'*). The seeds $\mathcal{S}$ used in many of the feature families are the same seeds used by the KE_{pat} extractor, described in Section 3.1.1.

The different seed families are designed to capture different semantic aspects: paradigmatic (D), syntagmatic (C and P), popularity (F), and term cohesiveness (T).

3.1.3 ML-based Ranker

Our *Modeler* adopts a supervised ML regression model. Specifically, we use a Gradient Boosted Decision Tree regression model - GBDT (Friedman, 2001), which consists of an ensemble of decision trees, fitted in a forward step-wise manner to current residuals. Friedman (2001) shows that by drastically easing the problem of overfitting on training data (which is common in boosting algorithms), GDBT competes with state-of-the-art machine learning algorithms such as SVM (Friedman, 2006) with much smaller resulting models and faster decoding time. The model is trained on a manually annotated random sample of entities taken from the *Aggregator*, using the features generated by the four generators presented in Section 3.1.2. The *Decoder* then ranks each entity according to the trained model.

3.2 Related Work

Entity extraction systems follow two main approaches: pattern-based and distributional. The *pattern-based approach* leverages lexico-syntactic patterns to extract instances of a given class. Most commonly used are *is-a* pattern families such as those first proposed by Hearst (1992) (e.g., *'Y such as X'* for matching *'actors such as Brad Pitt'*). Minimal supervision is used in the form of small sets of manually provided seed patterns or seed instances. This approach is very common in both the NLP and Semantic Web communities (Cimiano and Staab, 2004; Cafarella et al., 2005; Pantel and Pennacchiotti, 2006; Paşca et al., 2006).

The *distributional approach* uses contextual evidence to model the instances of a given class, following the distributional hypothesis (Harris, 1964). Weakly supervised, these methods take a small set of seed instances (or the class label) and extract new instances from noun phrases that are most similar to the seeds (i.e., that share similar contexts). Following Lin (1998), example systems include Fleischman and Hovy (2002), Cimiano and Volker (2005), Tanev and Magnini (2006), and Pantel et al. (2009).

4 Experimental Evaluation

This section reports our experiments, showing the effectiveness of our entity extraction system and the importance of our different feature families.

4.1 Experimental Setup

Evaluated classes. We evaluate our system over three classes: *Actors* (movie, tv and stage actors); *Athletes* (professional and amateur); *Musicians* (singers, musicians, composers, bands, and orchestras)

System setup. We instantiated our knowledge extractors, KE_{pat} and KE_{dis} from Section 3.1.1, over our *Web* crawl of 600 million documents (see Section 3.1.2). The documents were preprocessed using Brill's POS-tagger (Brill, 1995) and the Abney's chunker (Abney, 1991). For $\boldsymbol{KE_{dis}}$, context vectors are extracted for noun phrases recognized as NP-chunks with removed modifiers. The vector space includes the 250M most frequent noun chunks in the corpus. KE_{dis} returns as instances all noun phrases having a similarity with the seeds' centroid above $\tau = 0.005$[1]. The sets of seeds $\mathcal{S}$ for KE_{dis} include 10, 24 and 10 manually chosen instances for respectively the *Actors*, *Athletes* and *Musicians* classes[2]. The sets of seeds $\mathcal{P}$ for KE_{pat}

[1] Experimentally set on an independent development set.

[2] The higher number of seeds for *Athletes* is chosen to cover different sports.

Dataset	*Actors*	*Athletes*	*Musicians*
KE_{pat}	58,005	40,816	125,657
KE_{dis}	72,659	24,380	24,593
$KE_{pat} \cup KE_{dis}$	113,245	61,709	142,694
$KE_{pat} \cap KE_{dis}$	17,419	3,487	7,556
$\mathcal{R}$	500	500	500
	P=80	*P=258*	*P=134*
	N=420	*N=242*	*N=366*

Table 2: Number of extracted instances and the sample sizes (P and N indicate positive and negative annotations).

include 11, 8 and 9 pairs respectively for the *Actors* (relation *acts-in*), *Athletes* (relation *plays-for*) and *Musicians* (relation *part-of-band*) classes. Table 6 lists all seeds for both KE_{dis} and KE_{pat}. The ***GBDT ranker*** uses an ensemble of 300 trees.[3]

Goldset Preparation. The number of instances extracted by KE_{pat} and KE_{dis} for each class is reported in Table 2. For each class, we extract a random sample $\mathcal{R}$ of 500 instances from $KE_{pat} \cup KE_{dis}$. A pool of 10 paid expert editors annotated the instances of each class in $\mathcal{R}$ as positive or negative. Inter-annotator overlap was 0.88. Uncertain instances were manually adjudicated by a separate paid expert editor, yielding a gold standard dataset for each class.

Evaluation Metrics. Entity extraction performance is evaluated using the *average precision* (AP) statistic, a standard information retrieval measure for evaluating ranking algorithms, defined as:

$$AP(L) = \frac{\sum_{i=1}^{|L|} P(i) \cdot corr(i)}{\sum_{i=1}^{|L|} corr(i)} \qquad (1)$$

where L is a ranked list produced by an extractor, $P(i)$ is the precision of L at rank i, and *corr(i)* is 1 if the instance at rank i is correct, and 0 otherwise. AP is computed over $\mathcal{R}$ for each class.

We also evaluate the *coverage*, i.e. the percentage of instances extracted by a system wrt those extracted by all systems.

In order to accurately compute statistical significance, our experiments are performed using 10-fold cross validation.

Baselines and comparisons. We compare our proposed ES entity extractor, using different feature configurations, with state-of-the-art systems (referred to as baselines *B** below):

[3]GBDT model parameters were experimentally set on an independent development set as follows: trees=300, shrinkage=0.01, max_nodes_per_tree=12, sample_rate=0.5.

System	Actors		Athletes		Musicians	
	AP	*Cov*	*AP*	*Cov*	*AP*	*Cov*
B1	0.729	51.2%	0.616	66.1%	0.570	88.1%
B2	0.618	64.1%	0.687	39.5%	0.681	17.2%
B3	0.676	100%	0.664	100%	0.576	100%
B4	0.715	100%	0.697	100%	0.579	100%
ES-all	**0.860**‡	100%	**0.915**‡	100%	**0.788**‡	100%

Table 3: Average precision (AP) and coverage (Cov) results for our proposed system *ES-all* and the baselines. ‡ indicates AP statistical significance at the 0.95 level wrt all baselines.

ES-all. Our ES system, using KE_{pat} and KE_{dis}, the full set of feature families described in Section 3.1.2, and the GBDT ranker.

B1. KE_{pat} alone, a state-of-the-art pattern-based extractor reimplementing (Paşca et al., 2006), where the *Ranker* assigns scores to instances using the confidence score returned by KE_{pat}.

B2. KE_{dis} alone, a state-of-the-art distributional system implementing (Pantel et al., 2009), where the *Ranker* assigns scores to instances using the similarity score returned by KE_{dis} alone.

B3. A rule-based ES system, combining *B1* and *B2*. This system uses both KE_{pat} and KE_{dis} as extractors, and a *Ranker* that assigns scores to instances according to the sum of their normalized confidence scores.

B4. A state-of-the-art machine learning system based on (Mirkin et al., 2006). This ES system uses KE_{pat} and KE_{dis} as extractors. The *Ranker* is a GBDT regression model, using the full sets of features derived from the two extractors, i.e., wP and wD (see Table 1). GBDT parameters are set as for our proposed *ES-all* system.

4.2 Experimental Results

Table 3 summarizes the average-precision (AP) and coverage results for our *ES-all* system and the baselines. Figure 2 reports the precision at each rank for the *Athletes* class (the other two classes follow similar trends). Table 6 lists the top-10 entities discovered for each class on one test fold. *ES-all* outperforms all baselines in AP (all results are statistically significant at the 0.95 level), offering at the same time full coverage[4].

[4]Recall that coverage is reported relative to all instances retrieved by extractors KE_{pat} and KE_{dis}.

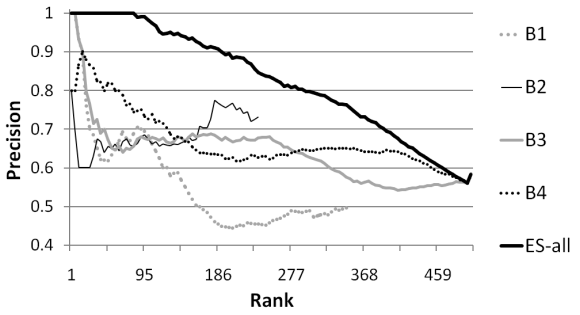

Figure 2: Precision at rank for the different systems on the *Athletes* class.

Es-all	$\mathbf{0.860}^{\ddagger}$	$0.915^{\ddagger}$	$\mathbf{0.788}^{\ddagger}$	$\mathbf{0.854}^{\ddagger}$

Table 4: Overall AP results of the different feature configurations, compared to two baselines. † indicates statistical significance at the 0.95 level wrt *B3*. ‡ indicates statistical significance at 0.95 level wrt both *B3* and *B4*.

Our simple rule-based combination baseline, *B3*, leads to a large increase in coverage wrt the individual extractors alone (*B1* and *B2*) without significant impact on precision. The supervised ML-based combination baseline (*B4*) consistently improves AP across classes wrt the rule-based combination (*B3*), but without statistical significance. These results corroborate those found in (Mirkin et al., 2006), where this ML-based combination was reported to be significantly better than a rule-based one on the task of lexical entailment acquisition.

The large set of features adopted in *ES-all* accounts for a dramatic improvement in AP, indicating that existing state-of-the-art systems for entity extraction (reflected by our baselines strategies) are not making use of enough semantic cues. The adoption of evidence other than distributional and pattern-based, such as features coming from web documents, HTML tables and query logs, is here demonstrated to be highly valuable.

The above empirical claim can be grounded and corroborated by a deeper semantic analysis. From a semantic perspective, the above results translate in the observation that distributional and pattern-based evidence do not completely capture all semantic aspects of entities. Other evidence, such as popularity, term cohesiveness and co-occurrences capture other aspects. For instance, in one of our *Actors* folds, the *B3* system ranks the incorrect instance *'Tom Sellek'* (a misspelling of *'Tom Selleck'*) in 9^{th} position (out of 142), while *ES-all* lowers it to the 33^{rd} position, by relying on table-based features (intuitively, tables contain much fewer misspelling than running text). Other than misspellings, *ES-all* fixes errors that are either typical of distributional approaches, such as the inclusion of instances of other classes (e.g. the movie *'Someone Like You'* often appears in contexts similar to those of *actors*); errors typical of pattern-based approaches, such as incorrect instances highly-associated with an ambiguous pattern (e.g., the pattern *'X of the rock band Y'* for finding *Musicians* matched an incorrect instance *'song submission'*); or errors typical of both, such as the inclusion of common nouns (e.g. *'country music hall'*) or too generic last names (e.g. *'Johnson'*). *ES-all* successfully recovers all these error by using termness, co-occurrence and frequency features.

We also compare *ES-all* with a state-of-the-art random walk system (*RW*) presented by Talukdar et al. (2008) (see Section 2.2 for a description). As we could not reimplement the system, we report the following indirect comparison. *RW* was evaluated on five entity classes, one of which, *NFL players*, overlaps with our *Athletes* class. On this class, they report 0.95 precision on the top-100 ranked entities. Unfortunately, they do not report coverage or recall statistics, making the interpretation of this analysis difficult. In an attempt to compare *RW* with *ES-all*, we evaluated the precision of our top-100 *Athletes*, obtaining 0.99. Using a random sample of our extracted *Athletes*, we approximate the precision of the top-22,000 *Athletes* to be 0.97 ± 0.01 (at the 0.95 level).

4.3 Feature Analysis

Feature family analysis: Table 4 reports the average precision (AP) for our system using different feature family combinations (see Table 1). Column 1 reports the family combinations; columns

2-4 report AP for each class; and column 5 reports the mean-average-precision (*MAP*) across classes. In all configurations, except the k family alone, and along all classes, our system significantly outperforms (at the 0.95 level) the baselines.

Rows 3-6 report the performance of each feature family alone. w and t are consistently better than q and k, across all classes. k is shown to be the least useful family. This is mostly due to data sparseness, e.g., in our experiments almost 40% of the test instances in the *Actors* sample do not have any occurrence in Wikipedia. However, without access to richer resources such as a webcrawl or query logs, the features from k do indeed provide large gains over current baselines (on average +10.2% and +7.7% over *B3* and *B4*).

Rows 7-12 report results for combinations of two feature families. All combinations (except those with k) appear valuable, substantially increasing the single-family results in rows 3-6, indicating that combining different feature families (as suggested by the ES paradigm) is helpful. Second, it indicates that q, w and t convey complementary information, thus boosting the regression model when combined together. It is interesting to notice that *q+t* tends to be the best combination, surprising given that t alone did not show high performance (row 5). One would expect the combination *q+w* to outperform *q+t*, but the good performance of *q+t* is mainly due to the fact that these two families are more complementary than *q+w*. To verify this intuition, we compute the Spearman correlation coefficient r among the rankings produced by the different combinations. As expected, *q* and *w* have a higher correlation ($r = 0.82$) than *q* and *t* ($r = 0.67$) and *w* and *t* ($r = 0.66$), suggesting that q and w tend to subsume each other (i.e. no added information for the regression model).

Rows 13-15 report results for combinations of three feature families. As expected, the best combination is *q+w+t* with an average precision nearly identical to the full *ES-all* system. If one has access to Web or query log sources, then the value of the Wikipedia features tends to be subsumed by our web and query log features.

Feature by feature analysis: The feature families analyzed in the previous section consist of 402 features. For each trained GBDT model, one can inspect the resulting most important features (Friedman, 2001). Consistently, the two most important features for *ES-all* are, as expected, the confidence scores of KE_{pat} and KE_{dis}. This suggests that syntagmatic and paradigmatic information are most important in defining the semantics of entities. Also very important, in third position, is a feature from qT, namely the ratio between the number of queries matching the instance and the number of queries containing it as a substring. This feature is a strong indicator of termness.

System	*AP*			*MAP*
	Actors	**Athletes**	**Musicians**	
B4	0.715	0.697	0.579	0.664
B4+**w**	**0.813**	**0.908**	**0.724**	**0.815**
B4+wF	0.798	0.865	0.679	0.781
B4+wT	0.806	0.891	0.717	0.805
B4+**t**	**0.784**	**0.825**	**0.727**	**0.779**
B4+tF	0.760	0.802	0.701	0.781
B4+tC	0.771	0.815	0.718	0.805
B4+**q**	**0.815**	**0.905**	**0.743**	**0.821**

B4+qF+qW+qT	0.816	0.906	0.743	0.822
ES-all	**0.860**	**0.915**	**0.788**	**0.854**

Table 5: Ablation study of the web (w), query-log (q) and table (t) features (bold letters indicate whole feature families).

Webcrawl term frequencies and document frequencies (from the wF set) are also important. Very frequent and infrequent instances were found to be often incorrect (e.g., respectively *'song'* and *'Brad Pitttt'*). Table PMI (a feature in the qC family) also ranked high in importance: instances that co-occurr very frequently in the same column/row with seeds $\mathcal{S}$ are often found to be correct (e.g., a column containing the seeds *'Brad Pitt'* and *'Tom Hanks'* will likely contains other actors). Other termness (T), frequency-based (F) and co-occurrence (C) features also play some role in the model.

Variable importance is only an intrinsic indicator of feature relevance. In order to better assess the actual impact of the single features on AP, we ran our system on each feature type: results for the web (w), query log (q) and table (t) families are reported in Table 5. For reason of space constraints, we here only focus on some high level observations. The set of web termness features (wT) and frequency features (wF) are alone able to provide a large improvement over *B4* (row 1), while their combination (row 2) does not improve much over the features taken individually.

Seed instances for KE_{dis}

Actors	Athletes			Musicians
Jodie Foster	Bob Gibson	Jared Allen	Randy Moss	Rise Against the Machine
Humphrey Bogart	Don Drysdale	Andres Romero	Peyton Manning	Pink Floyd

George Macready	Muhammad Bakri	Chad Kreuter	Robbie Alomar	*Doomwatch	John Moen

Table 6: Listing of all seeds used for KE_{dis} and KE_{pat}, as well as the top-10 entities discovered by *ES-all* on one of our test folds.

This suggests that wT and wF capture very similar information: they are indeed highly correlated ($r = 0.80$). Rows 5-7 refer to web table features: the features tC outperform and subsume the frequency features tF ($r = 0.92$). For query log features (rows 8-14), only qF, qP and qT significantly increase performance. Distributional and co-occurrence features (qD and qC) have very low effect, as they are mostly subsumed by the others. The combination of qF, qP and qT (row 14) performs as well as the whole ***q*** (row 8).

Experiment conclusions: From our experiments, we can draw the following conclusions:

1. Wikipedia features taken alone outperform the baselines, however, web and query log features, if available, subsume Wikipedia features;

2. q, t and w are all important, and should be used in combination, as they drive mostly independent information;

3. the syntagmatic and paradigmatic information conveyed by the two extractors are most relevant, and can be significantly boosted by adding frequency- and termness-based features from other sources.

5 Conclusions and Future Work

In this paper, we presented a general information extraction framework, called Ensemble Semantics, for combining multiple sources of knowledge, and we instantiated the framework to build a novel ML-based entity extraction system. The system significantly outperforms state-of-the-art ones by up to 22% in mean average precision. We provided an in-depth analysis of the impact of our proposed 402 features, their feature families (Web documents, HTML tables, query logs, and Wikipedia), and feature types.

There is ample directions for future work. On entity extraction, exploring more knowledge extractors from different sources (such as the HTML tables and query log sources used for our features) is promising. Other feature types may potentially capture other aspects of the semantics of entities, such as WordNet and search engine click logs. For the ranking system, semi- or weakly-supervised algorithms may provide competing performance to our model with reduced manual labor. Finally, there are many opportunities for applying the general Ensemble Semantics framework to other information extraction tasks such as fact extraction and event extraction.

Labeled LDA: A supervised topic model for credit attribution in multi-labeled corpora

Daniel Ramage, David Hall, Ramesh Nallapati and Christopher D. Manning

Stanford University
{dramage,dlwh,nmramesh,manning}@cs.stanford.edu

Abstract

A significant portion of the world's text is tagged by readers on social bookmarking websites. *Credit attribution* is an inherent problem in these corpora because most pages have multiple tags, but the tags do not always apply with equal specificity across the whole document. Solving the credit attribution problem requires associating each word in a document with the most appropriate tags and vice versa. This paper introduces *Labeled LDA*, a topic model that constrains Latent Dirichlet Allocation by defining a one-to-one correspondence between LDA's latent topics and user tags. This allows Labeled LDA to directly learn word-tag correspondences. We demonstrate Labeled LDA's improved expressiveness over traditional LDA with visualizations of a corpus of tagged web pages from *del.icio.us*. Labeled LDA outperforms SVMs by more than 3 to 1 when extracting tag-specific document snippets. As a multi-label text classifier, our model is competitive with a discriminative baseline on a variety of datasets.

1 Introduction

From news sources such as *Reuters* to modern community web portals like *del.icio.us*, a significant proportion of the world's textual data is labeled with multiple human-provided tags. These collections reflect the fact that documents are often about more than one thing—for example, a news story about a highway transportation bill might naturally be filed under both *transportation* and *politics*, with neither category acting as a clear subset of the other. Similarly, a single web page in *del.icio.us* might well be annotated with tags as diverse as *arts*, *physics*, *alaska*, and *beauty*.

However, not all tags apply with equal specificity across the whole document, opening up new opportunities for information retrieval and corpus analysis on tagged corpora. For instance, users who browse for documents with a particular tag might prefer to see summaries that focus on the portion of the document most relevant to the tag, a task we call *tag-specific snippet extraction*. And when a user browses to a particular document, a tag-augmented user interface might provide overview visualization cues highlighting which portions of the document are more or less relevant to the tag, helping the user quickly access the information they seek.

One simple approach to these challenges can be found in models that explicitly address the *credit attribution* problem by associating individual words in a document with their most appropriate labels. For instance, in our news story about the transportation bill, if the model knew that the word "highway" went with *transportation* and that the word "politicians" went with *politics*, more relevant passages could be extracted for either label. We seek an approach that can automatically learn the posterior distribution of each word in a document conditioned on the document's label set.

One promising approach to the credit attribution problem lies in the machinery of Latent Dirichlet Allocation (LDA) (Blei et al., 2003), a recent model that has gained popularity among theoreticians and practitioners alike as a tool for automatic corpus summarization and visualization. LDA is a completely unsupervised algorithm that models each document as a mixture of topics. The model generates automatic summaries of topics in terms of a discrete probability distribution over words for each topic, and further infers per-document discrete distributions over topics. Most importantly, LDA makes the explicit assumption that each word is generated from one underlying topic.

Although LDA is expressive enough to model

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 248–256,
Singapore, 6-7 August 2009.

multiple topics per document, it is not appropriate for multi-labeled corpora because, as an unsupervised model, it offers no obvious way of incorporating a supervised label set into its learning procedure. In particular, LDA often learns some topics that are hard to interpret, and the model provides no tools for tuning the generated topics to suit an end-use application, even when time and resources exist to provide some document labels.

Several modifications of LDA to incorporate supervision have been proposed in the literature. Two such models, Supervised LDA (Blei and McAuliffe, 2007) and DiscLDA (Lacoste-Julien et al., 2008) are inappropriate for multiply labeled corpora because they limit a document to being associated with only a single label. Supervised LDA posits that a label is generated from each document's empirical topic mixture distribution. DiscLDA associates a single categorical label variable with each document and associates a topic mixture with each label. A third model, MM-LDA (Ramage et al., 2009), is not constrained to one label per document because it models each document as a bag of words with a bag of labels, with topics for each observation drawn from a shared topic distribution. But, like the other models, MM-LDA's learned topics do not correspond directly with the label set. Consequently, these models fall short as a solution to the credit attribution problem. Because labels have meaning to the people that assigned them, a simple solution to the credit attribution problem is to assign a document's words to its labels rather than to a latent and possibly less interpretable semantic space.

This paper presents *Labeled LDA* (L-LDA), a generative model for multiply labeled corpora that marries the multi-label supervision common to modern text datasets with the word-assignment ambiguity resolution of the LDA family of models. In contrast to standard LDA and its existing supervised variants, our model associates each label with one topic in direct correspondence. In the following section, L-LDA is shown to be a natural extension of both LDA (by incorporating supervision) and Multinomial Naive Bayes (by incorporating a mixture model). We demonstrate that L-LDA can go a long way toward solving the credit attribution problem in multiply labeled documents with improved interpretability over LDA (Section 4). We show that L-LDA's credit attribution ability enables it to greatly outperform support vector machines on a tag-driven snippet extraction task on web pages from *del.icio.us* (Section 6). And despite its generative semantics, we show that Labeled LDA is competitive with a strong baseline discriminative classifier on two multi-label text classification tasks (Section 7).

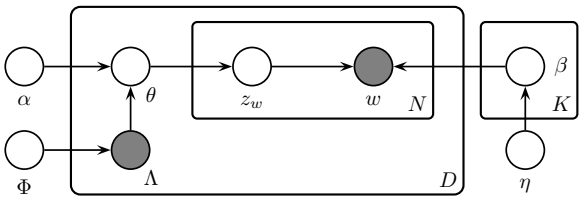

Figure 1: Graphical model of Labeled LDA: unlike standard LDA, both the label set $\mathbf{\Lambda}$ as well as the topic prior $\boldsymbol{\alpha}$ influence the topic mixture $\boldsymbol{\theta}$.

2 Labeled LDA

Labeled LDA is a probabilistic graphical model that describes a process for generating a labeled document collection. Like Latent Dirichlet Allocation, Labeled LDA models each document as a mixture of underlying topics and generates each word from one topic. Unlike LDA, L-LDA incorporates supervision by simply constraining the topic model to use only those topics that correspond to a document's (observed) label set. The model description that follows assumes the reader is familiar with the basic LDA model (Blei et al., 2003).

Let each document d be represented by a tuple consisting of a list of word indices $\mathbf{w}^{(d)} = (w_1, \ldots, w_{N_d})$ and a list of binary topic presence/absence indicators $\mathbf{\Lambda}^{(d)} = (l_1, \ldots, l_K)$ where each $w_i \in \{1, \ldots, V\}$ and each $l_k \in \{0, 1\}$. Here N_d is the document length, V is the vocabulary size and K the total number of unique labels in the corpus.

We set the number of topics in Labeled LDA to be the number of unique labels K in the corpus. The generative process for the algorithm is found in Table 1. Steps 1 and 2—drawing the multinomial topic distributions over vocabulary $\boldsymbol{\beta}_k$ for each topic k, from a Dirichlet prior $\boldsymbol{\eta}$—remain the same as for traditional LDA (see (Blei et al., 2003), page 4). The traditional LDA model then draws a multinomial mixture distribution $\boldsymbol{\theta}^{(d)}$ over all K topics, for each document d, from a Dirichlet prior $\boldsymbol{\alpha}$. However, we would like to restrict $\boldsymbol{\theta}^{(d)}$ to be defined only over the topics that correspond to

1 For each topic $k \in \{1, \ldots, K\}$:
2 Generate $\boldsymbol{\beta}_k = (\beta_{k,1}, \ldots, \beta_{k,V})^T \sim \text{Dir}(\cdot|\boldsymbol{\eta})$
3 For each document d:
4 For each topic $k \in \{1, \ldots, K\}$
5 Generate $\Lambda_k^{(d)} \in \{0, 1\} \sim \text{Bernoulli}(\cdot|\Phi_k)$
6 Generate $\boldsymbol{\alpha}^{(d)} = L^{(d)} \times \boldsymbol{\alpha}$
7 Generate $\boldsymbol{\theta}^{(d)} = (\theta_{l_1}, \ldots, \theta_{l_{M_d}})^T \sim \text{Dir}(\cdot|\boldsymbol{\alpha}^{(d)})$
8 For each i in $\{1, \ldots, N_d\}$:
9 Generate $z_i \in \{\lambda_1^{(d)}, \ldots, \lambda_{M_d}^{(d)}\} \sim \text{Mult}(\cdot|\boldsymbol{\theta}^{(d)})$
10 Generate $w_i \in \{1, \ldots, V\} \sim \text{Mult}(\cdot|\boldsymbol{\beta}_{z_i})$

Table 1: Generative process for Labeled LDA: $\boldsymbol{\beta}_k$ is a vector consisting of the parameters of the multinomial distribution corresponding to the k^{th} topic, $\boldsymbol{\alpha}$ are the parameters of the Dirichlet topic prior and $\boldsymbol{\eta}$ are the parameters of the word prior, while Φ_k is the label prior for topic k. For the meaning of the projection matrix $L^{(d)}$, please refer to Eq 1.

its labels $\boldsymbol{\Lambda}^{(d)}$. Since the word-topic assignments z_i (see step 9 in Table 1) are drawn from this distribution, this restriction ensures that all the topic assignments are limited to the document's labels.

Towards this objective, we first generate the document's labels $\boldsymbol{\Lambda}^{(d)}$ using a Bernoulli coin toss for each topic k, with a labeling prior probability Φ_k, as shown in step 5. Next, we define the vector of document's labels to be $\boldsymbol{\lambda}^{(d)} = \{k|\Lambda_k^{(d)} = 1\}$. This allows us to define a document-specific label projection matrix $L^{(d)}$ of size $M_d \times K$ for each document d, where $M_d = |\boldsymbol{\lambda}^{(d)}|$, as follows: For each row $i \in \{1, \ldots, M_d\}$ and column $j \in \{1, \ldots, K\}$:

$$L_{ij}^{(d)} = \begin{cases} 1 & \text{if } \lambda_i^{(d)} = j \\ 0 & \text{otherwise.} \end{cases} \quad (1)$$

In other words, the i^{th} row of $L^{(d)}$ has an entry of 1 in column j if and only if the i^{th} document label $\lambda_i^{(d)}$ is equal to the topic j, and zero otherwise. As the name indicates, we use the $L^{(d)}$ matrix to project the parameter vector of the Dirichlet topic prior $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_K)^T$ to a lower dimensional vector $\boldsymbol{\alpha}^{(d)}$ as follows:

$$\boldsymbol{\alpha}^{(d)} = L^{(d)} \times \boldsymbol{\alpha} = (\alpha_{\lambda_1^{(d)}}, \ldots, \alpha_{\lambda_{M_d}^{(d)}})^T \quad (2)$$

Clearly, the dimensions of the projected vector correspond to the topics represented by the labels of the document. For example, suppose $K = 4$ and that a document d has labels given by $\boldsymbol{\Lambda}^{(d)} = \{0, 1, 1, 0\}$ which implies $\boldsymbol{\lambda}^{(d)} = \{2, 3\}$, then $L^{(d)}$ would be:

$$\begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix}.$$

Then, $\boldsymbol{\theta}^{(d)}$ is drawn from a Dirichlet distribution with parameters $\boldsymbol{\alpha}^{(d)} = L^{(d)} \times \boldsymbol{\alpha} = (\alpha_2, \alpha_3)^T$ (i.e., with the Dirichlet restricted to the topics 2 and 3).

This fulfills our requirement that the document's topics are restricted to its own labels. The projection step constitutes the deterministic step 6 in Table 1. The remaining part of the model from steps 7 through 10 are the same as for regular LDA.

The dependency of $\boldsymbol{\theta}$ on both $\boldsymbol{\alpha}$ and $\boldsymbol{\Lambda}$ is indicated by directed edges from $\boldsymbol{\Lambda}$ and $\boldsymbol{\alpha}$ to $\boldsymbol{\theta}$ in the plate notation in Figure 1. This is the only additional dependency we introduce in LDA's representation (please compare with Figure 1 in (Blei et al., 2003)).

2.1 Learning and inference

In most applications discussed in this paper, we will assume that the documents are multiply tagged with human labels, both at learning and inference time.

When the labels $\boldsymbol{\Lambda}^{(d)}$ of the document are observed, the labeling prior Φ is d-separated from the rest of the model given $\boldsymbol{\Lambda}^{(d)}$. Hence the model is same as traditional LDA, except the constraint that the topic prior $\boldsymbol{\alpha}^{(d)}$ is now restricted to the set of labeled topics $\boldsymbol{\lambda}^{(d)}$. Therefore, we can use collapsed Gibbs sampling (Griffiths and Steyvers, 2004) for training where the sampling probability for a topic for position i in a document d in Labeled LDA is given by:

$$P(z_i = j|\mathbf{z}_{-i}) \propto \frac{n_{-i,j}^{w_i} + \eta_{w_i}}{n_{-i,j}^{(\cdot)} + \boldsymbol{\eta}^T\mathbf{1}} \times \frac{n_{-i,j}^{(d)} + \alpha_j}{n_{-i,\cdot}^{(d)} + \boldsymbol{\alpha}^T\mathbf{1}} \quad (3)$$

where $n_{-i,j}^{w_i}$ is the count of word w_i in topic j, that does not include the current assignment z_i, a missing subscript or superscript (e.g. $n_{-i,j}^{(\cdot)}$)) indicates a summation over that dimension, and $\mathbf{1}$ is a vector of 1's of appropriate dimension.

Although the equation above looks exactly the same as that of LDA, we have an important distinction in that, the target topic j is restricted to belong to the set of labels, i.e., $j \in \boldsymbol{\lambda}^{(d)}$.

Once the topic multinomials $\boldsymbol{\beta}$ are learned from the training set, one can perform inference on any new labeled test document using Gibbs sampling

restricted to its tags, to determine its per-word label assignments $\mathbf{z}$. In addition, one can also compute its posterior distribution $\boldsymbol{\theta}$ over topics by appropriately normalizing the topic assignments $\mathbf{z}$.

It should now be apparent to the reader how the new model addresses some of the problems in multi-labeled corpora that we highlighted in Section 1. For example, since there is a one-to-one correspondence between the labels and topics, the model can display automatic topical summaries for each label k in terms of the topic-specific distribution $\boldsymbol{\beta}_k$. Similarly, since the model assigns a label z_i to each word w_i in the document d automatically, we can now extract portions of the document relevant to each label k (it would be all words $w_i \in \mathbf{w}^{(d)}$ such that $z_i = k$). In addition, we can use the topic distribution $\boldsymbol{\theta}^{(d)}$ to rank the user specified labels in the order of their relevance to the document, thereby also eliminating spurious ones if necessary.

Finally, we note that other less restrictive variants of the proposed L-LDA model are possible. For example, one could consider a version that allows topics that do not correspond to the label set of a given document with a small probability, or one that allows a common background topic in all documents. We did implement these variants in our preliminary experiments, but they did not yield better performance than L-LDA in the tasks we considered. Hence we do not report them in this paper.

2.2 Relationship to Naive Bayes

The derivation of the algorithm so far has focused on its relationship to LDA. However, Labeled LDA can also be seen as an extension of the event model of a traditional Multinomial Naive Bayes classifier (McCallum and Nigam, 1998) by the introduction of a mixture model. In this section, we develop the analogy as another way to understand L-LDA from a supervised perspective.

Consider the case where no document in the collection is assigned two or more labels. Now for a particular document d with label l_d, Labeled LDA draws each word's topic variable z_i from a multinomial constrained to the document's label set, i.e. $z_i = l_d$ for each word position i in the document. During learning, the Gibbs sampler will assign each z_i to l_d while incrementing $\beta_{l_d}(w_i)$, effectively counting the occurences of each word type in documents labeled with l_d. Thus in the singly labeled document case, the probability of each document under Labeled LDA is equal to the probability of the document under the Multinomial Naive Bayes event model trained on those same document instances. Unlike the Multinomial Naive Bayes classifier, Labeled LDA does not encode a decision boundary for unlabeled documents by comparing $P(\mathbf{w}^{(d)}|l_d)$ to $P(\mathbf{w}^{(d)}|\neg l_d)$, although we discuss using Labeled LDA for multi-label classification in Section 7.

Labeled LDA's similarity to Naive Bayes ends with the introduction of a second label to any document. In a traditional one-versus-rest Multinomial Naive Bayes model, a separate classifier for each label would be trained on all documents with that label, so each word can contribute a count of 1 to every observed label's word distribution. By contrast, Labeled LDA assumes that each document is a mixture of underlying topics, so the count mass of single word instance must instead be distributed over the document's observed labels.

3 Credit attribution within tagged documents

Social bookmarking websites contain millions of tags describing many of the web's most popular and useful pages. However, not all tags are uniformly appropriate at all places within a document. In the sections that follow, we examine mechanisms by which Labeled LDA's credit assignment mechanism can be utilized to help support browsing and summarizing tagged document collections.

To create a consistent dataset for experimenting with our model, we selected 20 tags of medium to high frequency from a collection of documents dataset crawled from *del.icio.us*, a popular social bookmarking website (Heymann et al., 2008). From that larger dataset, we selected uniformly at random four thousand documents that contained at least one of the 20 tags, and then filtered each document's tag set by removing tags not present in our tag set. After filtering, the resulting corpus averaged 781 non-stop words per document, with each document having 4 distinct tags on average. In contrast to many existing text datasets, our tagged corpus is highly multiply labeled: almost 90% of of the documents have more than one tag. (For comparison, less than one third of the news documents in the popular RCV1-v2 collection of newswire are multiply labeled). We will refer to

this collection of data as the del.icio.us tag dataset.

4 Topic Visualization

A first question we ask of Labeled LDA is how its topics compare with those learned by traditional LDA on the same collection of documents. We ran our implementations of Labeled LDA and LDA on the del.icio.us corpus described above. Both are based on the standard collapsed Gibbs sampler, with the constraints for Labeled LDA implemented as in Section 2.

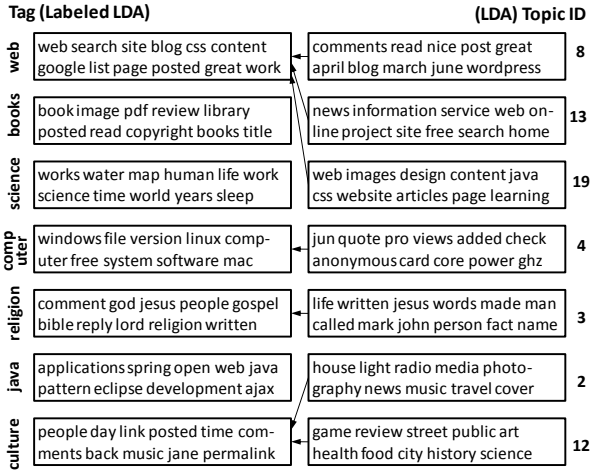

Figure 2: Comparison of some of the 20 topics learned on del.icio.us by Labeled LDA (left) and traditional LDA (right), with representative words for each topic shown in the boxes. Labeled LDA's topics are named by their associated tag. Arrows from right-to-left show the mapping of LDA topics to the closest Labeled LDA topic by cosine similarity. Tags not shown are: *design*, *education*, *english*, *grammar*, *history*, *internet*, *language*, *philosophy*, *politics*, *programming*, *reference*, *style*, *writing*.

Figure 2 shows the top words associated with 20 topics learned by Labeled LDA and 20 topics learned by unsupervised LDA on the del.icio.us document collection. Labeled LDA's topics are directly named with the tag that corresponds to each topic, an improvement over standard practice of inferring the topic name by inspection (Mei et al., 2007). The topics learned by the unsupervised variant were matched to a Labeled LDA topic highest cosine similarity.

The topics selected are representative: compared to Labeled LDA, unmodified LDA allocates many topics for describing the largest parts of the corpus and under-represents tags that are less uncommon: of the 20 topics learned, LDA learned multiple topics mapping to each of five tags (*web*, *culture*, and *computer*, *reference*, and *politics*, all of which were common in the dataset) and learned no topics that aligned with six tags (*books*, *english*, *science*, *history*, *grammar*, *java*, and *philosophy*, which were rarer).

The Elements of Style, William Strunk, Jr.

Asserting that one must first know the rules to break them, this classic reference book is a must-have for any student and conscientious writer. Intended for use in which the practice of composition is combined with the study of literature, it gives in brief space the principal requirements of plain English style and concentrates attention on the rules of usage and principles of composition most commonly violated.

Figure 3: Example document with important words annotated with four of the page's tags as learned by Labeled LDA. Red (single underline) is *style*, green (dashed underline) *grammar*, blue (double underline) *reference*, and black (jagged underline) *education*.

5 Tagged document visualization

In addition to providing automatic summaries of the words best associated with each tag in the corpus, Labeled LDA's credit attribution mechanism can be used to augment the view of a single document with rich contextual information about the document's tags.

Figure 3 shows one web document from the collection, a page describing a guide to writing English prose. The 10 most common tags for that document are *writing, reference, english, grammar, style, language, books, book, strunk*, and *education*, the first eight of which were included in our set of 20 tags. In the figure, each word that has high posterior probability from one tag has been annotated with that tag. The red words come from the *style* tag, green from the *grammar* tag, blue from the *reference* tag, and black from the *education* tag. In this case, the model does very well at assigning individual words to the tags that, subjectively, seem to strongly imply the presence of that tag on this page. A more polished rendering could add subtle visual cues about which parts of a page are most appropriate for a particular set of tags.

Figure 4: Representative snippets extracted by L-LDA and tag-specific SVMs for the web page shown in Figure 3.

6 Snippet Extraction

Another natural application of Labeled LDA's credit assignment mechanism is as a means of selecting snippets of a document that best describe its contents from the perspective of a particular tag. Consider again the document in Figure 3. Intuitively, if this document were shown to a user interested in the tag *grammar*, the most appropriate snippet of words might prefer to contain the phrase "rules of usage," whereas a user interested in the term *style* might prefer the title "Elements of Style."

To quantitatively evaluate Labeled LDA's performance at this task, we constructed a set of 29 recently tagged documents from del.icio.us that were labeled with two or more tags from the 20 tag subset, resulting in a total of 149 (document,tag) pairs. For each pair, we extracted a 15-word window with the highest tag-specific score from the document. Two systems were used to score each window: Labeled LDA and a collection of one-vs-rest SVMs trained for each tag in the system. L-LDA scored each window as the expected probability that the tag had generated each word. For SVMs, each window was taken as its own document and scored using the tag-specific SVM's un-thresholded scoring function, taking the window with the most positive score. While a complete solution to the tag-specific snippet extraction problem might be more informed by better linguistic features (such as phrase boundaries), this experimental setup suffices to evaluate both kinds of models for their ability to appropriately assign words to underlying labels.

Model	Best Snippet	Unanimous
L-LDA	**72 / 149**	24 / 51
SVM	21 / 149	2 / 51

Table 2: Human judgments of tag-specific snippet quality as extracted by L-LDA and SVM. The center column is the number of document-tag pairs for which a system's snippet was judged superior. The right column is the number of snippets for which all three annotators were in complete agreement (numerator) in the subset of document scored by all three annotators (denominator).

Figure 3 shows some example snippets output by our system for this document. Note that while SVMs did manage to select snippets that were vaguely on topic, Labeled LDA's outputs are generally of superior subjective quality. To quantify this intuition, three human annotators rated each pair of snippets. The outputs were randomly labeled as "System A" or "System B," and the annotators were asked to judge which system generated a better tag-specific document subset. The judges were also allowed to select neither system if there was no clear winner. The results are summarized in Table 2.

L-LDA was judged superior by a wide margin: of the 149 judgments, L-LDA's output was selected as preferable in 72 cases, whereas SVM's was selected in only 21. The difference between these scores was highly significant ($p < .001$) by the sign test. To quantify the reliability of the judgments, 51 of the 149 document-tag pairs were labeled by all three annotators. In this group, the judgments were in substantial agreement,[1] with Fleiss' Kappa at .63.

Further analysis of the triply-annotated subset yields further evidence of L-LDA's advantage over SVM's: 33 of the 51 were tag-page pairs where L-LDA's output was picked by at least one annotator as a better snippet (although L-LDA might not have been picked by the other annotators). And of those, 24 were unanimous in that

[1] Of the 15 judgments that were in contention, only two conflicted on *which* system was superior (L-LDA versus SVM); the remaining disagreements were about whether or not one of the systems was a clear winner.

all three judges selected L-LDA's output. By contrast, only 10 of the 51 were tag-page pairs where SVMs' output was picked by at least one annotator, and of those, only 2 were selected unanimously.

7 Multilabeled Text Classification

In the preceding section we demonstrated how Labeled LDA's credit attribution mechanism enabled effective modeling within documents. In this section, we consider whether L-LDA can be adapted as an effective multi-label classifier for documents as a whole. To answer that question, we applied a modified variant of L-LDA to a multi-label document classification problem: given a training set consisting of documents with multiple labels, predict the set of labels appropriate for each document in a test set.

Multi-label classification is a well researched problem. Many modern approaches incorporate label correlations (e.g., Kazawa et al. (2004), Ji et al. (2008)). Others, like our algorithm are based on mixture models (such as Ueda and Saito (2003)). However, we are aware of no methods that trade off label-specific word distributions with document-specific label distributions in quite the same way.

In Section 2, we discussed learning and inference when labels are observed. In the task of multilabel classification, labels are available at training time, so the learning part remains the same as discussed before. However, inferring the best set of labels for an unlabeled document at test time is more complex: it involves assessing all label assignments and returning the assignment that has the highest posterior probability. However, this is not straight-forward, since there are 2^K possible label assignments. To make matters worse, the support of $\boldsymbol{\alpha}(\Lambda^{(d)})$ is different for different label assignments. Although we are in the process of developing an efficient sampling algorithm for this inference, for the purposes of this paper we make the simplifying assumption that the model reduces to standard LDA at inference, where the document is free to sample from any of the K topics. This is a reasonable assumption because allowing the model to explore the whole topic space for each document is similar to exploring all possible label assignments. The document's most likely labels can then be inferred by suitably thresholding its posterior probability over topics.

As a baseline, we use a set of multiple one-vs-rest SVM classifiers which is a popular and extremely competitive baseline used by most previous papers (see (Kazawa et al., 2004; Ueda and Saito, 2003) for instance). We scored each model based on Micro-F1 and Macro-F1 as our evaluation measures (Lewis et al., 2004). While the former allows larger classes to dominate its results, the latter assigns an equal weight to all classes, providing us complementary information.

7.1 Yahoo

We ran experiments on a corpus from the Yahoo directory, modeling our experimental conditions on the ones described in (Ji et al., 2008).[2] We considered documents drawn from 8 top level categories in the Yahoo directory, where each document can be placed in any number of subcategories. The results were mixed, with SVMs ahead on one measure: Labeled LDA beat SVMs on five out of eight datasets on MacroF1, but didn't win on any datasets on MicroF1. Results are presented in Table 3.

Because only a processed form of the documents was released, the Yahoo dataset does not lend itself well to error analysis. However, only 33% of the documents in each top-level category were applied to more than one sub-category, so the credit assignment machinery of L-LDA was unused for the majority of documents. We therefore ran an artificial second set of experiments considering only those documents that had been given more than one label in the training data. On these documents, the results were again mixed, but Labeled LDA comes out ahead. For MacroF1, L-LDA beat SVMs on four datasets, SVMs beat L-LDA on one dataset, and three were a statistical tie.[3] On MicroF1, L-LDA did much better than on the larger subset, outperforming on four datasets with the other four a statistical tie.

It is worth noting that the Yahoo datasets are skewed by construction to contain many documents with highly overlapping content: because each collection is within the same super-class such as "Arts", "Business", etc., each sub-categories'

[2] We did not carefully tune per-class thresholds of each of the one vs. rest classifiers in each model, but instead tuned only one threshold for all classifiers in each model via cross-validation on the Arts subsets. As such, our numbers were on an average 3-4% less than those reported in (Ji et al., 2008), but the methods were comparably tuned.

[3] The difference between means of multiple runs were not significantly different by two-tailed paired t-test.

Dataset	%MacroF1		%MicroF1	
	L-LDA	SVM	L-LDA	SVM
Arts	30.70(1.62)	23.23 (0.67)	39.81(1.85)	48.42 (0.45)
Business	30.81(0.75)	22.82 (1.60)	67.00(1.29)	72.15 (0.62)
Computers	27.55(1.98)	18.29 (1.53)	48.95(0.76)	61.97 (0.54)
Education	33.78(1.70)	36.03 (1.30)	41.19(1.48)	59.45 (0.56)
Entertainment	39.42(1.38)	43.22 (0.49)	47.71(0.61)	62.89 (0.50)
Health	45.36(2.00)	47.86 (1.72)	58.13(0.43)	72.21 (0.26)
Recreation	37.63(1.00)	33.77 (1.17)	43.71(0.31)	59.15 (0.71)
Society	27.32(1.24)	23.89 (0.74)	42.98(0.28)	52.29 (0.67)

Table 3: Averaged performance across ten runs of multi-label text classification for predicting subsets of the named Yahoo directory categories. Numbers in parentheses are standard deviations across runs. L-LDA outperforms SVMs on 5 subsets with MacroF1, but on no subsets with MicroF1.

vocabularies will naturally overlap a great deal. L-LDA's credit attribution mechanism is most effective at partitioning semantically distinct words into their respective label vocabularies, so we expect that Labeled-LDA's performance as a text classifier would improve on collections with more semantically diverse labels.

7.2 Tagged Web Pages

We also applied our method to text classification on the del.icio.us dataset, where the documents are naturally multiply labeled (more than 89%) and where the tags are less inherently similar than in the Yahoo subcategories. Therefore we expect Labeled LDA to do better credit assignment on this subset and consequently to show improved performance as a classifier, and indeed this is the case.

We evaluated L-LDA and multiple one-vs-rest SVMs on 4000 documents with the 20 tag subset described in Section 3. L-LDA and multiple one-vs-rest SVMs were trained on the first 80% of documents and evaluated on the remaining 20%, with results averaged across 10 random permutations of the dataset. The results are shown in Table 4. We tuned the SVMs' shared cost parameter $C(= 10.0)$ and selected raw term frequency over tf-idf weighting based on 4-fold cross-validation on 3,000 documents drawn from an independent permutation of the data. For L-LDA, we tuned the shared parameters of threshold and proportionality constants in word and topic priors. L-LDA and SVM have very similar performance on MacroF1, while L-LDA substantially outperforms on MicroF1. In both cases, L-LDA's improvement is statistically significantly by a 2-tailed paired t-test at 95% confidence.

Model	%MacroF1	%MicroF1
L-LDA	**39.85** (.989)	**52.12** (.434)
SVM	39.00 (.423)	39.33 (.574)

Table 4: Mean performance across ten runs of multi-label text classification for predicting 20 tags on del.icio.us data. L-LDA outperforms SVMs significantly on both metrics by a 2-tailed, paired t-test at 95% confidence.

8 Discussion

One of the main advantages of L-LDA on multiply labeled documents comes from the model's document-specific topic mixture θ. By explicitly modeling the importance of each label in the document, Labeled LDA can effective perform some contextual word sense disambiguation, which suggests why L-LDA can outperform SVMs on the del.icio.us dataset.

As a concrete example, consider the excerpt of text from the *del.icio.us* dataset in Figure 5. The document itself has several tags, including *design* and *programming*. Initially, many of the likelihood probabilities $p(w|label)$ for the (content) words in this excerpt are higher for the label *programming* than *design*, including "content", "client", "CMS" and even "designed", while *design* has higher likelihoods for just "website" and "happy". However, after performing inference on this document using L-LDA, the inferred document probability for *design* ($p(design)$) is much higher than it is for *programming*. In fact, the higher probability for the tag more than makes up the difference in the likelihood for all the words except "CMS" (Content Management System), so

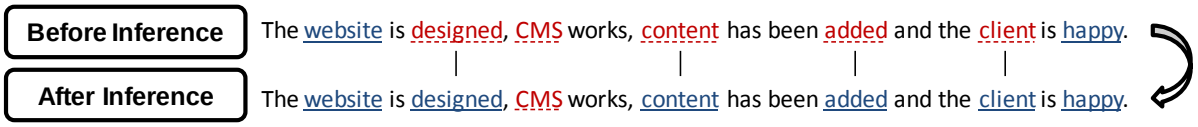

Figure 5: The effect of tag mixture proportions for credit assignment in a web document. Blue (single underline) words are generated from the *design* tag; red (dashed underline) from the *programming* tag. By themselves, most words used here have a higher probability in *programming* than in *design*. But because the document as a whole is more about *design* than *programming*(incorporating words not shown here), inferring the document's topic-mixture θ enables L-LDA to correctly re-assign most words.

that L-LDA correctly infers that most of the words in this passage have more to do with *design* than *programming*.

9 Conclusion

This paper has introduced Labeled LDA, a novel model of multi-labeled corpora that directly addresses the credit assignment problem. The new model improves upon LDA for labeled corpora by gracefully incorporating user supervision in the form of a one-to-one mapping between topics and labels. We demonstrate the model's effectiveness on tasks related to credit attribution within documents, including document visualizations and tag-specific snippet extraction. An approximation to Labeled LDA is also shown to be competitive with a strong baseline (multiple one vs-rest SVMs) for multi-label classification.

Because Labeled LDA is a graphical model in the LDA family, it enables a range of natural extensions for future investigation. For example, the current model does not capture correlations between labels, but such correlations might be introduced by composing Labeled LDA with newer state of the art topic models like the Correlated Topic Model (Blei and Lafferty, 2006) or the Pachinko Allocation Model (Li and McCallum, 2006). And with improved inference for unsupervised $\mathbf{\Lambda}$, Labeled LDA lends itself naturally to modeling semi-supervised corpora where labels are observed for only some documents.

Abstract

Keyphrases are widely used as a brief summary of documents. Since manual assignment is time-consuming, various unsupervised ranking methods based on importance scores are proposed for keyphrase extraction. In practice, the keyphrases of a document should not only be statistically important in the document, but also have a good coverage of the document. Based on this observation, we propose an unsupervised method for keyphrase extraction. Firstly, the method finds exemplar terms by leveraging clustering techniques, which guarantees the document to be semantically covered by these exemplar terms. Then the keyphrases are extracted from the document using the exemplar terms. Our method outperforms sate-of-the-art graph-based ranking methods (TextRank) by 9.5% in F1-measure.

1 Introduction

With the development of Internet, information on the web is emerging exponentially. How to effectively seek and manage information becomes an important research issue. Keyphrases, as a brief summary of a document, provide a solution to help organize, manage and retrieve documents, and are widely used in digital libraries and information retrieval.

Keyphrases in articles of journals and books are usually assigned by authors. However, most articles on the web usually do not have human-assigned keyphrases. Therefore, automatic keyphrase extraction is an important research task. Existing methods can be divided into supervised and unsupervised approaches.

The supervised approach (Turney, 1999) regards keyphrase extraction as a classification task. In this approach, a model is trained to determine whether a candidate term of the document is a keyphrase, based on statistical and linguistic features. For the supervised keyphrase extraction approach, a document set with human-assigned keyphrases is required as training set. However, human labelling is time-consuming. Therefore, in this study we focus on unsupervised approach.

As an example of an unsupervised keyphrase extraction approach, the graph-based ranking (Mihalcea and Tarau, 2004) regards keyphrase extraction as a ranking task, where a document is represented by a term graph based on term relatedness, and then a graph-based ranking algorithm is used to assign importance scores to each term. Existing methods usually use term cooccurrences within a specified window size in the given document as an approximation of term relatedness (Mihalcea and Tarau, 2004).

As we know, none of these existing works gives an explicit definition on what are appropriate keyphrases for a document. In fact, the existing methods only judge the importance of each term, and extract the most important ones as keyphrases.

From the observation of human-assigned keyphrases, we conclude that good keyphrases of a document should satisfy the following properties:

1. **Understandable**. The keyphrases are understandable to people. This indicates the extracted keyphrases should be grammatical. For example, “machine learning” is a grammatical phrase, but “machine learned” is not.

2. **Relevant**. The keyphrases are semantically relevant with the document theme. For example, for a document about “machine learning”, we want the keyphrases all about this theme.

3. **Good coverage**. The keyphrases should

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 257–266,
Singapore, 6-7 August 2009.

cover the whole document well. Suppose we have a document describing "Beijing" from various aspects of "location", "atmosphere" and "culture", the extracted keyphrases should cover all the three aspects, instead of just a partial subset of them.

The classification-based approach determines whether a term is a keyphrase in isolation, which could not guarantee Property 3. Neither does the graph-based approach guarantee the top-ranked keyphrases could cover the whole document. This may cause the resulting keyphrases to be inappropriate or badly-grouped.

To extract the appropriate keyphrases for a document, we suggest an unsupervised clustering-based method. Firstly the terms in a document are grouped into clusters based on semantic relatedness. Each cluster is represented by an exemplar term, which is also the centroid of each cluster. Then the keyphrases are extracted from the document using these exemplar terms.

In this method, we group terms based on semantic relatedness, which guarantees a good coverage of the document and meets Property 2 and 3. Moreover, we only extract the keyphrases in accordance with noun group (chunk) patterns, which guarantees the keyphrases satisfy Property 1.

Experiments show that the clustering-based method outperforms the state-of-the-art graph-based approach on precision, recall and F1-measure. Moreover, this method is unsupervised and language-independent, which is applicable in the web era with enormous information.

The rest of the paper is organized as follows. In Section 2, we introduce and discuss the related work in this area. In Section 3, we give an overview of our method for keyphrase extraction. From Section 4 to Section 7, the algorithm is described in detail. Empirical experiment results are demonstrated in Section 8, followed by our conclusions and plans for future work in Section 9.

2 Related Work

A straightforward method for keyphrase extraction is to select keyphrases according to frequency criteria. However, the poor performance of this method drives people to explore other methods. A pioneering achievement is carried out in (Turney, 1999), as mentioned in Section 1, a supervised machine learning method was suggested in this paper which regards keyphrase extraction as a classification task. In this work, parameterized heuristic rules are combined with a genetic algorithm into a system for keyphrase extraction. A different learning algorithm, Naive Bayes method, is applied in (Frank et al., 1999) with improved results on the same data used in (Turney, 1999). Hulth (Hulth, 2003; Hulth, 2004) adds more linguistic knowledge, such as syntactic features, to enrich term representation, which significantly improves the performance. Generally, the supervised methods need manually annotated training set, which may sometimes not be practical, especially in the web scenario.

Starting with TextRank (Mihalcea and Tarau, 2004), graph-based ranking methods are becoming the most widely used unsupervised approach for keyphrase extraction. The work in (Litvak and Last, 2008) applies HITS algorithm on the word graph of a document under the assumption that the top-ranked nodes should be the document keywords. Experiments show that classification-based supervised method provides the highest keyword identification accuracy, while the HITS algorithm gets the highest F-measure. Work in (Huang et al., 2006) also considers each document as a term graph where the structural dynamics of these graphs can be used to identify keyphrases. Wan and Xiao (Wan and Xiao, 2008b) use a small number of nearest neighbor documents to provide more knowledge to improve graph-based keyphrase extraction algorithm for single document. Motivated by similar idea, Wan and Xiao (Wan and Xiao, 2008a) propose to adopt clustering methods to find a small number of similar documents to provide more knowledge for building word graphs for keyword extraction. Moreover, after our submission of this paper, we find that a method using community detection on semantic term graphs is proposed for keyphrase extraction from multi-theme documents (Grineva et al., 2009). In addition, some practical systems, such as KP-Miner (Elbeltagy and Rafea, 2009), also do not need to be trained on a particular human-annotated document set.

In recent years, a number of systems are developed for extracting keyphrases from web documents (Kelleher and Luz, 2005; Chen et al., 2005), email (Dredze et al., 2008) and some other specific sources, which indicates the importance of keyphrase extraction in the web era. However,

none of these previous works has overall consideration on the essential properties of appropriate keyphrases mentioned in Section 1.

We should also note that, although the precision and recall of most current keyphrase extractors are still much lower compared to other NLP-tasks, it does not indicate the performance is poor because even different annotators may assign different keyphrases to the same document. As described in (Wan and Xiao, 2008b), when two annotators were asked to label keyphrases on 308 documents, the Kappa statistic for measuring inter-agreement among them was only 0.70.

3 Algorithm Overview

The method proposed in this paper is mainly inspired by the nature of appropriate keyphrases mentioned in Section 1, namely *understandable*, semantically *relevant* with the document and *high coverage* of the whole document.

Let's analyze the document describing "Beijing" from the aspects of "location", "atmosphere" and "culture". Under the bag-of-words assumption, each term in the document, except for function words, is used to describe an aspect of the theme. Based on these aspects, terms are grouped into different clusters. The terms in the same cluster are more relevant with each other than with the ones in other clusters. Taking the terms "temperature", "cold" and "winter" for example, they may serve the aspect "atmosphere" instead of "location" or some other aspects when talking about "Beijing".

Based on above description, it is thus reasonable to propose a clustering-based method for keyphrase extraction. The overview of the method is:

1. **Candidate term selection.** We first filter out the stop words and select candidate terms for keyphrase extraction.

2. **Calculating term relatedness.** We use some measures to calculate the semantic relatedness of candidate terms.

3. **Term clustering.** Based on term relatedness, we group candidate terms into clusters and find the exemplar terms of each cluster.

4. **From exemplar terms to keyphrases.** Finally, we use these exemplar terms to extract keyphrases from the document.

In the next four sections we describe the algorithm in detail.

4 Candidate Term Selection

Not all words in a document are possible to be selected as keyphrases. In order to filter out the noisy words in advance, we select candidate terms using some heuristic rules. This step proceeds as follows. Firstly the text is tokenized for English or segmented into words for Chinese and other languages without word-separators. Then we remove the stop words and consider the remaining single terms as candidates for calculating semantic relatedness and clustering.

In methods like (Turney, 1999; Elbeltagy and Rafea, 2009), candidate keyphrases were first found using n-gram. Instead, in this method, we just find the single-word terms as the candidate terms at the beginning. After identifying the exemplar terms within the candidate terms, we extract multi-word keyphrases using the exemplars.

5 Calculating Term Relatedness

After selecting candidate terms, it is important to measure term relatedness for clustering. In this paper, we propose two approaches to calculate term relatedness: one is based on term cooccurrence within the document, and the other by leveraging human knowledge bases.

5.1 Cooccurrence-based Term Relatedness

An intuitive method for measuring term relatedness is based on term cooccurrence relations within the given document. The cooccurrence relation expresses the cohesion relationships between terms.

In this paper, cooccurrence-based relatedness is simply set to the count of cooccurrences within a window of maximum w words in the whole document. In the following experiments, the window size w is set from 2 to 10 words.

Each document can be regarded as a word sequence for computing cooccurrence-based relatedness. There are two types of word sequence for counting term cooccurrences. One is the original word sequence without filtering out any words, and the other is after filtering out the stop words or the words with specified part-of-speech (POS) tags. In this paper we select the first type because each word in the sequence takes important role for measuring term cooccurrences, no matter whether

it is a stop word or something else. If we filter out some words, the term relatedness will not be as precise as before.

In experiments, we will investigate how the window size influences the performance of keyphrase extraction.

5.2 Wikipedia-based Term Relatedness

Many methods have been proposed for measuring the relatedness between terms using external resources. One principled method is leveraging human knowledge bases. Inspired by (Gabrilovich and Markovitch, 2007), we adopt Wikipedia, the largest encyclopedia collected and organized by human on the web, as the knowledge base to measure term relatedness.

The basic idea of computing term relatedness by leveragting Wikipedia is to consider each Wikipedia article as a concept. Then the semantic meaning of a term could be represented as a weighted vector of Wikipedia concepts, of which the values are the term's TFIDF within corresponding Wikipedia articles. We could compute the term relatedness by comparing the concept vectors of the terms. Empirical evaluations confirm that the idea is effective and practical for computing term relatedness (Gabrilovich and Markovitch, 2007).

In this paper, we select cosine similarity, Euclidean distance, Point-wise Mutual Information and Normalized Google Similarity Distance (Cilibrasi and Vitanyi, 2007) for measuring term relatedness based on the vector of Wikipedia concepts.

Denote the Wikipedia-concept vector of the term t_i as $C_i = \{c_{i1}, c_{i2}, ..., c_{iN}\}$, where N indicates the number of Wikipedia articles, and c_{ik} is the TFIDF value of w_i in the kth Wikipedia article. The cosine similarity is defined as

$$cos(i,j) = \frac{C_i \cdot C_j}{\|C_i\|\|C_j\|} \tag{1}$$

The definition of Euclidean distance is

$$euc(i,j) = \sqrt{\sum_{k=1}^{N}(c_{ik} - c_{jk})^2} \tag{2}$$

Point-wise Mutual Information (PMI) is a common approach to quantify relatedness. Here we take three ways to measure term relatedness using PMI. One is based on Wikipedia page count,

$$pmi_p(i,j) = \log_2 \frac{N \times p(i,j)}{p(i) \times p(j)} \tag{3}$$

where $p(i,j)$ is the number of Wikipedia articles containing both t_i and t_j, while $p(i)$ is the number of articles which contain t_i. The second is based on the term count in Wikipedia articles,

$$pmi_t(i,j) = \log_2 \frac{T \times t(i,j)}{t(i) \times t(j)} \tag{4}$$

where T is the number of terms in Wikipedia, $t(i,j)$ is the number of t_i and t_j occurred adjacently in Wikipedia, and $t(i)$ is the number of t_i in Wikipedia. The third one is a combination of the above two PMI ways,

$$pmi_c(i,j) = \log_2 \frac{N \times pt(i,j)}{p(i) \times p(j)} \tag{5}$$

where $pt(i,j)$ indicates the number of Wikipedia articles containing t_i and t_j as adjacency. It is obvious that $pmi_c(i,j) \leq pmi_p(i,j)$, and $pmi_c(i,j)$ is more strict and accurate for measuring relatedness.

Normalized Google Similarity Distance (NGD) is a new measure for measuring similarity between terms proposed by (Cilibrasi and Vitanyi, 2007) based on information distance and Kolmogorov complexity. It could be applied to compute term similarity from the World Wide Web or any large enough corpus using the page counts of terms. NGD used in this paper is based on Wikipedia article count, defined as

$$ngd(i,j) = \frac{\max(\log p(i), \log p(j)) - logp(i,j)}{\log N - \min(logp(i), logp(j))} \tag{6}$$

where N is the number of Wikipedia articles used as normalized factor.

Once we get the term relatedness, we could then group the terms using clustering techniques and find exemplar terms for each cluster.

6 Term Clustering

Clustering is an important unsupervised learning problem, which is the assignment of objects into groups so that objects from the same cluster are more similar to each other than objects from different clusters (Han and Kamber, 2005). In this paper, we use three widely used clustering algorithms, hierarchical clustering, spectral clustering and Affinity Propagation, to cluster the candidate terms of a given document based on the semantic relatedness between them.

6.1 Hierarchical Clustering

Hierarchical clustering groups data over a variety of scales by creating a cluster tree. The tree is a multilevel hierarchy, where clusters at one level are joined as clusters at the next level. The hierarchical clustering follows this procedure:

1. Find the distance or similarity between every pair of data points in the dataset;
2. Group the data points into a binary and hierarchical cluster tree;
3. Determine where to cut the hierarchical tree into clusters. In hierarchical clustering, we have to specify the cluster number m in advance.

In this paper, we use the hierarchical clustering implemented in Matlab Statistics Toolbox. Note that although we use hierarchical clustering here, the cluster hierarchy is not necessary for the clustering-based method.

6.2 Spectral Clustering

In recent years, spectral clustering has become one of the most popular modern clustering algorithms. Spectral clustering makes use of the spectrum of the similarity matrix of the data to perform dimensionality reduction for clustering into fewer dimensions, which is simple to implement and often outperforms traditional clustering methods such as k-means. Detailed introduction to spectral clustering could be found in (von Luxburg, 2006).

In this paper, we use the spectral clustering toolbox developed by Wen-Yen Chen, et al. (Chen et al., 2008) [1]. Since the cooccurrence-based term relatedness is usually sparse, the traditional eigenvalue decomposition in spectral clustering will sometimes get run-time error. In this paper, we use the singular value decomposition (SVD) technique for spectral clustering instead.

For spectral clustering, two parameters are required to be set by the user: the cluster number m, and σ which is used in computing similarities from object distances

$$s(i,j) = \exp(\frac{-d(i,j)^2}{2\sigma^2}) \quad (7)$$

where $s(i,j)$ and $d(i,j)$ are the similarity and distance between i and j respectively.

[1]The package could be accessed via `http://www.cs.ucsb.edu/~wychen/sc.html`.

6.3 Affinity Propagation

Another powerful clustering method, Affinity Propagation, is based on message passing techniques. AP was proposed in (Frey and Dueck, 2007), where AP was reported to find clusters with much lower error than those found by other methods. In this paper, we use the toolbox developed by Frey, et al. [2].

Detailed description of the algorithm could be found in (Frey and Dueck, 2007). Here we introduced three parameters for AP:

- **Preference**. Rather than requiring predefined number of clusters, Affinity Propagation takes as input a real number p for each term, so that the terms with larger p are more likely to be chosen as exemplars, i.e., centroids of clusters. These values are referred to as "preferences". The preferences are usually be set as the maximum, minimum, mean or median of $s(i,j), i \neq j$.
- **Convergence criterion**. AP terminates if (1) the local decisions stay constant for I_1 iterations; or (2) the number of iterations reaches I_2. In this work, we set I_1 to 100 and I_2 to $1,000$.
- **Damping factor**. When updating the messages, it is important to avoid numerical oscillations by using damping factor. Each message is set to λ times its value from the previous iteration plus $1-\lambda$ times its prescribed updated value, where the damping factor λ is between 0 and 1. In this paper we set $\lambda = 0.9$.

7 From Exemplar Terms to Keyphrases

After term clustering, we select the exemplar terms of each clusters as seed terms. In Affinity Propagation, the exemplar terms are directly obtained from the clustering results. In hierarchical clustering, exemplar terms could also be obtained by the Matlab toolbox. While in spectral clustering, we select the terms that are most close to the centroid of a cluster as exemplar terms.

As reported in (Hulth, 2003), most manually assigned keyphrases turn out to be noun groups. Therefore, we annotate the document with POS

[2]The package could be accessed via `http://www.psi.toronto.edu/affinitypropagation/`.

tags using Stanford Log-Linear Tagger [3], and then extract the noun groups whose pattern is zero or more adjectives followed by one or more nouns. The pattern can be represented using regular expressions as follows

$$(JJ) * (NN|NNS|NNP)+$$

where JJ indicates adjectives and various forms of nouns are represented using NN, NNS and NNP. From these noun groups, we select the ones that contain one or more exemplar terms to be the keyphrases of the document.

In this process, we may find single-word keyphrases. In practice, only a small fraction of keyphrases are single-word. Thus, as a part of postprocessing process, we have to use a frequent word list to filter out the terms that are too common to be keyphrases.

8 Experiment Results

8.1 Datasets and Evaluation Metric

The dataset used in the experiments is a collection of scientific publication abstracts from the *Inspec* database and the corresponding manually assigned keyphrases [4]. The dataset is used in both (Hulth, 2003) and (Mihalcea and Tarau, 2004). Each abstract has two kinds of keyphrases: controlled keyphrases, restricted to a given dictionary, and uncontrolled keyphrases, freely assigned by the experts. We use the uncontrolled keyphrases for evaluation as proposed in (Hulth, 2003) and followed by (Mihalcea and Tarau, 2004).

As indicated in (Hulth, 2003; Mihalcea and Tarau, 2004), in uncontrolled manually assigned keyphrases, only the ones that occur in the corresponding abstracts are considered in evaluation. The extracted keyphrases of various methods and manually assigned keyphrases are compared after stemming.

In the experiments of (Hulth, 2003), for her supervised method, Hulth splits a total of $2,000$ abstracts into $1,000$ for training, 500 for validation and 500 for test. In (Mihalcea and Tarau, 2004), due to the unsupervised method, only the test set was used for comparing the performance of TextRank and Hulth's method.

For computing Wikipedia-based relatedness, we use a snapshot on November 11, 2005 [5]. The frequent word list used in the postprocessing step for filtering single-word phrases is also computed from Wikipedia. In the experiments of this paper, we add the words that occur more than $1,000$ times in Wikipedia into the list.

The clustering-based method is completely unsupervised. Here, we mainly run our method on test set and investigate the influence of relatedness measurements and clustering methods with different parameters. Then we compare our method with two baseline methods: Hulth's method and TextRank. Finally, we analyze and discuss the performance of the method by taking the abstract of this paper as a demonstration.

8.2 Influence of Relatedness Measurements

We first investigate the influence of semantic relatedness measurements. By systematic experiments, we find that Wikipedia-based relatedness outperforms cooccurrence-based relatedness for keyphrase extraction, though the improvement is not significant. In Table 1, we list the performance of spectral clustering with various relatedness measurements for demonstration. In this table, the w indicates the window size for counting cooccurrences in cooccurrence-based relatedness. cos, euc, etc. are different measures for computing Wikipedia-based relatedness which we presented in Section 5.2.

Table 1: Influence of relatedness measurements for keyphrase extraction.

Parameters	Precision	Recall	F1-measure
Cooccurrence-based Relatedness			
$w = 2$	0.331	0.626	0.433
$w = 4$	0.333	0.621	0.434
$w = 6$	0.331	0.630	0.434
$w = 8$	0.330	0.623	0.432
$w = 10$	0.333	0.632	0.436
Wikipedia-based Relatedness			
cos	0.348	0.655	0.455
euc	0.344	0.634	0.446
pmi_p	0.344	0.621	0.443
pmi_t	0.344	0.619	0.442
pmi_c	0.350	0.660	**0.457**
ngd	0.343	0.620	0.442

[3] The package could be accessed via `http://http://nlp.stanford.edu/software/tagger.shtml`.

[4] Many thanks to Anette Hulth for providing us the dataset.

[5] The dataset could be get from `http://www.cs.technion.ac.il/~gabr/resources/code/wikiprep/`.

We use spectral clustering here because it outperforms other clustering techniques, which will be shown in the next subsection. The results in Table 1 are obtained when the cluster number $m = \frac{2}{3}n$, where n is the number of candidate terms obtained in Section 5. Besides, for Euclidean distance and Google distance, we set $\sigma = 36$ of Formula 7 to convert them to corresponding similarities, where we get the best result when we conduct different trails with $\sigma = 9, 18, 36, 54$, though there are only a small margin among them.

As shown in Table 1, although the method using Wikipedia-based relatedness outperforms that using cooccurrence-based relatedness, the improvement is not prominent. Wikipedia-based relatedness is computed according to global statistical information on Wikipedia. Therefore it is more precise than cooccurrence-based relatedness, which is reflected in the performance of the keyphrase extraction. However, on the other hand, Wikipedia-based relatedness does not catch the document-specific relatedness, which is represented by the cooccurrence-based relatedness. It will be an interesting future work to combine these two types of relatedness measurements.

From this subsection, we conclude that, although the method using Wikipedia-based relatedness performs better than cooccurrence-based one, due to the expensive computation of Wikipedia-based relatedness, the cooccurrence-based one is good enough for practical applications.

8.3 Influence of Clustering Methods and Their Parameters

To demonstrate the influence of clustering methods for keyphrase extraction, we fix the relatedness measurement as Wikipedia-based pmi_c, which has been shown in Section 8.2 to be the best relatedness measurement.

In Table 2, we show the performance of three clustering techniques for keyphrase extraction. For hierarchical clustering and spectral clustering, the cluster number m are set explicitly as the proportion of candidate terms n, while for Affinity Propagation, we set preferences as the minimum, mean, median and maximum of $s(i, j)$ to get different number of clusters, denoted as min, $mean$, $median$ and max in the table respectively.

As shown in the table, when cluster number m is large, spectral clustering outperforms hierarchical clustering and Affinity Propagation. Among these methods, only Affinity Propagation under some parameters performs poorly.

Table 2: Influence of clustering methods for keyphrase extraction.

Parameters	Precision	Recall	F1-measure
Hierarchical Clustering			
$m = \frac{1}{4}n$	0.365	0.369	0.367
$m = \frac{1}{3}n$	0.365	0.369	0.367
$m = \frac{1}{2}n$	0.351	0.562	0.432
$m = \frac{2}{3}n$	0.346	0.629	0.446
$m = \frac{4}{5}n$	0.340	0.657	0.448
Spectral Clustering			
$m = \frac{1}{4}n$	0.385	0.409	0.397
$m = \frac{1}{3}n$	0.374	0.497	0.427
$m = \frac{1}{2}n$	0.374	0.497	0.427
$m = \frac{2}{3}n$	0.350	0.660	**0.457**
$m = \frac{4}{5}n$	0.340	0.679	0.453
Affinity Propagation			
$p = max$	0.331	0.688	0.447
$p = mean$	0.433	0.070	0.121
$p = median$	0.422	0.078	0.132
$p = min$	0.419	0.059	0.103

8.4 Comparing with Other Algorithms

Table 3 lists the results of the clustering-based method compared with the best results reported in (Hulth, 2003; Mihalcea and Tarau, 2004) on the same dataset. For each method, the table lists the total number of assigned keyphrases, the mean number of keyphrases per abstract, the total number of correct keyphrases, and the mean number of correct keyphrases. The table also lists precision, recall and F1-measure. In this table, hierarchical clustering, spectral clustering and Affinity Propagation are abbreviated by "HC", "SC" and "AP" respectively.

The result of Hulth's method listed in this table is the best one reported in (Hulth, 2003) on the same dataset. This is a supervised classification-based method, which takes more linguistic features in consideration for keyphrase extraction. The best result is obtained using n-gram as candidate keyphrases and adding POS tags as candidate features for classification.

The result of TextRank listed here is the best one reported in (Mihalcea and Tarau, 2004) on the same dataset. To obtain the best result, the authors built an undirected graph using window $w = 2$ on word sequence of the given document, and ran

Table 3: Comparison results of Hulth's method, TextRank and our clustering-based method.

	Assigned		Correct				
Method	Total	Mean	Total	Mean	Precision	Recall	F1-measure
Hulth's	7,815	15.6	1,973	3.9	0.252	0.517	0.339
TextRank	6,784	13.7	2,116	4.2	0.312	0.431	0.362
HC	7,303	14.6	2,494	5.0	0.342	0.657	0.449
SC	7,158	14.3	2,505	5.0	**0.350**	0.660	**0.457**
AP	8,013	16.0	2,648	5.3	0.330	**0.697**	0.448

PageRank on it.

In this table, the best result of hierarchical clustering is obtained by setting the cluster number $m = \frac{2}{3}n$ and using Euclidean distance for computing Wikipedia-based relatedness. The parameters of spectral clustering are the same as in last subsection. For Affinity Propagation, the best result is obtained under $p = max$ and using Wikipedia-based Euclidean distance as relatedness measure.

From this table, we can see clustering-based method outperforms TextRank and Hulth's method. For spectral clustering, F1-measure achieves an approximately 9.5% improvement as compared to TextRank.

Furthermore, since the clustering-based method is unsupervised, we do not need any set for training and validation. In this paper, we also carry out an experiment on the whole Hulth's dataset with $2,000$ abstracts. The performance is similar to that on 500 abstracts as shown above. The best result is obtained when we use spectral clustering by setting $m = \frac{2}{3}n$ with Wikipedia-based pmi_c relatedness, which is the same in 500 abstracts. In this result, we extract $29,517$ keyphrases, among which $9,655$ are correctly extracted. The precision, recall and F1-measure are 0.327, 0.653 and 0.436 respectively. The experiment results show that the clustering-based method is stable.

8.5 Analysis and Discussions

From the above experiment results, we can see the clustering-based method is both robust and effective for keyphrase extraction as an unsupervised method.

Here, as an demonstration, we use spectral clustering and Wikipedia-based pmi_c relatedness to extract keyphrases from the abstract of this paper. The extracted stemmed keyphrases under various cluster numbers are shown in Figure 1. In this figure, we find that when $m = \frac{1}{4}n, \frac{1}{3}n, \frac{1}{2}n$, the extracted keyphrases are identical, where the exemplar terms under $m = \frac{1}{3}n$ are marked in boldface. We find several aspects like "unsupervised", "exemplar term" and "keyphrase extraction" are extracted correctly. In fact, "clustering technique" in the abstract should also be extracted as a keyphrase. However, since "clustering" is tagged as a verb that ends in -ing, which disagrees the noun group patterns, thus the phrase is not among the extracted keyphrases.

When $m = \frac{2}{3}n$, the extracted keyphrases are noisy with many single-word phrases. As the cluster number increases, more exemplar terms are identified from these clusters, and more keyphrases will be extracted from the document based on exemplar terms. If we set the cluster number to $m = n$, all terms will be selected as exemplar terms. In this extreme case, all noun groups will be extracted as keyphrases, which is obviously not proper for keyphrase extraction. Thus, it is important for this method to appropriately specify the cluster number.

In the experiments, we also notice that frequent word list is important for keyphrase extraction. Without the list for filtering, the best F1-measure will decrease by about 5 percent to 40%. However, the solution of using frequent word list is somewhat too simple, and in future work, we plan to investigate a better combination of clustering-based method with traditional methods using term frequency as the criteria.

9 Conclusion and Future Work

In this paper, we propose an unsupervised clustering-based keyphrase extraction algorithm. This method groups candidate terms into clusters and identify the exemplar terms. Then keyphrases are extracted from the document based on the exemplar terms. The clustering based on term semantic relatedness guarantees the extracted keyphrases have a good coverage of the document. Experiment results show the method has a good ef-

fectiveness and robustness, and outperforms baselines significantly.

Future work may include:

1. Investigate the feasibility of clustering directly on noun groups;

2. Investigate the feasibility of combining cooccurrence-based and Wikipedia-based relatedness for clustering;

3. Investigate the performance of the method on other types of documents, such as long articles, product reviews and news;

4. The solution of using frequent word list for filtering out too common single-word keyphrases is undoubtedly simple, and we plan to make a better combination of the clustering-based method with traditional frequency-based methods for keyphrase extraction.

Abstract

One of the most desired information types when planning a trip to some place is the knowledge of transport, roads and geographical connectedness of prominent sites in this place. While some transport companies or repositories make some of this information accessible, it is not easy to find, and the majority of information about uncommon places can only be found in web free text such as blogs and forums. In this paper we present an algorithmic framework which allows an automated acquisition of map-like information from the web, based on surface patterns like "from X to Y". Given a set of locations as initial seeds, we retrieve from the web an extended set of locations and produce a map-like network which connects these locations using transport type edges. We evaluate our framework in several settings, producing meaningful and precise connection sets.

1 Introduction

Textual geographical information such as location descriptions, directions, travel guides and transport tables is extensively used by people. Discovering such information automatically can assist NLP applications such as question answering (Santos and Cardoso, 2008), and can be useful for a variety of other applications, including automatic map annotation.

Some textual geographical information can be found in web sites of transport companies, tourist sites and repositories such as Wikipedia. Such sites usually utilize structured information such as machine-readable meta-data, tables, schedule forms or lists, which are relatively convenient for processing. However, automatic utilization of such information is limited. Even on these sites, only a small fraction of the available geographical information is stored in a well-structured and freely accessible form. With the growth of the web, information can be frequently found in 'ordinary' web pages such as forums, travelogues or news. In such sites, information is usually noisy, unstructured and present in the form of free text.

This type of information can be addressed by lexical patterns. Patterns were shown to be very useful in all sorts of lexical acquisition tasks, giving high precision results at relatively low computational costs (Pantel et al., 2004). Pattern-driven search engine queries allow to access such information and gather the required data very efficiently (Davidov et al., 2007).

In this paper we present a framework that given a few seed locations as a specification of a region, discovers additional locations (including alternate location names) and map-like travel paths through this region labeled by transport type labels.

The type of output produced by our framework here differs from that in previous pattern-based studies. Unlike mainstream pattern-based web mining, it does not target some specific two-slot relationship and attempts to extract word tuples for this relationship. Instead, it discovers geographical networks of transport or access connections. Such networks are not unstructured sets of word pairs, but a structured graph with labeled edges.

Our algorithm utilizes variations of the basic pre-defined pattern "[Transport] from Location1 to Location2" which allows location names and connections to be captured starting from the given seed location set. We acquire search engine snippets and extract contexts where location names co-appear. Next we construct a location graph and merge transport edges to identify main transport group types. Finally, we improve the obtained data by reducing transitive connections and identifying key locations.

Singapore, 6-7 August 2009.

The obtained location data can be used as a draft for preparation of travel resources and on-demand travel plans. It can also be used for question answering systems and for automated enrichment and verification of existing geographical resources.

We evaluate our framework on three different regions of different scale and type: Annapurna in Nepal, the south Israel area and the Cardiff area in England. In our evaluation we estimated precision and the amount of discovered locations and transport edges, and examined the quality of the obtained map as a whole by visually comparing the overall connectedness of the graph to an actual road or transport map.

2 Related Work

In this paper we utilize a pattern-based lexical acquisition framework for the discovery of geographical information. Due to the importance of lexical databases for many NLP tasks, substantial research has been done on direct or indirect automated acquisition of concepts (sets of terms sharing a significant aspect of their meaning) and concept relationships in the form of graphs connecting concepts or terms inside concepts into usually hierarchical or bipartite networks. In the case of geo-mining, concepts can include sets of alternative names for some place, or sets of all locations of the same type (e.g., all countries). Geographical relationships can include nearness of two locations and entity-location relationships such as institute-address, capital-country, tourist site-city etc.

The major differences between relationship acquisition frameworks come from the types and annotation requirements of the supplied input and the basic algorithmic approach used to process this input. A first major algorithmic approach is to represent word contexts as vectors in some space and use distributional measures and automatic clustering in that space. Curran (2002) and Lin (1998) use syntactic features in the vector definition. Caraballo (1999) uses conjunction and appositive annotations in the vector representation.While efforts have been made for improving the computational complexity of these methods (Gorman and Curran, 2006), they remain data and computation intensive.

The second major algorithmic approach is to use lexico-syntactic patterns, which have been shown to produce more accurate results than feature vectors at a lower computational cost on large corpora (Pantel et al., 2004). Most related work deals with discovery of hypernymy (Hearst, 1992; Pantel and Lin, 2002) and synonymy (Widdows and Dorow, 2002; Davidov and Rappoport, 2006). Some studies deal with the discovery of more specific relation sub-types, including inter-verb relations (Chklovski and Pantel, 2004) and semantic relations between nominals (Davidov and Rappoport, 2008). Extensive frameworks were proposed for iterative discovery of pre-specified (e.g., (Riloff and Jones, 1999)) and unspecified (e.g., (Agichtein and Gravano, 2000)) relation types.

Some concepts and relationships examined by seed-based discovery methods were of a geographical nature. For example, (Etzioni et al., 2004) discovered a set of countries and (Davidov et al., 2007) discovered diverse country relationships, including location relationships between a country and its capital and a country and its rivers. As noted in Section 1, the type of output that we produce here is not an unstructured collection of word pairs but a labeled network. As such, our task here is much more complex.

Our study is related to geographical information retrieval (GIR) systems. However, our problem is very far from classic GIR problem settings. In GIR, the goal is to classify or retrieve possibly multilingual documents in response to queries in the form 'theme, spatial relationship, location', e.g., 'mountains near New York' (Purves et al., 2006). Our goal, in contrast, is not document retrieval, but the generation of a structured information resource, a labeled location graph.

Spatial relationships used in natural language tend to be qualitative and descriptive rather than quantitative. The concept of Naive Geography, which reflects the way people think and write about geographical space, is described in (Egenhofer and Shariff, 1995). Later in (Egenhofer and Shariff, 1998) they proposed a way to convert coordinate-based relationships between spatial entities to natural language using terms as 'crosses', 'goes through' or 'runs into'. Such terms can be potentially used in patterns to extract geographical information from text. In this paper we start from a different pattern, 'from ... to', which helps in discovering transport or connectedness relationships between places, e.g., 'bus from X to Y' and 'road from X to Y'.

The majority of geographical data mining

frameworks utilize structured data such as available gazetteers and Wikipedia metadata. Several other studies utilize semi-structured data like Wikipedia links (Overell and Ruger, 2007) or substructures in web pages, including addresses and phone numbers (Borges et al., 2007).

The recent Schockaert et al.(2008) framework for extraction of topological relationships from the web has some similarities to our study. In both cases the algorithm produces map-like structures using the web. However, there are significant differences. They utilize relatively structured address data on web pages and rely on the order of named entities in address data for extracting containment relationships. They also use co-appearances in addresses (e.g., 'R1 / R2' and 'R1 & R2' as in "Newport & Gabalfa, Cardiff") to deduce location boundaries. This allows them to get high precision data for modern and heavily populated regions like Cardiff, where the majority of offices have available well-formatted web pages.

However, in less populated regions (a major target for tourist information requests), this strategy could be problematic since a major information source about these places would be not local web sites (in which local addresses are likely to be found) but foreign visitor sites, web forums and news. We rely on free text available in all types of web pages, which allows us to capture unstructured information which contains a significant portion of the web-available geographical knowledge.

Our goals are also different from Schockaert et al.(2008), since we focus on obtaining information based on paths and transport between locations, while in their work the goal is to find a network representing nearness of places rather than their connectivity by means of transport or walking. Nevertheless, in one of our evaluation settings we targeted the area of Cardiff as in (Schockaert et al., 2008). This allowed us to make an indirect comparison of a relevant part of our results to previous work, achieving state-of-the-art performance.

3 The Algorithm

As input to our algorithm we are given a seed of a few location names specifiying some geographical region. In this section we describe the algorithm which, given these names, extracts the labeled structure of connections between entities in the desired region. We first use a predefined pattern for recursive extraction of the first set of entities. Then we discover additional patterns from co-appearing location pairs and use them to get more terms. Next, we label and merge the obtained location pairs. Finally, we construct and refine the obtained graph.

3.1 Pattern-based discovery with web queries

In order to obtain the first set of location connections, we use derivatives of the basic pattern 'from X to Y'. Using Yahoo! BOSS, we have utilized the API's ability to search for phrases with wildcards. Given a location name L we start the search with patterns "from * to L", "from * * to L". These are Yahoo! BOSS queries where enclosing words in "" means searching for an exact phrase and '*' means a wildcard for exactly one arbitrary word.

This pattern serves a few goals beyond the discovery of connectedness. Thus putting '*'s inside the pattern rather than using "from L to" allowed us to avoid arbitrary truncation of multiword expressions as in 'from Moscow to St. Petersburg' and reduced the probability of capturing unrelated sentence parts like 'from Moscow to cover deficit'.

Location names are usually ambiguous and this type of web queries can lead to a significant amount of noise or location mix. There are two types of ambiguity. First, as in 'from Billericay to Stock....', stock can be a location or a verb. We filter most such cases by allowing only capitalized location names. Besides, such an ambiguity is rarely captured by 'from * to L' patterns. The second type is location ambiguity. Thus 'Moscow' refers to at least 5 location names including farms in Africa and Australia and a locality in Ireland. In order to reduce mixing of locations we use the following simple disambiguation technique. Before performing "from...to" queries, we downloaded up to 100 web pages pointed by each possible *pair* from the given seed locations, generating from a location pair L_1, L_2 a conjunctive query "L_1 * L_2". Then we extracted the most informative terms using a simple probabilistic metric:

$$Rank(w) = \frac{P(w|QueryCorpus)}{P(w|GeneralCorpus)},$$

comparing word distribution in the downloaded $QueryCorpus$ to a large general purpose offline $GeneralCorpus$[1]. We thus obtained a set of

[1]We used the DMOZ corpus (Gabrilovich and Markovitch, 2005).

query-specific disambiguating words. Then we added to all queries the same most frequent word (*DW*) out of the ten words with highest ranks. Thus for the seed set {Moscow, St. Petersburg}, an example of a query is <"from * to Moscow" Russia>.

3.2 Iterative location retrieval

We retrieved all search engine snippets for each of these initial queries[2]. If we succeeded to get more than 50 snippets, we did not download the complete documents. In case where only a handful of snippets were obtained, the algorithm downloaded up to 25 documents pointed by these snippets in an attempt to get more pattern instances. In the majority of tested cases, snippets provide enough information for our task, and this information was not significantly extended by downloading the whole documents.

Once we retrieve snippets we identify terms appearing in the snippets in wildcard slots. For example, if the query is <"from * to Moscow" Russia> and we encounter a snippet "...from Vladivostok to Moscow...", we add 'Vladivostok' to our set of seeds. We then continue the search in a breadth first search setting, stopping the search on three conditions: (1) runaway detected – the total frequency of newly obtained terms through some term's patterns is greater than the total frequency of previously discovered terms+seeds. In this case we stop exploration through the problematic term and continue exploration through other terms[3]; (2) we reached a predefined maximal depth D[4]; (3) no new terms discovered.

At the end of this stage we get the extended set of terms using the set of snippets where these terms co-appear in patterns.

3.3 Enhancement of initial pattern set

In order to get more data, we enhance the pattern set both by discovery of new useful secondary patterns and by narrowing existing patterns. After obtaining the new pattern set we repeat the extraction stage described in Section 3.2.

[2]Yahoo! Boss allows downloading up to a 1000 descriptions, up to 50 in each request. Thus for each seed word, we have performed a few dozen search requests.

[3]Note that the 'problematic' term may be the central term in the region we focus upon – if this happen it means that the seeds do not specify the region well.

[4]Depth is a function of the richness of transport links in the domain. For connected domains (Cardiff, Israel) we used 4, for less connected ones (Nepal) we used 10.

Adding secondary patterns. As in a number of previous studies, we improve our results discovering additional patterns from the obtained term set. The algorithm selects a subset of up to 50 discovered (t_1, t_2) term pairs appearing in 'from t_1 to t_2' patterns and performs the set of additional queries of the form <"t_1 * t_2" DW>.

We then extract from the obtained snippets the patterns of the form 'Prefix t_1 Infix t_2 Postfix', where Prefix and Postfix should contain either a punctuation symbol or 1-3 words. Prefix/Postfix should also be bounded from left/right by a punctuation or one of the 50 most frequent words in the language (based on word counts in the offline general corpus). Infix should contain 1-3 words with the possible addition of punctuation symbols[5].

We examine patterns and select useful ones according to the following ranking scheme, based on how well each pattern captures named entities. For each discovered pattern we scan the obtained snippets and offline general corpus for instances where this pattern connects one of the original or discovered location terms to some other term. Let T be the set of all one to three word terms in the language, $T_d \subset T$ the set of discovered terms, $T_c \subset T$ the set of all capitalized terms and $Pat(t_1, t_2)$ indicates one or more co-appearances of t_1 and t_2 in pattern Pat in the retrieved snippets or offline general corpus. The rank R of pattern Pat is defined by:

$$R(Pat) = \frac{|\{Pat|Pat(t_1, t_2), t_1 \in T_c, t_2 \in T_d\}|}{|\{Pat|Pat(t_1, t_2), t_1 \in T, t_2 \in T_d\}|}$$

In other words, we rank patterns according to the percentage of capitalized words connected by this pattern. We sort patterns by rank and select the top 20% patterns. Once we have discovered a new pattern set, we repeat the term extraction in Section 3.2. We do this only once and not reiterate this loop in order to avoid potential runaway problems. Obtained secondary patterns include different from/to templates "to X from Y by bus"; time/distance combinations "X -N km bus- Y", "X (bus, N min) Y" or patterns in different languages with English location/transport names.

Narrowing existing patterns. When available data volume is high, we would like to take advantage of more data by utilizing more specific pattern

[5]Search engines do not support punctuation in queries, hence these symbols were omitted in web requests and considered only when processing the retrieved snippets.

sets. Since Yahoo! allows to obtain only the first 1K snippets, in case we get more than 10K hits, we extend our queries by adding the most common term sequences appearing before or after the pattern. Thus if for the query "from * to Moscow" we got more than 10K hits and among the snippets we see '... bus from X to Moscow...' we create an extended pattern 'bus from * to Moscow' and use the term extraction in Section 3.2 to get additional terms. Unlike the extraction of secondary patterns, this narrowing process can be repeated recursively as long as a query brings more than 10K results.

3.4 Extraction of labeled connections

At the end of the discovery stage we get an extended set of patterns and a list of search engine snippets discovered using these patterns. Each snippet which captures terms t_1, t_2 in either primary 'from t_1 to t_2' or secondary patterns represents a potential connection between entities.

Using an observed property of the primary pattern, we select as a label a term or set of terms appearing directly before 'from' and delimited with some high frequency word or punctuation. For example, labels for snippets based on 'from...to' patterns and containing 'the road from...', 'got a bus from', 'a TransSiberian train from...' would be road, bus and TransSiberian train.

Once we acquire labels for the primary patterns, we also attempt to find labels in snippets obtained for secondary patterns discovered as described in Section 3.3. We first locate some already labeled pairs in secondary patterns' snippets where we can see both label and the labeled term pair. Then, based on the label's position in this snippet, we define a label slot position for this type of snippet. Suppose that during the labeling of primary pattern snippets we assigned the label 'bus' to the pair (Novgorod, Moscow) and during the pattern extension stage the algorithm discovered a pattern P_{new} = 'ride to t_2 from t_1,' with a corresponding snippet '... getting bus ride to Moscow from Novgorod...'. Then using the labeled pair our algorithm defines the label slot in such a snippet type: 'getting [label] ride to t_2 from t_1'. Once a label slot is defined, all other pairs captured by P_{new} can be successfully labeled.

3.5 Merging connection labels

Some labels may denote the same type of connection. Also, large sets of connections can share the same set of transport types. In this case it is desired to assign a single label for a shared set of transports. We do this by a simple merging technique. Let C_1, C_2 be sets of pairs assigned to labels L_1, L_2. We merge two labels if one of the following conditions holds:

$$(1)|C_1 \cap C_2| > 0.75 * min(|C_1|, |C_2|)$$

$$(2)|C_1 \cap C_2| > 0.45 * max(|C_1|, |C_2|)$$

Thus, either one group is nearly included in the other or each group shares nearly half with the other group. We apply this rule only once and do not iterate recursively. At this stage we also dismiss weakly populated labels, keeping the 10 most populated labels.

3.6 Processing of connection graph

Now once we have merged and assigned the labels we create a pattern graph for each label and attempt to clean the graph of noise and unnecessary edges. Our graph definition follows (Widdows and Dorow, 2002). In our pattern graph for label L, nodes represent terms and directed edges represent co-appearance of two terms in some pattern in snippet labeled by L. We do not add unlabeled snippets to the graph. Now we use a set of techniques to reduce noise and unnecessary edges.

3.6.1 Transitivity elimination

One of the main problems with the pattern-based graph is transitivity of connections. Thus if location A is connected to B and B to C, we frequently acquire a "shortcut" edge connecting A to C. Such an edge diminishes our ability to create a clear and meaningful spatial graph. In order to reduce such edges we employ the following two strategies.

First, neighboring places frequently form fully connected subgraphs. We would like to simplify such cliques to reduce the amount of transitive connections. If three overlapping sets of nodes $\{A_1 \dots A_{n-2}\}$,$\{A_2 \dots A_{n-1}\}$,$\{A_3 \dots A_n\}$ form three different cliques, then we remove all edges between A_1 and the nodes in the third clique and between A_n and the nodes in the first clique.

Second, in paths obtained by directional patterns, it is common that if there is a path $A_1 \rightarrow A_2 \cdots \rightarrow A_n$ where A_1 and A_n are some major 'key' locations[6], then each of the nodes $A_2 \dots A_{n-1}$ tend to be connected both to A_1 and

[6]Such locations will be shown in double circles in the evaluation.

to A_n while intermediate nodes are usually connected only to their close neighbors. We would like to eliminate such transitive edges leaving only the inter-neighbor connections.

We define as key nodes in a graph, nodes whose degree is more than 1.5 times the average graph degree. Then we eliminate the transitive connections: if A_1 is a key node and A_1 is connected to each of the nodes $A_2 \dots A_{n-1}$, and $\forall i \in \{2 \dots n-1\}, A_i$ is connected to A_{i+1}, then we remove the connection of A_1 to all nodes $A_3 \dots A_{n-1}$, leaving A_1 only connected to A_2.

3.6.2 Clearing noise and merging names

Finally we remove potential noise which accidentally connects remote graph parts. If some edge discovered through a single pattern instance connects distant (distance>3) parts of the graph we remove it.

Additionally, we would like to merge common name alternations and misspellings of places. We merge two nodes A and B into one node if either (1) A, B have exactly the same edges, and their edge count is greater than 2; or (2) edges of A are subset of B's edges and the string edit distance between A and B is less than a third of min(StringLength(A), StringLength(B)).

4 Evaluation

Since our problem definition differs significantly from available related work, it is not possible to make direct comparisons. We selected three different cases (in Nepal, Israel, Wales) where the obtained information can be reliably verified, and applied our framework on these settings. As a development set, we used the Russian rail network.

We have estimated the quality of our framework using several measures and observations. First, we calculated the precision and quantity of obtained locations using map information. Then we manually estimated precision of the proposed edges and their labels, comparing them with factual information obtained from maps[7], transport companies and tourist sites. Finally we visually compared a natural drawing of the obtained graph with a real map. In addition, while our goals differ, the third evaluation setting has deliberate significant similarities to (Schockaert et al., 2008), which allows us to make some comparisons.

[7]We recognize that in case of some labels, e.g. 'walk', the precision measure is subjective. Nevertheless it provides a good indication for the quality of our results.

4.1 The Annapurna trek area

One of the most famous sites in Nepal is the Annapurna trekking circuit. This is a 14-21 day walking path which passes many villages. Most of the tourists going through this path spend weeks in prior information mining and preparations. However, even when using the most recent maps and guides, they discover that available geographical knowledge is far from being complete and precise. This trek is a good example of a case when formal information is lacking while free-text shared experience in the web is abundant. Our goal was to test whether the algorithm can discover such knowledge automatically starting from few seed location names (we used Pokhara, which is one of the central cities in the area, and Khudi, a small village). The quality of results for this task was very good. While even crude recall estimation is very hard for this type of task, we have discovered 100% of the Annapurna trek settlements with population over 1K, all of the flight and bus connections, and about 80% of the walking connections.

On Figure 1 we can compare the real map and the obtained map[8]. This discovered map includes a partial map[9] for 4 labels – flights, trek, bus and jeep. You can see on the map different lines for each label. The algorithm discovered 132 entities, all of them Annapurna-related locations. This includes correctly recognized typos and alternative spellings, and the average was 1.2 names per place. For example for Besisahar and Pokhara the following spellings were recognized based both on string distance and spatial collocation: *Besishahar, Bensisahar, BesiSahar, Besi Sahar, Beshishahar, Beisahar, Phokra, Pohkala, Pokahara, Pokhara, Pokhar, Pokra, Pokhura, Pokhra.*

We estimated correctness of edges comparing to existing detailed maps. 95% of the edges were correctly placed and labeled. Results were good since this site is well covered and also not very interconnected – most of it is connected in a single possible way. After the elimination process described in the previous section, only 6% of the nodes participate in 3-cliques. Thus, due to the linearity of the original path, our method success-

[8]Graph nodes were manually positioned such that edges do not intersect. Recall that our goal is to build a network graph, which is an abstract structure. The 2-D embedding of the graph shown here is only for illustrative purposes and is not part of our algorithm.

[9]A few dozens of correctly discovered places were omitted to make the picture readable.

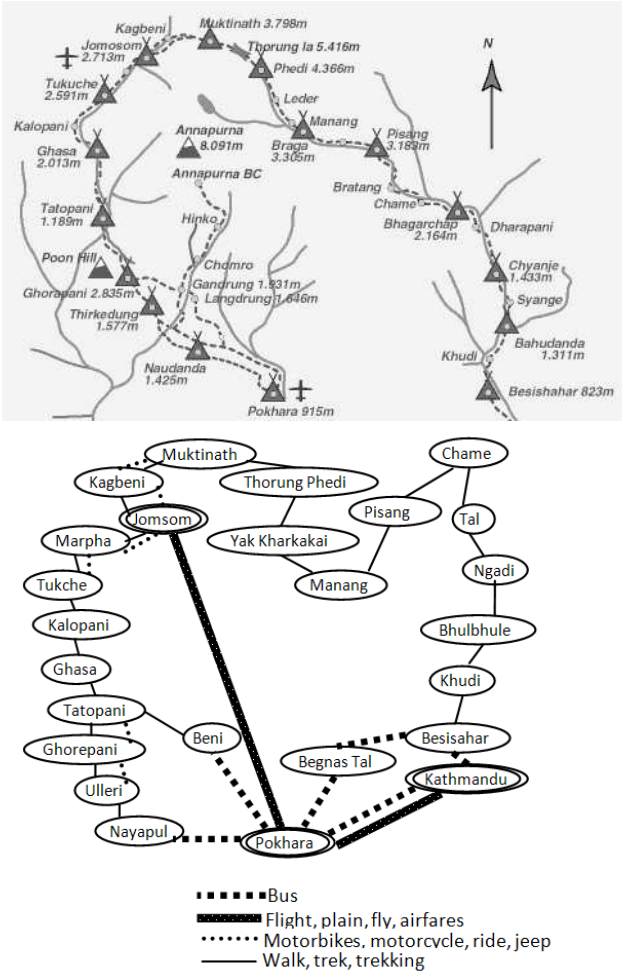

Figure 1: Real path map of Annapurna circuit (above) compared to automatically acquired graph (below). The graph nodes were manually positioned such that edges do not cross each other. Dozens of correctly discovered places were omitted for readability. Double circles indicate key nodes as explained in section 3.6.1

fully avoided the problem of mixing transitively connected nodes into one large clique.

4.2 The Israeli south

The southern part of Israel (mostly the Negev desert) is a sparsely populated region containing a few main roads and a few dozen towns. There is a limited number of tourists sites in the Negev and hence little web information is supposed to be available. Our goal was to see if the algorithm can successfully detect at least major entities and to discover their connectedness.

We discovered 56 names of different places, of them 50 correctly belong to the region, where the region is defined as south from the Ashquelon-Jerusalem-Yericho line, the other 6 were Israeli cities/locations outside the region (Tiberias, Metulla, Ben Gurion, Tel Aviv, Ashdod, Haifa). In addition we discovered 23 alternative names for some of the 56 places. We also constructed the corresponding connectedness graphs.

We tested the usefulness of this data attempting to find the discovered terms in the NGA GEOnet Names Server[10] which is considered one of the most exhaustive geographical resources. We could find in the database only 60% of the correctly discovered English terms denoting towns, so 40% of the terms were discovered by us and ignored by this huge coverage database. We also tested the quality of edges, and found that 80% of the discovered edges were correctly placed and labeled. Figure 2 shows a partial graph of the places obtained for the 'road' label.

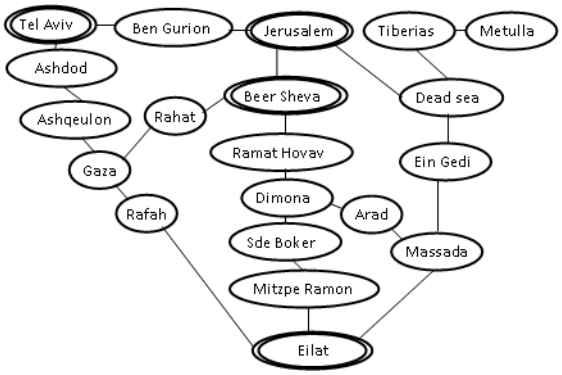

Figure 2: Partial graph for Israel south settings.

4.3 The Cardiff area

Cardiff is the capital, largest city and most populous county in Wales. Our goal was to see if we can discover basic means of transport and corresponding locations connected to and inside Cardiff. This exploration also allowed us to compare some of our results to related studies. We executed our algorithm using as seeds Grangetown, Cardiff and Barry. Table 1 shows the most utilized merged labels obtained for most edge-populated graphs together with graph size and estimated precision. In case of flights, treks and trains, precision was estimated using exact data. In other cases we estimated precision based on reading relevant web pages. We can see that the majority of connectivity sets are meaningful and the precision obtained for most of these sets is high. Figure 3 shows a partial graph for 'walking'-type labels and Figure

[10] http://earth-info.nga.mil/gns/html/

Nodes	Edges(Prec)	Label
88	120(81)	walking,walk,cycling,short ride taxis, Short bus ride,short walk
131	140(95)	flights, airlines,# flights a day
12	16(100)	foot path, trek, walking # miles
36	51(89)	train, railway, rail travel,rail
32	98(65)	bus, road, drive,direct bus

Table 1: The merged labels obtained for 5 most edge-populated graphs, including number of nodes and edges for each label. The estimated precision according to each label definition is shown in parentheses.

4 shows such a graph for train labels[11]. Comparing the obtained map with real map data we notice a definite correlation between actual and induced relative connection of discovered places.

(Schockaert et al., 2008) used their framework to discover neighborhoods of Cardiff. In our case, the most appropriate relation which connects neighborhood locations is walking/cycling. Hence, comparing the results to previous work, we have examined the results obtained for the 'walking' label in details. (Schockaert et al., 2008) report discovery of 68 locations, of them 7 are alternate entries, 4 can be considered vernacular or colloquial, 10 are not considered to be neighborhoods, and 5 are either close to, but not within, Cardiff, or are areas within Cardiff that are not recognized neighborhoods. In our set we have discovered 88 neighborhood names, of them 18 are alternate entries of correct neighborhoods, 4 can be considered vernacular or colloquial, 3 are not considered to be neighborhoods, and 15 are areas outside the Cardiff area.

Considering alternate entries as hits, we got superior precision of $66/88 = 0.75$ in comparison to $49/68 = 0.72$. It should be noted however that we found many more alternative names possibly due to our larger coverage. Also both our framework and the goal were substantially different.

5 Discussion

In this paper we presented a framework which, given a small set of seed terms describing a geographical region, discovers an underlying connectivity and transport graph together with the extraction of common and alternative location names in this region. Our framework is based on the observation that 'from...to'-like patterns can encode connectedness in very precise manner. In our framework, we have combined iterative pattern- and web-based relationship acquisition with the discovery of new patterns and refinement of the location graph. In our evaluation we showed that our framework is capable of extracting high quality non-trivial information from free text given very restricted input and not relying on any heavy preprocessing techniques such as parsing or NER.

The success of the proposed framework opens many challenging directions for its enhancement. Thus we would like to incorporate in our network patterns which allow traveling times and distances to be extracted, such as 'N miles from X to Y'. While in this paper we focus on specific type of geographical relationships, similar frameworks can be useful for a wider class of spatial relationships. Automated acquisition of spatial data can significantly help many NLP tasks, e.g., question answering. We would also like to incorporate some patterns based on (Egenhofer and Shariff, 1998), such as 'crosses', 'goes through' or 'runs into', which may allow automated acquisition of complex spatial relationships. Finally, we would like to incorporate in our framework mod-

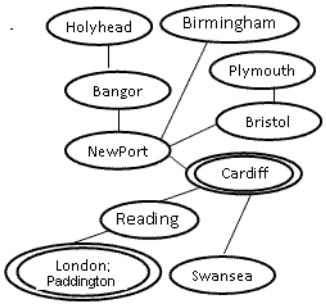

Figure 4: Partial graph of the obtained Cardiff region for the railway/train label.

[11] Spatial position of displayed graph components is arbitrary, we only made sure that there are no intersecting edges.

ules which may allow recognition of structured data, like those developed by (Schockaert et al., 2008).

Abstract

In this paper, we address the issue of automatic extending lexical resources by exploiting existing knowledge repositories. In particular, we deal with the new task of linking FrameNet and Wikipedia using a word sense disambiguation system that, for a given pair frame – lexical unit (F, l), finds the Wikipage that best expresses the the meaning of l. The mapping can be exploited to straightforwardly acquire new example sentences and new lexical units, both for English and for all languages available in Wikipedia. In this way, it is possible to easily acquire good-quality data as a starting point for the creation of FrameNet in new languages. The evaluation reported both for the monolingual and the multilingual expansion of FrameNet shows that the approach is promising.

1 Introduction

Many applications in the context of natural language processing or information retrieval have proved to convey significant improvement by exploiting lexical databases with high-quality annotation such as *FrameNet* (Fillmore et al., 2003) and *WordNet* (Fellbaum, 1998). Nevertheless, the practical use of similar resources is often biased by their limited coverage because manual annotation is time-consuming and requires a relevant financial effort. For this reason, some research activities have focused on the automatic enrichment of such resources with annotated information in (near) manual quality. The main strategy proposed was the mapping between resources in order to reciprocally enrich different lexical databases by linking their information layers. This has proved to be useful in several tasks, from verb classification (Chow and Webster, 2007) to semantic role labeling (Giuglea and Moschitti, 2006), open text semantic parsing (Shi and Mihalcea, 2004) and textual entailment (Burchardt and Frank, 2006).

In this work, we focus on the automatic enrichment of the FrameNet database for English and we propose a new framework to extend this procedure to new languages. While similar works in the past have mainly proposed to automatically extend the FrameNet database by mapping frames and WordNet synsets (Shi and Mihalcea (2005), Johansson and Nugues (2007), and Tonelli and Pighin (2009)), we present an explorative approach that for the first time exploits Wikipedia to this purpose. In particular, given a lexical unit l belonging to a frame F, we devise a strategy to link l to the Wikipedia article that best captures the sense of l in F. This is basically a word disambiguation (WSD) problem (Erk, 2004) and to this purpose we employ a state-of-the-art WSD system (Gliozzo et al., 2005). The mapping between (F, l) pairs and Wikipedia pages could then be exploited for three further subtasks: (a) automatically extract from Wikipedia all sentences pointing to the Wikipage mapped with (F, l) and assign them to F; (b) automatically expand the lexical units sets in the English FrameNet by exploiting the redirecting and linking strategy of Wikipedia; and (c) since Wikipedia is available in 260 languages, use the English Wikipedia article linked to (F, l) as a bridge to carry out sentence and lexical unit retrieval in other languages. The set of automatically collected data would represent the starting point for the creation of FrameNet in new languages. In fact, having a repository of sentences extracted from Wikipedia which have already been divided by sense would significantly speed up the annotation process. In this way, the annotators would not need to extract all sentences in a corpus containing l and classify them by sense. Instead, they should simply validate the given sentences and assign the correct frame elements.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 276–285,
Singapore, 6-7 August 2009.

In the following, we start by providing a brief overview of FrameNet and Wikipedia and we present their structure and organization. Next, we describe the algorithm for mapping lexical units and Wikipages and the word sense disambiguation algorithm employed by the system. In Section 5 we describe the dataset used in the first experiment and report evaluation results of the mapping between (F, l) pairs and Wikipedia senses. In Section 6 we describe an application of the mapping, i.e. the automatic enrichment of English FrameNet. We describe the data extraction process and evaluate the quality of the data. In Section 7 we describe and evaluate another application of the mapping, i.e. the acquisition of data for the automatic creation of Italian FrameNet using the Italian Wikipedia. Finally, we draw conclusions and present future research directions.

2 FrameNet and Wikipedia

FrameNet (Fillmore et al., 2003) is a lexical resource for English based on corpus evidence, whose conceptual model comprises a set of prototypical situations called *frames*, the frame-evoking words or expressions called *lexical units* (LUs) and the roles or participants involved in these situations, called *frame elements*. All lexical units belonging to the same frame have similar semantics but, differently from WordNet synsets, they can belong to different categories and present different parts of speech. For example, the KILLING frame is described in the FrameNet database[1] as *"A Killer or Cause causes the death of the Victim"*. The elements in capitals are the semantic roles (*frame elements*) typically involved in the KILLING situation. The frame definition comes also with the list of frame-evoking lexical units, namely *annihilate.v, annihilation.n, butchery.n, carnage.n, crucify.v, deadly.a*, etc. Since FrameNet is a corpus-based resource, every lexical unit should be instantiated by a set of example sentences, where the frame elements are annotated as well. Instead, FrameNet is still an ongoing project and in the latest release (v. 1.3) there are about 3,380 lexical units out of 10,195 that come with no example sentences. In this work we focus on these lexical units and propose how to automatically collect the missing sentences. Anyhow, the algorithm we propose is suitable also for expanding sentence sets already present in FrameNet.

Wikipedia[2] is one of the largest online repositories of encyclopedic knowledge, with millions of articles available for a large number of languages (>2,800,000 for English). The *article* (or *page*) is the basic entry in Wikipedia. Every article has an unique reference, i.e., one or more words that identify the page and are present in its URL. For example, *Ball_(dance)* identifies the page that describes several types of ball intended as formal dance, while *Dance_(musical_form)* describes the dance as musical genre. Every Wikipedia article is linked to others, and in the body of every page there are plenty of links to connect the most relevant terms to other pages. Another important attribute is the presence of about 3,000,000 redirection pages, that given an identifier that is not present in Wikipedia, automatically display the page with the most semantically similar identifier (for example *Killing* is redirected to the *Murder* page). Wikipedia contains also more than 100,000 disambiguation pages listing all senses (pages) for an ambiguous entity. For example, *Book* has 9 senses, which correspond to 9 different articles. Wikipedia structure and quality make this resource particularly suitable for information extraction and word sense disambiguation tasks (Csomai and Mihalcea (2008) and Milne and Witten (2008)). In fact, page references can be seen as senses and Wikipedia as a large sense inventory. From this point of view, also linking a lexical unit to the correct Wikipedia page is a word sense disambiguation issue because it implies recognizing what meaning the lexical unit has in the given frame. For example, *dance.n* in the SOCIAL_EVENT frame should be linked to *Ball_(dance)* and not to *Dance_(musical_form)*.

3 The Mapping Algorithm

In this section, we describe how to map a frame – lexical unit pair (F, l) into the Wikipedia article that best captures the sense of l as defined in F. The mapping problem is casted as a supervised WSD problem, in which l must be disambiguated using F to provide the context and Wikipedia to provide the sense inventory and the training data. Even if the idea of using Wikipedia links for disambiguation is not novel (Cucerzan, 2007), it is applied for the first time to FrameNet lexical units, considering a frame as a sense definition. The proposed algorithm is summarized as follows:

[1] http://framenet.icsi.berkeley.edu

[2] http://en.wikipedia.org

Step 1 For each lexical unit l, we collect from the English Wikipedia dump[3] all contexts[4] where l is the anchor of an internal link (wiki link). The set of targets represents the senses of l in Wikipedia and the contexts are used as labelled training examples. For example, the lexical unit *building.n* in the frame *Buildings* is an anchor in 708 different contexts that point to 42 different Wikipedia pages (senses).

Step 2 The set of contexts with their corresponding senses is then used to train the WSD system described in Section 4. For example, the context "The *building*, which date from the mid-to-late 19th century, were built in a variety of High Victorian architectural styles." is a training example for the sense defined by the Wikipedia page *Building*.

Step 3 Finally, the disambiguation model learned in the previous step is used to map a pair (F, l) to a Wikipedia article. (F, l) is represented as a fictitious-context derived by aggregating the frame definition and all lexical units associated to F. We used the term "fictitious-context" to remark the slight difference in structure compared with the training contexts (i.e., the Wikipedia paragraphs). For example, "... structures forming an enclosure and providing protection from the elements ... acropolis arena auditorium bar building ..." is the fictitious-context built for the pair *(Buildings, building.n)*. The sense, i.e., the Wikipedia article, assigned to the fictitious-context by the disambiguation algorithm uniquely defines the mapping. The previous example is assigned to the Wikipedia page *Building*.

4 The WSD Algorithm

Gliozzo et al. (2005) proposed an elegant approach to WSD based on kernel methods. The algorithm proved effective at Senseval-3 (Mihalcea and Edmonds, 2004) and, nowadays, it still represents the state-of-the-art in WSD (Pradhan et al., 2007). Specifically, they addressed these issues: (i) independently modeling domain and syntagmatic aspects of sense distinction to improve feature representativeness; and (ii) exploiting external knowledge acquired from unlabeled data, with the purpose of drastically reducing the amount of labeled training data. The first direction is based on the linguistic assumption that syntagmatic and domain (associative) relations are crucial for representing sense distictions, but they are originated by different phenomena. Regarding the second direction, it is possible to obtain a more accurate prediction by taking into account unlabeled data relevant for the learning problem (Chapelle et al., 2006).

On the other hand, kernel methods are theoretically well founded in statistical learning theory and shown good empirical results in many applications (Shawe-Taylor and Cristianini, 2004). The strategy adopted by kernel methods consists of splitting the learning problem into two parts. They first embed the input data in a suitable feature space, and then use a linear algorithm (e.g., support vector machines) to discover nonlinear patterns in the input space. The kernel function is the only task-specific component of the learning algorithm. Thus, to develop a WSD system, one only needs to define appropriate kernel functions to represent the domain and syntagmatic aspects of sense distinction and to exploit the properties of kernel functions in order to define a composite kernel that combines and extends individual kernels.

The WSD system described in the following consists of a composite kernel (Section 4.3) that combines the domain and syntagmatic kernels. The former (Section 4.1) models the domain aspects of sense distinction, the latter (Section 4.2) represents the syntagmatic aspects of sense distinction.

4.1 Domain Kernel

It is been shown that domain information is fundamental for WSD (Magnini et al., 2002). For instance, the (domain) polysemy between the computer science and the medicine senses of the word "virus" can be solved by considering the domain of the context in which it appears.

In the context of kernel methods, domain information can be exploited by defining a kernel function that estimates the domain similarity between the contexts of the word to be disambiguated. The simplest method to estimate the domain similarity between two texts is to compute the cosine similarity of their vector representations in the vector space model (VSM). The VSM is a k-dimensional space $\mathbb{R}^k$, in which the text t_j is represented by a vector $\vec{t_j}$, where the i^{th} component is the term

[3] http://download.wikimedia.org/enwiki/20090306

[4] A context corresponds to a line of text in the Wikipedia dump and it is represented as a paragraph in a Wikipedia article.

frequency of the term w_i in t_j. However, such an approach does not deal well with lexical variability and ambiguity. For instance, despite the fact that the sentences "he is affected by AIDS" and "HIV is a virus" express concepts closely related, their similarity is zero in the VSM because they have no words in common (they are represented by orthogonal vectors). On the other hand, due to the ambiguity of the word "virus" , the similarity between the sentences "the laptop has been infected by a virus" and "HIV is a virus" is greater than zero, even though they convey very different messages.

To overcome this problem, Gliozzo et al. (2005) introduced the domain model (DM) and show how to define a domain VSM in which texts and terms are represented in a uniform way. A DM is composed of soft clusters of terms. Each cluster represents a semantic domain, that is, a set of terms that often co-occur in texts having similar topics. A DM is represented by a $k \times k'$ rectangular matrix $\mathbf{D}$, containing the degree of association among terms and domains.

The matrix $\mathbf{D}$ is used to define a function $\mathcal{D} : \mathbb{R}^k \rightarrow \mathbb{R}^{k'}$, that maps the vector $\vec{t_j}$ represented in the standard VSM, into the vector $\vec{t'_j}$ in the domain VSM. $\mathcal{D}$ is defined by

$$\mathcal{D}(\vec{t_j}) = \vec{t_j}(\mathbf{I^{IDF}D}) = \vec{t'_j}, \tag{1}$$

where $\vec{t_j}$ is represented as a row vector, $\mathbf{I^{IDF}}$ is a $k \times k$ diagonal matrix such that $i^{IDF}_{i,i} = IDF(w_i)$, and $IDF(w_i)$ is the inverse document frequency of w_i.

In the domain space, the similarity is estimated by taking into account second order relations among terms. For example, the similarity of the two sentences "He is affected by AIDS" and "HIV is a virus" is very high, because the terms AIDS, HIV and virus are strongly associated with the domain medicine.

Singular valued decomposition (SVD) is used to acquire in a unsupervised way the DM from a corpus represented by its term-by-document matrix $\mathbf{T}$. SVD decomposes the term-by-document matrix $\mathbf{T}$ into three matrixes $\mathbf{T} \simeq \mathbf{V}\mathbf{\Sigma_{k'}}\mathbf{U}^T$, where $\mathbf{V}$ and $\mathbf{U}$ are orthogonal matrices (i.e., $\mathbf{V}^T\mathbf{V} = \mathbf{I}$ and $\mathbf{U}^T\mathbf{U} = \mathbf{I}$) whose columns are the eigenvectors of $\mathbf{T}\mathbf{T}^T$ and $\mathbf{T}^T\mathbf{T}$ respectively, and $\mathbf{\Sigma_{k'}}$ is the diagonal $k \times k$ matrix containing the highest $k' \ll k$ eigenvalues of $\mathbf{T}$, and all the remaining elements set to 0. The parameter k' is the dimensionality of the domain VSM and can be fixed in advance. Under this setting, the domain matrix $\mathbf{D}$ is defined by

$$\mathbf{D} = \mathbf{I^N}\mathbf{V}\sqrt{\mathbf{\Sigma_{k'}}} \tag{2}$$

where $\mathbf{I^N}$ is a diagonal matrix such that $\mathbf{i^N_{i,i}} = \frac{1}{\sqrt{\langle \vec{w'_i}, \vec{w'_i} \rangle}}$, $\vec{w'_i}$ is the i^{th} row of the matrix $\mathbf{V}\sqrt{\mathbf{\Sigma_{k'}}}$. The domain kernel is explicitly defined by

$$K_D(t_i, t_j) = \langle \mathcal{D}(t_i), \mathcal{D}(t_j) \rangle, \tag{3}$$

where $\mathcal{D}$ is the domain mapping defined in Equation 1. Finally, the domain kernel is further extended to include the standard bag-of-word kernel.

4.2 Syntagmatic Kernel

Kernel functions are not restricted to operate on vectorial objects $\vec{x} \in \mathbb{R}^k$. In principle, kernels can be defined for any kind of object representation, such as strings and trees. As syntagmatic relations hold among words collocated in a particular temporal order, they can be modeled by analyzing sequences of words. Therefore, the string kernel (Shawe-Taylor and Cristianini, 2004) is a valid tool to represent such relations. It counts how many times a (non-contiguous) subsequence of symbols u of length n occurs in the input string s, and penalizes non-contiguous occurrences according to the number of gaps they contain. Formally, let V be the vocabulary, the feature space associated with the string kernel of length n is indexed by a set I of subsequences over V of length n. The (explicit) mapping function is defined by

$$\phi^n_u(s) = \sum_{\mathbf{i}:u=s(\mathbf{i})} \lambda^{l(\mathbf{i})}, u \in V^n, \tag{4}$$

where $u = s(\mathbf{i})$ is a subsequence of s in the positions given by the tuple $\mathbf{i}$, $l(\mathbf{i})$ is the length spanned by u, and $\lambda \in]0, 1]$ is the decay factor used to penalize non-contiguous subsequences.

The associated string kernel is defined by

$$K_n(s_i, s_j) = \langle \phi^n(s_i), \phi^n(s_j) \rangle = \sum_{u \in V^n} \phi^n(s_i)\phi^n(s_j) \tag{5}$$

Gliozzo et al. (2005) modified the generic definition of the string kernel in order to take into account (sparse) collocations. Specifically, they defined syntagmatic kernels as a combination of string kernels applied to sequences of words in a fixed-size window centered on the word to be disambiguated. This formulation allows estimating the number of common (sparse) subsequences of

words (i.e., collocations) between two examples, in order to capture syntagmatic similarity. The syntagmatic kernel is defined by

$$K_S(s_i, s_j) = \sum_{n=1}^{p} K_n(s_i, s_j), \quad (6)$$

where K_n is the string kernel defined in Equation 5 and the parameter n represents the length of the subsequences analyzed when estimating the similarity between contexts. Notice that the syntagmatic kernel is only effective for those fictitious contexts in which the lexical units do occur in meaningful sentences, however this is not guaranteed for the lexical units without examples.

4.3 Composite Kernel

Finally, to combine domain and syntagmatic information, the composite kernel is defined by

$$K_{WSD}(t_i, t_j) = \hat{K}_D(t_i, t_j) + \hat{K}_S(t_i, t_j), \quad (7)$$

where $\hat{K}_D$ and $\hat{K}_S$ are normalized kernels defined in Equation 3 and 6, respectively.[5] It follows directly from the explicit construction of the feature space and from closure properties of kernels that it is a valid kernel.

5 Mapping task

In this section we report the first experiment, namely the mapping between (F, l) pairs and a Wikipedia pages. We describe the experimental setup and then present the corresponding evaluation.

5.1 Experimental setup

We applied our algorithm to all lexical units that do not have any example sentence in the FrameNet database. In principle, the proposed approach can be applied to every lexical unit, and we expect the algorithm performance to improve if some example sentences are already available because they could be added to the fictitious-context used to represent (F, l) in the system. Nevertheless, in this explorative study we wanted to focus on the harder cases, even if results are likely to be worse than on the whole FrameNet database.

In FrameNet, 3,305 (F, l) pairs have no example sentences (536 pairs with adjectival LU, 1313 verbal LU, 1456 nominal LU). Since Wikipedia is basically a resource organized by concepts, which are generally expressed by nouns, we decided to restrict our experiment to nominal lexical units. Besides, many verbal and adjectival concepts in Wikipedia are redirected to nominal identifiers. So, we randomly selected 900 pairs with nominal lexical units. For the moment, we decided to discard lexical units expressed by multiwords (about 150), which will be taken into account in a future version of our system. The average ambiguity of the 900 LUs considered is 1.24 in FrameNet. Instead, every LU corresponds to about 35 candidate senses in Wikipedia.

In order to perform WSD, we built the domain model from the 200,000 most visited Wikipedia articles. After removing terms that occur less than 5 times, the resulting dictionaries contain about 300,000 terms. We used the SVDLIBC package[6] to compute the SVD, truncated to 100 dimensions. The experiments were performed using the SVM package *LIBSVM* (Chang and Lin, 2001) customized to embed the kernels described in Section 4.

5.2 Evaluation

In this first evaluation step, we focus on the quality of the mapping between (F, l) pairs and Wikipedia articles. In order to evaluate the system output, we created a gold standard where 250 (F, l) pairs randomly extracted from the nominal subset described above have been manually linked to the Wikipedia page (if available) that best corresponds to the meaning of l in F. The pairs have been chosen in order to maximize the frame variability, i.e. every pair corresponds to a different frame. Since our gold standard contains 34% of all frames in the FrameNet database, we believe that, despite its limited size, it is well representative of FrameNet characteristics. Evaluation was carried out comparing the system output against the gold standard. Results are reported in Table 1. The baseline was computed considering the *most frequent sense* of every lexical unit in Wikipedia. This element is obtained by taking into account all occurrences in Wikipedia where the lexical unit LU we consider is anchored to a given page. The most frequent sense for LU is the page to which LU is most frequently linked in Wikipedia. Since about 14% of the lexical units in the gold standard are not present in Wikipedia, we also estimated an upper bound accuracy of 0.86. This confirms our in-

[5] $\hat{K}(x_i, x_j) = \frac{K(x_i, x_j)}{\sqrt{K(x_j, x_j)K(x_i, x_i)}}$

[6] http://tedlab.mit.edu/~dr/svdlibc/

tuition that FrameNet and Wikipedia are linkable resources to a large extent and that our task is well-founded.

	Accuracy
Baseline	0.66
System output	**0.71**
Upper bound	0.86

Table 1: Accuracy evaluation.

Wrong assignments include also problematic cases that are not directly connected to proper system errors. One of the most relevant issues is the different granularity between FrameNet frames and Wikipages. For example, the NETWORK frame is defined as *"a set of entities of the same or similar types (Nodes) are linked to each other by Connections to form a Network allowing for the flow of information, resources, etc."*. Even if the listed lexical units (*network.n* and *web.n*) and some examples refer to the informatics domain, the situation described in the FrameNet database is more general. Wikipedia instead lists several pages that may be seen as subdomains of NETWORK such as *Computer_network*, *Social_network*, *Telecommunications_network*, etc. In the future, it may be worth modifying the system in order to allow multiple assignments of Wikipages for every frame.

In other cases, frame definitions seem not to be very consistent and it is very difficult to discriminate between two frames even for a human annotator. For example, ESTIMATED_VALUE and ESTIMATING include both *estimation.n* as lexical unit, but since their frame definitions are almost the same and the other lexical units in the same frame are not discriminative, the system links both (F, l) pairs to the same Wikipedia article.

6 English FrameNet expansion

In the following part of the experiment, we want to investigate to what extent the FrameNet – Wikipedia mapping can be effectively applied to automatically expand the FrameNet database with new example sentences, and eventually to acquire new lexical units. For every (F, l) pair, we consider the linked Wikipedia sense *s* and extract all sentences C_s in Wikipedia with a reference to s. In this way, we can assume that, if s was linked to (F, l), C_s can be included in the example sentences of F. This repository of sentences is already divided by sense and can significantly speed-up manual annotation. On the other hand, the extracted sentences could enrich the training set of machine learning systems for frame annotation to improve the frame identification step. In fact, this task has raised growing interest in the NLP community, with a devoted challenge at the last SemEval campaign (Baker et al., 2007).

This retrieval process allows also to extract from C_s all words W_s that have an embedded reference to s in the form *word*. In this way, W_s are automatically included in F as new lexical units. In this phase, redirecting links are very useful because they automatically connect a word or expression to its nearest sense in case there is no specific page for this word. The information about redirecting allows also to account for orthographic variations of the same lexical unit, for example *collectible* is redirected to *collectable*.

We explain the data extraction process in the light of an example from our dataset. Our WSD system assigned to the (F, l) pair (WORD_RELATIONS – *homonym.n*) the Wikipage `http://en.wikipedia.org/wiki/Homonym`. So, we extracted from the English Wikipedia dump all sentences where the anchor *<a href="/wiki/Homonym"...* > appears and assumed that the word or multiword expression that is linked to the *Homonym* site may be a good candidate as lexical unit for the WORD_RELATIONS frame. In this case, the example sentences were 186. Apart from *homonym*, the candidate lexical units are *homograph*, *homophone*, *homophonous*, *homonymic*, *heteronym*, *same*. Among them, only the latter is not appropriate, even if the sentence where it occurs is semantically connected to the WORD_RELATIONS frame: "In Hebrew the word 'thus' has the *same* triconsonantal root". Instead, *homonymic* and *heteronym* can be acquired as new lexical units for WORD_RELATIONS, and *homograph*, for which no example sentences are provided in FrameNet, can be automatically instantiated by a set of examples.

6.1 Experimental setup

We considered 893 frame – lexical unit pairs assigned to Wikipedia pages following the algorithm described in Section 3. We discarded 7 pairs for which the system reported an assignment failure, i.e. the best sense delivered is the disambigua-

tion page. Then we extracted a set of sentences for every (F, l) pair as described in the previous paragraph. Statistics about the retrieved data is reported in Table 2.

	English Wikipedia
(F, l) pairs	893
N. of extracted sents	964,268
Avg. sents per (F, l)	1,080

Table 2: Extracted data from English Wikipedia

6.2 Evaluation

The dimension of the extracted corpus does not allow to carry out a comprehensive evaluation. For this reason, we manually evaluated 1,000 sentences, i.e. we considered 20 (F, l) pairs, and for each of them we evaluated 50 sentences extracted from our large repository. Both (F, l) pairs and the assigned sentences were randomly selected. In particular, the 20 (F, l) pairs do not contain only correctly assigned pairs, in fact three of them are wrong. Anyhow, the 20 pairs seem to be a representative subset of the 893 pairs considered in our experiment because they include both monosemic lexical units (*gynaecology.n* in MEDICAL_SPECIALTIES) and more ambiguous ones (*club.n* in the WEAPON frame).

Our evaluation shows that 78% of the sentences were correctly linked to (F, l) pairs. This value is higher that the mapping accuracy between (F, l) and Wikipages reported in Section 5.2. In fact, we noticed that even if the Wikipage assigned to (F, l) is not the article that best corresponds to the meaning of l in F, some sentences pointing to it may be appropriate to express l.

As we already mentioned in Section 5.2, the different granularity of the information encoded by frames and Wikipages impacts on the output quality. For example, *conversion.n* in CAUSE_CHANGE has a causative meaning, while it implies a personal process in UNDERGO_CHANGE. The mapping, instead, links (CAUSE_CHANGE – *conversion.n*) to the *Religious_conversion* page, and all the sentences collected point to religious conversion, regardless of their causative form or not. Another characteristic of this approach is that we can acquire new lexical units regardless of their part-of-speech, even if we start from nominal lexical units. This proves that we do not need to apply the initial mapping to verbal or adjectival LUs to obtain new data for all parts of speech. For example, we linked (MEDICAL_SPECIALTIES – *gynaecology.n*) to the *Gynaecology* Wikipage. Consequently, we could include the adjective *gynaecologic*, pointing to the *Gynaecology* page, into the MEDICAL_SPECIALTIES frame for sentences like "Fellowship training in a *gynaecologic* subspeciality can range from one to four years". However, this advantage can also turn into a weakness, because *gynaecologist* is also redirected to the *Gynaecology* page, but it belongs to MEDICAL_PROFESSIONALS and should not be included into MEDICAL_SPECIALTIES.

For the 20 (F, l) pairs considered in the given sentences, it was possible also to retrieve 8 lexical units that are not present in FrameNet, for example *billy-club* for the WEAPON frame. Exploiting redirections and anchoring strategies, our induction method can account for orthographical variations, for example it acquires both *memorize* and *memorise*. On the other hand, also misspelled words may be collected, for instance *gynaecologial* instead of *gynaecological*.

7 Multilingual FrameNet expansion

One of the great advantages of Wikipedia is its availability in several languages. The English version is by far the most extended, but a considerable repository of pages is available also for other languages, esp. European ones. In general, articles on the same object in different languages are edited independently and do not have to be translations of one another, but are linked to each other by their authors. In this way, the multilingual versions of Wikipedia can be easily exploited to build comparable corpora, with connected Wikipages in different languages dealing with the same contents.

In this research step, we focus on this aspect of Wikipedia and propose a methodology that, using the English Wikipages as a bridge, automatically acquires new lexical units and example sentences also for other languages. This would represent the starting point towards the creation of FrameNet for new languages. Indeed, FrameNet structure comprises a language-independent level of information, namely frame and frame element definitions, and a language-dependent one, i.e. the lexical units and the example sentences. This makes the resource particularly suitable to corpus-based (semi) automatic creation of FrameNet for new languages, because the descriptive part can be pre-

served and the language-dependent layer can be populated with new instances in other languages (Crespo and Buitelaar, 2008).

We apply our extraction algorithm to the Italian Wikipedia. Since several approaches have been experimented to (semi) automatically build Italian FrameNet using WordNet (De Cao et al. (2008) and Tonelli and Pighin (2009)), we believe that our new proposal to exploit Wikipedia may be of interest in the research community. Anyhow, the approach can be exploited in principle for every language available in Wikipedia.

7.1 Experimental setup

Similarly to the data extraction process described in Section 6, we consider for every (F, l) pair in English the linked Wikipedia sense s, in English as well. Then, we retrieve the Italian Wikipedia sense s_i linked to s and extract all sentences C_i in the Italian Wikipedia dump[7] with a reference to s_i. In this way, we can assume that C_i are example sentences of F and that the words or expressions W_i in C_i containing an embedded reference to s_i are good candidate lexical units of F in the Italian FrameNet. For example, if we link `http://en.wikipedia.org/wiki/Court` to the JUDICIAL_BODY frame, we first retrieve the Italian version of the site `http://it.wikipedia.org/wiki/Tribunale`. Then, with a top-down strategy, we further extract all Italian sentences pointing to the `Tribunale` page and acquire as lexical units all words with an embedded reference to this concept, for example *tribunale* and *corte*. In this way, we can include the extracted lexical units and the sentences where they occur in the JUDICIAL_BODY frame for Italian.

Given the 893 (F, l) pairs in English and the linked Wikipedia senses described in 6.2, we first extracted the Italian Wikipages that are linked to the English ones. Then for every linked Wikipage in Italian, we retrieved all sentences with a reference pointing to that page in the Italian Wikipedia dump. Statistics about the extracted data are reported in Table 3.

Since the Italian Wikipedia is about one fifth of the English one, it was not possible to map every English Wikipage with an Italian article. In fact, only 371 senses out of 893 in English were linked to an Italian page. Also the average number of sentences extracted for every sense is much smaller (62 vs. 1,080). Anyhow, this does not represent a problem because in the English FrameNet, the lexical units whose annotation is considered to be *complete* are usually instantiated by set of 20 annotated sentences on average. So, according to the FrameNet standard, 60 sentences are more than enough to represent the meaning of a lexical unit in a frame.

	Italian Wikipedia
Linked Wikipages in Italian	371
N. of extracted sents	23,078
Avg. sents per Italian sense	62

Table 3: Extracted data from Italian Wikipedia

7.2 Evaluation

In this evaluation part, we took into account 1,000 sentences, in order to have a comparable dataset w.r.t. the evaluation for English. However, the sets of Italian sentences extracted for every (F, l), i.e. for every Wikipedia article, were much smaller, so we increased the number of randomly chosen (F, l) pairs to 80. Our evaluation is focused on the quality of the sentences and aims at assessing if the given sentences are correctly assigned to the (F, l) pairs. We report 69% accuracy, which is 9% lower than for English. Apart from the same errors and issues reported for English, a decrease in performance can be explained by the fact that, since less articles are present w.r.t. the English version, redirections and internal links tend to be less precise and fine-grained. For example, the word "*diritti*" in the sense of "*(human) rights*" redirects to the article about *Diritto*, corresponding to *Law* as a system of rules. On the contrary, *Law* and *Rights* have two different pages in English. Besides, the different quality of the two resources can also depend on the smaller number of users that edit and check the Italian articles. From the 1,000 sentences evaluated we extracted 145 new lexical units: since Italian FrameNet does not exist yet, every lexical unit in a sentence that is correct can be straightforwardly included in the first version of the resource.

8 Conclusions and Future work

In this work, we have proposed to apply a word sense disambiguation system to a new task, namely the linking between FrameNet and Wikipedia. Results are promising and show that

[7] `http://download.wikimedia.org/itwiki/20090203`

the task is adequately substantiated. The proposed approach can help enriching FrameNet with new example sentences and lexical units and provide a starting point for the creation of FrameNet-like resources in all Wikipedia languages. On the one hand, the retrieved data could speed up human annotation, requiring only a manual validation. On the other hand, the extracted sentences could provide enough training data to machine learning systems for frame assignment, since insufficient frame attestations in the FrameNet database are a major problem for such systems.

In the next research step, we plan to carry out an extended evaluation process in order to compute inter-annotator agreement and eventually point out validation problems. Then, we want to extend the mapping and the data extraction process to all (F, l) pairs in FrameNet (about 10,000). The retrieved sentences will be made available as training or annotation material. Besides, we want to create an online resource where the links between (F, l) pairs and Wikipages are made explicit and where users can browse the retrieved sentences. The resource can be produced and made available with a reduced effort for every language in Wikipedia. Anyway, the English version has proved to be more precise, while the resource for new languages would require a more accurate revision.

Fast, Cheap, and Creative: Evaluating Translation Quality Using Amazon's Mechanical Turk

Chris Callison-Burch
Center for Language and Speech Processing
Johns Hopkins University
Baltimore, Maryland
ccb@cs.jhu.edu

Abstract

Manual evaluation of translation quality is generally thought to be excessively time consuming and expensive. We explore a fast and inexpensive way of doing it using Amazon's Mechanical Turk to pay small sums to a large number of non-expert annotators. For $10 we redundantly recreate judgments from a WMT08 translation task. We find that when combined non-expert judgments have a high-level of agreement with the existing gold-standard judgments of machine translation quality, and correlate more strongly with expert judgments than Bleu does. We go on to show that Mechanical Turk can be used to calculate human-mediated translation edit rate (HTER), to conduct reading comprehension experiments with machine translation, and to create high quality reference translations.

1 Introduction

Conventional wisdom holds that manual evaluation of machine translation is too time-consuming and expensive to conduct. Instead, researchers routinely use automatic metrics like Bleu (Papineni et al., 2002) as the sole evidence of improvement to translation quality. Automatic metrics have been criticized for a variety of reasons (Babych and Hartley, 2004; Callison-Burch et al., 2006; Chiang et al., 2008), and it is clear that they only loosely approximate human judgments. Therefore, having people evaluate translation output would be preferable, if it were more practical.

In this paper we demonstrate that the manual evaluation of translation quality is not as expensive or as time consuming as generally thought. We use Amazon's Mechanical Turk, an online labor market that is designed to pay people small sums of money to complete *human intelligence tests* – tasks that are difficult for computers but easy for people. We show that:

- Non-expert annotators produce judgments that are very similar to experts and that have a stronger correlation than Bleu.
- Mechanical Turk can be used for complex tasks like human-mediated translation edit rate (HTER) and creating multiple reference translations.
- Evaluating translation quality through reading comprehension, which is rarely done, can be easily accomplished through creative use of Mechanical Turk.

2 Related work

Snow et al. (2008) examined the accuracy of labels created using Mechanical Turk for a variety of natural language processing tasks. These tasks included word sense disambiguation, word similarity, textual entailment, and temporal ordering of events, but not machine translation. Snow et al. measured the quality of non-expert annotations by comparing them against labels that had been previously created by expert annotators. They report inter-annotator agreement between expert and non-expert annotators, and show that the average of many non-experts converges on performance of a single expert for many of their tasks.

Although it is not common for manual evaluation results to be reported in conference papers, several large-scale manual evaluations of machine translation quality take place annually. These include public forums like the NIST MT Evaluation Workshop, IWSLT and WMT, as well as the project-specific Go/No Go evaluations for the DARPA GALE program. Various types of human judgments are used. NIST collects 5-point fluency and adequacy scores (LDC, 2005), IWSLT and

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 286–295,
Singapore, 6-7 August 2009.

WMT collect relative rankings (Callison-Burch et al., 2008; Paul, 2006), and DARPA evaluates using HTER (Snover et al., 2006). The details of these are provided later in the paper. Public evaluation campaigns provide a ready source of gold-standard data that non-expert annotations can be compared to.

3 Mechanical Turk

Amazon describes its Mechanical Turk web service[1] as *artificial* artificial intelligence. The name and tag line refer to a historical hoax from the 18th century where an automaton appeared to be able to beat human opponents at chess using a clockwork mechanism, but was, in fact, controlled by a person hiding inside the machine. The Mechanical Turk web site provides a way to pay people small amounts of money to perform tasks that are simple for humans but difficult for computers. Examples of these Human Intelligence Tasks (or HITs) range from labeling images to moderating blog comments to providing feedback on relevance of results for a search query.

Anyone with an Amazon account can either submit HITs or work on HITs that were submitted by others. Workers are sometimes referred to as "Turkers" and people designing the HITs are "Requesters." Requesters can specify the amount that they will pay for each item that is completed. Payments are frequently as low as $0.01. Turkers are free to select whichever HITs interest them.

Amazon provides three mechanisms to help ensure quality: First, Requesters can have each HIT be completed by multiple Turkers, which allows higher quality labels to be selected, for instance, by taking the majority label. Second, the Requester can require that all workers meet a particular set of qualications, such as sufficient accuracy on a small test set or a minimum percentage of previously accepted submissions. Finally, the Requester has the option of rejecting the work of individual workers, in which case they are not paid.

The level of good-faith participation by Turkers is surprisingly high, given the generally small nature of the payment.[2] For complex undertakings like creating data for NLP tasks, Turkers do not have a specialized background in the subject, so there is an obvious tradeoff between hiring individuals from this non-expert labor pool and seeking out annotators who have a particular expertise.

[1] http://www.mturk.com/

[2] For an analysis of the demographics of Turkers and why they participate, see: http://behind-the-enemy-lines.blogspot.com/2008/03/mechanical-turk-demographics.html

4 Experts versus non-experts

We use Mechanical Turk as an inexpensive way of evaluating machine translation. In this section, we measure the level of agreement between expert and non-expert judgments of translation quality. To do so, we recreate an existing set of gold-standard judgments of machine translation quality taken from the Workshop on Statistical Machine Translation (WMT), which conducts an annual large-scale human evaluation of machine translation quality. The experts who produced the gold-standard judgments are computational linguists who develop machine translation systems.

We recreated all judgments from the WMT08 German-English News translation task. The output of the 11 different machine translation systems that participated in this task was scored by ranking translated sentences relative to each other. To collect judgements, we reproduced the WMT08 web interface in Mechanical Turk and provided these instructions:

Evaluate machine translation quality *Rank each translation from Best to Worst relative to the other choices (ties are allowed). If you do not know the source language then you can read the reference translation, which was created by a professional human translator.*

The web interface displaced 5 different machine translations of the same source sentence, and had radio buttons to rate them.

Turkers were paid a grand total of $9.75 to complete nearly 1,000 HITs. These HITs exactly replicated the 200 screens worth of expert judgments that were collected for the WMT08 German-English News translation task, with each screen being completed by five different Turkers. The Turkers were shown a source sentence, a reference translation, and translations from five MT systems. They were asked to rank the translations relative to each other, assigning scores from best to worst and allowing ties.

We evaluate non-expert Turker judges by measuring their inter-annotator agreement with the WMT08 expert judges, and by comparing the correlation coefficient across the rankings of the machine translation systems produced by the two sets of judges.

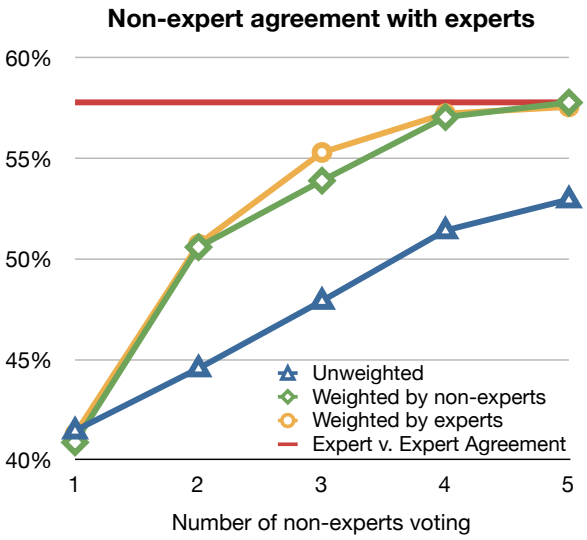

Figure 1: Agreement on ranking translated sentences increases as more non-experts vote. Weighting non-experts' votes based on agreement with either experts or other non-expert increases it up further. Five weighted non-experts reach the top line agreement between experts.

Combining ranked judgments Each item is redundantly judged by five non-experts. We would like to combine of their judgments into a single judgment. Combining ranked judgments it is more complicated than taking simple majority vote. We use techniques from *preference voting*, in which voters rank a group of candidates in order of preference. To create an ordering from the the ranks assigned to the systems by multiple Turkers, we use Schulze's method (Schulze, 2003). It is guaranteed to correctly pick the winner that is preferred pairwise over the other candidates. It further allows a complete ranking of candidates to be constructed, making it a suitable method for combining ranked judgments.

Figure 1 shows the effect of combining non-experts judgments on their agreement with experts. Agreement is measured by examining each pair of translated sentence and counting when two annotators both indicated that A $>$ B, A $<$ B, or A $=$ B. Chance agreement is $\frac{1}{3}$. The top line indicates the inter-annotator agreement between WMT08 expert annotators, who agreed with each other 58% of the time. When we have only a single non-expert annotator's judgment for each item, the agreement with experts is only 41%. As we increase the number of non-experts to five, their agreement with experts improves to 53%, if their votes are counted equally.

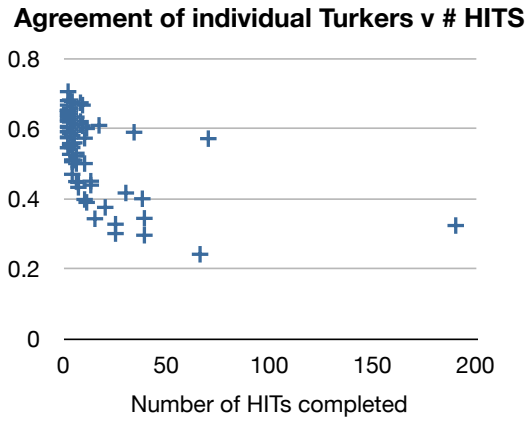

Figure 2: The agreement of individual Turkers with the experts. The most prolific Turker performed barely above chance, indicating random clicking. This suggests that users who contribute more tend to have lower quality.

Weighting votes Not all Turkers are created equal. The quality of their works varies. Figure 2 shows the agreement of individual Turkers with expert annotators, plotted against the number of HITs they completed. The figure shows that their agreement varies considerably, and that Turker who completed the most judgments was among the worst performing.

To avoid letting careless annotators drag down results, we experimented with weighted voting. We weighted votes in two ways:

- Votes were weighted by measuring agreement with experts on the 10 initial judgments made. This would be equivalent to giving Turkers a pretest on gold standard data and then calibrating their contribution based on how well they performed.
- Votes were weighted based on how often one Turker agreed with the rest of the Turkers over the whole data set. This does not require any gold standard calibration data. It goes beyond simple voting, because it looks at a Turker's performance over the entire set, rather than on an item-by-item basis.

Figure 1 shows that these weighting mechanisms perform similarly well. For this task, deriving weights from agreement with other non-experts is as effective as deriving weights from experts. Moreover, by weighting the votes of five Turkers,

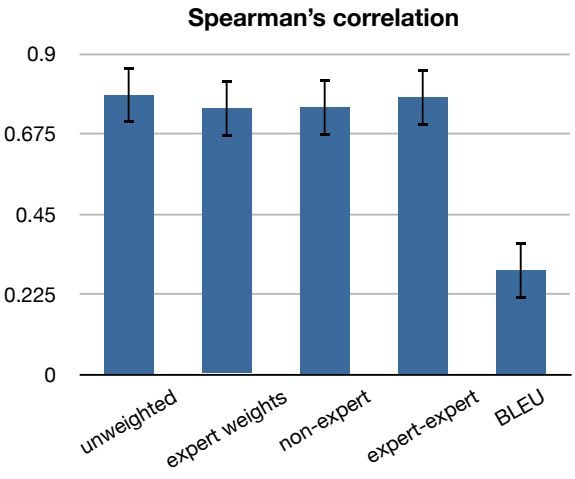

Figure 3: Correlation with experts' ranking of systems. All of the different ways of combining the non-expert judgments perform at the upper bound of expert-expert correlation. All correlate more strongly than Bleu.

we are able to achieve the same rate of agreement with experts as they achieve with each other.

Correlation when ranking systems In addition to measuring agreement with experts at the sentence-level, we also compare non-expert *system-level* rankings with experts. Following Callison-Burch et al. (2008), we assigned a score to each of the 11 MT systems based on how often its translations were judged to be better than or equal to any other system. These scores were used to rank systems and we measured Spearman's ρ against the system-level ranking produced by experts.

Figure 3 shows how well the non-expert rankings correlate with expert rankings. An upper bound is indicated by the *expert-expert* bar. This was created using a five-fold cross validation where we used 20% of the expert judgments to rank the systems and measured the correlation against the rankings produced by the other 80% of the judgments. This gave a ρ of 0.78. All ways of combining the non-expert judgments resulted in nearly identical correlation, and all produced correlation within the range of with what we would experts to.

The rankings produced using Mechanical Turk had a much stronger correlation with the WMT08 expert rankings than the Blue score did. It should be noted that the WMT08 data set does not have multiple reference translations. If multiple references were used that Bleu would likely have stronger correlation. However, it is clear that the cost of hiring professional translators to create multiple references for the 2000 sentence test set would be much greater than the $10 cost of collecting manual judgments on Mechanical Turk.

5 Feasibility of more complex evaluations

In this section we report on a number of creative uses of Mechanical Turk to do more sophisticated tasks. We give evidence that Turkers can create high quality translations for some languages, which would make creating multiple reference translations for Bleu less costly than using professional translators. We report on experiments evaluating translation quality with HTER and with reading comprehension tests.

5.1 Creating multiple reference translations

In addition to evaluating machine translation quality, we also investigated the possibility of using Mechanical Turk to create additional reference translations for use with automatic metrics like Bleu. Before trying this, we were skeptical that Turkers would have sufficient language skills to produce translations. Our translation HIT had the following instructions:

Translate these sentences *Your task is to translate 10 sentences into English. Please make sure that your English translation:*

- *Is faithful to the original in both meaning and style*
- *Is grammatical, fluent, and natural-sounding English*
- *Does not add or delete information from the original text*
- *Does not contain any spelling errors*

When creating your translation, please:

- *Do not use any machine translation systems*
- *You may look up a word on wordreference.com if you do not know its translation*

Afterwards, we'll ask you a few quick questions about your language abilities.

We solicited translations for 50 sentences in French, German, Spanish, Chinese and Urdu, and designed the HIT so that five Turkers would translate each sentence.

Filtering machine translation Upon inspecting the Turker's translations it became clear that many had ignored the instructions, and had simply cut-and-paste machine translation rather then translating the text themselves. We therefore set up a second HIT to filter these out. After receiving the

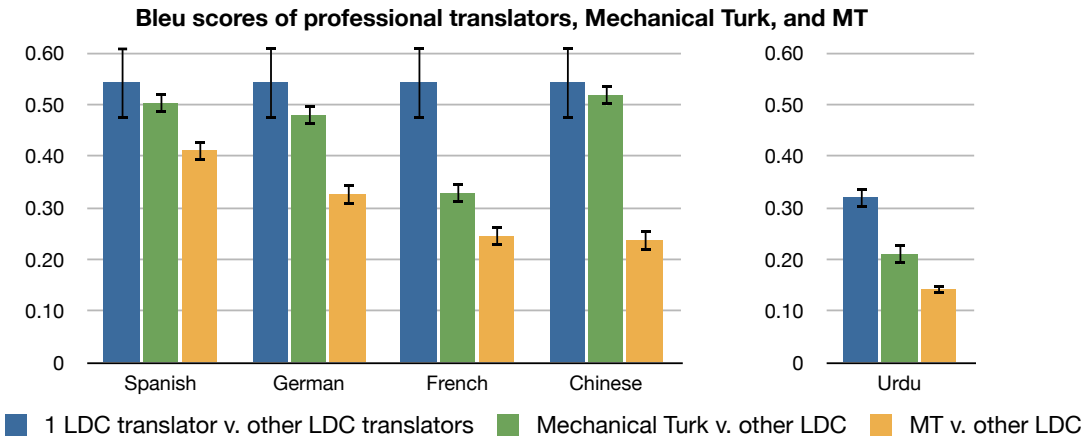

Figure 4: Bleu scores quantifying the quality of Turkers' translations. The chart shows the average Bleu score when one LDC translator is compared against the other 10 translators (or the other 2 translators in the case of Urdu). This gives an upper bound on the expected quality. The Turkers' translation quality falls within a standard deviation of LDC translators for Spanish, German and Chinese. For all languages, Turkers produce significantly better translations than an online machine translation system.

translations, we had a second group of Turkers clean the results.

Detect machine translation *Please use two online machine translation systems to translate the text into English, and then copy-and-paste the translations into the boxes below. Finally, look at a list of translations below and click on the ones that look like they came from the online translation services.*

We automatically excluded Turkers whose translations were flagged 30% of the time or more.

Quality of Turkers' translations Our 50 sentence test sets were selected so that we could compare the translations created by Turkers to translations commissioned by the Linguistics Data Consortium. For the Chinese, French, Spanish, and German translations we used the the Multiple-Translation Chinese Corpus.[3] This corpus has 11 reference human translations for each Chinese source sentence. We had bilingual graduate students translate the first 50 English sentences of that corpus into French, German and Spanish, so that we could re-use the multiple English reference translations. The Urdu sentences were taken from the NIST MT Eval 2008 Urdu-English Test Set[4] which includes three distinct English translations for every Urdu source sentence.

Figure 4 shows the Turker's translation quality in terms of the Bleu metric. To establish an upper bound on expected quality, we determined what the Bleu score would be for a professional translator when measured against other professionals. We calculated a Bleu score for each of the 11 LDC translators using the other 10 translators as the reference set. The average Bleu score for LDC2002T01 was 0.54, with a standard deviation of 0.07. The average Bleu for the Urdu test set is lower because it has fewer reference translations.

To measure the Turkers' translation quality, we randomly selected translations of each sentence from Turkers who passed the Detect MT HIT, and compared them against the same sets of 10 reference translations that the LDC translators were compared against. We randomly sampled the Turkers 10 times, and calculated averages and standard deviations for each source language. Figure 4 the Bleu scores for the Turkers' translations of Spanish, German and Chinese are within the range of the LDC translators. For all languages, the quality is significantly higher than an online machine translation system. We used Yahoo's Babelfish for Spanish, German, French and Chinese,[5] was likely and Babylon for Urdu.

Demographics We collected demographic information about the Turkers who completed the translation task. We asked how long they had spoken the source language, how long they had spo-

[3]LDC catalog number LDC2002T01

[4]LDC catalog number LDC2009E11

[5]We also compared against Google Translate, but excluded the results since its average Bleu score was better than the LDC translators, likely because the test data was used to train Google's statistical system.

Table 1: Self-reported demographic information from Turkers who completed the translation HIT. The statistics on the left are for people who appeared to do the task honestly. The statistics on the right are for people who appeared to be using MT (marked as using it 20% or more in the Detect MT HIT).

ken English, what their native language was, and where they lived. Table 1 gives their replies.

Cost and speed We paid Turkers $0.10 to translate each sentence, and $0.006 to detect whether a sentence was machine translated. The cost is low enough that we could create a multiple reference set quite cheaply; it would cost less than $1,000 to create 4 reference translations for 2000 sentences.

The time it took for the 250 translations to be completed for each language varied. It took less than 4 hours for Spanish, 20 hours for French, 22.5 hours for German, 2 days for Chinese, and nearly 4 days for Urdu.

5.2 HTER

Human-mediated translation edit rate (HTER) is the official evaluation metric of the DARPA GALE program. The evaluation is conducted annually by the Linguistics Data Consortium, and it is used to determine whether the teams participating the program have met that year's benchmarks. These evaluations are used as a "Go / No Go" determinant of whether teams will continue to receive funding. Thus, each team have a strong incentive to get as good a result as possible under the metric.

Each of the three GALE teams encompasses multiple sites and each has a collection of machine translation systems. A general strategy employed by all teams is to perform system combination over these systems to produce a synthetic translation that is better than the sum of its parts (Matusov et al., 2006; Rosti et al., 2007). The contribution of each component system is weighted by the expectation that it will produce good output. To our knowledge, none of the teams perform their own HTER evaluations in order to set these weights.

We evaluated the feasibility of using Mechanical Turk to perform HTER. We simplified the official GALE post-editing guidelines (NIST and LDC, 2007). We provided these instructions:

Edit Machine Translation *Your task is to edit the machine translation making as few changes as possible so that it matches the meaning of the human translation and is good English. Please follow these guidelines:*

- *Change the machine translation so that it has the same meaning as the human translation.*
- *Make the machine translation into intelligible English.*
- **Use as few edits as possible.**
- *Do not insert or delete punctuation simply to follow traditional rules about what is "proper."*
- *Please* **do not** *copy-and-paste the human translation into the machine translation.*

	Number of editors					
System	0	1	2	3	4	5
google.fr-en	.44	.29	.24	.22	.20	.19
google.de-en	.48	.34	.30	.28	.25	.24
rbmt5.de-en	.53	.41	.33	.28	.27	.25
geneva.de-en	.65	.56	.50	.48	.45	.45
tromble.de-en	.77	.75	.74	.73	.71	.70

Table 2: HTER scores for five MT systems. The edit rate decreases as the number of editors increases from zero (where HTER is simply the TER score between the MT output and the reference translation) and five.

We displayed 10 sentences from a news article. In one column was the reference English translation, in the other column were text boxes containing the MT output to be edited. To minimize the edit rate, we collected edits from five different Turkers for every machine translated segment. We verified these with a second HIT were we prompted Turkers to:

Judge edited translations *First, read the reference human translation. After that judge the edited machine translation using two criteria:*

- *Does the edited translation have the same meaning as the reference human translation?*
- *Is it acceptable English? Some small errors are OK, so long as its still understandable.*

For the final score, we choose the edited segment which passed the criteria and which minimized the edit distance to the unedited machine translation output. If none of the five edits was deemed to be acceptable, then we used the edit distance between the MT and the reference.

Setup We evaluated five machine translation systems using HTER. These systems were selected from WMT09 (Callison-Burch et al., 2009). We wanted a spread in quality, so we took the top two and bottom two systems from the German-English task, and the top system from the French-English task (which significantly outperformed everything else). Based on the results of the WMT09 evaluation we would expect the see the following ranking from the least edits to the most edits: google.fr-en, google.de-en, rbmt5.de-en, geneva.de-en and tromble.de-en.

Results Table 2 gives the HTER scores for the five systems. Their ranking is as predicted, indicating that the editing is working as expected. The table reports averaged scores when the five annotators are subsampled. This gives a sense of how much each additional editor is able to minimize the score for each system. The difference between the TER score with zero editors, and the HTER five editors is greatest for the rmbt5 system, which has a delta of .29 and is smallest for jhu-tromble with .07.

5.3 Reading comprehension

One interesting technique for evaluating machine translation quality is through reading comprehension questions about automatically translated text. The quality of machine translation systems can be quantified based on how many questions are answered correctly.

Jones et al. (2005) evaluated translation quality using a reading comprehension test the Defense Language Proficiency Test (DLPT), which is administered to military translators. The DLPT contains a collection of foreign articles of varying levels of difficulties, and a set of short answer questions. Jones et al used the Arabic DLPT to do a study of machine translation quality, by automatically translating the Arabic documents into English and seeing how many human subjects could successfully pass the exam.

The advantage of this type of evaluation is that the results have a natural interpretation. They indicate how understandable the output of a machine translation system is better than Bleu does, and better than other manual evaluation like the relative ranking. Despite this advantage, evaluating MT through reading comprehension hasn't caught on, due to the difficulty of administering it and due to the fact that the DLPT or similar tests are not publicly available.

We conducted a reading comprehension evaluation using Mechanical Turk. Instead of simply administering the test on Mechanical Turk, we used it for all aspects from test creation to answer grading. Our procedure was as follows:

Test creation We posted human translations of foreign news articles, and ask Tukers to write three questions and provide sample answers. We gave simple instructions on what qualifies as a good reading comprehension question.

Reading comprehension test *Please read the short newspaper article, and then write three reading comprehension questions about it, giving sample answers for each of your questions. Good reading comprehension questions:*

- *Ask about why something happened or why someone did something.*
- *Ask about relationships between people or things.*
- *Should be answerable in a few words.*

Poor reading comprehension questions:

- *Ask about numbers or dates.*
- *Only require a yes/no answer.*

Question selection We posted the questions for each article back to Mechanical Turk, and asked other Turkers to vote on whether each question was a good and to indicate if it was redundant with any other questions in the set. We sorted questions to maximize the votes and minimized redundancies using a simple perl script, which discarded questions below a threshold, and eliminated all redundancies.

Taking the test We posted machine translated versions of the foreign articles along with the questions, and had Turkers answer them. We ensured that no one would see multiple translations of the same article.

Answer questions about a machine translated text *You will answer questions about an article that has been automatically translated from another language into English. The translation contains many errors, but the goal is to see how understandable it is. Please do your best to guess at the right answers to the questions. Please:*

- *Read through the automatically translated article.*
- *Answer the questions listed below, using just a few words.*
- *Give your best guess at the answers, even if the translation is hard to understand.*
- *Don't use any other information to answer the questions.*

Grading the answers We aggregated the answers and used Mechanical Turk to grade them. We showed the human translation of the article, one question, the sample answer, and displayed all answers to it. After the Turkers graded the answers, we calculated the percentage of questions that were answered correctly for each system.

Turkers created 90 questions for 10 articles, which were subsequently filtered down to 47 good questions, ranging from 3–6 questions per article. 25 Turkers answered questions about each translated article. To avoid them answering the questions multiple times, we randomly selected which system's translation was shown to them. Each system's translation was displayed an average of 5 times per article. As a control, we had three Turkers answer the reading comprehension questions using the reference translation.

System	% Correct Answers
reference	0.94
google.fr-en	0.85
google.de-en	0.80
rbmt5.de-en	0.77
geneva.de-en	0.63
jhu-tromble.de-en	0.50

Table 3: The results of evaluating the MT output using a reading comprehension test

Table 3 gives the percent of questions that were correctly answered using each of the different systems' outputs and using the reference translation. The ranking is exactly what we would expect, based on the HTER scores and on the human evaluation of the systems in WMT09. This again helps to validate that the reading comprehension methodology. The scores are more interpretable than Blue scores and than the WMT09 relative rankings, since it gives an indication of how understandable the MT output is.

Appendix A shows some sample questions and answers for an article.

6 Conclusions

Mechanical Turk is an inexpensive way of gathering human judgments and annotations for a wide variety of tasks. In this paper we demonstrate that it is feasible to perform manual evaluations of machine translation quality using the web service. The low cost of the non-expert labor found on Mechanical Turk is cheap enough to collect redundant annotations, which can be utilized to ensure translation quality. By combining the judgments of many non-experts we are able to achieve the equivalent quality of experts.

The suggests that manual evaluation of translation quality could be straightforwardly done to validate performance improvements reported in conference papers, or even for mundane tasks like tracking incremental system updates. This challenges the conventional wisdom which has long held that automatic metrics must be used since manual evaluation is too costly and time-consuming.

We have shown that Mechanical Turk can be used creatively to produce quite interesting things.

We showed how a reading comprehension test could be created, administered, and graded, with only very minimal intervention.

We believe that it is feasible to use Mechanical Turk for a wide variety of other machine translated tasks like creating word alignments for sentence pairs, verifying the accuracy of document- and sentence-alignments, performing non-simulated active learning experiments for statistical machine translation, even collecting training data for low resource languages like Urdu.

The cost of using Mechanical Turk is low enough that we might consider attempting quixotic things like human-in-the-loop minimum error rate training (Zaidan and Callison-Burch, 2009), or doubling the amount of training data available for Urdu.

A Example reading comprehension questions

Actress Heather Locklear arrested for driving under the influence of drugs

The actress Heather Locklear, Amanda on the popular series Melrose Place, was arrested this weekend in Santa Barbara (California) after driving under the influence of drugs. A witness saw her performing inappropriate maneuvers while trying to take her car out of a parking space in Montecito, as revealed to People magazine by a spokesman for the Californian Highway Police. The witness stated that around 4.30pm Ms. Locklear "hit the accelerator very roughly, making excessive noise and trying to take the car out from the parking space with abrupt back and forth maneuvers. While reversing, she passed several times in front of his sunglasses." Shortly after, the witness, who at first, apparently had not recognized the actress, saw Ms. Locklear stopping in a nearby street and leaving the vehicle.

It was this person who alerted the emergency services, because "he was concerned about Ms. Locklear's life." When the patrol arrived, the police found the actress sitting inside her car, which was partially blocking the road. "She seemed confused," so the policemen took her to a specialized centre for drugs and alcohol and submitted her a test. According to a spokesman for the police, the actress was cooperative and excessive alcohol was ruled out from the beginning, even if "as the officers initially observed, we believe Ms. Locklear was under the influences drugs." Ms. Locklear was arrested under suspicion of driving under the influence of some - unspecified substance, and imprisoned in the local jail at 7.00pm, to be released some hours later. Two months ago, Ms. Locklear was released from a specialist clinic in Arizona where she was treated after an episode of anxiety and depression.

4 questions were selected

- Why did the bystander call emergency services?
  He was concerned for Ms. Locklear's life.
- Why was Heather Locklear arrested in Santa Barbara?
  Because she was driving under the influence of drugs
- Where did the witness see her acting abnormally?
  Pulling out of parking in Montecito
- Where was Ms. Locklear two months ago?
  She was at a specialist clinic in Arizona.

5 questions were excluded as being redundant

- What was Heather Locklear arrested for?
  Driving under the influence of drugs
- Where was she taken for testing?
  A specialized centre for drugs and alcohol
- Why was Heather Locklear arrested?
  She was arested on suspicion of driving under the influence of drugs.
- Why did the policemen lead her to a specialized centre for drugs and alcohol
  Because she seemed confused.
- For what was she cured for two months ago?
  She was cured for anxiety and depression.

Answers to *Where was Ms. Locklear two months ago?* that were judged to be correct:

Arizona hospital for treatment of depression; at a treatmend clinic in Arizona; in the Arizona clinic being treated for nervous breakdown; a clinic in Arizona; Arizona, under treatment for depression; She was a patient in a clinic in Arizona undergoing treatment for anxiety and depression; In an Arizona mental health facility ; A clinic in Arizona.; In a clinic being treated for anxiety and depression.; at an Arizona clinic

These answers were judged to be incorrect: *Locklear was retired in Arizona; Arizona; Arizona; in Arizona; Ms.Locklaer were laid off after a treatment out of the clinic in Arizona.*

Abstract

Machine involvement has the potential to speed up language documentation. We assess this potential with timed annotation experiments that consider annotator expertise, example selection methods, and suggestions from a machine classifier. We find that better example selection and label suggestions improve efficiency, but effectiveness depends strongly on annotator expertise. Our expert performed best with uncertainty selection, but gained little from suggestions. Our non-expert performed best with random selection and suggestions. The results underscore the importance both of measuring annotation cost reductions with respect to time and of the need for cost-sensitive learning methods that adapt to annotators.

1 Introduction

Data annotated with linguistically interesting labels is used in a wide variety of contexts. Computational linguists generally use annotated data as training and evaluation material for natural language processing systems; corpus linguists use it to test hypotheses about language; documentary linguists create interlinear glossed texts to preserve examples of endangered languages and hypotheses about the grammars of those languages. Regardless of the context, creating annotated data is costly in terms of time and/or money. Since both time and money are undeniably in limited supply, there is a widely shared desire to reduce this cost.

Reducing cost involves strategies that do more with fewer human-annotated labels and/or reduce the per-label cost. An example of the former is active learning, which focuses annotation effort on data points selected by the learner(s) for their expected utility in developing a more accurate model (Settles, 2009). Examples of the latter include providing suggestions from a machine labeler and using extremely cheap human labelers, e.g. with the Amazon Mechanical Turk (Snow et al., 2008). Different techniques may be more or less applicable depending on the language being annotated, the kind of labels which are desired (tags, syntactic structures, etc.), and the desired use of the annotated data (e.g., for training models, testing linguistic hypotheses, or preserving a language).

This paper discusses experiments that measure the effectiveness of machine-aided annotation for language documentation using both active learning simulation experiments and annotation experiments which involve actual documentary linguists interacting with machine example selection and label suggestion. Specifically, we deal with the task of labeling morphemes of the Mayan language Uspanteko with fine-grained parts-of-speech. We also run active learning simulation experiments for part-of-speech tagging for Danish, Dutch, English, Swedish, and Uspanteko to show the validity of our models and methods in a standard setting. For Uspanteko, we provide results from annotation experiments in which annotation cost is measured in terms of the actual annotation time required while varying three factors: (1) example selection, (2) machine label suggestions, and (3) annotator expertise.

Our findings indicate that there is considerable promise for reducing the cost of producing IGT, but they also demonstrate considerable variation due to the interaction of these factors. This suggests different prescriptions for appropriate strategies in different contexts. Most clearly, the worst performing strategy—by far—is that used in nearly all documentary work: sequential annotation without automation. Also, our expert annotator did best with examples picked by uncertainty selection, while our non-expert did best with random selection aided by machine label sug-

Table 1: Corpora: number of words and sentences, number of possible tags, and average sentence length.

gestions. This difference confirms the importance of cost-sensitive active learning strategies that are not just learner-guided, but also take into account modeling of the annotators (Settles et al., 2008; Haertel et al., 2008; Vijayanarasimhan and Grauman, 2008). Finally, we confirm the importance of using actual annotation time to measure annotation cost: a unit-cost assumption—even at a fine-grained level—can dramatically misrepresent the actual effectiveness of different strategies.

2 Task and data

Annotation task: language documentation The amount of money spent on obtaining human annotations is an extremely important concern in much language annotation. However, there is a further urgency for annotation in the case of language documentation: languages are dying at the rate of two each month. By the end of this century, half of the approximately 6000 extant spoken languages will cease to be transmitted effectively from one generation of speakers to the next (Crystal, 2000). Recorded and transcribed texts annotated with detailed linguistic information create an important multi-faceted record of these languages, but there are few trained linguists with adequate time and appropriate levels of funding relative to the size of the problem. Annotation cost—in both time and money—is thus keenly felt in the work of documenting and describing endangered languages. Active learning and automated label suggestions could help deal with this language documentation bottleneck.

We focus on one stage of language documentation, the production of interlinear glossed text (IGT), a standard form of annotation that involves both morphological and grammatical analysis. IGT is generally created following transcription and translation of recorded speech, with the annotations often being provided by trained annotators with varying levels of expertise. The result is generally a small amount of IGT annotated data and a greater amount of unannotated data.

Data We use a collection of 32 interlinear glossed texts (IGT) in the Mayan language Uspanteko. This corpus was cleaned up and adapted by Palmer et al. (2009) from an original collection of 67 texts that were collected, transcribed, translated and annotated by the OKMA language documentation project (Pixabaj et al., 2007).

Two core tasks in creating IGT are morphological analysis and tagging morphemes with their glosses (labels indicating part-of-speech and/or grammatical function). We deal with the latter task and assume texts are morphologically segmented. Standard four-line IGT has morphemes on one line and their glosses on the next. The gloss line includes labels for grammatical morphemes (e.g. `PL` or `COM`) and translations of stems (e.g. *hablar* or *idioma*). The following is an Uspanteko example:

(1)
TEXT: `Kita' tinch'ab'ej laj inyolj iin`
MORPH: `kita' t-in-ch'abe-j laj in-yol-j iin`
GLOSS: NEG INC-E1S-hablar-SC PREP A1S-idioma-SC yo
POS: PART TAM-PERS-VT-SUF PREP PERS-S-SUF PRON
TRANS: 'No le hablo en mi idioma.'

We use a single layer that is a combination of the GLOSS and POS layers (Palmer et al., 2009). For (1), the morphemes and labels for our task are:

(2)
kita' t- in- ch'abe -j laj in- yol -j iin
NEG INC E1S VT SC PREP A1S S SC PRON

We also consider POS-tagging for Danish, Dutch, English, and Swedish; the English is from sections 00-05 (as training set) and 19-21 (as development set) of the Penn Treebank (Marcus et al., 1993), and the other languages are from the CoNLL-X dependency parsing shared task (Buchholz and Marsi, 2006).[1] We split the original training data into training and development sets. Table 1 shows the number of words and sentences in each split of each dataset, as well as the number of possible labels and the average sentence length. The Uspanteko data is counted in morphemes rather than words; also, the Uspanteko texts are divided at the clause rather than sentence level. This gives the corpus a much lower average clause length than the other languages (Table 1).

[1]The subset of the Penn Treebank was chosen to be of comparable size to the CoNLL datasets.

3 Model and methods

Classification model. We use a standard maximum entropy classifier for tagging Danish, Dutch, English, and Swedish words with POS-tags and tagging Uspanteko morphemes with Gloss/POS tags. The label for a word/morpheme is predicted based on the word/morpheme itself plus a window of two units before and after. Standard part-of-speech tagging features (Ratnaparkhi, 1998; Curran and Clark, 2003) are extracted from the morpheme to help with predicting labels for previously unseen morphemes. This is a strong but standard model; better, more complex models could be used, but the gains are likely to be small. Thus, we opted for simplicity in our model so as to focus more on the interaction between the annotator and different levels of machine involvement.

The accuracy of the tagger on the datasets when trained on all available training material is given in the following table, along with accuracy of a unigram model (learned from the training set and constrained by a tag dictionary for known words).

	Unigram	Model
Danish	91.62%	95.58%
Dutch	90.92%	93.57%
English	87.87%	93.25%
Swedish	84.91%	87.74%
Uspanteko	77.84%	79.39%

Sample selection. We consider three sample selection methods: **seq**uential, **rand**om, and **unc**ertainty. Sequential selection is important to consider as it is the default in documentary projects. It is sub-optimal for corpora with contiguous sub-domains, since it necessitates working through many similar examples before getting to possibly more informative examples. Random selection is a model-free method that avoids the sub-domain trap by sampling freely from the entire corpus. It generally works better than sequential selection and provides a strong baseline against which to compare learner-guided selection.

Uncertainty selection (Cohn et al., 1995) identifies examples the model is least confident about. We measure uncertainty as the entropy of the label distribution predicted by the maximum entropy model for each example. Uncertainty for a clause is calculated as the average entropy per morpheme; clauses with the highest average entropy are selected for labeling.

A recent development in active learning is cost-sensitive selection that is guided not only by the learner but also by the expected cost of labeling an example based on its likely complexity and/or the reliability of the annotator. Settles et al. (2008) provide empirical validation for cost-related intuitions; for example, that cost of annotation is static neither per example nor per annotator. Also, they show that taking annotation cost into account can improve active learning effectiveness, but that learning to predict annotation cost is not yet well-understood. A cost-sensitive Return on Investment heuristic is developed in Haertel et al. (2008) and tested in a simulated POS-tagging context. Our experiments do not employ cost-sensitive selection, but our results—from live (non-simulated) active learning experiments of real-world scale—empirically support the need to consider cost-sensitive selection if better cost reductions are to be achieved.

Annotation setup. We compare results from two annotators with different levels of exposure to Uspanteko. Both are documentary linguists with extensive field experience. Our **expert annotator** is a native speaker of K'ichee', a closely related Mayan language, and has worked extensively on Uspanteko. Our **non-expert annotator** had no prior experience with Uspanteko and only limited exposure to Mayan languages. During annotation, he used an Uspanteko-Spanish dictionary.

For each selection method, we consider two conditions for providing classifier labels: a **do-suggest** (**ds**) condition where the labels predicted by the machine learner are shown to the annotator, and a **no-suggest** (**ns**) condition where the annotator does not see the predictions. With **ds**, the annotator is shown the most probable label and a ranked list of all labels assigned a probability greater than half that of the best label. For **ns**, the annotator sees a frequency-ranked list of labels previously seen in training data for the given morpheme.

Annotators improve as they see more examples. To minimize the impact of this learning process, annotation is done in rounds. Each round consists of sixty clauses—six batches of ten each for the six experimental cases. The annotator is free to break between batches. Following annotation, the newly-labeled clauses are added to the training data, and a new model is trained and evaluated. Both annotators completed fifty-six rounds of annotation. See Palmer et al. (2009) for more details on the annotation setup.

Measuring annotation cost. Active learning studies usually *simulate* annotation and use a unit cost assumption that each word, sentence, constituent, document, etc. takes the same time to annotate. This is often the only option since corpora typically do not retain annotation time, but it is likely to exaggerate the annotation cost reductions achieved. This is exacerbated with active learning: the informative examples it seeks to find are typically harder to annotate (Hachey et al., 2005).

Baldridge and Osborne (2008) correlate a unit cost in terms of *discriminants* (decisions made by annotators about valid parses) to annotation time. This is a better approximation than unit costs where such a relationship cannot be established. However, it is based on a *static* measurement of annotation time, and clearly the time taken to annotate an example is not a function of the example alone. Annotation time is actually *dynamic* in that it is dependent on how many and what kinds of examples have already been annotated. An "informative" example is likely to take longer to annotate if selected early than it would after the annotator has seen many other examples.

Thus, it is important to measure annotation time *embedded in the context* of a particular annotation experiment with the sample selection/labeling strategies of interest. In our annotation experiments, we measure the exact time taken to annotate each example by each annotator and use this as the cost metric, inspired by Ngai and Yarowsky (2000). In the simulation studies, as we are unable to measure time, we measure cost by sentence/clause and word/morpheme.

Learning curve comparison. We are interested in comparative evaluation of many different experimental settings, across which we vary selection methods, use of label suggestions, and annotators. To achieve this, it is useful to have a summary value for comparing the results from two individual experiments. One such measure is the percentage error reduction (PER), measured over a discrete set of points on the first 20% of the points on the learning curve (Melville and Mooney, 2004).[2]

We use a new related measure, which we call the *overall* percentage error reduction (**OPER**), that uses the *entire* area under the curves given by fitted nonlinear regression models rather than averaging over a subset of data points. Specifically, we fit a modified Michaelis-Menton model:

$$f(cost, (K, V_m, A)) = \frac{V_m(A + cost)}{K + cost}$$

The (original) parameters V_m and K respectively correspond to the horizontal asymptote and the cost where accuracy is halfway between 0 and V_m. The additional parameter A allows for a better fit to our data by allowing for less sharp elbows and letting $cost$ be zero. Model parameters were determined with `nls` in R (Ritz and Streibig, 2008).

With the fitted regression models, it is straightforward to calculate the area under the curve between a start cost c_i and end cost c_j by taking the integral from c_i to c_j. The overall accuracy for the experiment is given by dividing that area by $100 \times (c_j - c_i)$. Call this the overall curve accuracy (OCA). Then, for experiment A compared to experiment B, OPER(A,B) = $\frac{OCA_A - OCA_B}{100 - OCA_B}$. For the simulation experiments we calculate OPER for only the first 20% of cost units, like Melville and Mooney. For the annotation experiments, we calculate it for the minimum amount of time spent on any of the experiments (which ended up using less than 10% of all available morphemes).

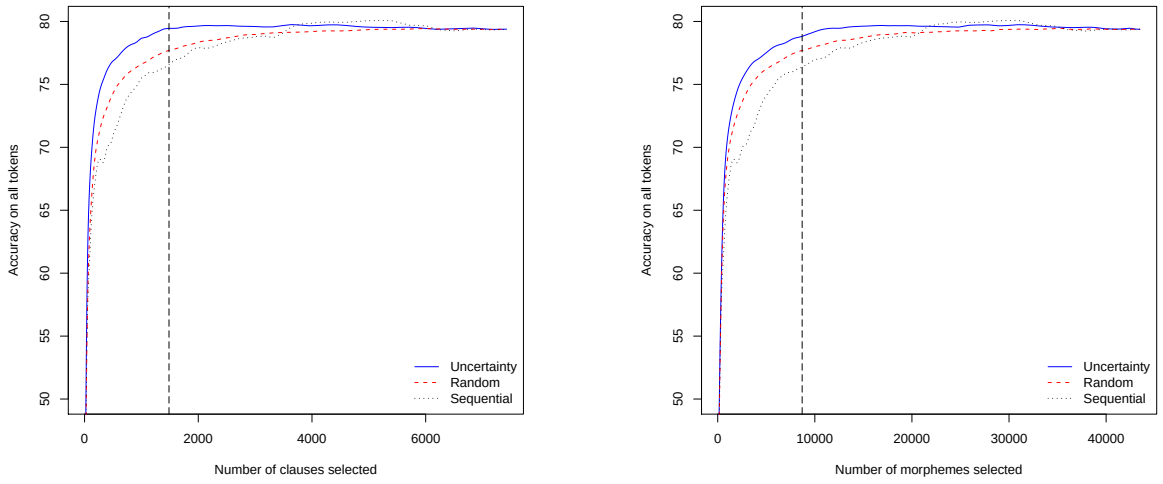
4 Simulation experiments

We verify that our tagger and dataset behave as expected in standard active learning experiments by running simulations on the Uspanteko data set, and on POS-tagging for Danish, Dutch, English, and Swedish. Here, we vary only the selection method: **seq**uential, **rand**om, or **unc**ertainty.

For each language, we randomly select a seed set of 10 labeled sentences. The number of examples selected to be labeled in each round begins at 10 and doubles after every 20 rounds. For **rand** and **unc**, each batch of examples is selected from a pool (size of 1000) that is itself randomly selected from the entire set of remaining unlabeled examples. **rand** and **unc** experiments for each language are replicated 5 times; splines and regressions are computed over all runs for each condition.

Figure 1 gives learning curves for the Uspanteko simulations, with cost measured in terms of (a) clauses and (b) morphemes. Both graphs show the usual behavior found in active learning experiments. **rand** and **unc** both rise more quickly than **seq**, and **unc** is well above **rand**. The relationship between the methods is the same regardless

[2]This is justified in standard conditions, sampling from a finite corpus: active learning runs out of interesting examples after considering a fraction of the data, so the curve is *artificially* pulled down by the remaining, boring examples.



(a) (b)

Figure 1: Learning curves for simulations; (a) clause cost and (b) morphemes cost. The dashed vertical lines indicate (a) #clauses=1485 and (b) #morphemes=8695 (to compare OPER values).

	$\frac{\textbf{rand}}{\textbf{seq}}$	$\frac{\textbf{unc}}{\textbf{seq}}$	$\frac{\textbf{unc}}{\textbf{rand}}$
Uspanteko-Clauses	5.86	13.27	7.86
Uspanteko-Morphs	7.47	11.68	4.55

Table 2: OPER values for Uspanteko simulations, comparing **clause** and **morpheme** cost. $\frac{A}{B}$ indicates we compute OPER(A,B).

	$\frac{\textbf{rand}}{\textbf{seq}}$	$\frac{\textbf{unc}}{\textbf{seq}}$	$\frac{\textbf{unc}}{\textbf{rand}}$
Danish	4.58	6.95	2.48
Dutch	21.95	23.68	2.20
English	6.55	8.00	1.56
Swedish	9.56	9.29	-0.30
Uspanteko	7.47	11.68	4.55

Table 3: OPER values for **morpheme** cost for simulations. $\frac{A}{B}$ indicates we compute OPER(A,B).

of the cost metric, but the relative differences in cost-savings are not, which we see when we look at OPER values.

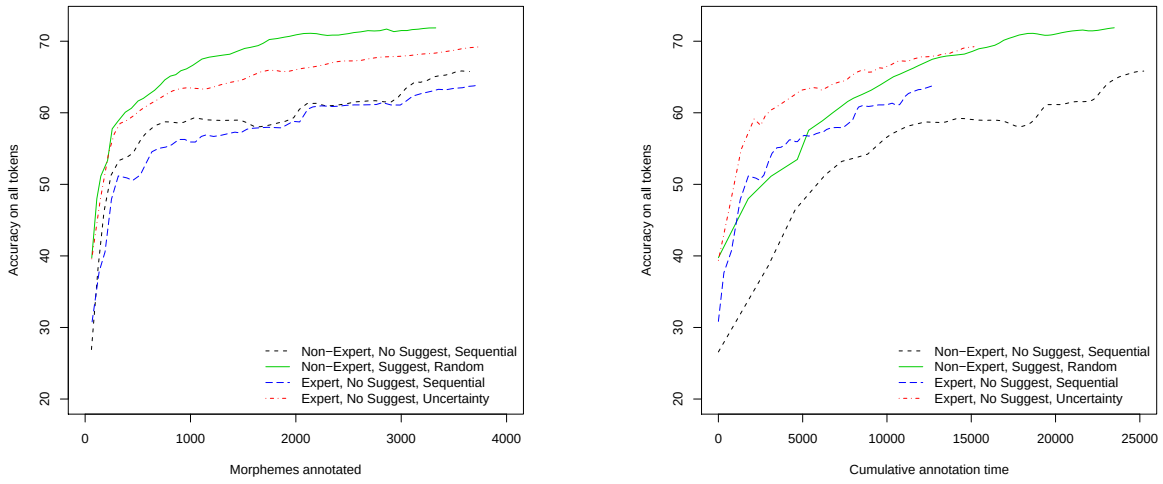
The dashed vertical lines in the two graphs correspond to the 20% mark used to calculate OPER values, which are given in Table 2. Most importantly, note the much larger OPER for **unc** over **rand** with clause cost (7.86 vs 4.55). Also note that OPER(**rand**,**seq**) is *lower* with clause cost—this indicates that the beginning portions of the corpus contain longer sentences with more morphemes, an accident which overstates how well **seq** would likely work in general.

Since **rand** is unbiased with respect to picking longer sentences, the large increase of OPER(**unc**,**rand**) from 4.55 to 7.86 is a clear indication of the well-known—but not always attended to—tendency of uncertainty sampling to select longer sentences. Consequently, one should at least use sub-sentence cost in order not to overstate the gains from active learning. The annotation experiments in the next section take this word of caution one step further: even sub-sentence cost (morpheme cost, in our setting) can overestimate gains since the morphemes selected are actually harder to annotate and thus take more time.

Table 3 gives overall percentage error reductions (OPER) between different selection methods based on word/morpheme cost, for each language. For all languages, **rand** and **unc** are better than **seq**. Only in the case of Swedish is there no benefit from **unc** over **rand**. For Dutch, the large gains over **seq** for both **rand** and **unc** accurately reflect the heterogeneity of the underlying Alpino corpus.[3] Most importantly, for Uspanteko, there are large reductions from **unc** to **rand** to **seq**, mirroring the clear trends in Figure 1b.

These simulations have an unrealistic "perfect" annotator, the corpus. Next, we discuss results with real annotators—who may be fallible or may (reasonably) beg to differ with the corpus analysis.

[3] `http://www.let.rug.nl/vannoord/trees/`



(a) (b)

Figure 2: A sample of the learning curves with (a) morpheme cost and (b) time cost. Morpheme cost ranks strategies for a given annotator similarly to time cost, but it gives dramatically different results from time cost when used to compare different annotators.

5 Annotation experiments

With two annotators (**expert**, **non-expert**), three selection methods (**seq**, **rand**, **unc**), and two machine labeling settings (**ns**, **ds**), we obtain 12 different experiments. Each experiment measures accuracy in terms of all words and unknown words and cost in terms of clauses, morphemes and time; this produces six views on every experiment. In this paper we focus on one view: accuracy over all words with time-based evaluation of cost.

As with the simulations, clause cost in the annotation experiments overestimates the cost reductions. For morpheme cost, the annotation experiments show that (a) it also overstates cost reductions compared to time, and (b) it can mis-state relative effectiveness when comparing annotators.

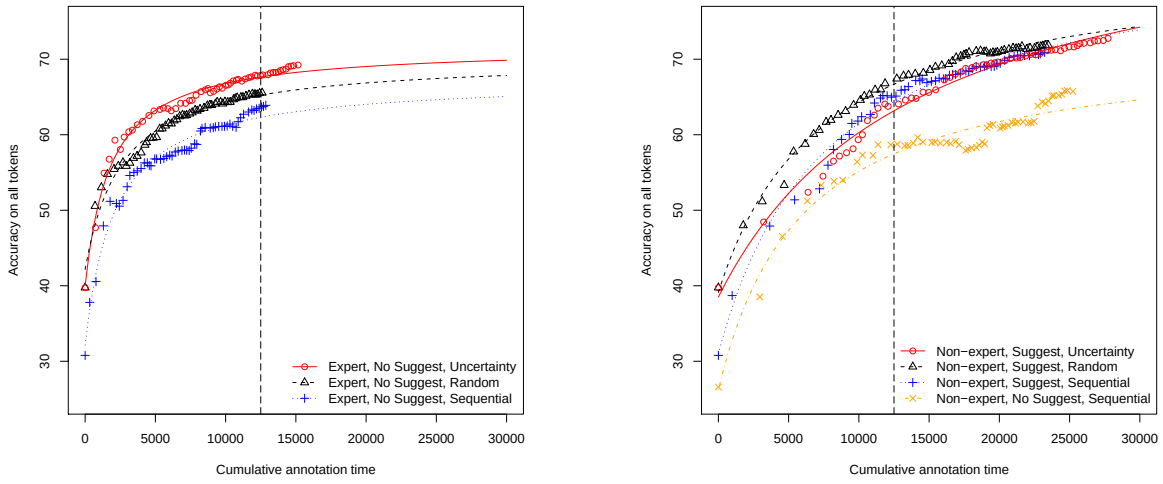
The big picture. Figure 2 shows curves for four experiments: **seq**-**ns** for both annotators[4] and the most effective overall condition for each annotator. Figure 2a uses morpheme cost evaluation; on that metric, both annotators appear to be about equally effective with **seq**-**ns** and much more effective with machine involvement (**unc** or **ds**) than without. Additionally, the non-expert's **rand**-**ds** appears to beat the expert's **unc**-**ns**. However, the time cost evaluation in Figure 2b tells a dramatically different story. Each annotator's machine-involved experiment is much better than their **seq**-**ns**, but now the expert's best is clearly better than the non-expert's. We see this as clear evidence for the need for cost-sensitive learning over vanilla active learning (as we do here).[5]

The non-expert with **rand**-**ds** caught up to and surpassed the unaided expert in about six hours total annotation time, and he caught up to her **unc**-**ns** curve after 35 hours. This is encouraging since often language documentation projects have participants with a wide range of expertise levels, and these results suggest that assistance from machine learning, if done properly, may increase the effectiveness of participants with less language-specific expertise. We are also encouraged, with respect to the effectiveness of active learning, that the expert's best performance is obtained with uncertainty-based selection.

Within annotator comparisons. Figure 3 shows both actual measurements and the fitted nonlinear regression curves used to compute OPER. Figure 3a, the expert without suggestions, exhibits typical active learning behavior similar to that seen in the simulation experiments. Figure 3b,

[4]Recall that sequential annotation is the default mode for producing IGT, so this strategy is of particular interest.

[5]It is also clear to see that, unsurprisingly, the expert spent much less time to complete the 56 rounds than the non-expert. In general, the expert annotator was much quicker, particularly in early rounds, averaging 4.1 seconds per morpheme annotated against the non-expert's 8.0 second average. See Palmer et al. (2009) for more details.



(a) (b)

Figure 3: Sample measurements and fitted nonlinear regression curves for (a) the expert and (b) the non-expert. Note that the scale is consistent for comparability. The dashed vertical lines indicate 12,500 seconds (about 35 hours), which is the upper limit used in computing OPER values for Table 4.

the non-expert *with* suggestions, shows that in the **ds** conditions the non-expert was less effective with **unc**. This is not unexpected: uncertainty selects harder examples that will either take longer to annotate or are easier to get wrong, especially if the annotator trusts the classifier and *especially* on examples the classifier is uncertain about. Nonetheless, in all **ds** cases, the non-expert performs better than with **seq-ns**.

OPER. Table 4 provides OPER values from time 0 to 12,500 seconds (about 35 hours), the minimum amount of annotation time logged in any one of the twelve experiments.[6] The table mixes three types of comparison: (1) the boxed values on the diagonal give OPER for the expert versus the non-expert given the same selection and suggestion conditions; (2) the upper (right) triangle gives OPER for the expert versus herself for different conditions; and (3) the lower (left) triangle is the non-expert versus himself. For example: (1) the expert obtained an 11.52 OPER versus the non-expert when both used **rand-ns**; (2) the expert obtained a 10.52 OPER by using **rand-ds** rather than **seq-ns**; and (3) the non-expert obtained a 5.93 OPER over **rand-ns** by using **rand-ds**.

A number of patterns emerge. Quite unsurprisingly, the values on the diagonal show that the expert is more effective than the non-expert in all conditions. Also, every other condition is more effective than **seq-ns** for both annotators (first row for the expert, first column for the non-expert). **unc-ns** and **rand-ds** are particularly effective for the non-expert, giving OPERs of 19.20 and 18.59 over **seq-ns**, respectively. These reductions, bigger than the expert's reductions of 14.17 and 10.52 for the same conditions, considerably reduce the large gap in **seq-ns** effectiveness between the two annotators (see Figure 2b).

The expert actually gains very little from **ds** for both **rand** and **unc**: adding suggestions gave OPERs of just 1.83 and .39, respectively. In contrast, the non-expert obtains an improvement of 5.93 OPER when suggestions are used with **rand**,

non-exp \ exp	seq-ns	rand-ns	unc-ns	seq-ds	rand-ds	unc-ds
seq-ns	15.99	8.85	14.17	6.34	10.52	14.50
rand-ns	13.46	11.52	5.83	-2.76	1.83	6.20
unc-ns	19.20	6.63	10.76	-9.12	-4.25	0.39
seq-ds	10.24	-3.72	-11.09	12.34	4.46	8.72
rand-ds	18.59	5.93	-0.76	9.30	7.67	4.45
unc-ds	11.19	-2.62	-9.91	1.06	-9.09	19.13

Table 4: Overall percentage error reduction (OPER) comparisons, with timing cost. See explanation of table in the **OPER** subsection.

[6] Stopping at 12,500 seconds ensures a fair comparison, for example, between the expert and the non-expert because it requires no extrapolation of the expert's performance.

but performs *worse* when used with **unc** (-9.91 OPER). Even more striking: the non-expert's **unc-ds** is worse than **rand-ns** (-2.62 OPER), a completely model-free setting. These variations demonstrate the importance of modeling annotator fallibility and sensitivity to cost, as well as characteristics of the annotation task itself, if learner-guided selection and suggestion are to be used (Donmez and Carbonell, 2008; Arora et al., 2009).

Annotator accuracy. Another factor which must be considered when annotation is done by human annotators (rather than being simulated) is the accuracy of the humans' labels. Table 5 shows the overall accuracy of the annotators' labels for each condition (after 56 rounds) as measured against the original OKMA annotations. Unsurprisingly, **unc** selection picks examples that are more difficult to annotate: accuracy for both annotators suffers in both **unc-ns** and **unc-ds**.

It may seem surprising that the non-expert's accuracies are generally higher than the expert's. The main reason for this is that the non-expert took nearly twice as long to annotate his examples, so each one was done with more care. However, this difference also highlights challenges that arise when we bring active learning into non-simulated annotation contexts. The typical assumption is that gold standard labeled data represents a true, fixed target, against which annotator or machine-predicted labels should be measured. In language documentation, though, the analysis of the language is continually evolving, and analysis and annotation each inform the other. In fact, the expert recognized (in the morphological segmentation) several linguistic phenomena for which the analysis has changed since the original OKMA annotations were done. As she changed her analyses, her labels diverged from those of the original corpus—another reason for her "lower" accuracy. This is to say that the ground truth of the current OKMA annotations we had to work with can be viewed as one (valid) stage in the iterative reanalysis process that language documentation is.

Error analysis. Preliminary analysis of 'errors' made by the annotators supports the idea that the results seen in Table 5 are heavily influenced by changes in the expert's analysis of the language. Some duplicate clause annotation occurred for each annotator, because each of the twelve annotator-selection-suggestion conditions drew from the same global set of unlabeled examples. This duplication allows us to measure the consistency of each annotator on labeling such duplicate clauses. Table 6 shows the percentage of morphemes labeled consistently by each annotator. Numbers for the expert appear in the top (right) triangle, and for the non-expert in the bottom (left) triangle. Overall intra-annotator consistency is much higher for the expert (88.38%) than for the non-expert (81.64%), suggesting that the expert maintained a more consistent mental model of the language, but one which disagrees in some areas with the original annotations.

	expert	**non-expert**
seq-ns	73.17%	75.09%
rand-ns	69.90%	74.37%
unc-ns	61.23%	60.04%
seq-ds	67.48%	73.13%
rand-ds	68.34%	73.03%
unc-ds	59.79%	60.27%

Table 5: Overall accuracy of annotators' labels, measured against OKMA annotations.

Another key error source comes from differences in use of one individual label: the annotators could assign a label that does not appear in the original corpus. This is yet another issue that does not—in fact, *cannot*—arise in simulated active learning. The label **ESP** was introduced for labeling Spanish loans or insertions (such as the discourse marker *entonces*) which do not have a clear function in Uspanteko grammar. Such tokens are inconsistently labeled in the original corpus, usually with catch-all categories like particle or adverb. The annotators felt that the best analysis was to mark the tokens as of Spanish origin. The expert annotator used the **ESP** label for 2086 of 24129 tokens (8.65%) versus 221 of 22819 tokens (0.97%) for the non-expert. Any such token labeled with **ESP** is scored as incorrect when compared to the OKMA standard, so this label alone accounts for more than 7% of the expert annotator's total error.

Finally, Table 7 presents inter-annotator agreement measured as percent agreement on morphemes in clauses labeled by both annotators. Note that in general agreement seems to be lowest for clauses duplicated in **unc** conditions, supporting the expected result that uncertainty-based selection does indeed select clauses that are more difficult for human annotators to label.

non \ exp	seq-ns	rand-ns	unc-ns	seq-ds	rand-ds	unc-ds

6 Conclusion

Through actual annotation experiments that control for several factors, we have evaluated the potential of incorporating active learning and label suggestions to speed up morpheme glossing in a realistic language documentation context. Some configurations of learner-guided example selection and machine label suggestions perform far better than the standard strategy of sequential selection without suggestions. However, the effectiveness of any given strategy depends on annotator expertise. The impact of differences between annotators directly bears on the point made by Donmez and Carbonell (2008) that if cost reductions are to be reliably obtained with active learning techniques, annotators' fallibility, unreliability, and sensitivity to cost must be modeled.

Our results suggest some possible prescriptions for tuning techniques according to annotator expertise. However, even if we can estimate a relative level of expertise, following such broad prescriptions is unlikely to be more robust than an approach which *adapts* selection and suggestion to the individual annotator, perhaps working within an annotation group. Indeed, it seems that dealing with variation in annotators/oracles may be more important than devising better selection strategies.

The difference in performance due to expertise suggests that using multiple annotators to check relative annotation rate and accuracy of different annotators could be a key ingredient in any actually deployed active learning system. This could provide for better modeling of individual annotators as part of an annotation group they can be compared against, allowing the system, for example, to throttle active selection if an annotator appears to be too slow or inaccurate.

Another major issue we highlight is the uncertainty around the question of whether active learning works in practical applications. Respondents to the survey of Tomanek and Olsson (2009) indicated that this uncertainty—will active learning work? what methods or techniques will work best?—is one of the reasons active learning is not widely used in actual annotation. In addition, creating the necessary software infrastructure to build an active learning enabled annotation system—a system which must interface robustly between data, annotator, and machine classifier, yet still be easy to use—is a substantial hurdle. It seems unlikely that there will be much uptake until a) consistent, large cost reductions can be shown in actual annotation studies, and b) appropriate, *tunable*, widely-available software exists.

Automatically Evaluating Content Selection in Summarization without Human Models

Annie Louis
University of Pennsylvania
lannie@seas.upenn.edu

Ani Nenkova
University of Pennsylvania
nenkova@seas.upenn.edu

Abstract

We present a fully automatic method for content selection evaluation in summarization that does not require the creation of human model summaries. Our work capitalizes on the assumption that the distribution of words in the input and an informative summary of that input should be similar to each other. Results on a large scale evaluation from the Text Analysis Conference show that input-summary comparisons are very effective for the evaluation of content selection. Our automatic methods rank participating systems similarly to manual model-based pyramid evaluation and to manual human judgments of responsiveness. The best feature, Jensen-Shannon divergence, leads to a correlation as high as 0.88 with manual pyramid and 0.73 with responsiveness evaluations.

1 Introduction

The most commonly used evaluation method for summarization during system development and for reporting results in publications is the automatic evaluation metric ROUGE (Lin, 2004; Lin and Hovy, 2003). ROUGE compares system summaries against one or more model summaries by computing n-gram word overlaps between the two. The wide adoption of such automatic measures is understandable because they are convenient and greatly reduce the complexity of evaluations. ROUGE scores also correlate well with manual evaluations of content based on comparison with a single model summary, as used in the early editions of the Document Understanding Conferences (Over et al., 2007).

In our work, we take the idea of automatic evaluation to an extreme and explore the feasibility of developing *a fully automatic* evaluation method for content selection that does not make use of human model summaries at all. To this end, we show that evaluating summaries by comparing them with the input obtains good correlations with manual evaluations for both query focused and update summarization tasks.

Our results have important implications for future development of summarization systems and their evaluation.

High correlations between system ranking produced with the fully automatic method and manual evaluations show that the new evaluation measures can be used during system development when human model summaries are not available.

Our results provide validation of several features that can be optimized in the development of new summarization systems when the objective is to improve content selection on average, over *a collection of test inputs*. However, none of the features is consistently predictive of good summary content for *individual inputs*.

We find that content selection performance on standard test collections can be approximated well by the proposed fully automatic method. This result greatly underlines the need to require linguistic quality evaluations alongside content selection ones in future evaluations and research.

2 Model-free methods for evaluation

Proposals for developing fully automatic methods for summary evaluation have been put forward in the past. Their attractiveness is obvious for large scale evaluations, or for evaluation on non-standard test sets for which human models are not available.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 306–314,
Singapore, 6-7 August 2009.

For example in Radev et al. (2003), a large scale fully automatic evaluation of eight summarization systems on *18,000 documents* was performed without any human effort. A search engine was used to rank documents according to their relevance to a given query. The summaries for each document were also ranked for relevance with respect to the same query. For good summarization systems, the relevance ranking of summaries is expected to be similar to that of the full documents. Based on this intuition, the correlation between relevance rankings of summaries and original documents was used to compare the different systems. The approach was motivated by the assumption that the distribution of terms in a good summary is similar to the distribution of terms in the original document.

Even earlier, Donaway et al. (2000) suggested that there are considerable benefits to be had in adopting model-free methods of evaluation involving direct comparisons between the original document and its summary. The motivation for their work was the considerable variation in content selection choices in model summaries (Rath et al., 1961). The identity of the model writer significantly affects summary evaluations (also noted by McKeown et al. (2001), Jing et al. (1998)) and evaluations of the same systems can be rather different when different models are used. In their experiments, Donaway et al. (2000) demonstrated that the correlations between manual evaluation using a model summary and

a) manual evaluation using a different model summary

b) automatic evaluation by directly comparing input and summary[1],

are the same. Their conclusion was that such automatic methods should be seriously considered as an alternative to model based evaluation.

In this paper, we present a comprehensive study of fully automatic summary evaluation without any human models. A summary's content is judged for quality by directly estimating its closeness to the input. We compare several probabilistic and information-theoretic approaches for characterizing the similarity and differences between input and summary content. A simple information-theoretic measure, Jensen Shannon divergence between input and summary, emerges as the best feature. System rankings produced using this measure lead to correlations as high as 0.88 with human judgements.

[1]They used cosine similarity to perform the input-summary comparison.

3 TAC summarization track

3.1 Query-focused and Update Summaries

Two types of summaries, query-focused and update summaries, were evaluated in the summarization track of the 2008 Text Analysis Conference (TAC)[2]. Query-focused summaries were produced from input documents in response to a stated user information need. The update summaries require more sophistication: two sets of articles on the same topic are provided. The first set of articles represents the background of a story and users are assumed to be already familiar with the information contained in them. The update task is to produce a multi-document summary from the second set of articles that can serve as an update to the user. This task is reminiscent of the novelty detection task explored at TREC (Soboroff and Harman, 2005).

3.2 Data

The test set for the TAC 2008 summarization task contains 48 inputs. Each input consists of two sets of 10 documents each, called docsets A and B. Both A and B are on the same general topic but B contains documents published later than those in A. In addition, the user's information need associated with each input is given by a query statement consisting of a title and narrative. An example query statement is shown below.

Title: Airbus A380

Narrative: Describe developments in the production and launch of the Airbus A380.

A system must produce two summaries: (1) a query-focused summary of docset A, (2) a compilation of updates from docset B, assuming that the user has read all the documents in A. The maximum length for both types of summaries is 100 words.

There were 57 participating systems in TAC 2008. We use the summaries and evaluations of these systems for the experiments reported in the paper.

3.3 Evaluation metrics

Both manual and automatic evaluations were conducted at NIST to assess the quality of summaries

[2]http://www.nist.gov/tac

manual score	R-1 recall	R-2 recall
Query Focused summaries		
pyramid score	0.859	0.905
responsiveness	0.806	0.873
Update summaries		
pyramid score	0.912	0.941
responsiveness	0.865	0.884

Table 1: Spearman correlation between manual scores and ROUGE-1 and ROUGE-2 recall. All correlations are highly significant with p-value $<$ 0.00001.

produced by the systems.

Pyramid evaluation: The pyramid evaluation method (Nenkova and Passonneau, 2004) has been developed for reliable and diagnostic assessment of content selection quality in summarization and has been used in several large scale evaluations (Nenkova et al., 2007). It uses multiple human models from which annotators identify semantically defined Summary Content Units (SCU). Each SCU is assigned a weight equal to the number of human model summaries that express that SCU. An ideal maximally informative summary would express a subset of the most highly weighted SCUs, with multiple maximally informative summaries being possible. The pyramid score for a system summary is equal to the ratio between the sum of weights of SCUs expressed in a summary (again identified manually) and the sum of weights of an ideal summary with the same number of SCUs.

Four human summaries provided by NIST for each input and task were used for the pyramid evaluation at TAC.

Responsiveness evaluation: Responsiveness of a summary is a measure of overall quality combining both content selection and linguistic quality: summaries must present useful content in a structured fashion in order to better satisfy the user's need. Assessors directly assigned scores on a scale of 1 (poor summary) to 5 (very good summary) to each summary. These assessments are done without reference to any model summaries. The (Spearman) correlation between the pyramid and responsiveness metrics is high but not perfect: 0.88 and 0.92 respectively for query focused and update summarization.

ROUGE evaluation: NIST also evaluated the summaries automatically using ROUGE (Lin, 2004; Lin and Hovy, 2003). Comparison between a summary and the set of four model summaries is computed using unigram (R1) and bigram overlaps (R2)[3]. The correlations between ROUGE and manual evaluations is shown in Table 1 and varies between 0.80 and 0.94.

Linguistic quality evaluation: Assessors scored summaries on a scale from 1 (very poor) to 5 (very good) for five factors of linguistic quality: grammaticality, non-redundancy, referential clarity, focus, structure and coherence.

We do not make use of any of the linguistic quality evaluations. Our work focuses on fully automatic evaluation of content selection, so manual pyramid and responsiveness scores are used for comparison with our automatic method. The pyramid metric measures content selection exclusively, while responsiveness incorporates at least some aspects of linguistic quality.

4 Features for content evaluation

We describe three classes of features to compare input and summary content: distributional similarity, summary likelihood and use of topic signatures. Both input and summary words were stopword filtered and stemmed before computing the features.

4.1 Distributional Similarity

Measures of similarity between two probability distributions are a natural choice for the task at hand. One would expect good summaries to be characterized by low divergence between probability distributions of words in the input and summary, and by high similarity with the input.

We experimented with three common measures: KL and Jensen Shannon divergence and cosine similarity. These three metrics have already been applied for summary evaluation, albeit in different contexts. In Lin et al. (2006), KL and JS divergences between human and machine summary distributions were used to evaluate content selection. The study found that JS divergence always outperformed KL divergence. Moreover, the performance of JS divergence was better than standard ROUGE scores for multi-document summarization when multiple human models were used for the comparison.

The use of cosine similarity in Donaway et al. (2000) is more directly related to our work. They show that the difference between evaluations

[3]The scores were computed after stemming but stop words were retained in the summaries.

based on two different human models is about the same as the difference between system ranking based on one model summary and the ranking produced using input-summary similarity. Inputs and summaries were compared using only one metric: cosine similarity.

Kullback Leibler (KL) divergence: The KL divergence between two probability distributions P and Q is given by

$$D(P||Q) = \sum_w p_P(w) \log_2 \frac{p_P(w)}{p_Q(w)} \quad (1)$$

It is defined as the average number of bits wasted by coding samples belonging to P using another distribution Q, an approximate of P. In our case, the two distributions are those for words in the input and summary respectively. Since KL divergence is not symmetric, both input-summary and summary-input divergences are used as features. In addition, the divergence is undefined when $p_P(w) > 0$ but $p_Q(w) = 0$. We perform simple smoothing to overcome the problem.

$$p(w) = \frac{C + \delta}{N + \delta * B} \quad (2)$$

Here C is the count of word w and N is the number of tokens; $B = 1.5|V|$, where V is the input vocabulary and δ was set to a small value of 0.0005 to avoid shifting too much probability mass to unseen events.

Jensen Shannon (JS) divergence: The JS divergence incorporates the idea that the distance between two distributions cannot be very different from the average of distances from their mean distribution. It is formally defined as

$$J(P||Q) = \frac{1}{2}[D(P||A) + D(Q||A)], \quad (3)$$

where $A = \frac{P+Q}{2}$ is the mean distribution of P and Q. In contrast to KL divergence, the JS distance is symmetric and always defined. We use both smoothed and unsmoothed versions of the divergence as features.

Similarity between input and summary: The third metric is cosine overlap between the $tf * idf$ vector representations (with max-tf normalization) of input and summary contents.

$$cos\theta = \frac{v_{inp}.v_{summ}}{||v_{inp}||||v_{summ}||} \quad (4)$$

We compute two variants:

1. Vectors contain all words from input and summary
2. Vectors contain only topic signatures from the input and all words of the summary

Topic signatures are words highly descriptive of the input, as determined by the application of log-likelihood test (Lin and Hovy, 2000). Using only topic signatures from the input to represent text is expected to be more accurate because the reduced vector has fewer dimensions compared with using all the words from the input.

4.2 Summary likelihood

The likelihood of a word appearing in the summary is approximated as being equal to its probability in the input. We compute both a summary's unigram probability as well as its probability under a multinomial model.

Unigram summary probability:

$$(p_{inp}w_1)^{n_1}(p_{inp}w_2)^{n_2}...(p_{inp}w_r)^{n_r} \quad (5)$$

where $p_{inp}w_i$ is the probability in the input of word w_i, n_i is the number of times w_i appears in the summary, and $w_1...w_r$ are all words in the summary vocabulary.

Multinomial summary probability:

$$\frac{N!}{n_1!n_2!...n_r!}(p_{inp}w_1)^{n_1}(p_{inp}w_2)^{n_2}...(p_{inp}w_r)^{n_r} \quad (6)$$

where $N = n_1 + n_2 + ... + n_r$ is the total number of words in the summary.

4.3 Use of topic words in the summary

Summarization systems that directly optimize for more topic signatures during content selection have fared very well in evaluations (Conroy et al., 2006). Hence the number of topic signatures from the input present in a summary might be a good indicator of summary content quality. We experiment with two features that quantify the presence of topic signatures in a summary:

1. Fraction of the summary composed of input's topic signatures.
2. Percentage of topic signatures from the input that also appear in the summary.

While both features will obtain higher values for summaries containing many topic words, the first is guided simply by the presence of any topic word while the second measures the diversity of topic words used in the summary.

4.4 Feature combination using linear regression

We also evaluated the performance of a linear regression metric combining all of the above features. The value of the regression-based score for each summary was obtained using a leave-one-out approach. For a particular input and system-summary combination, the training set consisted only of examples which included neither the same input nor the same system. Hence during training, no examples of either the test input or system were seen.

5 Correlations with manual evaluations

In this section, we report the correlations between system ranking using our automatic features and the manual evaluations. We studied the predictive power of features in two scenarios.

MACRO LEVEL; PER SYSTEM: The values of features were computed for each summary submitted for evaluation. For each system, the feature values were averaged across all inputs. All participating systems were ranked based on the average value. Similarly, the average manual score, pyramid or responsiveness, was also computed for each system. The correlations between the two rankings are shown in Tables 2 and 4.

MICRO LEVEL; PER INPUT: The systems were ranked for each input separately, and correlations between the summary rankings for each input were computed (Table 3).

The two levels of analysis address different questions: *Can we automatically identify system performance across all test inputs (macro level) and can we identify which summaries for a given input were good and which were bad (micro level)?* For the first task, the answer is a definite "yes" while for the second task the results are mixed.

In addition, we compare our results to model-based evaluations using ROUGE and analyze the effects of stemming the input and summary vocabularies. In order to allow for in-depth discussion, we will analyze our findings only for query focused summaries. Similar results were obtained for the evaluation of update summaries and are described in Section 7.

5.1 Performance at macro level

Table 2 shows the Spearman correlation between manual and automatic scores averaged across the 48 inputs. We find that both distributional similarity and the topic signature features produce system rankings very similar to those produced by humans. Summary probabilities, on the other hand, turn out to be unpredictive of content selection performance. The linear regression combination of features obtains high correlations with manual scores but does not lead to better results than the single best feature: JS divergence.

Features	pyramid	respons.
JS div	-0.880	-0.736
JS div smoothed	-0.874	-0.737
% of input topic words	0.795	0.627
KL div summ-inp	-0.763	-0.694
cosine overlap	0.712	0.647
% of summ = topic wd	0.712	0.602
topic overlap	0.699	0.629
KL div inp-summ	-0.688	-0.585
mult. summary prob.	0.222	0.235
unigram summary prob.	-0.188	-0.101
regression	0.867	0.705
ROUGE-1 recall	0.859	0.806
ROUGE-2 recall	0.905	0.873

Table 2: Spearman correlation on macro level for the query focused task. All results are highly significant with p-values < 0.000001 except unigram and multinomial summary probability, which are not significant even at the 0.05 level.

JS divergence outperforms other features including the regression metric and obtains the best correlations with both types of manual scores, 0.88 with pyramid score and 0.74 with responsiveness. The regression metric performs comparably with correlations of 0.86 and 0.70. The correlations obtained by both JS divergence and the regression metric with pyramid evaluations are in fact better than that obtained by ROUGE-1 recall (0.85).

The best topic signature based feature—percentage of input's topic signatures that are present in the summary—ranks next only to JS divergence and regression. The correlation between this feature and pyramid and responsiveness evaluations is 0.79 and 0.62 respectively. The proportion of summary content composed of topic words performs worse as an evaluation metric with correlations 0.71 and 0.60. This result indicates that summaries that cover more topics from the input are judged to have better content than those in which fewer topics are mentioned.

Cosine overlaps and KL divergences obtain good correlations but still lower than JS divergence or percentage of input topic words. Further, rankings based on unigram and multinomial sum-

mary probabilities do not correlate significantly with manual scores.

5.2 Performance on micro level

On a per input basis, the proposed metrics are not that effective in distinguishing which summaries have better content. The minimum and maximum correlations with manual evaluations across the 48 inputs are given in Table 3. The number and percentage of inputs for which correlations were significant are also reported.

Now, JS divergence obtains significant correlations with pyramid scores for 73% of the inputs but for particular inputs, the correlation can be as low as 0.27. The results are worse for other features and for comparison with responsiveness scores.

At the micro level, combining features with regression gives the best result overall, in contrast to the findings for the macro level setting. This result has implications for system development; no single feature can reliably predict good content for a particular input. Even a regression combination of all features is a significant predictor of content selection quality in only 77% of the cases.

We should note however, that our features are based only on the distribution of terms in the input and therefore less likely to inform good content for all input types. For example, a set of documents each describing different opinion on a given issue will likely have less repetition on both lexical and content unit level. The predictiveness of features like ours will be limited for such inputs[4]. However, model summaries written for the specific input would give better indication of what information in the input was important and interesting. This indeed is the case as we shall see in Section 6.

Overall, the micro level results suggest that the fully automatic measures we examined will not be useful for providing information about summary quality for an individual input. For averages over many test sets, the fully automatic evaluations give more reliable and useful results, highly correlated with rankings produced by manual evaluations.

[4]In fact, it would be surprising to find an automatically computable feature or feature combination which would be able to consistently predict good content for all individual inputs. If such features existed, an ideal summarization system would already exist.

5.3 Effects of stemming

The analysis presented so far is on features computed after stemming the input and summary words. We also computed the values of the same features without stemming and found that divergence metrics benefit greatly when stemming is done. The biggest improvements in correlations are for JS and KL divergences with respect to responsiveness. For JS divergence, the correlation increases from 0.57 to 0.73 and for KL divergence (summary-input), from 0.52 to 0.69.

Before stemming, the topic signature and bag of words overlap features are the best predictors of responsiveness (correlations are 0.63 and 0.64 respectively) but do not change much after stemming (topic overlap—0.62, bag of words—0.64). Divergences emerge as better metrics only after stemming.

Stemming also proves beneficial for the likelihood features. Before stemming, their correlations are directed in the wrong direction, but they improve after stemming to being either positive or closer to zero. However, even after stemming, summary probabilities are not good predictors of content quality.

5.4 Difference in correlations: pyramid and responsiveness scores

Overall, we find that correlations with pyramid scores are higher than correlations with responsiveness. Clearly our features are designed to compare input-summary content only. Since responsiveness judgements were based on both content and linguistic quality of summaries, it is not surprising that these rankings are harder to replicate using our content based features. Nevertheless, responsiveness scores are dominated by content quality and the correlation between responsiveness and JS divergence is high, 0.73.

Clearly, metrics of linguistic quality should be integrated with content evaluations to allow for better predictions of responsiveness. To date, few attempts have been made to automatically evaluate linguistic quality in summarization. Lapata and Barzilay (2005) proposed a method for coherence evaluation which holds promise but has not been validated so far on large datasets such as those used in TAC and DUC. In a simpler approach, Conroy and Dang (2008) use higher order ROUGE scores to approximate both content and linguistic quality.

	pyramid			responsiveness

regression combining features comparing with background and update inputs (without averaging)

correlations = 0.8058 with pyramid, 0.6729 with responsiveness

Table 4: Spearman correlations at macro level for update summarization. Results are reported separately for features comparing update summaries with the update input only or with both update and background inputs and averaging the two.

6 Comparison with ROUGE

For manual pyramid scores, the best correlation, 0.88, we observed in our experiments was with JS divergence. This result is unexpectedly high for a fully automatic evaluation metric. Note that the best correlation between pyramid scores and ROUGE (for R2) is 0.90, practically identical with JS divergence. For ROUGE-1, the correlation is 0.85.

In the case of manual responsiveness, which combines aspects of linguistic quality along with content selection evaluation, the correlation with JS divergence is 0.73. For ROUGE, it is 0.80 for R1 and 0.87 for R2. Using higher order n-grams is obviously beneficial as observed from the differences between unigram and bigram ROUGE scores. So a natural extension of our features would be to use distance between bigram distributions. At the same time, for responsiveness, ROUGE-1 outperforms all the fully automatic features. This is evidence that the model summaries provide information that is unlikely to ever be approximated by information from the input alone, regardless of feature sophistication.

At the micro level, ROUGE does clearly better than all the automatic measures. The results are shown in the last two rows of Table 3. ROUGE-1 recall obtains significant correlations for over 95% of inputs for responsiveness and 98% of inputs for pyramid evaluation compared to 73% (JS divergence) and 77% (regression). Undoubtedly, at the input level, comparison with model summaries is substantially more informative.

When reference summaries are available, ROUGE provides scores that agree best with human judgements. However, when model sum-

maries are not available, our features can provide reliable estimates of system quality when averaged over a set of test inputs. For predictions at the level of individual inputs, our fully automatic features are less useful.

7 Update Summarization

In Table 4, we report the performance of our features for system evaluation on the update task. The column, "update input only" summarizes the correlations obtained by features comparing the summaries with only the update inputs (set B). We also compared the summaries individually to the update and background (set A) inputs. The two sets of features were then combined by a) averaging ("avg. update and background") and b) linear regression (last line of Table 4).

As in the case of query focused summarization, JS divergence and percentage of input topic signatures in summary are the best features for the update task as well. The overall best feature is JS divergence between the update input and the summaries—correlations of 0.82 and 0.76 with pyramid and responsiveness.

Interestingly, the features combining both update and background inputs do not lead to better correlations than those obtained using the update input only. The best performance from combined features is given by the linear regression metric. Although the correlation of this regression feature with pyramid scores (0.80) is comparable to JS divergence with update inputs, its correlation with responsiveness (0.67) is clearly lower. These results show that the term distributions in the update input are sufficiently good predictors of content for update summaries. The role of the background input appears to be negligable.

8 Discussion

We have presented a successful framework for model-free evaluations of content which uses the input as reference. The power of model-free evaluations generalizes across at least two summarization tasks: query focused and update summarization.

We have analyzed a variety of features for input-summary comparison and demonstrated that the strength of different features varies considerably. Similar term distributions in the input and the summary and diverse use of topic signatures in the summary are highly indicative of good content. We also find that preprocessing like stemming improves the performance of KL and JS divergence features.

Very good results were obtained from a correlation analysis with human judgements, showing that input can indeed substitute for model summaries and manual efforts in summary evaluation. The best correlations were obtained by a single feature, JS divergence (0.88 with pyramid scores and 0.73 with responsiveness at system level).

Our best features can therefore be used to evaluate the content selection performance of systems in a new domain where model summaries are unavailable. However, like all other content evaluation metrics, our features must be accompanied by judgements of linguistic quality to obtain wholesome indicators of summary quality and system performance. Evidence for this need is provided by the lower correlations with responsiveness than the content-only pyramid evaluations.

The results of our analysis zero in on JS divergence and topic signature as desirable objectives to optimize during content selection. On the macro level, they are powerful predictors of content quality. These findings again emphasize the need for always including linguistic quality as a component of evaluation.

Observations from our input-based evaluation also have important implications for the design of novel summarization tasks. We find that high correlations with manual evaluations are obtained by comparing query-focused summaries with the entire input and making no use of the query at all. Similarly in the update summarization task, the best predictions of content for update summaries were obtained using only the update input. The uncertain role of background inputs and queries expose possible problems with the task designs. Under such conditions, it is not clear if query-focused content selection or ability to compile updates are appropriately captured by any evaluation.

Classifier Combination for Contextual Idiom Detection Without Labelled Data

Abstract

We propose a novel unsupervised approach for distinguishing literal and non-literal use of idiomatic expressions. Our model combines an unsupervised and a supervised classifier. The former bases its decision on the cohesive structure of the context and labels training data for the latter, which can then take a larger feature space into account. We show that a combination of both classifiers leads to significant improvements over using the unsupervised classifier alone.

1 Introduction

Idiomatic expressions are abundant in natural language. They also often behave idiosyncratically and are therefore a significant challenge for natural language processing systems. For example, idioms can violate selectional restrictions (as in *push one's luck*), disobey typical subcategorisation constraints (e.g., *in line* without a determiner before *line*), or change the default assignments of semantic roles to syntactic categories (e.g., in *break sth with X* the argument *X* would typically be an instrument but for the idiom *break the ice* it is more likely to fill a patient role, as in *break the ice with Russia*).

In order to deal with such idiosyncracies and assign the correct analyses, NLP systems need to be able to recognise idiomatic expressions. Much previous research on idioms has been concerned with *type-based classification*, i.e., dividing expressions into 'idiom' or 'not idiom' irrespective of their actual use in a given context. However, while some expressions, such as *by and large*, always have an idiomatic meaning, several other expressions, such as *break the ice* or *spill the beans*, can be used literally as well as idiomatically (see examples (1) and (2), respectively). Sometimes the literal usage can even dominate in a domain, as for *drop the ball*, which occurs fairly frequently in a literal sense in the sports section of news texts.

(1) Dad had to break the ice on the chicken troughs so that they could get water.

(2) Somehow I always end up spilling the beans all over the floor and looking foolish when the clerk comes to sweep them up.

Hence, whether a particular occurrence of a potentially ambiguous expression has literal or non-literal meaning has to be inferred from the context (*token-based idiom classification*). Recently, there has been increasing interest in this classification task and both supervised and unsupervised techniques have been proposed. The work we present here builds on previous research by Sporleder and Li (2009), who describe an unsupervised method that exploits the presence or absence of cohesive ties between the component words of a potential idiom and its context to distinguish between literal and non-literal use. If strong ties can be found the expression is classified as literal otherwise as non-literal. While this approach often works fairly well, it has the disadvantage that it focuses exclusively on lexical cohesion, other linguistic cues that might influence the classification decision are disregarded.

We show that it is possible to improve on Sporleder and Li's (2009) results by employing a two-level strategy, in which a cohesion-based unsupervised classifier is combined with a supervised classifier. We use the unsupervised classifier to label a sub-set of the test data with high confidence. This sub-set is then passed on as training data to the supervised classifier, which then labels the remainder of the data set. Compared to a fully unsupervised approach, this two-stage method has the advantage that a larger feature set can be exploited. This is beneficial for examples, in which the cohesive ties are relatively weak but which contain other linguistic cues for literal or non-literal use.

Singapore, 6-7 August 2009.

2 Related Work

Most studies on idiom classification focus on type-based classification; few researchers have worked on token-based approaches (i.e., classification of an expression in a given context). Type-based methods frequently exploit the fact that idioms have a number of properties which differentiate them from other expressions. For example, they often exhibit a degree of syntactic and lexical fixedness. Some idioms, for instance, do not allow internal modifiers (**shoot the long breeze*) or passivisation (**the bucket was kicked*). They also typically only allow very limited lexical variation (**kick the vessel*, **strike the bucket*).

Many approaches for identifying idioms focus on one of these two aspects. For instance, measures that compute the association strength between the elements of an expression have been employed to determine its degree of compositionality (Lin, 1999; Fazly and Stevenson, 2006) (see also Villavicencio et al. (2007) for an overview and a comparison of different measures). Other approaches use Latent Semantic Analysis (LSA) to determine the similarity between a potential idiom and its components (Baldwin et al., 2003). Low similarity is supposed to indicate low compositionality. Bannard (2007) looks at the syntactic fixedness of idiomatic expressions, i.e., how likely they are to take modifiers or be passivised, and compares this to what would be expected based on the observed behaviour of the component words. Fazly and Stevenson (2006) combine information about syntactic and lexical fixedness (i.e., estimated degree of compositionality) into one measure.

The few token-based approaches include a study by Katz and Giesbrecht (2006), who devise a supervised method in which they compute the meaning vectors for the literal and non-literal usages of a given expression in the training data. An unseen test instance of the same expression is then labelled by performing a nearest neighbour classification.

Birke and Sarkar (2006) model literal vs. non-literal classification as a word sense disambiguation task and use a clustering algorithm which compares test instances to two automatically constructed seed sets (one with literal and one with non-literal expressions), assigning the label of the closest set. While the seed sets are created without immediate human intervention they do rely on manually created resources such as databases of known idioms.

Cook et al. (2007) and Fazly et al. (2009) propose an alternative method which crucially relies on the concept of *canonical form*, which is a fixed form (or a small set of those) corresponding to the syntactic pattern(s) in which the idiom normally occurs (Riehemann, 2001).[1] The canonical form allows for inflectional variation of the head verb but not for other variations (such as nominal inflection, choice of determiner etc.). It has been observed that if an expression is used idiomatically, it typically occurs in its canonical form. For example, Riehemann (2001, p. 34) found that for decomposable idioms 75% of the occurrences are in canonical form, rising to 97% for non-decomposable idioms.[2] Cook et al. exploit this behaviour and propose an unsupervised method which classifies an expression as idiomatic if it occurs in canonical form and literal otherwise.

Finally, in earlier work, we proposed an unsupervised method which detects the presence or absence of cohesive links between the component words of the idiom and the surrounding discourse (Sporleder and Li, 2009). If such links can be found the expression is classified as 'literal' otherwise as 'non-literal'. In this paper we show that the performance of such a classifier can be significantly improved by complementing it with a second-stage supervised classifier.

3 First Stage: Unsupervised Classifier

As our first-stage classifier, we use the unsupervised model proposed by Sporleder and Li (2009). This model exploits the fact that words in a coherent discourse exhibit *lexical cohesion* (Halliday and Hasan, 1976), i.e. concepts referred to in sentences are typically related to other concepts mentioned elsewhere in the discourse. Given a suitable measure of semantic relatedness, it is possible to compute the strength of such cohesive ties between pairs of words. While the component words of literally used expressions tend to exhibit lexical cohesion with their context, the words of non-literally used expressions do not. For example, in (3) the expression *play with fire* is used literally and the word *fire* is related to surrounding words like *grilling*, *dry-heat*, *cooking*, and *coals*. In (4), however *play with fire* is used non-literally and cohesive ties be-

[1] This is also the form in which an idiom is usually listed in a dictionary.

[2] Decomposable idioms are expressions such as *spill the beans* which have a composite meaning whose parts can be mapped to the words of the expression (e.g., *spill*→'reveal', *beans*→'secret').

tween *play* or *fire* and the context are absent.

(3) **Grilling** outdoors is much more than just another **dry-heat cooking** method. It's the chance to play with **fire**, satisfying a primal urge to stir around in **coals** .

(4) And PLO chairman Yasser Arafat has accused Israel of playing with fire by supporting HAMAS in its infancy.

To determine the strength of cohesive links, the unsupervised model builds a graph structure (called *cohesion graph*) in which all pairs of content words in the context are connected by an edge which is weighted by the pair's semantic relatedness. Then the *connectivity* of the graph is computed, defined as the average edge weight. If the connectivity increases when the component words of the idiom are removed, then there are no strong cohesive ties between the expression and the context and the example is labelled as 'non-literal', otherwise it is labelled as 'literal'.

To model semantic distance, we use the *Normalized Google Distance* (NGD, see Cilibrasi and Vitanyi (2007)), which computes relatedness on the basis of page counts returned by a search engine.[3] It is defined as follows:

$$NGD(x,y) = \frac{max\{log\ f(x), log\ f(y)\} - log\ f(x,y)}{log\ M - min\{log\ f(x), log\ f(y)\}} \quad (5)$$

where x and y are the two words whose association strength is computed (e.g., *fire* and *coal*), $f(x)$ is the page count returned by the search engine for x (and likewise for $f(y)$ and y), $f(x,y)$ is the page count returned when querying for "x AND y", and M is the number of web pages indexed by the search engine. The basic idea is that the more often two terms occur together, relative to their overall occurrence, the more closely they are related.

We hypothesise that the unsupervised classifier will give us relatively good results for some examples. For instance, in (3) there are several strong cues which suggest that *play with fire* is used literally. However, because the unsupervised classifier only looks at lexical cohesion, it misses many other clues which could help distinguish literal and non-literal usages. For example, if *break the ice* is followed by the prepositions *between* or *over* as in example (6), it is more likely to be used idiomatically (at least in the news domain).

(6) "Gujral will meet Sharif on Monday and discuss bilateral relations," the Press Trust of India added. The minister said Sharif and Gujral would be able to break the ice over Kashmir.

Furthermore, idiomatic usages also exhibit cohesion with their context but the cohesive ties are with the *non-literal* meaning of the expression. For example, in news texts, *break the ice* in its figurative meaning often co-occurs with *discuss*, *relations*, *talks* or *diplomacy* (see (6)). At the moment we do not have any way to model these cohesive links, as we do not know the non-literal meaning of the idiom.[4] However if we had labelled data we could train a supervised classifier to learn these and other contextual clues. The trained classifier might then be able to correctly classify examples which were misclassified by the unsupervised classifier, i.e., examples in which the cohesive ties are weak but where other clues exist which indicate how the expression is used.

For example, in (7) there is weak cohesive evidence for a literal use of *break the ice*, due to the semantic relatedness between *ice* and *water*. However, there are stronger cues for non-literal usage, such as the preposition *between* and the presence of words like *diplomats* and *talks*, which are indicative of idiomatic usage. Examples like this are likely to be misclassified by the unsupervised model; a supervised classifier, on the other hand, has a better chance to pick up on such additional cues and predict the correct label.

(7) Next week the two diplomats will meet in an attempt to break the ice between the two nations. A crucial issue in the talks will be the long-running water dispute.

4 Second Stage: Supervised Classifier

For the supervised classifier, we used Support Vector Machines as implemented by the LIBSVM package.[5] We implemented four types of features, which encode both cohesive information and word co-occurrence more generally.[6]

[3] We employ Yahoo! rather than Google since we found that it returns more stable counts.

[4] It might be possible to compute the Normalized Google Distance between the whole expression and the words in the context, assuming that whenever the whole expression occurs it is much more likely to be used figuratively than literally. For expressions in canonical form this is indeed often the case (Riehemann, 2001), however there are exceptions (see Section 6.1) for which such an approach would not work.

[5] Available from: `http://www.csie.ntu.edu.tw/~cjlin/libsvm/` We used the default parameters.

[6] We also experimented with linguistically more informed features, such as the presence of named entities in the local context of the expression, and properties of the subject or co-ordinated verbs, but we found that these features did not lead to a better performance of the supervised classifier. This is probably partly due to data sparseness.

Salient Words (salW) This feature aims to identify words which are particularly *salient* for literal usage. We used a frequency-based definition of salience and computed the *literal saliency score* for each word in a five-paragraph context around the target expression:

$$sal_{lit}(w) = \frac{\log f_{lit}(w) \times i_{lit}(w)}{\log f_{nonlit}(w) \times i_{nonlit}(w)} \quad (8)$$

where $sal_{lit}(w)$ is the saliency score of the word w for the class lit; $f_{lit}(w)$ is the token frequency of the word w for literally used expressions; $i_{lit}(w)$ is the number of instances of the target expressions classified as lit which co-occur with word w (and mutatis mutandis $nonlit$ for target expressions labelled as non-literal).[7]

Words with a high sal_{lit} occur much more frequently with literal usages than with non-literal ones. Conversely, words with a low sal_{lit} should be more indicative of the non-literal class. However, we found that, in practice, the measure is better at picking out indicative words for the literal class; non-literal usages tend to co-occur with a wide range of words. For example, among the highest scoring words for *break the ice* we find *thick, bucket, cold, water, reservoir* etc. While we do find words like *relations, diplomacy, discussions* among the lowest scoring terms (i.e., terms indicative of the non-literal class), we also find a lot of noise (*ask, month*). The effect is even more pronounced for other expressions (like *drop the ball*) which tend to be used idiomatically in a wider variety of situations (*drop the ball on a ban of chemical weapons*, *drop the ball on debt reduction* etc.).

We implement the saliency score in our model by encoding for the 300 highest scoring words whether the word is present in the context of a given example and how frequently it occurs.[8] Note that this feature (as well as the next one) can be computed in a per-idiom or a generic fashion. In the former case, we would encode the top 300 words separately for each idiom in the training set, in the latter across all idioms (with the consequence that more frequent idioms in the training set contribute to more positions in the feature vector). We found that, in practice, it does not make a big difference which variant is used. Moreover, in our bootstrapping scenario, we cannot ensure that we have sufficient examples of each idiom in the training set to train separate classifiers, so we opted for generic models throughout all experiments.

Related Words (relW) This feature set is a variant of the previous one. Here we score the words not based on their saliency but we determine the semantic relatedness between the noun in the idiomatic expression and each word in the global context, using the *Normalized Google Distance* mentioned in Section 3. Again we encode the 300 top-scoring words.

While the *related words* feature is less prone to overestimation of accidental co-occurrence than the saliency feature, it has the disadvantage of conflating different word senses. For example, among the highest scoring words for *ice* are *cold, melt, snow, skate, hockey* but also *cream, vanilla, dessert*.

Relatedness Score (relS) The fourth feature set implements the *relatedness score* which encodes the scores for the 100 most highly weighted edges in the cohesion graph of an instance.[9] If these scores are high, there are many cohesive ties with the surrounding discourse and the target expression is likely to be used literally.

Discourse Connectivity (connect.) Finally, we implemented two features which look at the cohesion graph of an instance. We encode the connectivity of the graph (i) when the target expression is included and (ii) when it is excluded. The unsupervised classifier uses the difference between these two values to make its prediction. By encoding the absolute connectivity values as features we enable the supervised classifier to make use of this information as well.

5 Combining the Classifiers

As mentioned before, we use the unsupervised classifier to label an initial training set for the supervised one. To ensure that the training set does not contain too much noise, we only add those examples about which the unsupervised classifier is

[7] Our definition of sal_{lit} bears similarities with the well known $tf.idf$ score. We include both the term frequencies (f_{lit}) and the instance frequencies (i_{lit}) in the formula because we believe both are important. However, the instance frequency is more informative and less sensitive to noise because it indicates that expression classified as 'literal' *consistently* co-occurs with the word in question. Therefore we weight down the effect of the term frequency by taking its log.

[8] We also experimented with different feature dimensions besides 300 but did not find a big difference in performance.

[9] We only used the 100 highest ranked edges because we are looking at a specific context here rather than the contexts of the literal or non-literal class overall. Since the contexts we use are only five paragraphs long, recording the 100 strongest edges seems sufficient.

most confident. We thus need to address two questions: (i) how to define a *confidence function* for the unsupervised classifier, and (ii) how to set the *confidence threshold* governing what proportion of the data set is used for training the second classifier.

The first question is relatively easy to answer: as the unsupervised classifier bases its decision on the difference in connectivity between including or excluding the component words of the idiom in the cohesion graph, an obvious choice for a confidence function is the difference in connectivity; i.e., the higher the difference, the higher the confidence of the classifier in the predicted label.

The confidence threshold could be selected on the basis of the unsupervised classifier's performance on a development set. Note that when choosing such a threshold there is usually a trade-off between the size of the training set and the amount of noise in it: the lower the threshold, the larger and the noisier the training set. Ideally we would like a reasonably-sized training set which is also relatively noise-free, i.e., does not contain too many wrongly labelled examples. One way to achieve this is to start with a relatively small training set and then expand it gradually.

A potential problem for the supervised classifier is that our data set is relatively imbalanced, with the non-literal class being four times as frequent as the literal class. Supervised classifiers often have problems with imbalanced data and tend to be overly biased towards the majority class (see, e.g., Japkowicz and Stephen (2002)). To overcome this problem, we experimented with boosting the literal class with additional examples.[10] We describe our methods for training set enlargement and boosting the literal class in the remainder of this section.

Iteratively Enlarging the Training Set A typical method for increasing the training set is to go through several iterations of enlargement and retraining.[11] We adopt a conservative enlargement strategy: we only consider instances on whose labels both classifiers agree and we use the confidence function of the unsupervised classifier to determine which of these examples to add to the training set. The motivation for this is that we hypothesise that the supervised classifier will not have a very good performance initially, as it is trained on a very small data set. As a consequence its confidence function may also not be very accurate. On the other hand, we know from Sporleder and Li (2009) that the unsupervised classifier has a reasonably good performance. So while we give the supervised classifier a veto-right, we do not allow it to select new training data by itself or overturn classifications made by the unsupervised classifier.

A similar strategy was employed by Ng and Cardie (2003) in a self-training set-up. However, while they use an ensemble of supervised classifiers, which they re-train after each iteration, we can only re-train the second classifier; the first one, being unsupervised, will never change its prediction. Hence it does not make sense to go through a large number of iterations; the more iterations we go through, the closer the performance of the combined classifier will be to that of the unsupervised one because that classifier will label a larger and larger proportion of the data. However, going through one or two iterations allows us to slowly enlarge the training set and thereby gradually improve the performance of the supervised classifier.

In each iteration, we select 10% of the remaining examples to be added to the training set.[12] We could simply add those 10% of the data about which the unsupervised classifier is most confident, but if the classifier was more confident about one class than about the other, we would risk obtaining a severely imbalanced training set. Hence, we decided to separate examples classified as 'literal' from those classified as 'non-literal' and add the top 10% from each set. Provided the automatic classification is reasonably accurate, this will ensure that the distribution of classes in the training set is roughly similar to that in the overall data set at least at the early stages of the bootstrapping.

Boosting the Literal Class As the process goes on, we are still likely to introduce more and more imbalance in the training set. This is due to the fact that the supervised classifier is likely to have some bias towards the majority class (and our experiments in Section 6.2 suggest that this is indeed the case). Hence, as the bootstrapping process goes on, potentially more and more examples will be labelled as 'non-literal' and if we always select the top 10% of these, our training set will gradually

[10] Throughout this paper, we use the term 'boosting' in a non-technical sense.

[11] In our case re-training also involves re-computing the ranked lists of salient and related words. As the process goes on the classifier will be able to discover more and more useful cue words and encode them in the feature vector.

[12] Since we do not have a separate development set, we chose the value of 10% intuitively as it seemed a reasonably good threshold.

become more imbalanced. This is a well-known problem for bootstrapping approaches (Blum and Mitchell, 1998; Le et al., 2006). We could counteract this by selecting a higher proportion of examples labelled as 'literal'. However given that the number of literal examples in our data set is relatively small, we would soon deplete our literal instance pool and moreover, because we would be forced to add less confidently labelled examples for the literal class, we are likely to introduce more noise in the training set.

A better option is to boost the literal class with external examples. To do this we exploit the fact that non-canonical forms of idioms are highly likely to be used literally. Given that our data set only contains canonical forms (see Section 6.1), we automatically extract non-canonical form variants and label them as 'literal'. To generate possible variants, we either (i) change the number of the noun (e.g., *rock the boat* becomes *rock the boats*), (ii) change the determiner (e.g., *rock a boat*), or (iii) replace the verb or noun by one of its synonyms, hypernyms, or siblings from WordNet (e.g., *rock the ship*). While this strategy does not give us additional literal examples for all idioms, for example we were not able to find non-canonical form occurrences of *sweep under the carpet* in the Gigaword corpus, for most idioms we were able to generate additional examples. Note that this data set is potentially noisy as not all non-canonical form examples are used literally. However, when checking a small sample manually, we found that only very small percentage ($<< 1\%$) was mis-labelled.

To reduce the classifier bias when enlarging the training set, we add additional literal examples during each iteration to ensure that the class distribution does not deviate too much from the distribution originally predicted by the unsupervised classifier.[13] The examples to be added are selected randomly but we try to ensure that each idiom is represented. When reporting the results, we disregard these additional external examples.

6 Experiments and Results

We carried out a number of different experiments. In Section 6.2 we investigate the performance of the different features of the supervised classifier and in Section 6.3 we look more closely at the behaviour of the combined classifier. We start by describing the data set.

6.1 Data

We used the data from Sporleder and Li (2009), which consist of 17 idioms that can be used both literally and non-literally (see Table 1). For each expression, all canonical form occurrences were extracted from the Gigaword corpus together with five paragraphs of context and labelled as 'literal' or 'non-literal'.[14] The inter-annotator agreement on a small sample of doubly annotated examples was 97% and the kappa score 0.7 (Cohen, 1960).

expression	literal	non-literal	all
back the wrong horse	0	25	25
bite off more than one can chew	2	142	144
bite one's tongue	16	150	166
blow one's own trumpet	0	9	9
bounce off the wall*	39	7	46
break the ice	20	521	541
drop the ball*	688	215	903
get one's feet wet	17	140	157
pass the buck	7	255	262
play with fire	34	532	566
pull the trigger*	11	4	15
rock the boat	8	470	478
set in stone	9	272	281
spill the beans	3	172	175
sweep under the carpet	0	9	9
swim against the tide	1	125	126
tear one's hair out	7	54	61
all	862	3102	3964

Table 1: Idiom statistics (* indicates expressions for which the literal usage is more common than the non-literal one)

6.2 Feature Analysis for the Supervised Classifier

In a first experiment, we tested the contribution of the different features (Table 2). For each set, we trained a separate classifier and tested it in 10-fold cross-validation mode. We also tested the performance of the first three features combined (salient and related words and relatedness score) as we wanted to know whether their combination leads to performance gains over the individual classifiers. Moreover, testing these three features in combination allows us to assess the contribution of the connectivity feature, which is most closely related to the unsupervised classifier. We report the accuracy, and because our data are fairly imbalanced,

[13] We are assuming that the true distribution is not known and use the predictions of the unsupervised classifier to approximate the true distribution.

[14] The restriction to canonical forms was motivated by the fact that for the mostly non-decomposable idioms in the set, the vast majority (97%) of non-canonical form occurrences will be used literally (see Section 2).

also the F-Score for the minority class ('literal').

Feature	Avg. literal (%) Prec.	Rec.	F-Score	Avg. (%) Acc.
salW	77.10	56.10	65.00	86.83
relW	78.00	43.20	55.60	84.99
relS	74.90	37.50	50.00	83.68
connectivity	78.30	2.10	4.10	78.58
salW+relW+relS	82.90	63.50	71.90	89.20
all	85.80	66.60	75.00	90.34

Table 2: Performance of different feature sets, 10-fold cross-validation

It can be seen that the *salient words* (*salW*) feature has the highest performance of the individual features, both in terms of accuracy and in terms of literal F-Score, followed by *related words* (*relW*), and *relatedness score* (*relS*). Intuitively, it is plausible that the saliency feature performs quite well as it can also pick up on linguistic indicators of idiom usage that do not have anything to do with lexical cohesion. However, a combination of the first three features leads to an even better performance, suggesting that the features do indeed model somewhat different aspects of the data.

The performance of the connectivity feature is also interesting: while it does not perform very well on its own, as it over-predicts the non-literal class, it noticeably increases the performance of the model when combined with the other features, suggesting that it picks up on complementary information.

6.3 Testing the Combined Classifier

We experimented with different variants of the combined classifier. The results are shown in Table 3. In particular, we looked at: (i) combining the two classifiers without training set enlargement or boosting of the literal class (*combined*), (ii) boosting the literal class with 200 automatically labelled non-canonical form examples (*combined+boost*), (iii) enlarging the training set by iteration (*combined+it*), and (iv) enlarging the training set by iteration and boosting the literal class after each iteration (*combined+boost+it*). The table shows the literal precision, recall and F-Score of the combined model (both classifiers) on the complete data set (excluding the extra literal examples). Note that the results for the set-ups involving iterative training set enlargement are optimistic: since we do not have a separate development set, we report the optimal performance achieved during the first seven iterations. In a real set-up, when the optimal number of iterations is chosen on the basis of a separate data set, the results may be lower. The table also shows the majority class baseline (*Base*$_{maj}$), and the overall performance of the unsupervised model (*unsup*) and the supervised model when trained in 10-fold cross-validation mode (*super 10CV*).

Model	Prec$_l$	Rec$_l$	F-Score$_l$	Acc.
Base$_{maj}$	-	-	-	78.25
unsup.	50.04	69.72	58.26	78.38
combined	83.86	45.82	59.26	86.30
combined+boost	70.26	62.76	66.30	86.13
combined+it*	85.68	46.52	60.30	86.68
combined+boost+it*	71.86	66.36	69.00	87.03
super. 10CV	85.80	66.60	75.00	90.34

Table 3: Results for different classifiers; $*$ indicates best performance (optimistic)

It can be seen that the combined classifier is 8% more accurate than both the majority baseline and the unsupervised classifier. This amounts to an error reduction of over 35% (the difference is statistically significant, χ^2 test, $p << 0.01$). While the F-Score of the unboosted combined classifier is comparable to that of the unsupervised one, boosting the literal class leads to a 7% increase, due to a significantly increased recall, with no significant drop in accuracy. These results show that complementing the unsupervised classifier with a supervised one, can lead to tangible performance gains. Note that the accuracy of the combined classifier, which uses no manually labelled training data, is only 4% below that of a fully supervised classifier; in other words, we do not lose much by starting with an automatically labelled data set. Iterative enlargement of the training set can lead to further improvements, especially when combined with boosting to reduce the classifier bias.

To get a better idea of the effect of training set enlargement, we plotted the accuracy and F-Score of the combined classifier for a given number of iterations with boosting (Figure 1) and without (Figure 2). It can be seen that enlargement has a noticeable positive effect if combined with boosting. If the literal class is not boosted, the increasing bias of the classifier seems to outweigh most of the positive effects from the enlarged training set. Figure 1 also shows that the best performance is obtained after a relatively small number of iterations (namely two), as expected.[15] With more iterations the performance decreases again. However, it decays rel-

[15] Note that this also depends on the confidence threshold. For example, if a threshold of 5% is chosen, more iterations may be required for optimal performance.

atively gracefully and even after seven iterations, when more than 40% of the data are classified by the unsupervised classifier, the combined classifier still achieves an overall performance that is significantly above that of the unsupervised classifier (84.28% accuracy compared to 78.38%, significant at $p << 0.01$). Hence, the combined classifier seems not to be very sensitive to the exact number of iterations and performs reasonably well even if the number of iterations is sub-optimal.

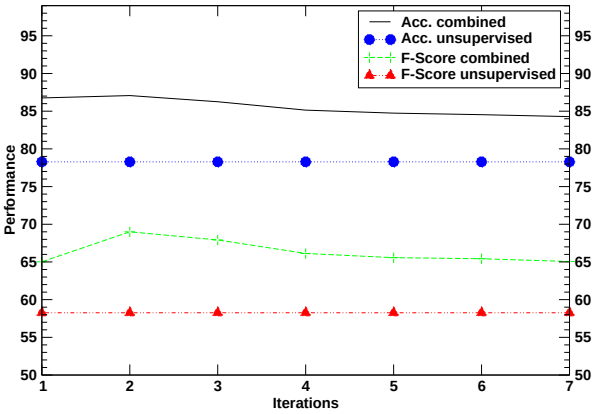

Figure 1: Accuracy and literal F-Score on complete data set after different iterations with boosting of the literal class

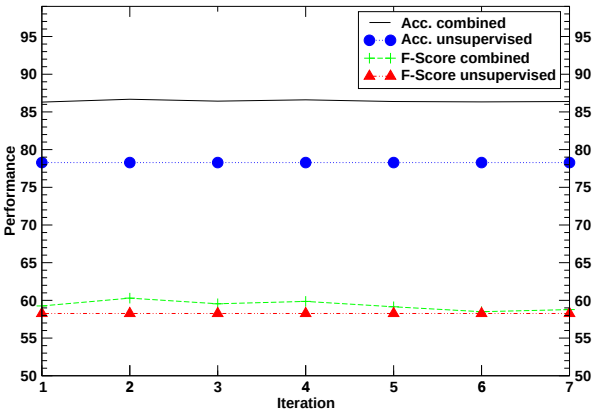

Figure 2: Accuracy and literal F-Score on complete data set after different iterations without boosting of the literal class

Figure 3 shows how the training set increases as the process goes on[16] and how the number of mis-classifications in the training set develops. Interestingly, when going from the first to the second iteration the training set nearly doubles (from 396 to 669 instances), while the proportion of errors is also reduced by a third (from 7% to 5%). Hence, the training set does not only grow but the proportion of noise in it decreases, too. This shows that our conservative enlargement strategy is fairly successful in selecting correctly labelled examples. Only at later stages, when the classifier bias takes over, does the proportion of noise increase again.

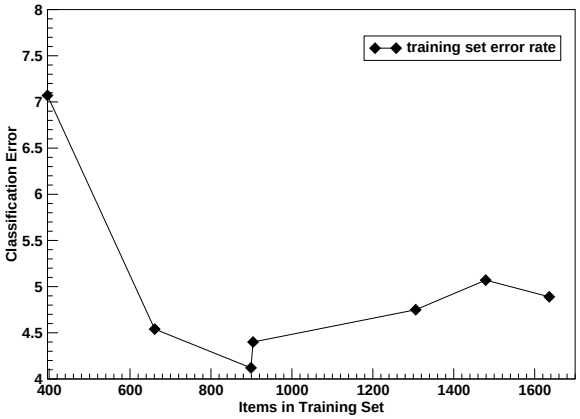

Figure 3: Training set size and error in training set at different iterations

7 Conclusion

We presented a two-stage classification approach for distinguishing literal and non-literal use of idiomatic expressions. Our approach complements an unsupervised classifier, which exploits information about the cohesive structure of the discourse, with a supervised classifier. The latter can make use of a range of features and therefore base its classification decision on additional properties of the discourse, besides lexical cohesion. We showed that such a combined classifier can lead to a significant reduction of classification errors. Its performance can be improved further by iteratively increasing the training set in a bootstrapping loop and by adding additional examples of the literal class, which is typically the minority class. We found that such examples can be obtained automatically by extracting non-canonical variants of the target idioms from an unlabelled corpus.

Future work should look at improving the supervised classifier, which so far has an accuracy of 90%. While this is already pretty good, a more sophisticated model might lead to further improvements. For example, one could experiment with linguistically more informed features. While our initial studies in this direction were negative, careful feature engineering might lead to better results.

Abstract

A number of recent publications have made use of the incremental output of stochastic parsers to derive measures of high utility for psycholinguistic modeling, following the work of Hale (2001; 2003; 2006). In this paper, we present novel methods for calculating separate lexical and syntactic surprisal measures from a single incremental parser using a lexicalized PCFG. We also present an approximation to entropy measures that would otherwise be intractable to calculate for a grammar of that size. Empirical results demonstrate the utility of our methods in predicting human reading times.

1 Introduction

Assessment of linguistic complexity has played an important role in psycholinguistics and neurolinguistics for a long time, from the use of mean length of utterance and related scores in child language development (Klee and Fitzgerald, 1985), to complexity scores related to reading difficulty in human sentence processing studies (Yngve, 1960; Frazier, 1985; Gibson, 1998). Operationally, such linguistic complexity scores are derived via deterministic manual (human) annotation and scoring algorithms of language samples. Natural language processing has been employed to automate the extraction of such measures (Sagae et al., 2005; Roark et al., 2007), which can have high utility in terms of reduction of time required to annotate and score samples. More interestingly, however, novel data driven methods are being increasingly employed in this sphere, yielding language sample characterizations that *require* NLP in their derivation. For example, scores derived from variously estimated language models have been used to evaluate and classify language samples associated with neurodevelopmental or neurodegenerative disorders (Roark et al., 2007; Solorio and Liu, 2008; Gabani et al., 2009), as well as within general studies of human sentence processing (Hale, 2001; 2003; 2006). These scores cannot feasibly be derived by hand, but rather rely on large-scale statistical models and structured inference algorithms to be derived. This is quickly becoming an important application of NLP, making possible new methods in the study of human language processing in both typical and impaired populations.

The use of broad-coverage parsing for psycholinguistic modeling has become very popular recently. Hale (2001) suggested a measure (surprisal) derived from an Earley (1970) parser using a probabilistic context-free grammar (PCFG) for psycholinguistic modeling; and in later work (Hale, 2003; 2006) he suggested an alternate parser-derived measure (entropy reduction) that may also account for some human sentence processing performance. Recent work continues to advocate surprisal in particular as a very useful measure for predicting processing difficulty (Boston et al., 2008a; Boston et al., 2008b; Demberg and Keller, 2008; Levy, 2008), and the measure has been derived using a variety of incremental (left-to-right) parsing strategies, including an Earley parser (Boston et al., 2008a), the Roark (2001) incremental top-down parser (Demberg and Keller, 2008), and an n-best version of the Nivre et al. (2007) incremental dependency parser (Boston et al., 2008a; 2008b). Deriving such measures by hand, even for a relatively limited set of stimuli, is not feasible, hence parsing plays a critical role in this developing psycholinguistic enterprise.

There is no single measure that can account for all of the factors influencing human sentence processing performance, and some of the most recent work on using parser-derived measures for psycholinguistic modeling has looked to try to derive multiple, complementary measures. One of

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 324–333,
Singapore, 6-7 August 2009.

the key distinctions being looked at is syntactic versus lexical expectations (Gibson, 2006). For example, in Demberg and Keller (2008), trials were run deriving surprisal from the Roark (2001) parser under two different conditions: fully lexicalized parsing, and fully unlexicalized parsing (to pre-terminal part-of-speech tags). Boston et al. (2008a) capture a similar distinction by making use of an unlexicalized PCFG within an Earley parser and a fully lexicalized unlabeled dependency parser (Nivre et al., 2007). As Demberg and Keller (2008) point out, fully unlexicalized grammars ignore important lexico-syntactic information when deriving the "syntactic" expectations, such as subcategorization preferences of particular verbs, which are generally accepted to impact syntactic expectations in human sentence processing (Garnsey et al., 1997). Demberg and Keller argue, based on their results, for unlexicalized surprisal instead of lexicalized surprisal. Here we present a novel method for deriving separate syntactic and lexical surprisal measures from a fully lexicalized incremental parser, to allow for rich probabilistic grammars to be used to derive either measure, and demonstrate the utility of this method versus that of Demberg and Keller in empirical trials.

The use of large-scale lexicalized grammars presents a problem for using an Earley parser to derive surprisal or for the calculation of entropy as Hale (2003; 2006) defines it, because both methods require matrix inversion of a matrix with dimensionality the size of the non-terminal set. With very large lexicalized PCFGs, the size of the non-terminal set is too large for tractable matrix inversion. The use of an incremental, beam-search parser provides a tractable approximation to both measures. Incremental top-down and left-corner parsers have been shown to effectively (and efficiently) make use of non-local features from the left-context to yield very high accuracy syntactic parses (Roark, 2001; Henderson, 2003; Collins and Roark, 2004), and we will use such rich models to derive our scores.

In addition to teasing apart syntactic and lexical surprisal (defined explicitly in §3), we present an approximation to the full entropy that Hale (2003; 2006) used to define the entropy reduction hypothesis. Such an entropy measure is derived via a predictive step, advancing the parses independently of the input, as described in §3.3. We also present syntactic and lexical alternatives for this measure, and demonstrate the utility of making such a distinction for entropy as well as surprisal.

The purpose of this paper is threefold. First, to present a careful and well-motivated decomposition of lexical and syntactic expectation-based measures from a given lexicalized PCFG. Second, to explicitly document methods for calculating these and other measures from a specific incremental parser. And finally, to present some empirical validation of the novel measures from real reading time trials. We modified the Roark (2001) parser to calculate the discussed measures[1], and the empirical results in §4 show several things, including: 1) using a fully lexicalized parser to calculate syntactic surprisal and entropy provides higher predictive utility for reading times than these measures calculated via unlexicalized parsing (as in Demberg and Keller); and 2) syntactic entropy is a useful predictor of reading time.

2 Notation and preliminaries

A probabilistic context-free grammar (PCFG) $G = (V, T, S^\dagger, P, \rho)$ consists of a set of non-terminal variables V; a set of terminal items (words) T; a special start non-terminal $S^\dagger \in V$; a set of rule productions P of the form $A \rightarrow \alpha$ for $A \in V$, $\alpha \in (V \cup T)^*$; and a function ρ that assigns probabilities to each rule in P such that for any given non-terminal symbol $X \in V$, $\sum_\alpha \rho(X \rightarrow \alpha) = 1$.

For a given rule $A \rightarrow \alpha \in P$, let the function RHS return the right-hand side of the rule, i.e., $\text{RHS}(A \rightarrow \alpha) = \alpha$. Without loss of generality, we will assume that for every rule $A \rightarrow \alpha \in P$, one of two cases holds: either $\text{RHS}(A \rightarrow \alpha) \in T$ or $\text{RHS}(A \rightarrow \alpha) \in V^*$. That is, the right-hand side sequences consist of either (1) exactly one terminal item, or (2) zero or more non-terminals.

Let $W \in T^n$ be a terminal string of length n, i.e., $W = W_1 \ldots W_n$ and $|W| = n$. Let $W[i, j]$ denote the substring beginning at word W_i and ending at word W_j of the string. Then $W_{|W|}$ is the last word in the string, and $W[1, |W|]$ is the string as a whole. Adjacent strings represent concatenation, i.e., $W[1, i]W[i{+}1, j] = W[1, j]$. Thus $W[1, i]w$ represents the string where $W_{i+1} = w$.

We can define a "derives" relation (denoted $\Rightarrow_G$ for a given PCFG G) as follows: $\beta A \gamma \Rightarrow_G \beta\alpha\gamma$ if and only if $A \rightarrow \alpha \in P$. A string $W \in T^*$ is in the language of a grammar G if and only if $S^\dagger \stackrel{+}{\Rightarrow}_G W$, i.e., a sequence of one or more derivation steps yields the string from the start

[1] The parser version will be made publicly available.

non-terminal. A *leftmost* derivation begins with $S^\dagger$ and each derivation step replaces the leftmost non-terminal A in the yield with some α such that $A \rightarrow \alpha \in P$. For a leftmost derivation $S^\dagger \stackrel{*}{\Rightarrow}_G \alpha$, where $\alpha \in (V \cup T)^*$, the sequence of derivation steps that yield α can be represented as a tree, with the start symbol $S^\dagger$ at the root, and the "yield" sequence α at the leaves of the tree. A *complete* tree has only terminal items in the yield, i.e., $\alpha \in T^*$; a *partial* tree has some non-terminal items in the yield. With a leftmost derivation, the yield $\alpha = \beta\gamma$ partitions into an initial sequence of terminals $\beta \in T^*$ followed by a sequence of non-terminals $\gamma \in V^*$. For a complete derivation, $\gamma = \epsilon$; for a partial derivation $\gamma \in V^+$, i.e., one or more non-terminals. Let $\mathcal{T}(G, W[1,i])$ be the set of complete trees with $W[1,i]$ as the yield of the tree, given PCFG G.

A leftmost derivation D consists of a sequence of $|D|$ steps. Let D_i represent the i^{th} step in the derivation D, and $D[i,j]$ represent the subsequence of steps in D beginning with D_i and ending with D_j. Note that $D_{|D|}$ is the last step in the derivation, and $D[1,|D|]$ is the derivation as a whole. Each step D_i in the derivation is a rule in G, i.e., $D_i \in P$ for all i. The probability of the derivation and the corresponding tree is:

$$\rho(D) \quad = \quad \prod_{i=1}^{m} \rho(D_i) \tag{1}$$

Let $\mathcal{D}(G, W[1,i])$ be the set of all possible leftmost derivations D (with respect to G) such that $\text{RHS}(D_{|D|}) = W_i$. These are the set of partial leftmost derivations whose last step used a production with terminal W_i on the right-hand side. The prefix probability of $W[1,i]$ with respect to G is

$$\text{PrefixProb}_G(W[1,i]) \quad = \sum_{D \in \mathcal{D}(G,W[1,i])} \rho(D) \tag{2}$$

From this prefix probability, we can calculate the conditional probability of each word $w \in T$ in the terminal vocabulary, given the preceding sequence $W[1,i]$ as follows:

$$\begin{aligned} P_G(w \mid W[1,i]) &= \frac{\text{PrefixProb}_G(W[1,i]w)}{\sum_{w' \in T} \text{PrefixProb}_G(W[1,i]w')} \\ &= \frac{\text{PrefixProb}_G(W[1,i]w)}{\text{PrefixProb}_G(W[1,i])} \end{aligned} \tag{3}$$

This, in fact, is precisely the conditional probability that is used for language modeling for such applications as speech recognition and machine translation, which was the motivation for various syntactic language modeling approaches (Jelinek and Lafferty, 1991; Stolcke, 1995; Chelba and Jelinek, 1998; Roark, 2001).

As with language modeling, it is important to model the end of the string as well, usually with an explicit end symbol, e.g., </s>. For a string $W[1,i]$, we can calculate its prefix probability as shown above. To calculate its complete probability, we must sum the probabilities over the set of complete trees $\mathcal{T}(G, W[1,i])$. In such a way, we can calculate the conditional probability of ending the string with </s> given $W[1,i]$ as follows:

$$P_G(\text{</s>} \mid W[1,i]) = \frac{\sum_{D \in \mathcal{T}(G,W[1,i])} \rho(D)}{\text{PrefixProb}_G(W[1,i])} \tag{4}$$

2.1 Incremental top-down parsing

In this section, we review relevant details of the Roark (2001) incremental top-down parser, as configured for use here. As presented in Roark (2004), the probabilities in the PCFG are smoothed so that the parser is guaranteed not to fail due to garden pathing, despite following a beam search strategy. Hence there is always a non-zero prefix probability as defined in Eq. 2.

The parser follows a top-down leftmost derivation strategy. The grammar is factored so that every production has either a single terminal item on the right-hand side or is of the form A $\rightarrow$ B A-B, where A,B $\in V$ and the factored A-B category can expand to any sequence of children categories of A that can follow B. This factorization of n-ary productions continues to nullary factored productions, i.e., the end of the original production A $\rightarrow$ $\text{B}_1 \ldots \text{B}_n$ is signaled with an empty production A-B_1-$\ldots$-$\text{B}_n \rightarrow \epsilon$.

The parser maintains a set of possible connected derivations, weighted via the PCFG. It uses a beam search, whereby the highest scoring derivations are worked on first, and derivations that fall outside of the beam are discarded. The reader is referred to Roark (2001; 2004) for specifics about the beam search.

The model conditions the probability of each production on features extracted from the partial tree, including non-local node labels such as parents, grandparents and siblings from the left-context, as well as c-commanding lexical items. Hence this is a lexicalized grammar, though the incremental nature precludes a general head-first strategy, rather one that looks to the left-context for c-commanding lexical items.

To avoid some of the early prediction of structure, the version of the Roark parser that we used

performs an additional grammar transformation beyond the simple factorization already described – a selective left-corner transform of left-recursive productions (Johnson and Roark, 2000). In the transformed structure, slash categories are used to avoid predicting left-recursive structure until some explicit indication of modification is present, e.g., a preposition.

The final step in parsing, following the last word in the string, is to "complete" all non-terminals in the yield of the tree. All of these open non-terminals are composite factored categories, such as S-NP-VP, which are "completed" by rewriting to ϵ. The probability of these ϵ productions is what allows for the calculation of the conditional probability of ending the string, shown in Eq. 4.

One final note about the size of the non-terminal set and the intractability of exact inference for such a scenario. The non-terminal set not only includes the original atomic non-terminals of the grammar, but also any categories created by grammar factorization (S-NP) or the left-corner transform (NP/NP). Additionally, however, to remain context-free, the non-terminal set must include categories that incorporate non-local features used by the statistical model into their label, including parents, grandparents and sibling categories in the left-context, as well as c-commanding lexical heads. These non-local features must be made local by encoding them in the non-terminal labels, leading to a very large non-terminal set and intractable exact inference. Heavy smoothing is required when estimating the resulting PCFG. The benefit of such a non-terminal set is a rich model, which enables a more peaked statistical distribution around high quality syntactic structures and thus more effective pruning of the search space. The fully connected left-context produced by top-down derivation strategies provides very rich features for the stochastic parsing models. See Roark (2001; 2004) for discussion of these issues.

We now turn to measures that can be derived from the parser which may be of use for psycholinguistic modeling.

3 Parser and grammar derived measures

3.1 Surprisal

The *surprisal* at word W_i is the negative log probability of W_i given the preceding words. Using prefix probabilities, this can be calculated as:

$$S_G(W_i) \;=\; -\log \frac{\text{PrefixProb}_G(W[1,i])}{\text{PrefixProb}_G(W[1,i-1])} \quad (5)$$

Substituting equation 2 into this, we get

$$S_G(W_i) \;=\; -\log \frac{\sum_{D \in \mathcal{D}(G,W[1,i])} \rho(D)}{\sum_{D \in \mathcal{D}(G,W[1,i-1])} \rho(D)} \quad (6)$$

If we are using a beam-search parser, some of the derivations are pruned away. Let $\mathcal{B}(G, W[1,i]) \subseteq \mathcal{D}(G, W[1,i])$ be the set of derivations in the beam. Then the surprisal can be approximated as

$$S_G(W_i) \;\approx\; -\log \frac{\sum_{D \in \mathcal{B}(G,W[1,i])} \rho(D)}{\sum_{D \in \mathcal{B}(G,W[1,i-1])} \rho(D)} \quad (7)$$

Any pruning in the beam search will result in a *deficient* probability distribution, i.e., a distribution that sums to less than 1. Roark's thesis (2001) showed that the amount of probability mass lost for this particular approach is very low, hence this provides a very tight bound on the actual surprisal given the model.

3.2 Lexical and Syntactic surprisal

High surprisal scores result when the prefix probability at word W_i is low relative to the prefix probability at word W_{i-1}. Sometimes this is due to the identity of W_i, i.e., it is a surprising word given the context. Other times, it may not be the lexical identity of the word so much as the syntactic structure that must be created to integrate the word into the derivations. One would like to tease surprisal apart into "syntactic surprisal" versus "lexical surprisal", which would capture this intuition of the lexical versus syntactic dimensions to the score. Our solution to this has the beneficial property of producing two scores whose sum equals the original surprisal score.

The original surprisal score is calculated via sets of partial derivations at the point when each word W_i is integrated into the syntactic structure, $\mathcal{D}(G, W[1,i])$. We then calculate the ratio from point to point in sequence. To tease apart the lexical and syntactic surprisal, we will consider sets of partial derivations *immediately before* each word W_i is integrated into the syntactic structure, i.e., $D[1, |D|-1]$ for $D \in \mathcal{D}(G, W[1,i])$. Recall that the last derivation move for every derivation in the set is from the POS-tag to the lexical item. Hence the sequence of derivation moves that excludes the last one includes all structure except the word W_i. Then the syntactic surprisal is calculated as:

$$\text{Syn}S_G(W_i) = -\log \frac{\sum_{D \in \mathcal{D}(G,W[1,i])} \rho(D[1,|D|-1])}{\sum_{D \in \mathcal{D}(G,W[1,i-1])} \rho(D)} \quad (8)$$

and the lexical surprisal is calculated as:

$$\text{Lex}S_G(W_i) = -\log \frac{\sum_{D \in \mathcal{D}(G,W[1,i])} \rho(D)}{\sum_{D \in \mathcal{D}(G,W[1,i])} \rho(D[1,|D|-1])} \quad (9)$$

Note that the numerator of $\text{Syn}S_G(W_i)$ is the denominator of $\text{Lex}S_G(W_i)$, hence they sum to form total surprisal $S_G(W_i)$. As with total surprisal, these measures can be defined either for the full set $\mathcal{D}(G, W[1,i])$ or for a pruned beam of derivations $\mathcal{B}(G, W[1,i]) \subseteq \mathcal{D}(G, W[1,i])$.

Finally, we replicated the Demberg and Keller (2008) "unlexicalized" surprisal by replacing every lexical item in the training corpus with its POS-tag, and then parsing the POS-tags of the language samples rather than the words. This differs from our syntactic surprisal by having no lexical conditioning events for rule probabilities, and by having no ambiguity about the POS-tag of the lexical items in the string. We will refer to the resulting surprisal measure as "POS surprisal" to distinguish it from our syntactic surprisal measure.

3.3 Entropy

Entropy scores of the sort advocated by Hale (2003; 2006) involve calculation over the set of complete derivations consistent with the set of partial derivations. Hale performs this calculation efficiently via matrix inversion, which explains the use of relatively small-scale grammars with tractably sized non-terminal sets. Such methods are not tractable for the kinds of richly conditioned, large-scale PCFGs that we advocate using here. At each word in the string, the Roark (2001) top-down parser provides access to the weighted set of partial analyses in the beam; the set of complete derivations consistent with these is not immediately accessible, hence additional work is required to calculate such measures.

Let $H(\mathcal{D})$ be the entropy over a set of derivations $\mathcal{D}$, calculated as follows:

$$H(\mathcal{D}) = -\sum_{D \in \mathcal{D}} \frac{\rho(D)}{\sum_{D' \in \mathcal{D}} \rho(D')} \log \frac{\rho(D)}{\sum_{D' \in \mathcal{D}} \rho(D')} \quad (10)$$

If the set of derivations $\mathcal{D} = \mathcal{D}(G, W[1,i])$ is a set of partial derivations for string $W[1,i]$, then $H(\mathcal{D})$ is a measure of uncertainty over the partial derivations, i.e., the uncertainty regarding the correct analysis of what has already been processed. This can be calculated directly from the existing parser operations. If the set of derivations are the complete derivations *consistent* with the set of partial derivations – complete derivations that could occur over the set of possible continuations of the string – then this is a measure of the uncertainty about what is yet to come. We would like measures that can capture this distinction between (a) uncertainty of what has already been processed ("current ambiguity") versus (b) uncertainty of what is yet to be processed ("predictive entropy"). In addition, as with surprisal, we would like to tease apart the syntactic uncertainty versus lexical uncertainty.

To calculate the predictive entropy after word sequence $W[1,i]$, we modify the parser as follows: the parser extends the set of partial derivations to include all possible next words (the entire vocabulary plus </s>), and calculates the entropy over that set. This measure is calculated from just one additional word beyond the current word, and hence is an approximation to Hale's conditional entropy of grammatical continuations, which is over complete derivations. We will denote this as $H^1_G(W[1,i])$ and calculate it as follows:

$$H^1_G(W[1,i]) = H(\bigcup_{w \in T \cup \{\text{</s>}\}} \mathcal{D}(G, W[1,i]w)) \quad (11)$$

This is performing a predictive step that the baseline parser does not perform, extending the parses to all possible next words.

Unlike surprisal, entropy does not decompose straightforwardly into syntactic and lexical components that sum to the original composite measure. To tease apart entropy due to syntactic uncertainty versus that due to lexical uncertainty, we can define the set of derivations up to the preterminal (POS-tag) non-terminals as follows. Let $S(\mathcal{D}) = \{D[1,|D|-1] : D \in \mathcal{D}\}$, i.e., the set of derivations achieved by removing the last step of all derivations in $\mathcal{D}$. Then we can calculate a "syntactic" H^1_G as follows:

$$\text{Syn}H^1_G(W[1,i]) = H(\bigcup_{w \in T \cup \{\text{</s>}\}} S(\mathcal{D}(G, W[1,i]w))) \quad (12)$$

Finally, "lexical" H^1_G is defined in terms of the conditional probabilities derived from prefix probabilities as defined in Eq. 3.

$$\text{Lex}H^1_G(W[1,i]) = -\sum_{w \in T \cup \{\text{</s>}\}} P_G(w \mid W[1,i]) \log P_G(w \mid W[1,i]) \quad (13)$$

As a practical matter, these values are calculated within the Roark parser as follows. A "dummy" word is created that can be assigned every POS-tag, and the parser extends from the current state to this dummy word. (The beam threshold is greatly

expanded to allow for many possible extensions.) Then every word in the vocabulary is substituted for the word, and the appropriate probabilities calculated over the beam. Finally, the actual next word is substituted, the beam threshold is reduced to the actual working threshold, and the requisite number of analyses are advanced to continue parsing the string. This represents a significant amount of additional work for the parser – particularly for vocabulary sizes that we currently use, on the order of tens of thousands of words.

As with surprisal, we can calculate an "unlexicalized" version of the measure by training and parsing just to POS-tags. We will refer to this sort of entropy as "POS entropy".

4 Empirical validation

4.1 Subjects and stimuli

In order to test the psycholinguistic relevance of the different measures produced by the parser, we conducted a word by word reading experiment. 23 native speakers of English read 4 short texts (mean length: 883.5 words, 49.25 sentences). The texts were the written versions of narratives used in a parallel fMRI experiment making use of the same parser derived measures and whose results will be published in a different paper (Bachrach et al., 2009). The narratives contained a high density of syntactically complex structures (in the form of sentential embeddings, relative clauses and other non-local dependencies) but were constructed so as to appear highly natural. The modified version of the Roark parser, trained on the Brown Corpus section of the Penn Treebank (Marcus et al., 1993), was used to parse the different narratives and produce the word by word measures.

4.2 Procedure

Each narrative was presented line by line (certain sentences required more than one line) on a computer screen (Dell Optiplex 755 running Windows XP Professional) using Linger 2.88[2]. Each line contained 11.5 words on average. Each word would appear in its relative position on the screen. The subject would then be required to push a keyboard button to advance to the next word. The original word would then disappear and the following word appear in the subsequent position on the screen. After certain sentences a comprehension question would appear on the screen (10 per narrative). This was done in order to encourage subjects to pay attention and to provide data for a post-hoc evaluation of comprehension. After each narrative, subjects were instructed to take a short break (2 minutes on average).

4.3 Data analysis

The log (base 10) of the reaction times were analyzed using a linear mixed effects regression analysis implemented in the language R (Bates et al., 2008). Reaction times longer than 1500 ms and shorter than 150 ms (raw) were excluded from the analysis (4.8% of total data). Since button press latencies inferior to 150 ms must have been planned prior to the presentation of the word, we considered that they could not reflect stimulus driven effects. Data from the first and last words on each line were discarded.

The combined data from the 4 narratives was first modeled using a model which included order of word in the narrative[3], word length, parser-derived lexical surprisal, unigram frequency, bigram probability, syntactic surprisal, lexical entropy, syntactic entropy and mean number of parser derivation steps as numeric regressors. We also included the unlexicalized POS variants of syntactic surprisal and entropy, along the lines of Demberg and Keller (2008), as detailed in § 3. Table 1 presents the correlations between these mean-centered measures.

In addition, we modeled word class (open/closed) as a categorical factor in order to assess interaction between class and the variables of interest, since such an interaction has been observed in the case of frequency (Bradley, 1983). Finally, the random effect part of the model included intercepts for subjects, words and sentences. We report significant effects at the threshold $p < .05$.

Given the presence of significant interactions between lexical class (open/closed) and a number of the variables of interests, we decided to split the data set into open and closed class words and model these separately (linear mixed effects with the same numeric variables as in the full model).

In order to evaluate the usefulness of splitting total surprisal into lexical and syntactic components we compared, using a likelihood ratio test, a model where lexical and syntactic surprisal are modeled as distinct regressors to a model where a single regressor equal to their sum (total surprisal)

[2] http://tedlab.mit.edu/∼dr/Linger/readme.html

[3] This is a regressor to control for the trend of subjects to read faster later in the narrative.

Table 1: Correlations between (mean-centered) predictors. Note that unigram frequencies were represented as logs, other scores as negative logs, hence the sign of the correlations.

was included. If the larger model provides a significantly better fit than the smaller model, this provides evidence that distinguishing between lexical and syntactic contributions to surprisal is relevant. Since total entropy is not a sum of syntactic and lexical entropy, an analogous test would not be valid in that case.

4.4 Results

All subjects successfully answered the comprehension questions (92.8% correct responses, S.D.=5.1). In the full model, we observed significant main effects of word class as well as of lexical surprisal, bigram probability, unigram frequency, syntactic entropy, POS entropy and of order in the narrative. Syntactic surprisal, lexical entropy and number of steps had no significant effect. Word length also had no significant main effect but interacted significantly with word class (open/closed). Word class also interacted significantly with lexical surprisal, unigram frequency and syntactic surprisal.

The presence of these interactions led us to construct models restricted to open and closed class items respectively. The estimated parameters are reported in Table 2. Reading time for open class words showed significant effects of unigram frequency, syntactic surprisal, syntactic entropy, POS entropy and order within the narrative. The positive effect of length approached significance. Reading time for closed class words exhibited significant effects of lexical surprisal, bigram probability, syntactic entropy and order in the narrative. Length had a non-significant negative effect, thus explaining the interaction observed in the full model.

The models with separate lexical and syntactic surprisal performed better than models including combined surprisal. For open class words, the Akaike's information criterion (AIC) was -54810 for the combined model and -54819 for the independent model (likelihood ratio test comparing the two, nested, models: $\chi^2(1)=10.7, p<.001$). For closed class items, combined model's AIC was -61467 and full model's AIC was -61469 (likelihood ratio test: $\chi^2(1)=3.54, p=0.06$).

4.5 Discussion

Our results demonstrate the relevance of modeling psycholinguistic processes using an incremental probabilistic parser, and the utility of the novel measures presented here. Of particular interest are: the significant effects of our syntactic entropy measure; the independent contributions of lexical surprisal, bigram probability and unigram frequency; and the differences between the predictions of the lexicalized parsing model and the unlexicalized (POS) parsing model.

The effect of entropy, or uncertainty regarding

the upcoming input independent of the surprise of that input, has been observed in non-linguistic tasks (Hyman, 1953; Bestmann et al., 2008) but to our knowledge has not been quantified before in the context of sentence processing. The usefulness of computational modeling is particularly evident in the case of entropy given the absence of any subjective procedure for its evaluation[4]. The results argue in favor of a predictive parsing architecture (Van Berkum et al., 2005). The approach to entropy here differs from the one described in Hale (2006) in a couple of ways. First, as discussed above, the calculation procedure is different – we focus on extending the derivations with just one word, rather than to all possible complete derivations. Second, and most importantly, Hale emphasizes entropy reduction (or the gain in information, given an input, regarding the rest of the sentence) as the correlate of cognitive cost while here we are interested in the amount of entropy itself (and not the size of change).

Interestingly, we observed only an effect of syntactic entropy, not lexical entropy. Recent ERP work has demonstrated that subjects do form specific lexical predictions in the context of sentence processing (Van Berkum et al., 2005; DeLong et al., 2005) and so we suspect that the absence of lexical entropy effect might be partly due to sparse data. Lexical surprisal and entropy were calculated using the internal state of a parser trained on the relatively small Brown corpus. Lexical entropy showed no significant effect while lexical surprisal affected only closed class words. This pattern of results might be due to the sparseness of the relevant information in such a small corpus (e.g., verb/object preferences) and the relevance of extra-textual dimensions (world knowledge, contextual information) to lexical-specific prediction. Closed class words are both more frequent (and hence better sampled) and are less sensitive to world knowledge, yet are often determined by the grammatical context.

Demberg and Keller (2008) made use of the same parsing architecture used here to compute a syntactic surprisal measure, but used an unlexicalized parser (down to POS-tags rather than words) for this score. Their "lexicalized" surprisal is equivalent to our total surprisal (lexical surprisal + syntactic surprisal), while their POS surprisal is derived from a completely different model. In contrast, our approach achieves lexical and syntactic measures from the same model. In order to evaluate the difference between the two approaches we added unlexicalized POS surprisal calculated along the lines of that paper to our model, along with an unlexicalized POS entropy from the same model. We found no effect of unlexicalized POS surprisal[5] and a significant (but relatively small) effect of unlexicalized POS entropy. While syntactic surprisal was correlated with POS surprisal (see Table 1) and syntactic entropy correlated with POS entropy, the fact that our syntactic measures still had a significant effect suggests that lexical information contributes towards the formation of syntactic expectations.

While the effect of surprisal calculated by an incremental top down parser has been already demonstrated (Demberg and Keller, 2008), our results argue for a distinction between the effect of lexical surprisal and that of syntactic surprisal without requiring unlexicalized parsing of the sort that Demberg and Keller advocate. It is important to keep in mind that this distinction between types of prediction (and as a consequence, prediction error) is not equivalent to the one drawn in the traditional cognitive science modularity debate, which has focused on the source of these predictions. We found a positive effect of syntactic surprisal in the case of open class words. The absence of an effect for closed class words remains to be explained.

We quantified word specific surprisal using 3 sources: the parser's internal state (lexical surprisal); probability given the preceding word (negative log bigram probability); and the unigram frequency of the word in a large corpus[6]. As can be observed in Table 1, these three measures are highly correlated[7]. This is the consequence of the smoothing in the estimation procedure but also relates to a more general fact about language use: overall, more frequent words are also words more expected to appear in a specific context (Anderson and Schooler, 1991). Despite these strong correlations, the three measures produced independent

[4]The Cloze procedure (Taylor, 1953) is one way to derive probabilities that could be used to calculate entropy, though this procedure is usually conducted with lexical elicitation, which would make syntactic entropy calculations difficult.

[5]We also ran the model including unlexicalized POS surprisal *without* our syntactic surprisal or syntactic entropy, and in this condition the unlexicalized POS surprisal measure had a nearly significant effect ($t = 1.85$), which is consistent with the results in Boston et al. (2008a) and Demberg and Keller (2008).

[6]The unigram frequencies came from the HAL corpus (Lund and Burgess, 1996). All other statistical models were estimated from the Brown Corpus.

[7]Unigram frequencies were represented as logs, the others as negative logs, hence the sign of the correlations.

effects. Unigram frequency had a significant effect for open class words while bigram probability and lexical surprisal each had an effect on reading time of closed class items. Bigram probability has been often found to affect reading time using eye movement measures. This is the first study to demonstrate an additional effect of contextual surprisal given the preceding sentential context (lexical surprisal). Demberg and Keller found no effect for surprisal once bigram and unigram probabilities were included in the model but, importantly, they did not distinguish lexical and syntactic surprisal, rather "lexicalized" and "unlexicalized" surprisal.

5 Summary

We have presented novel methods for teasing apart syntactic and lexical surprisal from a fully lexicalized parser, as well as for extending the operation of a predictive parser to capture novel entropy measures that are also shown to be relevant to psycholinguistic modeling. Such automatic methods provide psycholinguistically relevant measures that are intractable to calculate by hand. The empirical validation presented here demonstrated that the new measures – particularly syntactic entropy and syntactic surprisal – have high utility for modeling human reading time data. Our approach to calculating syntactic surprisal, based on fully lexicalized parsing, provided significant effects, while the POS-tag based (unlexicalized) surprisal – of the sort used in Boston et al. (2008a) and Demberg and Keller (2008) – did not provide a significant effect in our trials. Further, we showed an effect of lexical surprisal for closed class words even when combined with unigram and bigram probabilities in the same model. This work contributes to the important, developing enterprise of leveraging data-driven NLP approaches to derive new measures of high utility for psycholinguistic and neuropsychological studies.

Abstract

Automatically detecting human social intentions from spoken conversation is an important task for dialogue understanding. Since the social intentions of the speaker may differ from what is perceived by the hearer, systems that analyze human conversations need to be able to extract both the perceived and the intended social meaning. We investigate this difference between intention and perception by using a spoken corpus of speed-dates in which both the speaker and the listener rated the speaker on flirtatiousness. Our flirtation-detection system uses prosodic, dialogue, and lexical features to detect a speaker's intent to flirt with up to 71.5% accuracy, significantly outperforming the baseline, but also outperforming the human interlocuters. Our system addresses lexical feature sparsity given the small amount of training data by using an autoencoder network to map sparse lexical feature vectors into 30 compressed features. Our analysis shows that humans are very poor perceivers of intended flirtatiousness, instead often projecting their own intended behavior onto their interlocutors.

1 Introduction

Detecting human social meaning is a difficult task for automatic conversational understanding systems. One cause of this difficulty is the pervasive difference between intended social signals and the uptake by the perceiver. The cues that a speaker may use to attempt to signal a particular social meaning may not be the cues that the hearer focuses on, leading to misperception.

In order to understand the impact of this difference between perception and intention, in this paper we describe machine learning models that can detect both the social meaning intended by the speaker and the social meaning perceived by the hearer. Automated systems that detect and model these differences can lead both to richer socially aware systems for conversational understanding and more sophisticated analyses of conversational interactions like meetings and interviews.

This task thus extends the wide literature on social meaning and its detection, including the detection of emotions such as annoyance, anger, sadness, or boredom (Ang et al., 2002; Lee and Narayanan, 2002; Liscombe et al., 2003), speaker characteristics such as charisma (Rosenberg and Hirschberg, 2005), personality features like extroversion or agreeability (Mairesse et al., 2007; Mairesse and Walker, 2008), speaker depression or stress (Rude et al., 2004; Pennebaker and Lay, 2002; Cohn et al., 2004), and dating willingness or liking (Madan et al., 2005; Pentland, 2005).

We chose to work on the domain of *flirtation* in speed-dating. Our earlier work on this corpus showed that it is possible to detect whether speakers are perceived as flirtatious, awkward, or friendly with reasonable accuracy (Jurafsky et al., 2009). In this paper we extend that work to detect whether speakers themselves intended to flirt, explore the differences in these variables, and explore the ability and inability of humans to correctly perceive the flirtation cues.

While many of the features that we use to build these detectors are drawn from the previous literature, we also explore new features. Conventional methods for lexical feature extraction, for example, generally consist of hand coded classes of words related to concepts like *sex* or *eating* (Pennebaker et al., 2007). The classes tend to perform well in their specific domains, but may not be robust across domains, suggesting the need for unsupervised domain-specific lexical feature extraction. The naive answer to extracting domain-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 334–342,
Singapore, 6-7 August 2009.

specific lexical features would just be to throw counts for every word into a huge feature vector, but the curse of dimensionality rules this method out in small training set situations. We propose a new solution to this problem, using an unsupervised deep autoencoder to automatically compress and extract complex high level lexical features.

2 Dataset

Our experiments make use of the SpeedDate Corpus collected by the third author, and described in Jurafsky et al. (2009). The corpus is based on three speed-dating sessions run at an American university in 2005, inspired by prior speed-dating research (Madan et al., 2005). The graduate student participants volunteered to be in the study and were promised emails of persons with whom they reported mutual liking. All participants wore audio recorders on a shoulder sash, thus resulting in two audio recordings of the approximately 1100 4-minute dates. Each date was conducted in an open setting where there was substantial background noise. This noisy audio was thus hand-transcribed and turn start and end were hand-aligned with the audio. In addition to the audio, the corpus includes various attitude and demographic questions answered by the participants.

Each speaker was also asked to report how often their date's speech reflected different conversational styles (awkward, flirtatious, funny, assertive) on a scale of 1-10 (1=never, 10=constantly): "How often did the other person behave in the following ways on this 'date'?". In addition they were also asked to rate their own intentions: "How often did you behave in the following ways on this 'date'?" on a scale of 1-10.

In this study, we focus on the *flirtation* ratings, examining how often each participant said they were flirting, as well as how often each participant was judged by the interlocutor as flirting.

Of the original 1100 dates only 991 total dates are in the SpeedDate corpus due to various losses during recording or processing. The current study focuses on 946 of these, for which we have complete audio, transcript, and survey information.

3 Experiment

To understand how the perception of flirting differs from the intention of flirting, we trained binary classifiers to predict both perception and intention. In each date, the speaker and the interlocutor both labeled the speaker's behavioral traits on a Likert scale from 1-10. To generate binary responses we took the top ten percent of Likert ratings in each task and labeled those as positive examples. We similarly took the bottom ten percent of Likert ratings and labeled those as negative examples. We ran our binary classification experiments to predict this output variable. Our experiments were split by gender. For the female experiment the speaker was female and the interlocutor was male, while for the male experiment the speaker was male and the interlocutor was female.

For each speaker side of each 4-minute conversation, we extracted features from wavefiles and transcripts, as described in the next section. We then trained four separate binary classifiers (for each gender for both perception and intention).

4 Feature Descriptions

We used the features reported by Jurafsky et al. (2009), which are briefly summarized here. The features for a conversation side thus indicate whether a speaker who talks a lot, laughs, is more disfluent, has higher F0, etc., is more or less likely to consider themselves flirtatious, or be considered flirtatious by the interlocutor. We also computed the same features for the *alter* interlocutor. *Alter* features thus indicate the conversational behavior of the speaker talking with an interlocutor they considered to be flirtatious or not.

4.1 Prosodic Features

F0 and RMS amplitude features were extracted using Praat scripts (Boersma and Weenink, 2005). Since the start and end of each turn were time-marked by hand, each feature was easily extracted over a turn, and then averages and standard deviations were taken over the turns in an entire conversation side. Thus the feature F0 MIN for a conversation side was computed by taking the F0 min of each turn in that side (not counting zero values of F0), and then averaging these values over all turns in the side. F0 MIN SD is the standard deviation across turns of this same measure.

4.2 Dialogue and Disfluency Features

A number of discourse features were extracted, following Jurafsky et al. (2009) and the dialogue literature. The dialog acts shown in Table 2 were detected by hand-built regular expressions, based on analyses of the dialogue acts in the

F0 MIN	minimum (non-zero) F0 per turn, averaged over turns
F0 MIN SD	standard deviation from F0 min
F0 MAX	maximum F0 per turn, averaged over turns
F0 MAX SD	standard deviation from F0 max
F0 MEAN	mean F0 per turn, averaged over turns
F0 MEAN SD	standard deviation (across turns) from F0 mean
F0 SD	standard deviation (within a turn) from F0 mean, averaged over turns
F0 SD SD	standard deviation from the f0 sd
PITCH RANGE	f0 max - f0 min per turn, averaged over turns
PITCH RANGE SD	standard deviation from mean pitch range
RMS MIN	minimum amplitude per turn, averaged over turns
RMS MIN SD	standard deviation from RMS min
RMS MAX	maximum amplitude per turn, averaged over turns
RMS MAX SD	standard deviation from RMS max
RMS MEAN	mean amplitude per turn, averaged over turns
RMS MEAN SD	standard deviation from RMS mean
TURN DUR	duration of turn in seconds, averaged over turns
TIME	total time for a speaker for a conversation side, in seconds
RATE OF SPEECH	number of words in turn divided by duration of turn in seconds, averaged over turns

Table 1: Prosodic features from Jurafsky et al. (2009) for each conversation side, extracted using Praat from the hand-segmented turns of each side.

hand-labeled Switchboard corpus of dialog acts. *Collaborative completions*, turns where a speaker completes the utterance begun by the alter, were detected by finding sentences for which the first word of the speaker was extremely predictable from the last two words of the previous speaker, based on a trigram grammar trained on the Treebank 3 Switchboard transcripts. Laughter, disfluencies, and overlap were all marked in the transcripts by the transcribers.

4.3 Lexical Features

We drew our lexical features from the LIWC lexicons of Pennebaker et al. (2007), the standard for social psychological analysis of lexical features. We chose ten LIWC categories that have proven useful in detecting personality-related features (Mairesse et al., 2007): *Anger, Assent, Ingest, Insight, Negemotion, Sexual, Swear, I, We,* and *You*. We also added two new lexical features: "past tense auxiliary", a heuristic for automatically detecting narrative or story-telling behavior, and *Metadate*, for discussion about the speed-date itself. The features are summarized in Table 3.

4.4 Inducing New Lexical Features

In Jurafsky et al. (2009) we found the LIWC lexical features less useful in detecting social meaning than the dialogue and prosodic features, perhaps because lexical cues to flirtation lie in different classes of words than previously investigated. We therefore investigated the induction of lexical features from the speed-date corpus, using a probabilisitic graphical model.

We began with a pilot investigation to see whether lexical cues were likely to be useful; with a small corpus, it is possible that lexical features are simply too sparse to play a role given the limited data. The pilot was based on using Naive Bayes with word existence features (binomial Naive Bayes). Naive Bayes assumes all features are conditionally independent given the class, and is known to perform well with small amounts of data (Rish, 2001). Our Naive Bayes pilot system performed above chance, suggesting that lexical cues are indeed informative.

A simple approach to including lexical features in our more general classification system would be to include the word counts in a high dimensional feature vector with our other features. This method, unfortunately, would suffer from the well-known high dimensionality/small training set problem. We propose a method for building a much smaller number of features that would nonetheless capture lexical information. Our approach is based on using autoencoders to construct high level lower dimension features from the words in a nonlinear manner.

A deep autoencoder is a hierarchichal graphical model with multiple layers. Each layer consists of a number of units. The input layer has the same number of units as the output layer, where the output layer is the model's reconstruction of the input layer. The number of units in the intermediate layers tends to get progressively smaller to produce a compact representation.

We defined our autoencoder with visible units modeling the probabilities of the 1000 most common words in the conversation for the speaker and the probabilities of the 1000 most common words for the interlocutor (after first removing a stop list of the most common words). We train a deep autoencoder with stochastic nonlinear feature detectors and linear feature detectors in the final layer. As shown in Figure 1, we used a 2000-1000-500-250-30 autoencoder. Autoen-

BACKCHANNELS	number of backchannel utterances in side (*Uh-huh.*, *Yeah.*, *Right.*, *Oh, okay.*)
APPRECIATIONS	number of appreciations in side (*Wow*, *That's true*, *Oh, great*)
QUESTIONS	number of questions in side
NTRI	repair question (Next Turn Repair Indicator) (*Wait*, *Excuse me*)
COMPLETION	(an approximation to) utterances that were 'collaborative completions'
LAUGH	number of instances of laughter in side
TURNS	total number of turns in side
DISPREFERRED	(approximation to) dispreferred responses, beginning with discourse marker *well*
UH/UM	total number of filled pauses (*uh* or *um*) in conversation side
RESTART	total number of disfluent restarts in conversation side
OVERLAP	number of turns in side which the two speakers overlapped

Table 2: Dialog act and disfluency features from Jurafsky et al. (2009).

TOTAL WORDS	total number of words
PAST TENSE	uses of past tense auxiliaries *was, were, had*
METADATE	*horn, date, bell, survey, speed, form, questionnaire, rushed, study, research*
YOU	*you, you'd, you'll, your, you're, yours, you've* (not counting *you know*)
WE	*lets, let's, our, ours, ourselves, us, we, we'd, we'll, we're, we've*
I	*I'd, I'll, I'm, I've, me, mine, my, myself* (not counting *I mean*)
ASSENT	*yeah, okay, cool, yes, awesome, absolutely, agree*
SWEAR	*hell, sucks, damn, crap, shit, screw, heck, fuck**

INGEST	*food, eat*, water, bar/bars, drink*, cook*, dinner, coffee, wine, beer, restaurant, lunch, dish*

Table 3: Lexical features from Jurafsky et al. (2009). Each feature value is a total count of the words in that class for each conversation side; asterisks indicate including suffixed forms (e.g., *love, loves, loving*). All except the first three are from LIWC (Pennebaker et al., 2007) (modified slightly, e.g., by removing *you know* and *I mean*). The last five classes include more words in addition to those shown.

coders tend to perform poorly if they are initialized incorrectly, so we use the Restricted Boltzmann Machine (RBM) pretraining procedure described in Hinton and Salakhutdinov (2006) to initialize the encoder. Each individual RBM is trained using contrastive divergence as an update rule which has been shown to produce reasonable results quickly (Hinton et al., 2006). Finally, we use backpropagation to fine tune the weights of our encoder by minimizing the cross entropy error. To extract features from each conversation, we sample the code layer (30 unit layer in our encoder) with the visible units corresponding to the most common word probabilities from that document, creating 30 new features that we can use for classification. The conditional distributions of the first layer features can be given by the softmax of the activations for each gender:

$$p(v_i|h) = \frac{\exp(bias_i + \sum_j h_j * w_{ij})}{\sum_{k \in K} \exp(bias_k + \sum_j v_j * w_{kj})} \quad (1)$$

$$p(h_j|v) = \frac{1}{1 + \exp(bias_(j) + \sum_i v_i * w_{ij})} \quad (2)$$

where K is the set of all the units representing the same speaker as i [1], v_i is the ith visible unit, h_j is the jth hidden unit, w_{ij} is the weight between visible unit i and hidden unit j, and bias$_m$ is the offset of unit m. Intuitively, this means that the probability that a hidden unit is activated by the visible layer is sigmoid of the weighted sum of all the visible units plus the unit's bias term. Similarly, the visible units are activated through a weighted sum of the hidden units, but they undergo an additional normalization (softmax) over all the other visible units from the speaker to effectively model the multinomial distribution from each speaker. Since in a RBM hidden units are conditionally independent given the visible units, and visible units are

[1]The visible unit i models word probabilities of either the speaker or the interlocutor, so the softmax is done over the distribution of words for the speaker that unit i is modeling.

conditionally independent given hidden layer, the above equations completely specify the first layer of the model.

To account for the fact that each visible unit in the first layer contained 1000 observations from the underlying distribution we upweighted our features by that factor. During pretraining the "training data" for the higher layers is the activation probabilities of the hidden units of layer directly below when driven by that layer's input data. The intermediate layers in the model are symmetric where the activation probabilities for both the visible and hidden units are of the same form as $p(h_j|v)$ in layer 1. To produce real valued features in the code layer we used linear hidden units. In addition to the likelihood portion of the objective we penalized large weights by using l2 regularization and penalize all weights by applying a small constant weight cost that gets applied at every update. After training to find a good initial point for the autoencoder we unroll the weights and use backpropogation to fine tune our autoencoder.

While interpreting high level nonlinear features can be challenging, we did a pilot analysis of one of the 30 features fixing a large (positive or negative) weight on the feature unit (code layer) and sampling the output units.

The top weighted words for a positive weight are: *O_did, O_live, S_did, S_friends, S_went, O_live, S_lot, S_wait, O_two*, and *O_wasn't* (S for speaker and O for interlocutor). The top weighted words for a negative weight are: *S_long, O_school, S_school, S_phd, O_years, S_years, O_stanford, S_lot, O_research, O_interesting* and *O_education*. At least for this one feature, a large positive value seemed to indicate the prevalence of questions (*wait, did*) or storytelling (
em live, wasn't). A large negative weight indicates the conversation focused on the mundane details of grad student life.

5 Classification

Before performing the classification task, we preprocessed the data in two ways. First, we standardized all the variables to have zero mean and unit variance. We did this to avoid imposing a prior on any of the features based on their numerical values. Consider a feature A with mean 100 and a feature B with mean .1 where A and B are correlated with the output. Since the SVM problem minimizes the norm of the weight vector, there

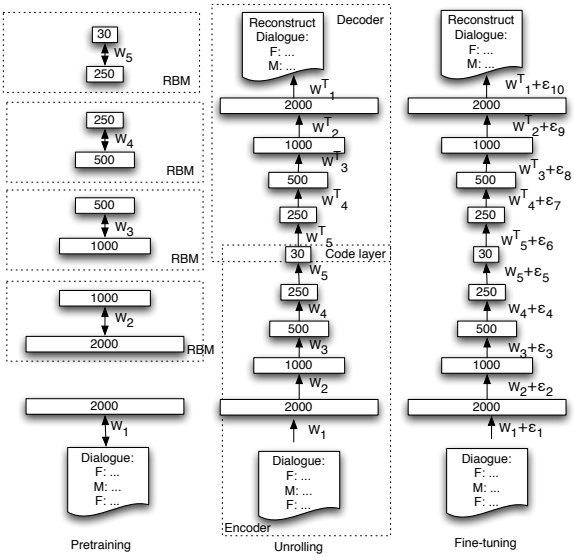

Figure 1: Pretraining is a fully unsupervised procedure that trains an RBM at each layer. Once the pretraining of one layer is complete, the top layer units are used as input to the next layer. We then fine-tune our weights using backprop. The 30 features are extracted from the code layer.

is a bias to put weight on feature A because intuitively the weight on feature B would need to be 1000 times larger to carry the same effect. This argument holds similarly for the reduction to unit variance. Second, we removed features correlated greater than .7. One goal of removing correlated features was to remove as much colinearity as possible from the regression so that the regression weights could be ranked for their importance in the classification. In addition, we hoped to improve classification because a large number of features require more training examples (Ng, 2004). For example for perception of female flirt we removed the number of turns by the alter (*O_turns*) and the number of sentence from the ego (*S_sentences*) because they were highly correlated with *S_turns*.

To ensure comparisons (see Section 7) between the interlocutors' ratings and our classifier (and because of our small dataset) we use k-fold cross validation to learn our model and evaluate our model. We train our binary model with the top ten percent of ratings labeled as positive class examples and bottom ten percent of ratings as the negative class examples. We used five-fold cross validation in which the data is split into five equal folds of size 40. We used four of the folds for training and one for test. K-fold cross validation does this in a round robin manner so every exam-

ple ends up in the test set. This yields a datasplit of 160 training examples and 40 test examples. To ensure that we were not learning something specific to our data split, we randomized our data ordering.

For classification we used a support vector machine (SVM). SVMs generally do not produce explicit feature weights for analysis because they are a kernelized classifier. We solved the linear C-SVM problem. Normally the problem is solved in the dual form, but to facilitate feature analysis we expand back to the primal form to retrieve w, the weight vector. Our goal in the C-SVM is to solve, in primal form,

$$\min_{\gamma,w,b} \frac{1}{2}||w||^2 + C\sum_{i=1}^{m}\xi_i$$
$$\text{s.t. } y^{(i)}(w^T x^{(i)} + b) \geq 1 - \xi_i,\ i = 1,\ldots,m$$
$$\xi_i \geq 0,\ i = 1,\ldots,m \quad (3)$$

where m is the number of training examples, $x^{(i)}$ is the ith training examples, and $y^{(i)}$ is the ith class (1 for the positive class, -1 for the negative class). The ξ_i are the slack variables that allow this algorithm to work for non linearly separable datasets.

A test example is classified by looking at the sign of $y(x) = w^T x^{(test)} + b$. To explore models that captured interactions, but do not allow for direct feature analysis we solved the C-SVM problem using a radial basis function (RBF) as a kernel (Scholkopf et al., 1997). Our RBF kernel is based on a Gaussian with unit variance.

$$K(x^{(i)}, x^{(j)}) = \exp(\frac{-||x^{(i)} - x^{(j)}||^2}{2\sigma}) \quad (4)$$

In this case predictions can be made by looking at $y(x^{(test)}) = \sum_{i=1}^{m} \alpha^{(i)} y^{(i)} \text{rbf}(x^{(i)}, t^{(test)}) + b$, where each $\alpha^{(i)}$, for $i = 1,\ldots,m$ is a member of the set of dual variables that comes from transforming the primal form into the dual form. The SVM kernel trick allows us to explore higher dimensions while limiting the curse of dimensionality that plagues small datasets like ours.

We evaluated both our linear C-SVM and our radial basis function C-SVM using parameters learned on the training sets by computing the accuracy on the test set. Accuracy is the number of correct examples / total number of test examples. We found that the RBM classifier that handled interaction terms outperformed linear methods like logistic regression.

For feature weight extraction we aggregated the feature weights calculated from each of the test folds by taking the mean between them.[2]

6 Results

We report in Table 4 the results for detecting flirt intention (whether a speaker said they were flirting) as well as flirt perception (whether the listener said the speaker was flirting).

	Flirt Intention		Flirt Perception	
	by M	by F	of M	of F
RBM SVM	61.5%	70.0%	77.0%	59.5%
+autoencoder features	69.0%	71.5%	79.5%	68.0%

Table 4: Accuracy of binary classification of each conversation side, where chance is 50%. The first row uses all the Jurafsky et al. (2009) features for both the speaker and interlocutor. The second row adds the new autoencoder features.

In our earlier study of flirt perception, we achieved 71% accuracy for men and 60% for women (Jurafsky et al., 2009). Our current numbers for flirt perception are much better for both men (79.5%), and women (68.0%). The improvement is due both to the new autoencoder features and the RBF kernel that considers feature interactions (feature interactions were not included in the logistic regression classifiers of Jurafsky et al. (2009)).

Our number for flirt intention are 69.0% for men and 71.5% for women. Note that our accuracies are better for detecting women's intentions as well as women's perceptions (of men) than men's intentions and perceptions.

7 Feature Analysis

We first considered the features that helped classification of flirt intention. Table 5 shows feature weights for the features (features were normed so weights are comparable), and is summarized in the following paragraphs:

• Men who say they are flirting ask more questions, and use more *you* and *we*. They laugh more, and use more sexual, anger, and negative emotional words. Prosodically they speak faster, with higher pitch, but quieter (lower intensity min).

[2]We could not use the zero median criteria used in Jurafsky et al. (2009) because C-SVMs under the l-2 metric provide no sparse weight guarantees.

Table 5: Feature weights (mean weights of the randomized runs) for the predictors with $|weight| > 0.01$ for the male and female classifiers. An S prefix indicates features of the speaker (the candidate flirter) while an O prefix indicates features of the other. Weights for autoencoder features were also significant but are omitted for compactness.

Features of the alter (the woman) that helped our system detect men who say they are flirting include the woman's laughing, sexual words or swear words, talking more, and having a higher f0 (max).

• Women who say they are flirting have a much expanded pitch range (lower pitch min, higher pitch max), laugh more, use more *I* and *well*, use repair questions but not other kinds of questions, use more sexual terms, use far less appreciations and backchannels, and use fewer, longer turns, with more words in general. Features of the alter (the man) that helped our system detect women who say they are flirting include the male use of *you*, questions, and faster and quieter speech.

We also summarize here the features for the perception classification task; predicting which people will be labeled by their dates as flirting. Here the task is the same as for Jurafsky et al. (2009) and the values are similar.

• Men who are labeled by their female date as flirting present many of the same linguistic behaviors as when they express their intention to flirt. Some of the largest differences are that men are perceived to flirt when they use less appreciations and overlap less, while these features were not significant for men who said they were flirting. We also found that fast speech and more questions are more important features for flirtation perception than intention.

• Women who are labeled by their male date as flirting also present much of the same linguistic behavior as women who intend to flirt. Laughter, repair questions, and taking fewer, longer turns were not predictors of women labeled as flirting, although these were strong predictors of women intending to flirt.

Both genders convey intended flirtation by laughing more, speaking faster, and using higher pitch. However, we do find gender differences; men ask more questions when they say they are flirting, women ask fewer, although they do use more repair questions, which men do not. Women use more "I" and less "we"; men use more "we" and "you". Men labeled as flirting are softer, but women labeled as flirting are not. Women flirting use much fewer appreciations; appreciations were not a significant factor in men flirting.

8 Human Performance on this task

To evaluate the performance of our classifiers we compare against human labeled data.

We used the same test set as for our machine classifier; recall that this was created by taking the top ten percent of Likert ratings of the speaker's intention ratings by gender and called those positive for flirtation intention. We constructed negative examples by taking the bottom ten percent of intention Likert ratings. We called the interlocutor correct on the positive examples if the interlocutor's rating was greater than 5. Symmetrically for the negative examples, we said the interlocutor was correct if their rating was less than or equal to 5. Note that this metric is biased somewhat toward the humans and against our systems, because we do not penalize for intermediate values, while the system is trained to make binary predictions only on extremes. The results of the human perceivers on classifying flirtation intent are shown in Table 6.

Male speaker (Female perceiver)	Female speaker (Male perceiver)
62.2%	56.2%

Table 6: Accuracy of human listeners at labeling speakers as flirting or not.

We were quite surprised by the poor quality of the human results. Our system outperforms both men's performance in detecting women flirters (system 71.5% versus human 56.2%) and also women's performance in detecting male flirters (system 69.0% versus human 62.2%).

Why are humans worse than machines at detecting flirtation? We found a key insight by examining how the participants in a date label themselves and each other. Table 7 shows the 1-10 Likert values for the two participants in one of the dates, between Male 101 and Female 127. The two participants clearly had very different perspectives on the date. More important, however, we see that each participant labels their own flirting (almost) identically with their partner's flirting.

	I am flirting	Other is flirting
Male 101 says:	8	7
Female 127 says:	1	1

Table 7: Likert scores for the date between Female 127 and Male 101.

We therefore asked whether speakers in general tend to assign similar values to their own flirting and their partner's flirting. The Pearson correlation coefficient between these two variables (my perception of my own flirting, and my perception of other's flirting) is .73. By contrast, the poor performance of subjects at detecting flirting in their partners is coherent with the lower (.15) correlation coefficient between those two variables (my perception of the other's flirting, and the other's perception of their own flirting). This discrepancy is summarized in boldface in Table 8.

Since the speed-date data was also labeled for three other variables, we then asked the same question about these variables. As Table 8 shows, for all four styles, speakers' perception of others is strongly correlated with the speakers' perception of themselves, far more so than with what the others actually think they are doing.[3]

[3]This was true no matter how the correlations were run, whether with raw Likert values, with ego-centered (transformed) values and with self ego-centered but other raw.

Variable	Self-perceive-Other & Self-perceive-Self	Self-perceive-Other & Other-perceive-Other
Flirting	**.73**	**.15**
Friendly	.77	.05
Awkward	.58	.07
Assertive	.58	.09

Table 8: Correlations between speaker intentions and perception for all four styles.

Note that although perception of the other does not correlate highly with the other's intent for any of the styles, the correlations are somewhat better (.15) for flirting, perhaps because in the speed-date setting speakers are focusing more on detecting this behavior (Higgins and Bargh, 1987). It is also possible that for styles with positive valence (friendliness and flirting) speakers see more similarity between the self and the other than for negative styles (awkward and assertive) (Krahé, 1983).

Why should this strong bias exist to link self-flirting with perception of the other? One possibility is that speakers are just not very good at capturing the intentions of others in four minutes. Speakers instead base their judgments on their own behavior or intentions, perhaps because of a bias to maintain consistency in attitudes and relations (Festinger, 1957; Taylor, 1970) or to assume there is reciprocation in interpersonal perceptions (Kenny, 1998).

9 Conclusion

We have presented a new system that is able to predict flirtation intention better than humans can, despite humans having access to vastly richer information (visual features, gesture, etc.). This system facilitates the analysis of human perception and human interaction and provides a framework for understanding why humans perform so poorly on intention prediction.

At the heart of our system is a core set of prosodic, dialogue, and lexical features that allow for accurate prediction of both flirtation intention and flirtation perception. Since previous word lists don't capture sufficient lexical information, we used an autoencoder to automatically capture new lexical cues. The autoencoder shows potential for being a promising feature extraction method for social tasks where cues are domain specific.

Abstract

We present an implicit discourse relation classifier in the Penn Discourse Treebank (PDTB). Our classifier considers the context of the two arguments, word pair information, as well as the arguments' internal constituent and dependency parses. Our results on the PDTB yields a significant 14.1% improvement over the baseline. In our error analysis, we discuss four challenges in recognizing implicit relations in the PDTB.

1 Introduction

In the field of discourse modeling, it is widely agreed that text is not understood in isolation, but in relation to its context. One focus in the study of discourse is to identify and label the relations between textual units (clauses, sentences, or paragraphs). Such research can enable downstream natural language processing (NLP) such as summarization, question answering, and textual entailment. For example, recognizing causal relations can assist in answering *why* questions. Detecting contrast and restatements is useful for paraphrasing and summarization systems. While different discourse frameworks have been proposed from different perspectives (Mann and Thompson, 1988; Hobbs, 1990; Lascarides and Asher, 1993; Knott and Sanders, 1998; Webber, 2004), most admit these basic types of discourse relationships between textual units.

When there is a discourse connective (e.g., *because*) between two text spans, it is often easy to recognize the relation between the spans, as most connectives are unambiguous (Miltsakaki et al., 2005; Pitler et al., 2008). On the other hand, it is difficult to recognize the discourse relations when there are no explicit textual cues. We term these cases explicit and implicit relations, respectively. While the recognition of discourse structure has been studied in the context of explicit relations (Marcu, 1998) in the past, little published work has yet attempted to recognize implicit discourse relations between text spans.

Detecting implicit relations is a critical step in forming a discourse understanding of text, as many text spans do not mark their discourse relations with explicit cues. Recently, the Penn Discourse Treebank (PDTB) has been released, which features discourse level annotation on both explicit and implicit relations. It provides a valuable linguistic resource towards understanding discourse relations and a common platform for researchers to develop discourse-centric systems. With the recent release of the second version of this corpus (Prasad et al., 2008), which provides a cleaner and more thorough implicit relation annotation, there is an opportunity to address this area of work.

In this paper, we provide classification of implicit discourse relations on the second version of the PDTB. The features we used include contextual modeling of relation dependencies, features extracted from constituent parse trees and dependency parse trees, and word pair features. We show an accuracy of 40.2%, which is a significant improvement of 14.1% over the majority baseline.

After reviewing related work, we first give an overview of the Penn Discourse Treebank. We then describe our classification methodology, followed by experimental results. We give a detailed discussion on the difficulties of implicit relation classification in the PDTB, and then conclude the paper.

2 Related Work

One of the first works that use statistical methods to detect implicit discourse relations is that of Marcu and Echihabi (2002). They showed that word pairs extracted from two text spans provide clues for detecting the discourse relation between

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 343–351,
Singapore, 6-7 August 2009.

the text spans. They used a set of textual patterns to automatically construct a large corpus of text span pairs from the web. These text spans were assumed to be instances of specific discourse relations. They removed the discourse connectives from the pairs to form an implicit relation corpus. From this corpus, they collected word pair statistics, which were used in a Naïve Bayes framework to classify discourse relations.

Saito et al. (2006) extended this theme, to show that phrasal patterns extracted from a text span pair provide useful evidence in the relation classification. For example, the pattern "... should have done ..." usually signals a contrast. The authors combined word pairs with phrasal patterns, and conducted experiments with these two feature classes to recognize implicit relations between adjacent sentences in a Japanese corpus.

Both of these previous works have the shortcoming of downgrading explicit relations to implicit ones by removing the explicit discourse connectives. While this is a good approach to automatically create large corpora, natively implicit relations may be signaled in different ways. The fact that explicit relations are explicitly signaled indicates that such relations need a cue to be unambiguous to human readers. Thus, such an artificial implicit relation corpus may exhibit marked differences from a natively implicit one. We validate this claim later in this work.

Wellner et al. (2006) used multiple knowledge sources to produce syntactic and lexico-semantic features, which were then used to automatically identify and classify explicit and implicit discourse relations in the Discourse Graphbank (Wolf and Gibson, 2005). Their experiments show that discourse connectives and the distance between the two text spans have the most impact, and event-based features also contribute to the performance. However, their system may not work well for implicit relations alone, as the two most prominent features only apply to explicit relations: implicit relations do not have discourse connectives and the two text spans of an implicit relation are usually adjacent to each other.

The work that is most related to ours is the forthcoming paper of Pitler et al. (2009) on implicit relation classification on the second version of the PDTB. They performed classification of implicit discourse relations using several linguistically informed features, such as word polarity, verb classes, and word pairs, showing performance increases over a random classification baseline.

3 Overview of the Penn Discourse Treebank

The Penn Discourse Treebank (PDTB) is a discourse level annotation (Prasad et al., 2008) over the one million word *Wall Street Journal* corpus. The PDTB adopts the predicate-argument view of discourse relations, where a discourse connective (e.g., *because*) is treated as a predicate that takes two text spans as its arguments. The argument that the discourse connective structurally attaches to is called Arg2, and the other argument is called Arg1. The PDTB provides annotations for explicit and implicit discourse relations. By definition, an explicit relation contains an explicit discourse connective. In the PDTB, 100 explicit connectives are annotated. Example 1 shows an explicit Contrast relation signaled by the discourse connective *but*. The last line shows the relation type and the file in the PDTB from which the example is drawn.

(1) **Arg1:** In any case, the brokerage firms are clearly moving faster to create new ads than they did in the fall of 1987.
Arg2: But it remains to be seen whether their ads will be any more effective.
(Contrast - wsj_2201)

In the PDTB, implicit relations are constrained by *adjacency*: only pairs of adjacent sentences within paragraphs are examined for the existence of implicit relations. When an implicit relation was inferred by an annotator, he/she inserted an implicit connective that best reflects the relation. Example 2 shows an implicit relation, where the annotator inferred a Cause relation and inserted an implicit connective *so* (i.e., the original text does not include *so*). The text in the box (*he says*) shows the attribution, i.e., the agent that expresses the arguments. The PDTB provides annotation for the attributions and supplements of the arguments.

(2) **Arg1:** "A lot of investor confidence comes from the fact that they can speak to us," he says .
Arg2: [**so**] "To maintain that dialogue is absolutely crucial."
(Cause - wsj_2201)

The PDTB provides a three level hierarchy of relation tags for its annotation. The first level consists of four major relation *classes*: Temporal, Contingency, Comparison, and Expansion. For each class, a second level of *types* is defined to provide finer semantic distinctions. A third level of *subtypes* is defined for only some types to specify the semantic contribution of each argument. Relation classes and types in the PDTB are reproduced in the first two columns of Table 1.

We focus on implicit relation classification of the Level 2 types in the PDTB, as we feel that Level 1 classes are too general and coarse-grained for downstream applications, while Level 3 subtypes are too fine-grained and are only provided for some types. Table 1 shows the distribution of the 16 Level 2 relation types of the implicit relations from the training sections, i.e., Sections 2 – 21. As there are too few training instances for Condition, Pragmatic Condition, Pragmatic Contrast, Pragmatic Concession, and Exception, we removed these five types from further consideration. We thus use the remaining 11 Level 2 types in our work. The initial distribution and adjusted distribution are shown in the last two columns of the table. We see that the three predominant types are Cause (25.63%), Conjunction (22.25%), and Restatement (19.23%).

Level 1 Class	Level 2 Type	Training instances	%	Adjusted %
Temporal	Asynchronous	583	4.36	4.36
	Synchrony	213	1.59	1.59
Contingency	Cause	3426	25.61	25.63
	Pragmatic Cause	69	0.52	0.52
	Condition	1	0.01	–
	Pragmatic Condition	1	0.01	–
Comparison	Contrast	1656	12.38	12.39
	Pragmatic Contrast	4	0.03	–
	Concession	196	1.47	1.47
	Pragmatic Concession	1	0.01	–
Expansion	Conjunction	2974	22.24	22.25
	Instantiation	1176	8.79	8.80
	Restatement	2570	19.21	19.23
	Alternative	158	1.18	1.18
	Exception	2	0.01	–
	List	345	2.58	2.58
Total		13375		
Adjusted total		13366		

Table 1: Distribution of Level 2 relation types of implicit relations from the training sections (Sec. 2 – 21). The last two columns show the initial distribution and the distribution after removing the five types that have only a few training instances.

4 Methodology

Our implicit relation classifier is built using supervised learning on a maximum entropy classifier. As such, our approach processes the annotated argument pairs into binary feature vectors suitable for use in training a classifier. Attributions and supplements are ignored from the relations, as our system does not make use of them. We chose the following four classes of features as they represent a wide range of information – contextual, syntactic, and lexical – that have been shown to be helpful in previous works and tasks. We now discuss the four categories of features used in our framework.

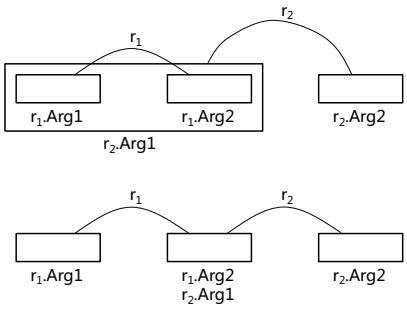

Figure 1: Two types of discourse dependency structures. Top: fully embedded argument, bottom: shared argument.

Contextual Features. Lee et al. (2006) showed that there are a variety of possible dependencies between pairs of discourse relations: independent, fully embedded argument, shared argument, properly contained argument, pure crossing, and partially overlapping argument. They argued that the last three cases – properly contained argument, pure crossing, and partially overlapping argument – can be factored out by appealing to discourse notions such as anaphora and attribution. Moreover, we also observed from the PDTB corpus that fully embedded argument and shared argument are the most common patterns, which are shown in Figure 1. The top portion of Figure 1 shows a case where relation r_1 is fully embedded in Arg1 of relation r_2, and the bottom portion shows r_1 and r_2 sharing an argument. We model these two patterns as contextual features. We believe that these discourse dependency patterns between a pair of adjacent relations are useful in identifying the relations. For example, if we have three items in a list, according to the PDTB binary predicate-argument definitions, there will be a List relation between

the first item and the second item, and another List relation between the previous List relation and the third item, where the previous List relation is fully embedded in Arg1 of the current List relation. As we are using the gold standard argument segmentation from the PDTB, we can extract and leverage these dependency patterns. For each relation *curr*, we use the previous relation *prev* and the next relation *next* as evidence to fire six binary features, as defined in Table 2.

Note that while *curr* is an implicit relation to be classified, both *prev* and *next* can be implicit or explicit relations. Pitler et al. (2008) showed that the type of a relation sometimes correlates to the type of its adjacent relation. When the adjacent relation is explicit, its type may be suggested by its discourse connective. Thus we include another two groups of contextual features representing the connectives of *prev* and *next* when they are explicit relations.

Fully embedded argument:
prev embedded in curr.Arg1
next embedded in curr.Arg2
curr embedded in prev.Arg2
curr embedded in next.Arg1
Shared argument:
prev.Arg2 = curr.Arg1
curr.Arg2 = next.Arg1

Table 2: Six contextual features derived from two discourse dependency patterns. *curr* is the relation we want to classify.

Constituent Parse Features. Research work from other NLP areas, such as semantic role labeling, has shown that features derived from syntactic trees are useful in semantic understanding. Such features include syntactic paths (Jiang and Ng, 2006) and tree fragments (Moschitti, 2004). From our observation of the PDTB relations, syntactic structure within one argument may constrain the relation type and the syntactic structure of the other argument. For example, the constituent parse structure in Figure 2(a) usually signals an Asynchronous relation when it appears in Arg2, as shown in Example 3, while the structure in Figure 2(b) usually acts as a clue for a Cause relation when it appears in Arg1, as shown in Example 4. In both examples, the lexicalized parts of the parse structure are bolded.

(3) **Arg1:** But the RTC also requires "working" capital to maintain the bad assets of thrifts that are sold
Arg2: [**subsequently**] That debt would be paid off **as** the assets are sold
(Asynchronous - wsj_2200)

(4) **Arg1:** It would **have been** too late to think about on Friday.
Arg2: [**so**] We had to think about it ahead of time.
(Cause - wsj_2201)

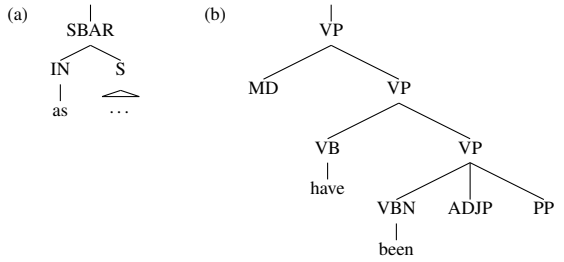

Figure 2: (a) constituent parse in Arg2 of Example 3, (b) constituent parse in Arg1 of Example 4.

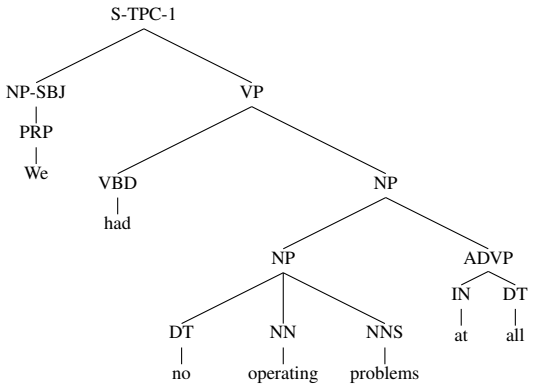

Figure 3: A gold standard subtree for Arg1 of an implicit discourse relation from wsj_2224.

For Arg1 and Arg2 of each relation, we extract the corresponding gold standard syntactic parse trees from the corpus. As an argument can be a single sentence, a clause, or multiple sentences, this results in a whole parse tree, parts of a parse tree, or multiple parse trees. From these parses, we extract all possible production rules. Although the structures shown in Figure 2 are tree fragments, tree fragments are not extracted as production rules act as generalization of tree fragments. As an example, Figure 3 shows the parse tree for Arg1 of an implicit discourse relation from the text wsj_2224. As Arg1 is a clause, the extracted tree

is a subtree. We then collect all production rules from this subtree, with function tags (e.g., SBJ) removed from internal nodes. POS tag to word production rules are collected as well. The resulting production rules include ones such as: S → NP VP, NP → PRP, PRP → "We", etc. Each production rule is represented as three binary features to check whether this rule appears in Arg1, Arg2, and both arguments.

Dependency Parse Features. We also experimented with features extracted from dependency trees of the arguments. We used the Stanford dependency parser (de Marneffe et al., 2006), which takes in a constituent parse tree and produces a dependency tree. Again, for an argument, we may collect a whole dependency tree, parts of a tree, or multiple trees, depending on the span of the argument. The reason for using dependency trees is that they encode additional information at the word level that is not explicitly present in the constituent trees. From each tree, we collect all words with the dependency types from their dependents. Figure 4 shows the dependency subtree for the same example in Figure 3, from which we collect three dependency rules: "had" ← nsubj dobj, "problems" ← det nn advmod, "at" ← dep.

Note that unlike the constituent parse features which are guaranteed to be accurate (as they are extracted from the gold parses of the corpus), the dependency parses occasionally contain errors. As with the constituent parse features, each dependency rule is represented as three binary features to check whether it appears in Arg1, Arg2, and both arguments.

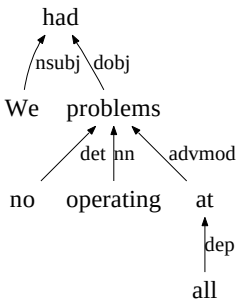

Figure 4: A dependency subtree for Arg1 of an implicit discourse relation from wsj_2224.

Lexical Features. Marcu and Echihabi (2002) demonstrated that word pairs extracted from the respective text spans are a good signal of the discourse relation between arguments. Thus we also consider word pairs as a feature class. We stemmed and collected all word pairs from Arg1 and Arg2, i.e., all (w_i, w_j) where w_i is a word from Arg1 and w_j a word from Arg2. Unlike their study, we limit the collection of word pair statistics to occurrences only in the PDTB corpus.

4.1 Feature Selection

For the collection of production rules, dependency rules, and word pairs, we used a frequency cutoff of 5 to remove infrequent features. From the implicit relation dataset of the training sections (i.e., Sec. 2 – 21), we extracted 11,113 production rules, 5,031 dependency rules, and 105,783 word pairs in total. We applied mutual information (MI) to these three classes of features separately, resulting in three ranked lists. A feature f has 11 MI values with all 11 types (for example, $MI(f, Cause)$ and $MI(f, Restatement)$), and we used the MI with the highest value for a feature to select features. In our experiments, the top features from the lists are used in the training and test phases.

5 Experiments

We experimented with a maximum entropy classifier from the OpenNLP MaxEnt package using various combinations of features to assess their efficacy. We used PDTB Sections 2 – 21 as our training set and Section 23 as the test set, and only used the implicit discourse relations.

In the PDTB, about 2.2% of the implicit relations are annotated with two types, as shown in Example 7 in Section 6. During training, a relation that is annotated with two types is considered as two training instances, each with one of the types. During testing, such a relation is considered one test instance, and if the classifier assigns either of the two types, we consider it as correct. Thus, the test accuracy is calculated as the number of correctly classified test instances divided by the total number of test instances.

In our work, we use the majority class as the baseline, where all instances are classified as Cause. This yields an accuracy of 26.1% on the test set. A random baseline yields an even lower accuracy of 9.1% on the test set.

5.1 Results and Analysis

To check the efficacy of the different feature classes, we trained individual classifiers on all features within a single feature class (Rows 1 to 4 in Table 3) as well as a single classifier trained

with all features from all feature classes (Row 5). Among the four individual feature classes, production rules and word pairs yield significantly better performance over the baseline with $p < 0.01$ and $p < 0.05$ respectively, while context features perform slightly better than the baseline.

	# Production rules	# Dependency rules	# Word pairs	Context	Acc.
R1	11,113	–	–	No	36.7%
R2	–	5,031	–	No	26.0%
R3	–	–	105,783	No	30.3%
R4	–	–	–	Yes	28.5%
R5	11,113	5,031	105,783	Yes	35.0%

Table 3: Classification accuracy with all features from each feature class. Rows 1 to 4: individual feature class; Row 5: all feature classes.

Interestingly, we noted that the performance with all dependency rules is slightly lower than the baseline (Row 2), and applying all feature classes does not yield the highest accuracy (Row 5), which we suspected were due to noise. To confirm this, we employed MI to select the top 100 production rules and dependency rules, and the top 500 word pairs (as word pairs are more sparse). We then repeated the same set of experiments, as shown in Table 4 (Row 4 of this table is repeated from Table 3 for consistency). With only the top features, production rules, dependency rules, and word pairs all gave significant improvement over the baseline with $p < 0.01$. When we used all feature classes, as in the last row, we obtained the highest accuracy of 40.2%.

	# Production rules	# Dependency rules	# Word pairs	Context	Acc.
R1	100	–	–	No	38.4%
R2	–	100	–	No	32.4%
R3	–	–	500	No	32.9%
R4	–	–	–	Yes	28.5%
R5	100	100	500	Yes	40.2%

Table 4: Classification accuracy with top rules/word pairs for each feature class. Rows 1 to 4: individual feature class; Row 5: all feature classes.

Table 4 also validates the pattern of predictiveness of the feature classes: production rules contribute the most to the performance individually, followed by word pairs, dependency rules, and finally, context features. A natural question to ask is whether any of these feature classes can be omitted to achieve the same level of performance as the combined classifier. To answer this question, we conducted a final set of experiments, in which we gradually added in feature classes in the order of their predictiveness (i.e., production rules $\succ$ word pairs $\succ$ dependency rules $\succ$ context features), with results shown in Table 5. These results confirm that each additional feature class indeed contributes a marginal performance improvement, (although it is not significant) and that all feature classes are needed for optimal performance.

	# Production rules	# Dependency rules	# Word pairs	Context	Acc.
R1	100	–	–	No	38.4%
R2	100	–	500	No	38.9%
R3	100	100	500	No	39.0%
R4	100	100	500	Yes	40.2%

Table 5: Accuracy with feature classes gradually added in the order of their predictiveness.

Note that Row 3 of Table 3 corresponds to Marcu and Echihabi (2002)'s system which applies only word pair features. The difference is that they used a Naïve Bayes classifier while we used a maximum entropy classifier. As we did not implement their Naïve Bayes classifier, we compare their method's performance using the result from Table 3 Row 3 with ours from Table 5 Row 4, which shows that our system significantly ($p < 0.01$) outperforms theirs.

Level 2 Type	Precision	Recall	F_1	Count in test set
Asynchronous	0.50	0.08	0.13	13
Synchrony	–	–	–	5
Cause	0.39	0.76	0.51	200
Pragmatic Cause	–	–	–	5
Contrast	0.61	0.09	0.15	127
Concession	–	–	–	5
Conjunction	0.30	0.51	0.38	118
Instantiation	0.67	0.39	0.49	72
Restatement	0.48	0.27	0.35	190
Alternative	–	–	–	15
List	0.80	0.13	0.23	30
All (Micro Avg.)	0.40	0.40	0.40	780

Table 6: Recall, precision, F_1, and counts for 11 Level 2 relation types. "–" indicates 0.00.

Table 6 shows the recall, precision, and F_1 measure for the 11 individual Level 2 relation types in the final experiment set up (Row 4 from Table 5). A point worth noting is that the classifier labels no instances of the Synchrony, Pragmatic Cause, Concession, and Alternative relation types. The reason is that the percentages for these four types are so small that the classifier is highly skewed towards the other types. From the distribution shown in Table 1, there are just 4.76% training data for these four types, but 95.24% for the remaining seven types. In fact, only 30 test instances are labeled with these four types, as shown in the last column of Table 6. As Cause is the most pre-

dominant type in the training data, the classifier tends to label uncertain relations as Cause, thus giving Cause high recall but low precision. We see that the F measures correlate well with the training data frequency, thus we hypothesize that accuracy may improve if more training data for low frequency relations can be provided.

Our work differs from that of (Pitler et al., 2009) in that our system performs classification at the more fine-grained Level 2 types, instead of the coarse-grained Level 1 classes. Their system applies a Naïve Bayes classifier whereas our system uses a maximum entropy classifier, and the sets of features used are also different. In addition, the data set of (Pitler et al., 2009) includes `EntRel` and `AltLex`, which are relations in which an implicit connective cannot be inserted between adjacent sentences, whereas ours excludes `EntRel` and `AltLex`.

6 Discussion: Why are implicit discourse relations difficult to recognize?

In the above experiments, we have shown that by using the four feature classes, we are able to increase the classification accuracy from 26.1% of the majority baseline to 40.2%. Although we feel a 14.1 absolute percentage improvement is a solid result, an accuracy of 40% does not allow downstream NLP applications to trust the output of such a classification system.

To understand the difficulties of the task more deeply, we analyzed individual training and validation data pairs, from which we were able to generalize four challenges to automated implicit discourse relation recognition. We hope that this discussion may motivate future work on implicit discourse relation recognition.

Ambiguity. There is ambiguity among the relations. For example, we notice that a lot of Contrast relations are mistakenly classified as Conjunction. When we analyzed these relations, we observed that Contrast and Conjunction in the PDTB annotation are very similar to each other in terms of words, syntax, and semantics, as Examples 5 and 6 show. In both examples, the same antonymous verb pair is used (*fell* and *rose*), different subjects are mentioned in Arg1 and Arg2 (*net* and *revenue* in the first example, and *net* and *sales* in the second), and these subjects are all compared to like items from the previous year. Moreover, the implicit discourse connective given by the annotators is *while* in both cases, which is an ambiguous connective as shown in (Miltsakaki et al., 2005).

(5) **Arg1:** In the third quarter, AMR said, net fell to $137 million, or $2.16 a share, from $150.3 million, or $2.50 a share.
Arg2: [**while**] Revenue rose 17% to $2.73 billion from $2.33 billion a year earlier.
(Contrast - wsj_1812)

(6) **Arg1:** Dow's third-quarter net fell to $589 million, or $3.29 a share, from $632 million, or $3.36 a share, a year ago.
Arg2: [**while**] Sales in the latest quarter rose 2% to $4.25 billion from $4.15 billion a year earlier.
(Conjunction - wsj_1926)

Relation ambiguity may be ameliorated if an instance is analyzed in context. However, according to the PDTB annotation guidelines, if the annotators could not disambiguate between two relation types, or if they felt both equally reflect their understanding of the relation between the arguments, they could annotate two types to the relation. In the whole PDTB corpus, about 5.4% of the explicit relations and 2.2% of the implicit relations are annotated with two relation types. Example 7 is such a case where the implicit connective *meanwhile* may be interpreted as expressing a Conjunction or Contrast relation.

(7) **Arg1:** Sales surged 40% to 250.17 billion yen from 178.61 billion.
Arg2: [**meanwhile**] Net income rose 11% to 29.62 billion yen from 26.68 billion.
(Conjunction; Contrast - wsj_2242)

Inference. Sometimes inference and a knowledge base are required to resolve the relation type. In Example 8, to understand that Arg2 is a restatement of Arg1, we need a semantic mechanism to show that either the semantics of Arg1 infers that of Arg2 or the other way around. In the below example, *I had calls all night long* infers *I was woken up every hour* semantically, as shown in: $receive\_call(I) \wedge duration(all\_night) \Rightarrow woken\_up(I) \wedge duration(every\_hour)$.

(8) **Arg1:** "I had calls all night long from the States," he said.
Arg2: "[**in fact**] I was woken up every hour – 1:30, 2:30, 3:30, 4:30."
(Restatement - wsj_2205)

In fact, most relation types can be represented using formal semantics (PDTB-Group, 2007), as shown in Table 7, where $|Arg1|$ and $|Arg2|$ represent the semantics extracted from Arg1 and Arg2, respectively. This kind of formal semantic reasoning requires a robust knowledge base, which is still beyond our current technology.

Relation type	Semantic representation
Cause	$\|Arg1\| \prec \|Arg2\| \quad \vee \quad \|Arg2\| \prec \|Arg1\|$
Concession	$A \prec C \quad \wedge \quad B \Rightarrow \neg C$ where $A \in \|Arg1\|, B \in \|Arg2\|$
Instantiation	$exemplify(\|Arg2\|, \lambda x.x \in E)$ where $E = extract(\|Arg1\|)$
Restatement	$\|Arg1\| \Rightarrow \|Arg2\| \quad \vee \quad \|Arg1\| \Leftarrow \|Arg2\|$
Alternative	$\|Arg1\| \wedge \|Arg2\| \quad \vee \quad \|Arg1\| \oplus \|Arg2\|$

Table 7: Some examples of relation types with their semantic representations, as taken from (PDTB-Group, 2007).

Context. PDTB annotators adopted the *Minimality Principle* in argument selection, according to which they only included in the argument the minimal span of text that is sufficient for the interpretation of the relation. While the context is not necessary to interpret the relation, it is usually necessary to understand the meaning of the arguments. Without an analysis of the context, Arg1 and Arg2 may seem unconnected, as the following example shows, where the meaning of Arg1 is mostly derived from its previous context (i.e., *West German ... technical reactions*).

(9) **Prev. Context:** West German Economics Minister Helmut Haussmann said, "In my view, the stock market will stabilize relatively quickly. There may be one or other psychological or technical reactions,
Arg1: but they aren't based on fundamentals.
Arg2: [**in short**] The economy of West Germany and the EC European Community is highly stable."
(Conjunction - wsj_2210)

Sometimes the range of the context may easily extend to the whole text, which would require a system to possess a robust context modeling mechanism. In Example 10, in order to realize the causal relation between Arg2 and Arg1, we possibly need to read the whole article and understand what was happening: the machinist union was having a strike and the strike prevented most of its union members from working.

(10) **Arg1:** And at the company's Wichita, Kan., plant, about 2,400 of the 11,700 machinists still are working, Boeing said.
Arg2: [**because**] Under Kansas right-to-work laws, contracts cannot require workers to be union members.
(Cause - wsj_2208)

World Knowledge. Sometimes even context modeling is not enough. We may also need world knowledge to understand the arguments and hence to interpret the relation. In the following example, from the previous sentence of Arg1, it is reported that "the Senate voted to send a delegation of congressional staffers to Poland to assist its legislature", and this delegation is viewed as a "gift" in Arg1. It is suggested in Arg2 that the Poles might view the delegation as a "Trojan Horse". Here we need world knowledge to understand that "Trojan Horse" is usually applied as a metaphor for a person or thing that appears innocent but has harmful intent, and hence understand that Arg2 poses a contrasting view of the delegation as Arg1 does.

(11) **Arg1:** Senator Pete Domenici calls this effort "the first gift of democracy".
Arg2: [**but**] The Poles might do better to view it as a Trojan Horse.
(Contrast - wsj_2237)

These four classes of difficulties – ambiguity between relations, inference, contextual modeling, and world knowledge – show that implicit discourse relation classification needs deeper semantic representations, more robust system design, and access to more external knowledge. These obstacles may not be restricted to recognizing implicit relations, but are also applicable to other related discourse-centric tasks.

7 Conclusion

We implemented an implicit discourse relation classifier and showed initial results on the recently released Penn Discourse Treebank. The features we used include the modeling of the context of relations, features extracted from constituent parse trees and dependency parse trees, and word pair features. Our classifier achieves an accuracy of 40.2%, a 14.1% absolute improvement over the baseline. We also conducted a data analysis and discussed four challenges that need to be addressed in future to overcome the difficulties of implicit relation classification in the PDTB.

Abstract

Tree based translation models are a compelling means of integrating linguistic information into machine translation. Syntax can inform lexical selection and reordering choices and thereby improve translation quality. Research to date has focussed primarily on decoding with such models, but less on the difficult problem of inducing the bilingual grammar from data. We propose a generative Bayesian model of tree-to-string translation which induces grammars that are both smaller and produce better translations than the previous heuristic two-stage approach which employs a separate word alignment step.

1 Introduction

Many recent advances in statistical machine translation (SMT) are a result of the incorporation of syntactic knowledge into the translation process (Marcu et al., 2006; Zollmann and Venugopal, 2006). This has been facilitated by the use of synchronous grammars to model translation as a generative process over pairs of strings in two languages. Such models are particularly attractive for translating between languages with divergent word orders, such as Chinese and English, where syntax-inspired translation rules can succinctly describe the requisite reordering operations. In contrast, standard phrase-based models (Koehn et al., 2003) assume a mostly monotone mapping between source and target, and therefore cannot adequately model these phenomena. Currently the most successful paradigm for the use of synchronous grammars in translation is that of string-to-tree transduction (Galley et al., 2004; Zollmann and Venugopal, 2006; Galley et al., 2006; Marcu et al., 2006). In this case a grammar is extracted from a parallel corpus, with strings on its source side and syntax trees on its target side, which is then used to translate novel sentences by performing inference over the space of target syntax trees licensed by the grammar.

To date grammar-based translation models have relied on heuristics to extract a grammar from a word-aligned parallel corpus. These heuristics are extensions of those developed for phrase-based models (Koehn et al., 2003), and involve symmetrising two directional word alignments followed by a projection step which uses the alignments to find a mapping between source words and nodes in the target parse trees (Galley et al., 2004). However, such approaches leave much to be desired. Word-alignments rarely factorise cleanly with parse trees (i.e., alignment points cross constituent structures), resulting in large and implausible translation rules which generalise poorly to unseen data (Fossum et al., 2008). The principal reason for employing a grammar based formalism is to induce rules which capture long-range reorderings between source and target. However if the grammar itself is extracted using word-alignments induced with models that are unable to capture such reorderings, it is unlikely that the grammar will live up to expectations.

In this work we draw on recent advances in Bayesian modelling of grammar induction (Johnson et al., 2007; Cohn et al., 2009) to propose a non-parametric model of synchronous tree substitution grammar (STSG), continuing a recent trend in SMT to seek principled probabilistic formulations for heuristic translation models (Zhang et al., 2008; DeNero et al., 2008; Blunsom et al., 2009b; Blunsom et al., 2009a). This model leverages a hierarchical Bayesian prior to induce a compact translation grammar directly from a parsed parallel corpus, unconstrained by word-alignments. We show that the induced grammars are more plausible and improve translation output.

This paper is structured as follows: In Section

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 352–361,
Singapore, 6-7 August 2009.

2 we introduce the STSG formalism and describe current heuristic approaches to grammar induction. We define a principled Bayesian model of string-to-tree translation in Section 3, and describe an inference technique using Gibbs sampling in Section 4. In Section 5 we analyse an induced grammar on a corpus of Chinese→English translation, comparing them with a heuristic grammar in terms of grammar size and translation quality.

2 Background

Current tree-to-string translation models are a form of *Synchronous Tree Substitution Grammar* (STSG; Eisner (2003)). Formally, a STSG is a 5-tuple, $G = (T, T', N, S, R)$, where T and T' are sets of *terminal symbols* in the target and source languages respectively, N is a set of *non-terminal symbols*, $S \in N$ is the distinguished *root non-terminal* and R is a set of productions (a.k.a. rules). Each production is a tuple comprising an *elementary tree* and a string, the former referring to a tree fragment of depth ≥ 1 where each internal node is labelled with a non-terminal and each leaf is labelled with either a terminal or a non-terminal. The string part of the rule describes the lexical component of the rule in the source language and includes a special variable for each *frontier non-terminal* in the elementary tree. These variables describe the reordering and form the recursion sites in the generative process of creating tree and string pairs with the grammar. For example, the rule

$$\langle (\text{NP NP}_{\boxed{1}} \text{ (PP (IN of) NP}_{\boxed{2}})), \boxed{2}\ 的\ \boxed{1} \rangle \quad (1)$$

rewrites a noun-phrase (NP) as a NP and prepositional phrase (PP) headed by 'of' in the target language. The rule generates the token '的' in the source and reverses the order of the two child noun-phrases, indicated by the numbering of the variables in the string part.

A *derivation* creates a (tree, string) pair by starting with the root non-terminal and an empty string, then choosing a rule to rewrite (substitute) the non-terminal and expand the string. This process repeats by rewriting all frontier non-terminals until there are none remaining. A *Probabilistic STSG* assigns a probability to each rule in the grammar. The probability of a derivation is the product of the probabilities of its component rules, and the probability of a (tree, string) pair is the sum of the probabilities over all its derivations.

2.1 Heuristic Grammar Induction

Grammar based SMT models almost exclusively follow the same two-stage approach to grammar induction developed for phrase-based methods (Koehn et al., 2003). In this approach they induce a finite-state grammar with phrase-pairs as rules by taking a sentence aligned parallel corpus and 1) predicting word alignments before 2) extracting transduction rules that are 'consistent' with the word aligned data. Although empirically effective, this two stage approach is less than ideal due to the disconnect between the word-based models used for alignment and the phrase-based translation model. This is problematic as the word-based model cannot recognise phrase-based phenomena. Moreover, it raises the problem of identifying and weighting the rules from the word alignment.

The same criticisms levied at the phrase-based models apply equally to the two-stage technique used for synchronous grammar induction (Galley et al., 2004; Zollmann and Venugopal, 2006; Galley et al., 2006; Marcu et al., 2006). Namely that the word alignment models typically do not use any syntax and therefore will not be able to model, e.g., consistent syntactic reordering effects, or the impact of the syntactic category on phrase translations. The identification and estimation of grammar rules from word aligned data is also non-trivial. Galley et al. (2004) describe an algorithm for inducing a string-to-tree grammar using a parallel corpus with syntax trees on target side. Their method projects the source strings onto nodes of the target tree using the word alignment, and then extracts the minimal transduction rules as well as rules composed of adjacent minimal units. The production weights are estimated either by heuristic counting (Koehn et al., 2003) or using the EM algorithm. Both estimation techniques are flawed. The heuristic method is inconsistent in the limit (Johnson, 2002) while EM is *degenerate*, placing disproportionate probability mass on the largest rules in order to describe the data with as few a rules as possible (DeNero et al., 2006). With no limit on rule size this method will learn a single rule for every training instance, and therefore will not generalise to unseen sentences. These problems can be ameliorated by imposing limits on rule size or early stopping of EM training, however neither of these techniques addresses the underlying problems.

In contrast, our model is trained in a single step, i.e., the alignment model *is* the translation model. This allows syntax to directly inform the alignments. We infer a grammar without resorting to word alignment constraints or limits on rule size. The model uses a prior to bias towards a compact grammar with small rules, thus solving the degeneracy problem.

3 Model

Our training data comprises parallel target trees and source strings and our aim is to induce a STSG that best describes this data. This is achieved by inferring a distribution over the derivations for each training instance, where the set of derivations collectively specify the grammar. In the following, we denote the source trees as $\mathbf{t}$, target strings $\mathbf{s}$, and derivations $\mathbf{r}$ which are sequences of grammar rules, r.

As described in section 2.1, previous methods for estimating a STSG have suffered from degeneracy. A principled way to correct for such degenerated behaviour is to use a *prior* over rules which biases towards small rules. This matches our intuition: we expect good translation rules to be small, with few internal nodes, frontier non-terminals and terminal strings. However, we recognise that on occasion larger rules will be necessary; we allow such rules when there is sufficient support in the data.

We model the grammar as a set of distributions, G_c, over the productions for each non-terminal symbol, c. We adopt a non-parametric Bayesian approach by treating each G_c as a random variable with a Dirichlet process (DP) prior,

$$\begin{aligned} r|c &\sim G_c \\ G_c|\alpha_c, P_0 &\sim \text{DP}(\alpha_c, P_0(\cdot|c))\,, \end{aligned}$$

where $P_0(\cdot|c)$ (the *base distribution*) is a distribution over the infinite space of trees rooted with c, and α_c (the *concentration parameter*) controls the model's tendency towards either reusing existing rules or creating novel ones as each training instance is encountered (and consequently, the tendency to infer larger or smaller grammars). We discuss the base distribution in more detail below.

Rather than representing the distribution G_c explicitly, we integrate over all possible values of G_c. This leads to the following predictive distribution for the rule r_i given the previously observed rules $\mathbf{r}^{-i} = r_1 \dots r_{i-1}$,

$$p(r_i|\mathbf{r}^{-i}, c, \alpha_c, P_0) = \frac{n_{r_i}^{-i} + \alpha_c P_0(r_i|c)}{n_c^{-i} + \alpha_c}\,, \quad (2)$$

where $n_{r_i}^{-i}$ is the number number of times r_i has been used to rewrite c in $\mathbf{r}^{-i}$, and $n_c^{-i} = \sum_{r,R(r)=c} n_r^{-i}$ is the total count of rewriting c (here $R(r)$ is the root non-terminal of r). The distribution is *exchangeable*, meaning that all permutations of the input sequence are assigned the same probability. This allows us to treat any item as being the last, which is fundamental for efficient Gibbs sampling. Henceforth we adopt the notation $\mathbf{r}^-$ and n^- to refer to the rules and counts for the whole data set excluding the current rules under consideration, irrespective of their location in the corpus.

The base distribution, P_0, assigns a prior probability to an infinite number of rules, where each rule is an (elementary tree, source string) pair denoted $r = (\mathbf{e}, \mathbf{w})$. While there are a myriad of possible distributions, we developed a very simple one. We decompose the probability into two factors,

$$P_0(\mathbf{e}, \mathbf{w}|c) = P(\mathbf{e}|c)P(\mathbf{w}|\mathbf{e})\,, \quad (3)$$

the probability of the target elementary tree and the probability of the source string, where $c = R(r)$.

The tree probability, $P(\mathbf{e}|c)$ in (3), is modelled using generative process whereby the root category c is expanded into a sequence of child non-terminals, then each of these are either expanded or left as-is. This process continues until there are no unprocessed children. The number of child nodes for each expansion is drawn from a geometric prior with parameter p_{child}, except in the case of pre-terminals where the number of children is always one. The binary expansion decisions are drawn from a Bernoulli prior with parameter p_{expand}, and non-terminals and terminals are drawn uniformly from N and T respectively. For example, the source side of rule (1) was generated as follows: 1) the NP was rewritten as two children; 2) an NP; and 4) a PP; 5) the NP child was not expanded; 6) the PP child was expanded; 7) as an IN; and 8) a NP; 9) the IN was expanded to the terminal 'of'; and 10) the final NP was not expanded. Each of these steps is a draw from the relevant distribution, and the total probability is the product of the probabilities for each step.

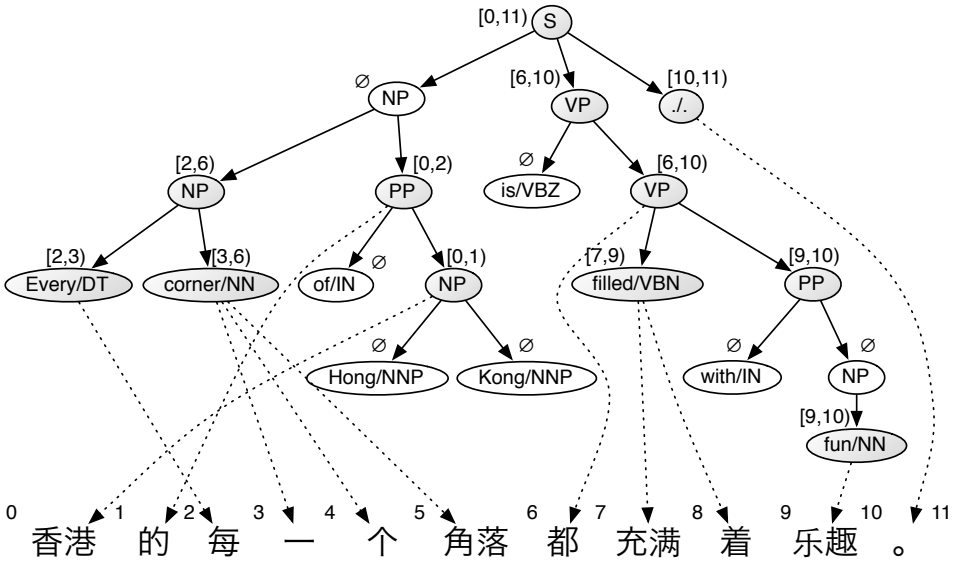

Figure 1: Example derivation. Each node is annotated with their span in the target string (aligned nodes are shaded). The dotted edges show the implied alignments. Preterminals are displayed with their child terminal in the leaf nodes.

The second factor in (3) is $P(\mathbf{w}|\mathbf{e})$, the probability of the source string (a sequence of source terminals and variables). We assume that the elementary tree is generated first, and condition the string probability on $l = F(\mathbf{e})$, its number of frontier nodes (i.e., variables). The string is then created by choosing a number of terminals from a geometric prior with parameter p_{term} then drawing each terminal from a uniform distribution over T'. Finally each of the l variables are inserted into the string one at a time using a uniform distribution over the possible placements. For the example rule in (1) the generative process corresponds to 1) deciding to create one terminal; 2) with value 的; 3) inserting the first variable after the terminal; and 4) inserting the second variable before the terminal. Again, the probability of the string is simply the product of the probabilities for each step.

Together both the factors in the base distribution penalise large trees with many nodes and long strings with many terminals and variables. P_0 decreases exponentially with rule size, thus discouraging the model from using larger rules; for this to occur the rules must significantly increase the likelihood.

4 Training

To train our model we use Gibbs sampling (Geman and Geman, 1984), a Markov chain Monte Carlo method (Gilks et al., 1996) in which variables are repeatedly sampled conditioned on the values of all other variables in the model.[1] After a period of burn-in, each sampler state (set of variable assignments) is a sample from the posterior distribution of the model. In our case, we wish to sample from the posterior over the grammar, $P(\mathbf{r}|\mathbf{t}, \mathbf{s}, \alpha)$.

To simplify matters we associate an alignment variable, a, with every internal node of the trees in the training set. This variable specifies the span of source tokens to which node is aligned. Alternatively, the node can be unaligned, which is encoded as an empty span. I.e. $a \in (J \times J) \cup \emptyset$ where J is the set of target word indices. Spans are written $[i, j)$: inclusive of i and exclusive of j. Each aligned node ($a \neq \emptyset$) forms the root of a rule as well as being a frontier non-terminal of an ancestor rule, while unaligned nodes form part of an ancestor rule.[2] The set of valid alignments are constrained by the tree in a number of ways. Child nodes can be aligned only to subspans of their ancestor nodes' alignments and no two nodes' alignments can overlap. Finally, the root node of the tree must be aligned to the full

[1] Previous approaches to bilingual grammar induction have used variational inference to optimise a bound on the data log-likelihood (Zhang et al., 2008; Blunsom et al., 2009b). Both these approaches truncated the grammar a priori in order to permit tractable inference. In contrast our Gibbs sampler can perform inference over the full space of grammars. See also Blunsom et al. (2009a) where we present a Gibbs sampler for inducing SCFGs without truncation.

[2] The Gibbs sampler is an extension of our sampler for monolingual tree-substitution grammar (Cohn et al., 2009), which used a binary substitution variable at each node to encode the segmentation of a training tree into elementary trees.

span of source words.

Collectively, the training trees and alignment variables specify the sequence of rules $\mathbf{r}$, which in turn specify the grammar. Figure 1 shows an example derivation with alignment variables. The corresponding STSG rules are shown in Table 1.

4.1 Gibbs operators

The Gibbs sampler works by sampling new values of the alignment variables, using two different Gibbs operators to make the updates. The first operator, EXPAND, takes a tree node, v, and samples a new alignment, a_v, given the alignments of all other nodes in the same tree and all other trees in the corpus, denoted $\mathbf{a}^-$. The set of valid labels is constrained by the other alignments in the tree, specifically that of the node's closest aligned ancestor, a_p, its closest aligned descendants, $\mathbf{a}_d$, and its aligned siblings, $\mathbf{a}_s$ (the aligned descendants of a). The alignment variable may be empty, $a_v = \emptyset$, while non-empty values must obey the tree constraints. Specifically the span must be a subspan of its ancestor, $a_v \subseteq a_p$, subsume its descendants, $a_v \supseteq \bigcup \mathbf{a}_d$, and not overlap its siblings, $j \notin \bigcup \mathbf{a}_s, \forall j \in a_v$. Figure 2 shows an example with the range of valid values for *corner/NN*'s alignment variable and the corresponding alignments that these encode.

Each alignment in the set of valid outcomes defines a set of grammar rules. The non-aligned outcome results in a single rule r_p rooted at ancestor node p. While the various aligned outcomes result in a pair of rules, $r_{p'}$ and r_v, rooted at p and v respectively. In the example in Figure 2, the top-right outcome has $a_v = \emptyset$ and

$$r_p = \langle (\text{NP DT}_{[1]}\ (\text{NN corner})), [1]\ 一\ 个\ 角落 \rangle .$$

The bottom-right outcome, $a_v = [4, 5)$, describes the pair of rules:

$$r_{p'} = \langle (\text{NP DT}_{[1]}\ \text{NN}_{[2]}), [1]\ 一\ [2]\ 角落 \rangle \text{ and}$$
$$r_v = \langle (\text{NN corner}), 个 \rangle .$$

The set of valid options are then scored according to the probability of their rules as follows:

$$P(r_p|\mathbf{r}^-) = \frac{n^-_{r_p} + \alpha P_0(r_p|c_p)}{n^-_{c_p} + \alpha} \quad (4)$$

$$\begin{aligned} P(r_{p'}, r_v|\mathbf{r}^-) &= P(r_{p'}|\mathbf{r}^-)P(r_v|\mathbf{r}^-, r_{p'}) \\ &= \frac{n^-_{r_{p'}} + \alpha P_0(r_{p'}|c_p)}{n^-_{c_p} + \alpha} \times \\ &\quad \frac{n^-_{r_v} + \delta(r_{p'}, r_v) + \alpha P_0(r_v|c_v)}{n^-_{c_v} + \delta(c_p, c_v) + \alpha} \end{aligned} \quad (5)$$

where c_p is the non-terminal at node p (similarly for c_v), n^- denote counts of trees (e.g., $n^-_{r_p}$) or the sum over all trees expanding a non-terminal (e.g., $n^-_{c_v}$) in the conditioning context, $\mathbf{r}^-$, and $\delta(\cdot, \cdot)$ is the Kronecker delta function, which returns 1 when its arguments are identical and 0 otherwise. For clarity, we have omitted some items from the conditioning context

in (4) and (5), namely $\mathbf{t}, \mathbf{s}$ and hyper-parameters $\alpha, p_{\text{child}}, p_{\text{expand}}, p_{\text{term}}$. The δ terms in the second factor of (5) account for the changes to n^- that would occur after observing $r_{p'}$, which forms part of the conditioning context for r_v. If the rules $r_{p'}$ and r_v are identical, then the count $n^-_{r_v}$ would increase by one, and if the rules expand the same root non-terminal, then $n^-_{c_v}$ would increase by one. Equation (4) is evaluated once for the unaligned outcome, $a_v = \emptyset$, and (5) is evaluated for each valid alignment. The probabilities are normalised and an outcome sampled.

The EXPAND operator is sufficient to move from one derivation to any other valid derivation, however it may take many steps to do so. These intermediate steps may require the sampler to pass through highly improbable regions of the state space, and consequently such moves are unlikely. The second operator, SWAP, is designed to help address this problem by increasing the mobility of the sampler, allowing it to mix more quickly. The operator considers pairs of nodes, v, w, in one tree and attempts to swap their alignment values.[3] This is illustrated in the example in Figure 3. There are two options being compared: preserving the alignments (left) or swapping them (right). This can change three rules implied by the derivation: that rooted at the nodes' common aligned ancestor, p, and those rooted at v and w. For the example, the left option implies rules

$$\begin{aligned}\{r_p &= \langle(\text{NP DT}\boxed{1}\ \text{NN}\boxed{2}), \boxed{1}\ \boxed{2}\rangle,\\ r_v &= \langle(\text{DT Every}), 每\rangle,\\ r_w &= \langle(\text{NN corner}), 一\ 个\ 角落\rangle\}\,,\end{aligned}$$

and the right option implies rules

$$\begin{aligned}\{r_p &= \langle(\text{NP DT}\boxed{1}\ \text{NN}\boxed{2}), \boxed{2}\ \boxed{1}\rangle,\\ r_v &= \langle(\text{DT Every}), 一\ 个\ 角落\rangle,\\ r_w &= \langle(\text{NN corner}), 每\rangle\}\,.\end{aligned}$$

We simply evaluate the probability of both triples of rules under our model, $P(r_p, r_v, r_w|\mathbf{r}^-) = P(r_p|\mathbf{r}^-)P(r_v|\mathbf{r}^-, r_p)$ $P(r_w|\mathbf{r}^-, r_p, r_v)$, where the additional rules in the conditioning context signify their inclusion in the counts $\mathbf{r}^-$ before applying (2) to evaluate the probability (much the same as in (5) where the δ functions encode the changes to the counts). An outcome is then sampled according to the normalised probabilities of the preserve vs. swap rules.

[3] We rarely need to consider the full quadratic space of node pairs, as the validity constraints mean that the only candidates for swapping are siblings (i.e., share the closest aligned ancestor) which do not have any aligned descendants.

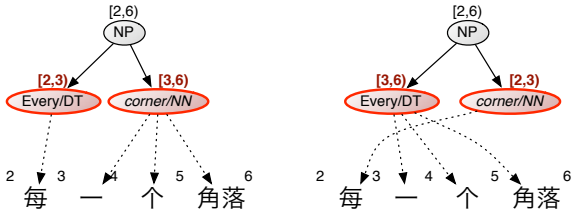

Figure 3: Possible state updates for the pair of nodes (DT every) and (NN corner) using the SWAP operator.

	English ← Chinese

Avg. Sent. Length	36	28
Longest Sent.	80	80

Table 2: NIST Chinese-English corpora statistics (LDC2003E14, LDC2005E47).

The Gibbs sampler makes use of both operators. The algorithm visits each (tree, string) pair in the training set in random order and applies the EXPAND operator to every node in the tree. After the tree has been processed, the SWAP operator is applied to all candidate pairs of nodes. Visiting all sentence pairs in this way constitutes a single sample from the Gibbs sampler.

5 Experiments

We evaluate our non-parametric model of grammar induction on a subset of the NIST Chinese-English translation evaluation, representing a realistic SMT experiment with millions of words and long sentences. The Chinese-English training data consists of the FBIS corpus (LDC2003E14) and the first 100k sentence pairs from the Sinorama corpus (LDC2005E47). The Chinese text was segmented with a CRF-based Chinese segmenter optimized for MT (Chang et al., 2008), and the English text was parsed using the Stanford parser (Klein and Manning, 2003).

As a baseline we implemented the heuristic grammar extraction technique of Galley et al. (2004) (henceforth GHKM). This method finds the minimum sized translation rules which are consistent with a word-aligned sentence pair, as

described in section 2.1. The rules are then treated as events in a relative frequency estimate.[4] We used Giza++ Model 4 to obtain word alignments (Och and Ney, 2003), using the `grow-diag-final-and` heuristic to symmetrise the two directional predictions (Koehn et al., 2003).

The model was sampled for 300 iterations to 'burn-in', where in each iteration we applied both sampling operators to all nodes (or node pairs) of all training instances. We initialised the sampler using the GHKM derivation of the training data (the baseline system). The final state of the sampler was used to extract the grammar. The hyperparameters were set by hand to $\alpha = 10^6$, $p_{\text{child}} = 0.5$, $p_{\text{expand}} = 0.5$, and $p_{\text{term}} = 0.5$.[5] Overall the model took on average 2,218s per full iteration of Gibbs sampling and 1 week in total to train, using a single core of a 2.3Ghz AMD Opteron machine.

5.1 Grammar Analysis

The resulting grammar had 1.62M rules, almost identical to the GHKM grammar which had 1.63M. Despite their similarity in size the grammars were quite different, as illustrated in Figure 4, which shows histograms over various measures of rule size for the two grammars. Under each measure the sampled grammar finds many more simple rules – shallower with fewer internal nodes, fewer variables and fewer terminals – than the GHKM method. This demonstrates that the prior is effective in shifting mass away from complex rules. To show how the rules themselves differ, Table 3 lists rules in the sampled grammar that are not in the GHKM grammar. Note that many of these rules are highly plausible, describing regular tree structures and lexicalisation. These rules have not been specified to the same extent in the GHKM grammar. For example the first rule incorporates

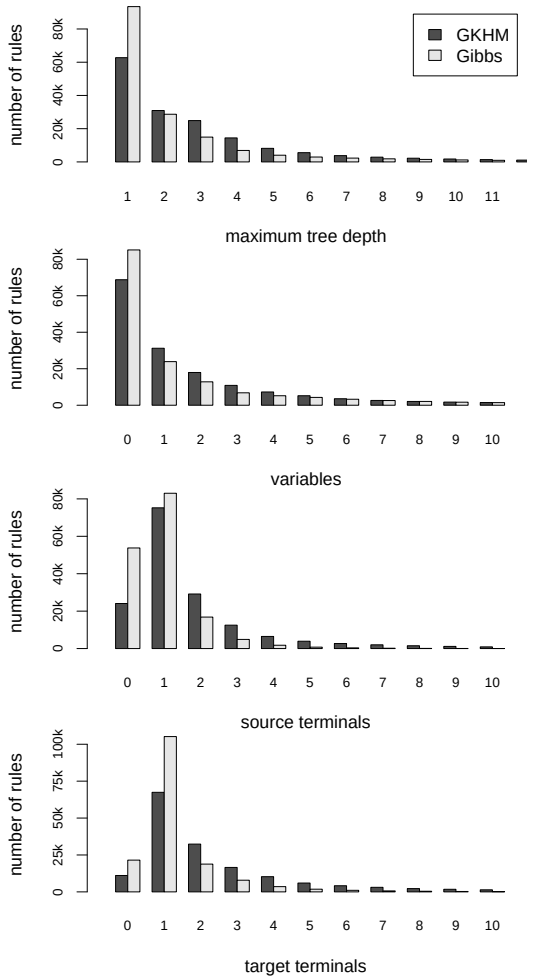

Figure 4: Histograms over rule statistics comparing the heuristic grammar (GHKM) and learnt grammar (Gibbs).

the TOP symbol, while the GHKM grammar instead relies on the rule $\langle(\text{TOP S}\boxed{1}), \boxed{1}\rangle$ to produce the same fragment. The model has learnt to distinguish between sentence-spanning and subsentential S constituents, which typically do not include final punctuation. The third and ninth (last) rule are particularly interesting. These rules encode reordering effects relating to noun phrases and subordinate prepositional phrases, in particular that Chinese prepositional modifiers precede the nouns they modify. Differences in word order such as these are quite common in Chinese-English corpora, so it is imperative that they are modelled accurately.

The rules in the GHKM grammar that do not appear in the sampled grammar are shown in Table 4. In contrast to the rules only present in the sampled grammar, these have much lower counts, i.e., are less probable. Each of these rules has been specified further by the Bayesian model.

[4] Our implementation of the GHKM algorithm attaches unaligned source words to the highest possible node in the source tree, rather than allowing all attachment points as in the original presentation (Galley et al., 2004). Allowing all attachments made no difference to translation performance, but did make the grammar considerably larger. We implemented only the minimal rule extraction, i.e., with no rule composition (Galley et al., 2006). Consequently there is no derivational ambiguity, obviating the need for expectation maximisation or similar for rule estimation.

[5] Note that although α seems large, it still encourages sparse distributions as the P_0 values are typically much smaller than its reciprocal, 10^{-6}, especially if the rule is large. $\alpha P_0 < 1$ implies a sparse Dirichlet prior.

⟨(NP (DT the) (NNS people) POS[1]), 人民 [1]⟩

Table 4: Top ten rules in the GHKM grammar that do not appear in the sampled grammar. These are quite low probability rules: their counts range from 1,137 to 103.

For example, every instance of the first rule had the same determiner and target translation, ⟨(PP (IN at) (NP (DT all) (NNS levels))), 各 級⟩, and therefore the model specified the determiner, resulting in a single rule. The model has correctly learnt that other translations for (DT all) are not appropriate in this context (e.g., 都, 所有 or 一切). In a number of the remaining rules the commas were lexicalised, or S rules were extended to include the TOP symbol.

To further illustrate the differences between the grammars, Table 5 shows the rules which include the possessive particle, 的, and at least one variable. In both grammars there are many fully lexicalised rules which translate the token to, e.g., a determiner or a preposition. The grammars differ on the complex rules which combine lexicalisation and frontier non-terminals. The GHKM rules are all very simple depth-1 SCFG rules, containing minimal information. In contrast, the sampled rules are more lexicalised, licensing the insertion of various English tokens and tree substructure. Note particularly the second and forth rule which succinctly describe the reordering of prepositional phrases with an noun phrase.

5.2 Translation

In order to test the translation performance of the grammars induced by our model and the GHKM method[6] we report BLEU (Papineni et al., 2002) scores on sentences of up to twenty words in length from the MT03 NIST evaluation. We built a synchronous beam search decoder to find the maximum scoring derivation, based on the CYK+ chart parsing algorithm and the cube-pruning method of Chiang (2007). Parse edges for all constituents spanning a given chart cell were cube-pruned together using a beam of width 1000, and only edges from the top ten constituents in each cell were retained. No artificial glue-rules or rule span limits were employed.[7] The parameters of the translation system were trained to maximize BLEU on the MT02 test set (Och, 2003). Decoding took roughly 10s per sentence for both grammars, using a 8-core 2.6Ghz Intel Xeon machine.

Table 6 shows the BLEU scores for the baseline using the GHKM rule induction algorithm, and our non-parametric Bayesian grammar induction method. We see a small increase in generalisation performance from our model. Our previous anal-

[6]Our decoder was unable to process unary rules (those which consume nothing in the source). Monolingual parsing with unary productions is fairly straightforward (Stolcke, 1995), however in the transductive setting these rules can licence infinite insertions in the target string. This is further complicated by the language model integration. Therefore we composed each unary rule instance with its descendant rule(s) to create a non-unary rule.

[7]Our decoder lacks certain features shown to be beneficial to synchronous grammar decoding, in particular rule binarisation (Zhang et al., 2006). As such the reported results for MT03 lag the state-of-the-art: the Moses phrase-based decoder (Koehn et al., 2007) achieves 26.8. We believe that improvements from a better decoder implementation would be orthogonal to the improvements presented here (and would allow us to relax the length restriction on the test set).

Model	BLEU score
GHKM	26.0
Our model	26.6

Table 6: Translation results on the NIST test set MT03 for sentences of length ≤ 20.

ysis (Section 5.1) of the grammars produced by the two approaches showed our method produced better lexicalised rules than those induced by the GHKM algorithm. Galley et al. (2006) noted that the GHKM algorithm often over generalised and proposed combining minimal rules to form composed rules as a solution. Although composing rules was effective at improving BLEU scores, the result was a massive expansion in the size of the grammar. By learning the appropriate level of lexicalisation we believe that our inference algorithm is having a similar effect as composing rules (Galley et al., 2006), however the resulting grammar remains compact, a significant advantage of our approach.

6 Conclusion

In this paper we have presented a method for inducing a tree-to-string grammar which removes the need for various heuristics and constraints from models of word alignment. Instead the model is capable of directly inferring a grammar in one step, using the syntactic fragments that it has learnt to better align the source and target data. Using a prior which favours sparse distributions and simpler rules, we demonstrate that the model finds a more parsimonious grammar than the heuristic technique. Moreover, this grammar results in improved translations on a standard evaluation set.

We expect that various extensions to the model would improve its performance. One avenue is to develop a more sophisticated prior over rules, e.g., one that recognises common types of rule via the shape of the tree and ordering pattern in the target. A second avenue is to develop better means of inference under the grammar, in order to ensure faster mixing and a means to escape from local optima. Finally, we wish to develop a method for decoding under the full Bayesian model, instead of the current beam search. With these extensions we expect that our model of grammar induction has the potential to greatly improve translation output.

Abstract

Binarization of Synchronous Context Free Grammars (SCFG) is essential for achieving polynomial time complexity of decoding for SCFG parsing based machine translation systems. In this paper, we first investigate the excess edge competition issue caused by a left-heavy binary SCFG derived with the method of Zhang et al. (2006). Then we propose a new binarization method to mitigate the problem by exploring other alternative equivalent binary SCFGs. We present an algorithm that iteratively improves the resulting binary SCFG, and empirically show that our method can improve a string-to-tree statistical machine translations system based on the synchronous binarization method in Zhang et al. (2006) on the NIST machine translation evaluation tasks.

1 Introduction

Recently Statistical Machine Translation (SMT) systems based on Synchronous Context Free Grammar (SCFG) have been extensively investigated (Chiang, 2005; Galley et al., 2004; Galley et al., 2006) and have achieved state-of-the-art performance. In these systems, machine translation decoding is cast as a synchronous parsing task. Because general SCFG parsing is an NP-hard problem (Satta and Peserico, 2005), practical SMT decoders based on SCFG parsing requires an equivalent binary SCFG that is directly learned from training data to achieve polynomial time complexity using the CKY algorithm (Kasami, 1965; Younger, 1967) borrowed from CFG parsing techniques. Zhang et al. (2006) proposed *synchronous binarization*, a principled method to binarize an SCFG in such a way that both the source-side and target-side virtual non-terminals have contiguous spans. This property of synchronous binarization guarantees the polynomial time complexity of SCFG parsers even when an *n*-gram language model is integrated, which has been proved to be one of the keys to the success of a string-to-tree syntax-based SMT system.

However, as shown by Chiang (2007), SCFG-based decoding with an integrated *n*-gram language model still has a time complexity of $\Theta(m^3|T|^{4(n-1)})$, where m is the source sentence length, and $|T|$ is the vocabulary size of the language model. Although it is not exponential in theory, the actual complexity can still be very high in practice. Here is an example extracted from real data. Given the following SCFG rule:

$$\boldsymbol{VP} \rightarrow \boldsymbol{VB}\ \boldsymbol{NP}\ 会\ \boldsymbol{JJR}\ ,\ \boldsymbol{VB}\ \boldsymbol{NP}\ \text{will be}\ \boldsymbol{JJR}$$

we can obtain a set of equivalent binary rules using the synchronous binarization method (Zhang et al., 2006) as follows:

$\boldsymbol{VP} \rightarrow \boldsymbol{V}_1\ \boldsymbol{JJR}$,	$\boldsymbol{V}_1\ \boldsymbol{JJR}$
$\boldsymbol{V}_1 \rightarrow \boldsymbol{VB}\ \boldsymbol{V}_2$,	$\boldsymbol{VB}\ \boldsymbol{V}_2$
$\boldsymbol{V}_2 \rightarrow \boldsymbol{NP}\ 会$,	$\boldsymbol{NP}$ will be

This binarization is shown with the solid lines as binarization (a) in Figure 1. We can see that binarization (a) requires that "NP 会" should be reduced at first. Data analysis shows that "NP 会" is a frequent pattern in the training corpus, and there are 874 binary rules of which the source language sides are "NP 会". Consequently these binary rules generate a large number of competing edges in the chart when "NP 会" is matched in decoding. To reduce the number of edges pro-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 362–370,
Singapore, 6-7 August 2009.

posed in decoding, hypothesis re-combination is used to combine the equivalent edges in terms of dynamic programming. Generally, two edges can be re-combined if they satisfy the following two constraints: 1) the LHS (left-hand side) non-terminals are identical and the sub-alignments are the same (Zhang et al., 2006); and 2) the boundary words[1] on both sides of the partial translations are equal between the two edges (Chiang, 2007). However, as shown in Figure 2, the decoder still generates 801 edges after the hypothesis re-combination. As a result, aggressive pruning with beam search has to be employed to reduce the search space to make the decoding practical. Usually in beam search only a very small number of edges are kept in the beam of each chart cell (e.g. less than 100). These edges have to compete with each other to survive from the pruning. Obviously, more competing edges proposed during decoding can lead to a higher risk of making search errors.

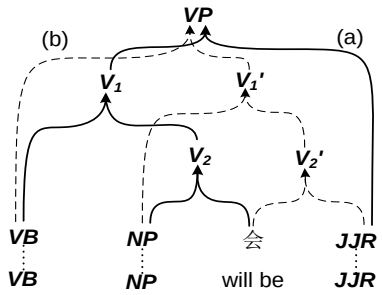

Figure 1: Two different binarizations (a) and (b) of the same SCFG rule distinguished by the solid lines and dashed lines

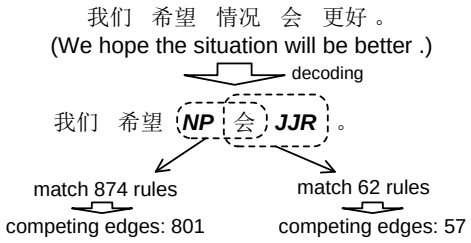

Figure 2: Edge competitions caused by different binarizations

The edge competition problem for SMT decoding is not addressed in previous work (Zhang et al., 2006; Huang, 2007) in which each SCFG rule is binarized in a fixed way. Actually the results of synchronous binarization may not be the only solution. As illustrated in Figure 1, the rule can also be binarized as binarization (b) which is shown with the dashed lines.

We think that this problem can be alleviated by choosing better binarizations for SMT decoders, since there is generally more than one binarization for a SCFG rule. In our investigation, about 96% rules that need to be binarized have more than one binarization under the contiguous constraint. As shown in binarization (b) (Figure 1), "会 JJR" is reduced first. In the decoder, the number of binary rules with the source-side "会 JJR" is 62, and the corresponding number of edges is 57 (Figure 2). The two numbers are both much smaller than those of "NP 会" in (a). This is an informative clue that the binarization (b) could be better than the binarization (a) based on the following: the probability of pruning the rule in (a) is higher than that in (b) as the rule in (b) has fewer competitors and has more chances to survive during pruning.

In this paper we propose a novel binarization method, aiming to find better binarizations to improve an SCFG-based machine translation system. We formulate the binarization optimization as a cost reduction process, where the cost is defined as the number of rules sharing a common source-side derivation in an SCFG. We present an algorithm, *iterative cost reduction* algorithm, to obtain better binarization for the SCFG learnt automatically from the training corpus. It can work with an efficient CKY-style binarizer to search for the lowest-cost binarization. We apply our method into a state-of-the-art string-to-tree SMT system. The experimental results show that our method outperforms the synchronous binarization method (Zhang et al., 2006) with over 0.8 BLEU scores on both NIST 2005 and NIST 2008 Chinese-to-English evaluation data sets.

2 Related Work

The problem of binarization originates from the parsing problem in which several binarization methods are studied such as left/right binarization (Charniak et al., 1998; Tsuruoka and Tsujii, 2004) and head binarization (Charniak et al., 2006). Generally, the pruning issue in SMT decoding is unnecessary for the parsing problem, and the accuracy of parsing does not rely on the binarization method heavily. Thus, many efforts on the binarization in parsing are made for the efficiency improvement instead of the accuracy improvement (Song et al., 2008).

Binarization is also an important topic in the research of syntax-based SMT. A synchronous

[1] For the case of *n*-gram language model integration, $2 \times (n-1)$ boundary words needs to be examined.

binarization method is proposed in (Zhang et al., 2006) whose basic idea is to build a left-heavy binary synchronous tree (Shapiro and Stephens, 1991) with a left-to-right shift-reduce algorithm. Target-side binarization is another binarization method which is proposed by Huang (2007). It works in a left-to-right way on the target language side. Although this method is comparatively easy to be implemented, it just achieves the same performance as the synchronous binarization method (Zhang et al., 2006) for syntax-based SMT systems. In addition, it cannot be easily integrated into the decoding of some syntax-based models (Galley et al., 2004; Marcu et al., 2006), because it does not guarantee contiguous spans on the source language side.

3 Synchronous Binarization Optimization by Cost Reduction

As discussed in Section 1, binarizing an SCFG in a fixed (left-heavy) way (Zhang et al., 2006) may lead to a large number of competing edges and consequently high risk of making search errors. Fortunately, in most cases a binarizable SCFG can be binarized in different ways, which provides us with an opportunity to find a better solution than the default left-heavy binarization. An ideal solution to this problem could be that we define an exact edge competition estimation function and choose the best binary SCFG based on it. However, even for the rules with a common source-side, generally it is difficult to estimate the exact number of competing edges in the dynamic SCFG parsing process for machine translation, because in order to integrate an *n*-gram language model, the actual number of edges not only depends on SCFG rules, but also depends on language model states which are specific to input sentences. Instead, we have to employ certain kinds of approximation of it. First we will introduce some notations frequently used in later discussions.

3.1 Notations

We use $G = \{R_i : X_i \rightarrow \alpha_i, \beta_i\}$ to denote an SCFG, where R_i is the i^{th} rule in G; X_i is the LHS (left hand side) non-terminal of R_i; α_i and β_i are the source-side and target-side RHS (right hand side) derivations of R_i respectively. We use $\mathcal{B}(G)$ to denote the set of equivalent binary SCFG of G. The goal of SCFG binarization is to find an appropriate binary SCFG $G' \in \mathcal{B}(G)$. For R_i, $\mathcal{B}(R_i) = \{v_{ij}\} \subseteq G' \in \mathcal{B}(G)$ is the set of equivalent binary rules based on R_i, where v_{ij} is the j^{th} binary rule in $\mathcal{B}(R_i)$. Figure 3 illustrates the meanings of these notations with a sample grammar.

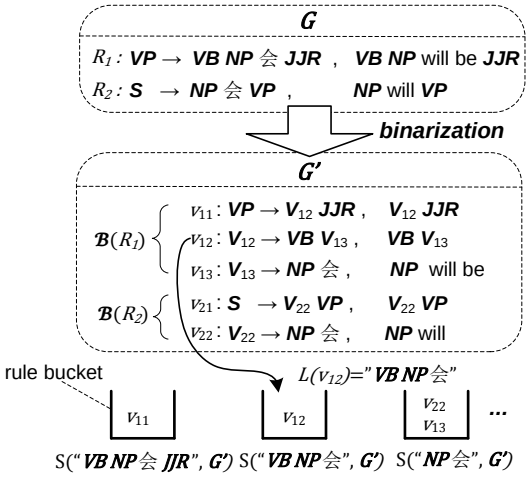

Figure 3: Binarization on a sample grammar

The function $L(\cdot)$ is defined to map a resulting binary rule $v_{ij} \epsilon G'$ to the sub-sequence in α_i derived from v_{ij}. For example, as shown in Figure 3, the binary rule v_{13} covers the source sub-sequence "NP 会" in R_1, so $L(v_{13}) =$ "NP 会". Similarly, $L(v_{12}) =$ "VB NP 会".

The function $L(\cdot)$ is used to group the rules in G' with a common right-hand side derivation for source language. Given a binary rule $v \in G'$, we can put it into a *bucket* in which all the binary rules have the same source sub-sequence $L(v)$. For example (Figure 3), as $L(v_{12}) =$ "VB NP 会", v_{12} is put into the bucket indexed by "VB NP 会". And v_{13} and v_{22} are put into the same bucket, since they have the same source sub-sequence "NP 会". Obviously, G' can be divided into a set of mutual exclusive rule buckets by $L(\cdot)$.

In this paper, we use $S(L(v), G')$ to denote the bucket for the binary rules having the source sub-sequence $L(v)$. For example, $S("NP\ 会", G')$ denotes the bucket for the binary rules having the source-side "NP 会". For simplicity, we also use $S(v, G')$ to denote $S(L(v), G')$.

3.2 Cost Reduction for SCFG Binarization

Given a binary SCFG G', it can be easily noticed that if a rule v in the bucket $S(v, G')$ can be applied to generate one or more new edges in SCFG parsing, any other rules in this bucket can also be applied because all of them can be reduced from the same underlying derivation $L(v)$.

Each application of other rules in the bucket $S(v, G')$ can generate competing edges with the one based on v. Intuitively, the size of bucket can be used to approximately indicate the actual number of competing edges on average, and reducing the size of bucket could help reduce the edges generated in a parsing chart by applying the rules in the bucket. Therefore, if we can find a method to greedily reduce the size of each bucket $S(v, G')$, we can reduce the overall expected edge competitions when parsing with G'.

However, it can be easily proved that the numbers of binary rules in any $G' \in \mathcal{B}(G)$ are same, which implies that we cannot reduce the sizes of all buckets at the same time – removing a rule from one bucket means adding it to another. Allowing for this fact, the excess edge competition example shown in Section 1 is essentially caused by the uneven distribution of rules among different buckets $S(\cdot)$. Accordingly, our optimization objective should be a more even distribution of rules among buckets.

In the following, we formally define a metric to model the evenness of rule distribution over buckets. Given a binary SCFG G' and a binary SCFG rule $v \in G'$, $Q(v)$ is defined as the *cost function* that maps v to the size of the bucket $S(v, G')$:

$$Q(v) = |S(v, G')| \tag{1}$$

Obviously, all the binary rules in $S(v, G')$ share a common cost value $|S(v, G')|$. For example (Figure 3), both v_{13} and v_{22} are put into the same bucket $S("NP \text{ 会}", G')$, so $Q(v_{13}) = Q(v_{22}) = 2$.

The cost of the SCFG G' is computed by summing up all the costs of SCFG rules in it:

$$Q(G') = \sum\nolimits_{v \in G'} Q(v) \tag{2}$$

Back to our task, we are to find an equivalent binary SCFG G' of G with the lowest cost in terms of the cost function $Q(.)$ given in Equation (2):

$$G^* = \text{argmin}_{G' \in \mathcal{B}(G)} Q(G') \tag{3}$$

Next we will show how G^* is related to the evenness of rule distribution among different buckets. Let $S(G') = \{S_1, \ldots, S_M\}$ be the set of rule buckets containing rules in G', then the value of $Q(G')$ can also be written as:

$$Q(G') = \sum\nolimits_{1 \le i \le M} |S_i|^2 \tag{4}$$

Assume $Y_i = |S_i|$ is an empirical distribution of a discrete random variable Y, then the square deviation of the empirical distribution is:

$$\sigma^2 = \frac{1}{M} \sum\nolimits_i (|S_i| - \bar{Y})^2 \tag{5}$$

Noticing that $\Sigma|S_i| = |G'|$ and $\bar{Y} = |G'|/M$, Equation (5) can be written as:

$$\sigma^2 = \frac{1}{M} \left(Q(G') - \frac{|G'|^2}{M} \right) \tag{6}$$

Since both M and $|G'|$ are constants, minimizing the cost function $Q(G')$ is equivalent to minimizing the square deviation of the distribution of rules among different buckets. A binary SCFG with the lower cost indicates the rules are more evenly distributed in terms of derivation patterns on the source language side.

3.3 Static Cost Reduction

Before moving on discussing the algorithm which can optimize Equation (3) based on rule costs specified in Equation (1), we first present an algorithm to find the optimal solution to Equation (3) if we have known the cost setting of G^* and can use the costs as static values during binarization. Using this simplification, the problem of finding the binary SCFG G^* with minimal costs can be reduced to find the optimal binarization $\mathcal{B}^*(R_i)$ for each rule R_i in G.

To obtain $\mathcal{B}^*(R_i)$, we can employ a CKY-style binarization algorithm which builds a compact binarization forest for the rule R_i in bottom-up direction. The algorithm combines two adjacent spans of α_i each time, in which two spans can be combined if and only if they observe the BTG constraints – their translations are either sequentially or reversely adjacent in β_i, the target-side derivation of R_i. The key idea of this algorithm is that we only use the binarization tree with the lowest cost of each span for later combination, which can avoid enumerating all the possible binarization trees of R_i using dynamic programming.

Let α_p^q be the sub-sequence spanning from p to q on the source-side, $v[p, q]$ be optimal binarization tree spanning α_p^q, $Q_v[p, q]$ be the cost of $v[p, q]$, and $Q_r[p, q]$ be the cost of any binary rules whose source-side is α_p^q, then the cost of optimal binarization tree spanning α_p^q can be computed as:

$$Q_v[p, q] = \min_{p \le k \le q-1} (Q_r[p, q] + Q_v[p, k] + Q_v[k+1, q])$$

The algorithm is shown as follows:

CYK-based binarization algorithm

Input: a SCFG rule R_i and the cost function $Q(.)$.
Output: the lowest cost binarization on R_i

1: **Function** CKYBINARIZATION(R_i, Q)
2: **for** l = 2 to n **do** ▷ Length of span
3: **for** p = 1 to $n - l + 1$ **do** ▷ Start of span
4: $q = p + l$ ▷ End of span
5: **for** $k = p$ to $q - 1$ **do** ▷ Partition of span
6: **if** not CONSECUTIVE($T(p,k)$, $T(k+1,q)$) **then next loop**
7: $Q_r[p,q] \leftarrow Q(\alpha_p^q)$
8: $curCost \leftarrow Q_r[p,q]+Q_v[p,k]+Q_v[k+1,q]$
9: **if** $curCost < minCost$ **then**
10: $minCost \leftarrow curCost$
11: $v[p,q] \leftarrow$ COMBINE($v[p,k]$, $v[k+1,q]$)
12: $Q_v[p,q] \leftarrow minCost$
13: **return** $v[1,n]$
14: **Function** CONSECUTIVE((*a*, *b*), (*c*, *d*))
15: **return** ($b = c - 1$) **or** ($d = a - 1$)

where n is the number of tokens (consecutive terminals are viewed as a single token) on the source-side of R_i. COMBINE($v[p,k]$, $v[k+1,q]$) combines the two binary sub-trees into a larger sub-tree over α_p^q. $T(p,q) = (a,b)$ means that the non-terminals covering α_p^q have the consecutive indices ranging from a to b on the target-side. If the target non-terminal indices are not consecutive, we set $T(p,q) = (-1,-1)$. $Q(\alpha_p^q) = Q(v')$ where v' is any rule in the bucket $S(\alpha_p^q, G')$.

In the algorithm, lines 9-11 implement dynamic programming, and the function CONSECUTIVE checks whether the two spans can be combined.

Table 1: Sub-sequences and corresponding costs

Figure 4 shows an example of the compact forest the algorithm builds, where the solid lines indicate the optimal binarization of the rule, while other alternatives pruned by dynamic programming are shown in dashed lines. The costs for binarization trees are computed based on the cost table given in Table 1.

The time complexity of the CKY-based binarization algorithm is $\Theta(n^3)$, which is higher than that of the linear binarization such as the synchronous binarization (Zhang et al., 2006). But it is still efficient enough in practice, as there are generally only a few tokens ($n < 5$) on the source-sides of SCFG rules. In our experiments, the linear binarization method is just 2 times faster than the CKY-based binarization.

3.4 Iterative Cost Reduction

However, $Q(\cdot)$ cannot be easily predetermined in a static way as is assumed in Section 3.3 because it depends on G' and should be updated whenever a rule in G is binarized differently. In our work this problem is solved using the *iterative cost reduction* algorithm, in which the update of G' and the cost function $Q(\cdot)$ are coupled together.

Iterative cost reduction algorithm

Input: An SCFG G
Output: An equivalent binary SCFG G' of G

1: **Function** ITERATIVECOSTREDUCTION(G)
2: $G' \leftarrow G_0$
3: **for** each $v \in G_0$ **do**
4: $Q(v) = |S(v, G_0)|$
5: **while** $Q(G')$ does not converge **do**
6: **for** each $R_i \in G$ **do**
7: $G_{[-R_i]} \leftarrow G' - \mathcal{B}(R_i)$
8: **for** each $v \in \mathcal{B}(R_i)$ **do**
9: **for** each $v' \in S(v, G')$ **do**
10: $Q(v') \leftarrow Q(v') - 1$
11: $\mathcal{B}(R_i) \leftarrow$ CKYBINARIZATION(R_i, Q)
12: $G' \leftarrow G_{[-R_i]} \cup \mathcal{B}(R_i)$
13: **for** each $v \in \mathcal{B}(R_i)$ **do**
14: **for** each $v' \in S(v, G')$ **do**
15: $Q(v') \leftarrow Q(v') + 1$
16: **return** G'

In the *iterative cost reduction* algorithm, we first obtain an initial binary SCFG G_0 using the synchronous binarization method proposed in (Zhang et al., 2006). Then G_0 is assigned to an iterative variable G'. The cost of each binary rule in G_0 is computed based on G_0 according to Equation (1) (lines 3-4 in the algorithm).

After initialization, G' is updated by iteratively finding better binarization for each rule in G. The basic idea is: for each R_i in G, we remove the current binarization result for R_i from G' (line 7), while the cost function $Q(\cdot)$ is updated accordingly since the removal of binary rule $v \in \mathcal{B}(R_i)$ results in the reduction of the size of the corresponding bucket $S(v, G')$. Lines 8-10 im-

plement the cost reduction of each binary rule in the bucket $S(v, G')$.

Next, we find the lowest cost binarization for R_i based on the updated cost function $Q(\cdot)$ with the CKY-based binarization algorithm presented in Section 3.3 (line 11).

At last, the new binarization for R_i is added back to G' and $Q(\cdot)$ is re-updated to synchronize with this change (lines 12-15). Figure 5 illustrates the differences between the static cost reduction and the iterative cost reduction.

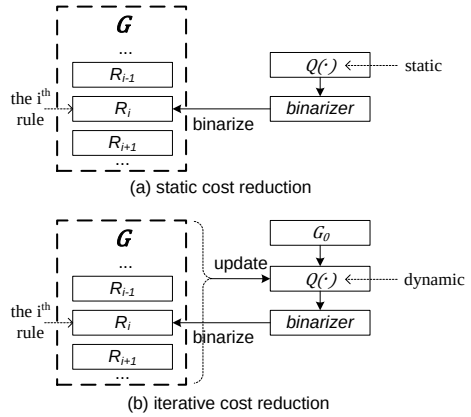

Figure 5: Comparison between the static cost reduction and the iterative cost reduction

The algorithm stops when $Q(G')$ does not decrease any more. Next we will show that $Q(G')$ is guaranteed not to increase in the iterative process.

For any $\mathcal{B}(R_i)$ on R_i, we have

$$Q\left(G_{[-R_i]} \cup \mathcal{B}(R_i)\right) = 2 \times Q\left(\mathcal{B}(R_i)\right) + |\mathcal{B}(R_i)| + Q\left(G_{[-R_i]}\right)$$

As both $|\mathcal{B}(R_i)|$ and $Q\left(G_{[-R_i]}\right)$ are constants with respect to $Q(\mathcal{B}(R_i))$, $Q\left(G_{[-R_i]} \cup \mathcal{B}(R_i)\right)$ is a linear function of $Q(\mathcal{B}(R_i))$, and the corresponding slope is positive. Thus $Q\left(G_{[-R_i]} \cup \mathcal{B}(R_i)\right)$ reaches the lowest value only when $Q(\mathcal{B}(R_i))$ reaches the lowest value. So $Q\left(G_{[-R_i]} \cup \mathcal{B}(R_i)\right)$ achieves the lowest cost when we replace the current binarization with the new binarization $\mathcal{B}^*(R_i)$ (line 12). Therefore $Q\left(G_{[-R_i]} \cup \mathcal{B}(R_i)\right)$ does not increase in the processing on each R_i (lines 7-15), and $Q(G')$ will finally converge to a local minimum when the algorithm stops.

4 Experiments

The experiments are conducted on Chinese-to-English translation in a state-of-the-art string-to-tree SMT system. All the results are reported in terms of case-insensitive BLEU4(%).

4.1 Experimental Setup

Our bilingual training corpus consists of about 350K bilingual sentences (9M Chinese words + 10M English words)[2]. Giza++ is employed to perform word alignment on the bilingual sentences. The parse trees on the English side are generated using the Berkeley Parser[3]. A 5-gram language model is trained on the English part of LDC bilingual training data and the Xinhua part of Gigaword corpus. Our development data set comes from NIST2003 evaluation data in which the sentences of more than 20 words are excluded to speed up the Minimum Error Rate Training (MERT). The test data sets are the NIST evaluation sets of 2005 and 2008.

Our string-to-tree SMT system is built based on the work of (Galley et al., 2006; Marcu et al., 2006), where both the minimal GHKM and SPMT rules are extracted from the training corpus, and the composed rules are generated by combining two or three minimal GHKM and SPMT rules. Before the rule extraction, we also binarize the parse trees on the English side using Wang et al. (2007) 's method to increase the coverage of GHKM and SPMT rules. There are totally 4.26M rules after the low frequency rules are filtered out. The pruning strategy is similar to the cube pruning described in (Chiang, 2007). To achieve acceptable translation speed, the beam size is set to 50 by default. The baseline system is based on the synchronous binarization (Zhang et al., 2006).

4.2 Binarization Schemes

Besides the baseline (Zhang et al., 2006) and iterative cost reduction binarization methods, we also perform right-heavy and random synchronous binarizations for comparison. In this paper, the random synchronous binarization is obtained by: 1) performing the CKY binarization to build the binarization forest for an SCFG rule; then 2) performing a top-down traversal of the forest. In the traversal, we randomly pick a feasible binarization for each span, and then go on the traversal in the two branches of the picked binarization.

Table 2 shows the costs of resulting binary SCFGs generated using different binarization methods. The costs of the baseline (left-heavy)

[2] LDC2003E14, LDC2003E07, LDC2005T06 and LDC2005T10

[3] http://code.google.com/p/berkeleyparser/

and right-heavy binarization are similar, while the cost of the random synchronous binarization is lower than that of the baseline method[4]. As expected, the iterative cost reduction method obtains the lowest cost, which is much lower than that of the other three methods.

Method	cost of binary SCFG G'
Baseline	4,897M
Right-heavy	5,182M
Random	3,479M
Iterative cost reduction	185M

Table 2: Costs of the binary SCFGs generated using different binarization methods.

4.3 Evaluation of Translations

Table 3 shows the performance of SMT systems based on different binarization methods. The iterative cost reduction binarization method achieves the best performance on the test sets as well as the development set. Compared with the baseline method, it obtains gains of 0.82 and 0.84 BLEU scores on NIST05 and NIST08 test sets respectively. Using the statistical significance test described by Koehn (2004), the improvements are significant ($p < 0.05$).

Method	Dev	NIST05	NIST08
Baseline	40.02	37.90	27.53
Right-heavy	40.05	37.87	27.40
Random	40.10	37.99	27.58
Iterative cost reduction	40.97*	38.72*	28.37*

Table 3: Performance (BLUE4(%)) of different binarization methods. * = significantly better than baseline ($p < 0.05$).

The baseline method and the right-heavy binarization method achieve similar performance, while the random synchronous binarization method performs slightly better than the baseline method, which agrees with the fact of the cost reduction shown in Table 2. A possible reason that the random synchronous binarization method can outperform the baseline method lies in that compared with binarizing SCFG in a fixed way, the random synchronous binarization tends to give a more even distribution of rules among buckets, which alleviates the problem of edge competition. However, since the high-frequency source sub-sequences still have high probabilities to be generated in the binarization and lead to the excess competing edges, it just achieves a very small improvement.

4.4 Translation Accuracy vs. Cost of Binary SCFG

We also study the impacts of cost reduction on translation accuracy over iterations in iterative cost reduction. Figure 6 and Figure 7 show the results on NIST05 and NIST08 test sets. We can see that the cost of the resulting binary SCFG drops greatly as the iteration count increases, especially in the first iteration, and the BLEU scores increase as the cost decreases.

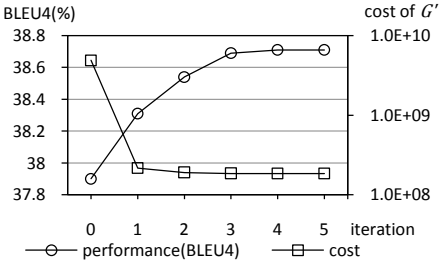

Figure 6: Cost of binary SCFG vs. BLEU4 (NIST05)

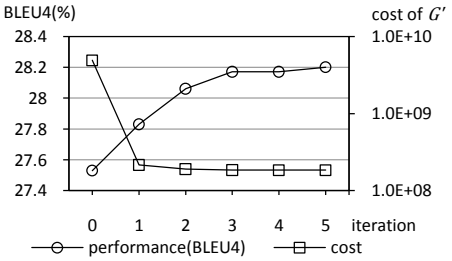

Figure 7: Cost of binary SCFG vs. BLEU4 (NIST08)

4.5 Impact of Beam Size

In this section, we study the impacts of beam sizes on translation accuracy as well as competing edges. To explicitly investigate the issue under large beam sizes, we use a subset of NIST05 and NIST08 test sets for test, which has 50 Chinese sentences of no longer than 10 words.

Figure 8 shows that the iterative cost reduction method is consistently better than the baseline method under various beam settings. Besides the experiment on the test set of short sentences, we also conduct the experiment on NIST05 test set. To achieve acceptable decoding speed, we range the beam size from 10 to 70. As shown in Figure 9, the iterative cost reduction method also outperforms the baseline method under various beam settings on the large test set.

Though enlarging beam size can reduce the search errors and improve the system performance, the decoding speed of string-to-tree SMT drops dramatically when we enlarge the beam size. The problem is more serious when long

[4] We perform random synchronous binarization for 5 times and report the average cost.

sentences are translated. For example, when the beam size is set to a larger number (e.g. 200), our decoder takes nearly one hour to translate a sentence whose length is about 20 on a 3GHz CPU. Decoding on the entire NIST05 and NIST08 test sets with large beam sizes is impractical.

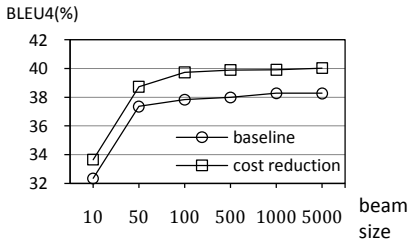

Figure 8: BLEU4 against beam size (small test set)

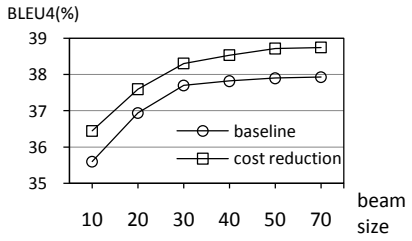

Figure 9: BLEU4 against beam size (NIST05)

Figure 10 compares the baseline method and the iterative cost reduction method in terms of translation accuracy against the number of edges proposed during decoding. Actually, the number of edges proposed during decoding can be regarded as a measure of the size of search space. We can see that the iterative cost reduction method outperforms the baseline method under various search effort.

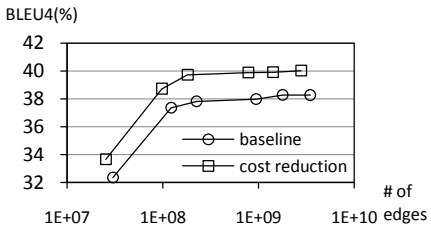

Figure 10: BLEU4 against competing edges

The experimental results of this section show that compared with the baseline method, the iterative cost reduction method can lead to much fewer edges (about 25% reduction) as well as the higher BLEU scores under various beam settings.

4.6 Edge Competition vs. Cost of Binary SCFG

In this section, we study the impacts of cost reduction on the edge competition in the chart cells of our CKY-based decoder. Two metrics are used to evaluate the degree of edge competition. They are the variance and the mean of the number of competing edges in the chart cells, where high variance means that in some chart cells the rules have high risk to be pruned due to the large number of competing edges. The same situation holds for the mean as well. Both of the two metrics are calculated on NIST05 test set, varying with the span length of chart cell.

Figure 11 shows the cost of resulting binary SCFG and the variance of competing edges against iteration count in iterative cost reduction. We can see that both the cost and the variance reduce greatly as the iteration count increases. Figure 12 shows the case for mean, where the reduction of cost also leads to the reduction of the mean value. The results shown in Figure 11 and Figure 12 indicate that the cost reduction is helpful to reduce edge competition in the chart cells.

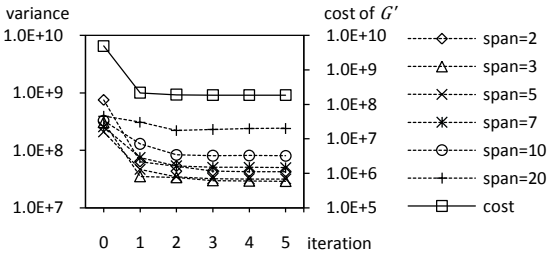

Figure 11: Cost of binary SCFG vs. variance of competing edge number (NIST05)

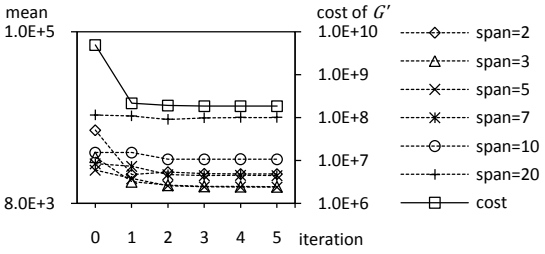

Figure 12: Cost of binary SCFG vs. mean of competing edge number (NIST05)

We also perform decoding without pruning (i.e. beam size = ∞) on a very small set which has 20 sentences of no longer than 7 words. In this experiment, the baseline system and our iterative cost reduction based system propose 14,454M and 10,846M competing edges respectively. These numbers can be seen as the real numbers of the edges proposed during decoding instead of an approximate number observed in the pruned search space. It suggests that our method can reduce the number of the edges in real search space effectively. A possible reason to

this result is that the cost reduction based binarization could reduce the probability of rule mismatching caused by binarization, which results in the reduction of the number of edges proposed during decoding.

5 Conclusion and Future Work

This paper introduces a new binarization method, aiming at choosing better binarization for SCFG-based SMT systems. We demonstrate the effectiveness of our method on a state-of-the-art string-to-tree SMT system. Experimental results show that our method can significantly outperform the conventional synchronous binarization method, which indicates that better binarization selection is very beneficial to SCFG-based SMT systems.

In this paper the cost of a binary rule is defined based on the competition among the binary rules that have the same source-sides. However, some binary rules with different source-sides may also have competitions in a chart cell. We think that the cost of a binary rule can be better estimated by taking the rules with different source-sides into account. We intend to study this issue in our future work.

Abstract

In this work we present a novel technique to rescore fragments in the Data-Oriented Translation model based on their contribution to translation accuracy. We describe three new rescoring methods, and present the initial results of a pilot experiment on a small subset of the Europarl corpus. This work is a proof-of-concept, and is the first step in directly optimizing translation decisions solely on the hypothesized accuracy of potential translations resulting from those decisions.

1 Introduction

The Data-Oriented Translation (DOT) (Poutsma, 2000) model is a tree-structured translation model, in which linked subtree fragments extracted from a parsed bitext are composed to cover a source-language sentence to be translated. Each linked fragment pair consists of a source-language side and a target-language side, similar to (Wu, 1997). Translating a new sentence involves composing the linked fragments into derivations so that a new source-language sentence is covered by the source tree fragments of the linked pairs, where the yields of the target-side derivations are the candidate translations. Derivations are scored according to their likelihood, and the translation is selected from the derivation pair with the highest score. However, we have no reason to believe that maximizing likelihood is the best way to maximize translation accuracy – likelihood and accuracy do not necessarily correlate well.

We can frame the problem as a search problem, where we are searching a space of derivations for the one that yields the highest scoring translation. By putting weights on the derivations in the search space, we wish to point the decoder in the direction of the optimal translation. Since we want the decoder to find the translation with the highest evaluation score, we would want to score the derivations with weights that correlate well with the particular evaluation measure in mind.

Much of the work in the MT literature has focused on the scoring of translation decisions made. (Yamada and Knight, 2001) follow (Brown et al., 1993) in using the noisy channel model, by decomposing the translation decisions modeled by the translation model into different types, and inducing probability distributions via maximum likelihood estimation over each decision type. This model is then decoded as described in (Yamada and Knight, 2002). This type of approach is also followed in (Galley et al., 2006).

There has been some previous work on accuracy-driven training techniques for SMT, such as MERT (Och, 2003) and the Simplex Armijo Downhill method (Zhao and Chen, 2009), which tune the parameters in a linear combination of various phrase scores according to a held-out tuning set. While this does tune the relative weights of the scores to maximize the accuracy of candidates in the tuning set, the scores themselves in the linear combination are not necessarily correlated with the accuracy of the translation. Tillmann and Zhang (2006) present a procedure to directly optimize the global scoring function used by a phrase-based decoder on the accuracy of the translations. Similarly to MERT, Tillmann and Zhang estimate the parameters of a weight vector on a linear combination of (binary) features using a global objective function correlated with BLEU (Papineni et al., 2002).

In this work, we prototype some methods for moving directly towards incorporating a measure of the translation quality of each fragment used, bringing DOT more into the mainstream of current SMT research. In Section 2 we describe probability-based DOT fragment scoring. In Section 3 we describe our rescoring setup and the

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 371–380,
Singapore, 6-7 August 2009.

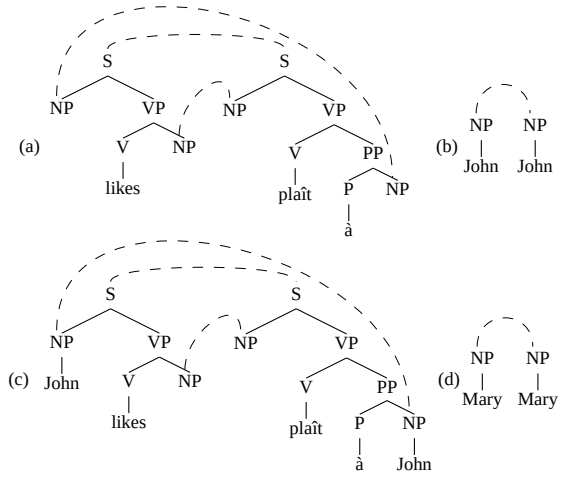

Figure 1: Example DOT Fragments.

three rescoring methods. In Section 4, we describe our experiments. In Section 5 we compare the results of rescoring the fragments with the three methods. In Section 6 we discuss some of the decisions that are affected by our rescoring methods. Finally, we discuss the next steps in training the DOT system by optimizing over a translation accuracy-based objective function in Section 7.

2 DOT Scoring

As described in previous work (Poutsma, 2000; Hearne and Way, 2003), DOT scores translations according to the probabilities of the derivations, which are in turn computed from the relative frequencies of linked tree fragments in a parallel treebank. Linked fragment pairs are conditionally independent, so the score of a derivation is the product of the probabilities of all the linked fragments used. To find the probability of a translation, DOT marginalizes over the scores of all derivations yielding the translation.

From a parallel treebank aligned at the subsentential level, we extract all possible linked fragment pairs by first selecting all linked pairs of nodes in the treebank to be the roots of a new subtree pair, and then selecting a (possibly empty) set of linked node pairs that are descendants of the newly selected fragment roots and deleting all subtree pairs dominated by these nodes. Leaves of fragments can either be terminals, or non-terminal *frontier nodes* where we can compose other fragments (c.f. (Eisner, 2003)). We give example DOT fragment pairs in Figure 1.

Given two subtree pairs $\langle s_1, t_1 \rangle$ and $\langle s_2, t_2 \rangle$, we can compose them using the DOT composition operator $\circ$ if the leftmost non-terminal frontier node of s_1 is equal to the root node of s_2, and the leftmost non-terminal frontier node of s_1's *linked counterpart* in t_1 is equal to the root node of t_2. The resulting tree pair consists of a copy of s_1 where s_2 has been inserted at the leftmost frontier node, and a copy of t_1 where t_2 has been inserted at the node linked to s_1's leftmost frontier node (Hearne and Way, 2003).

In Figure 1, fragment pair (a) is a fragment with two open substitution sites. If we compose this fragment pair with fragment pair (b), the source side composition must take place on the leftmost non-terminal frontier node (the leftmost NP). On the target side we compose on the frontier linked to the leftmost source side non-terminal frontier. The result is fragment pair (c). If we now compose the resulting fragment pair with fragment pair (d), we obtain a fragment pair with no open substitution sites whose source-side yield is *John likes Mary* and whose target-side yield is *Mary plaît à John*. Note that there are two different derivations using the fragment pairs in Figure 1 that result in the same fragment pair, namely (a) $\circ$ (b) $\circ$ (d), and (c) $\circ$ (d).

For a given linked fragment pair $\langle d_s, d_t \rangle$, the probability assigned to it is

$$P(\langle d_s, d_t \rangle) = \frac{|\langle d_s, d_t \rangle|}{\sum_{r(u_s)=r(d_s) \wedge r(u_t)=r(d_t)} |\langle u_s, u_t \rangle|} \quad (1)$$

where $|\langle d_s, d_t \rangle|$ is the number of times the fragment pair $\langle d_s, d_t \rangle$ is found in the bitext, and $r(d)$ is the root nonterminal of d. Essentially, the probability assigned to the fragment pair is the relative frequency of the fragment pair to the pair of nonterminals that root the fragments.

Then, with the assumption that DOT fragments are conditionally independent, the probability of a derivation is

$$\begin{aligned} P(\mathbf{d}) &= P(\langle d_s, d_t \rangle_1 \circ \ldots \circ \langle d_s, d_t \rangle_N) \\ &= \prod_i P(\langle d_s, d_t \rangle_i) \end{aligned} \quad (2)$$

In the original DOT formulation, DOT disambiguated translations according to their probabilities. Since a translation can have many possible derivations, to obtain the probability of a translation it is necessary to marginalize over the distinct derivations yielding a translation. The probability of a translation w_t of a source sentence w_s, is

given by (3):

$$P(w_s, w_t) = \sum_{\mathbf{d} \in \mathbf{D}} P(\mathbf{d}_{\langle w_s, w_t \rangle}) \quad (3)$$

and the translation is chosen so as to maximize (4):

$$\hat{w_t} = \underset{w_t}{\operatorname{argmax}} P(w_s, w_t) \quad (4)$$

Hearne and Way (2006) examined alternative disambiguation strategies. They found that rather than disambiguating on the translation probability, the translation quality would improve by disambiguating on the derivation probability, as in (5):

$$\hat{w_t} = \underset{\mathbf{d}}{\operatorname{argmax}} P(\mathbf{d}) \quad (5)$$

Our analysis suggest that this is because many derivations with very low probabilities generate the same, poor translation. When applying Equation (3) to marginalize over those derivations, the resulting score is higher for the poor translation than a better translation with fewer derivations but where the derivations had higher likelihood.

Using the DOT model directly is difficult – the number of fragments extracted from a parallel treebank is exponential in the size of the treebank. Therefore we use the Goodman reduction of DOT (Hearne, 2005) to create an isomorphic PCFG representation of the DOT model that is linear in the size of the treebank. The idea behind the Goodman reduction is that rather than storing fragments in the grammar and translating via composition, we simultaneously build up the fragments using the PCFG reduction and compose them together. To perform the reduction, we first relabel the two linked nodes (X, Y) with the new label X=Y. We then label each node in the parallel treebank with a unique Goodman index. Each binary-branching node and its two children can be internal or root/frontier. We add rules to the grammar reflecting the role that each node can take, keeping unaligned nodes as fragment-internal nodes. So in the case where a node and both of its children are aligned, we commit 8 rules into the grammar, as follows:

LHS → RHS1 RHS2	LHS+a → RHS1 RHS2
LHS → RHS1+b RHS2	LHS+a → RHS1+b RHS2
LHS → RHS1 RHS2+c	LHS+a → RHS1 RHS2+c
LHS → RHS1+b RHS+c	LHS+a → RHS1+b RHS2+c

A category label which ends in a '+' symbol followed by a Goodman index is fragment-internal and all other nodes are either fragment roots or

Figure 2: A parallel tree and its corresponding Goodman reduction.

frontier nodes. A fragment pair, then, is a pair of subtrees in which the root does not have an index, all internal nodes have indices, and all the leaves are either terminals or un-indexed nodes. We give an example Goodman reduction in Figure 2.

While we store the source grammar and the target grammar separately, we also keep track of the correspondence between source and target Goodman indices and can easily identify the alignments according to the Goodman indices. Probabilities for the PCFG rules are computed monolingually as in the standard Goodman reduction for DOP (Goodman, 1996). In decoding with the Goodman reduction, we first find the *n*-best parses on the source side, and for each source fragment, we construct the *k*-best fragments on the target side. We finally compute the bilingual derivation probabilities by multiplying the source and target derivation probabilities by the target fragment relative frequencies conditioned on the source fragment.

There are a few problems with a likelihood-based scoring scheme. First, it is not clear that if a fragment is more likely to be seen in training data then it is more likely to be used in a correct translation of an unseen sentence. In our analysis of the candidate translations of the DOT system, we observed that frequently, the highest-likelihood candidate translation output by the system was not the highest-accuracy candidate inferred. An additional problem is that, as described in (Johnson, 2002), the relative frequency estimator for DOP

(and by extension, DOT) is known to be biased and inconsistent.

3 Accuracy-Based Fragment Scoring

In our work, we wish to incorporate a measure of fragment accuracy into the scoring. To do so, we reformulate the scoring of DOT as log-linear rather than probabilistic, in order to incorporate non-likelihood features into the derivation scores. For all tree fragment pairs $\langle d_s, d_t \rangle$, let

$$l(\langle d_s, d_t \rangle) = \log(p(\langle d_s, d_t \rangle)) \quad (6)$$

The general form of a rescored tree fragment will be

$$s(\langle d_s, d_t \rangle) = \alpha_0 l(\langle d_s, d_t \rangle) + \sum_{i=1}^{k} \alpha_i f_i(\langle d_s, d_t \rangle) \quad (7)$$

where each α_i is the weight of that term in the final score, and each $f_i(d)$ is a feature. In this work, we only consider $f_1(d)$, an accuracy-based score, although in future work we will consider a wide variety of features in the scoring function, including combinations of the different scoring schemes described below, binary lexical features, binary source-side syntactic features, and local target side features. The score of a derivation is now given by (8):

$$\begin{aligned} s(d) &= s(\langle d_s, d_t \rangle_1 \circ \ldots \circ \langle d_s, d_t \rangle_N) \\ &= \sum_i s(\langle d_s, d_t \rangle_i) \end{aligned} \quad (8)$$

In order to disambiguate between candidate translations, we follow (Hearne and Way, 2006) by using Equation (5).

3.1 Structured Fragment Rescoring

In all our approaches, we rescore fragments according to their contribution to the accuracy of a translation. We would like to give fragments that contribute to good translations relatively high scores, and give fragments that contribute to bad translations relatively low scores, so that during decoding fragments that are known to contribute to good translations would be chosen over those that are known to contribute to bad translations. Furthermore, we would like to score each fragment in a derivation independently, since bad translations may contain good fragments, and vice-versa.

In practice, it is infeasible to rescore only those fragments seen during the rescoring process, due to the Goodman reduction for DOT. If we were to properly rescore each fragment, a new rule would need to be added to the grammar for each rule appearing in the fragment. Since the number of fragments is exponential, this would lead to a substantial increase in grammar size. Instead, we rescore the individual rules in the fragments, by evenly dividing the total amount of scoring mass among the rules of the particular fragment, and then assigning them the average of the rule scores over all fragments in which they appear. That is for each rule r in a fragment f consisting of $c_f(r)$ rules with score $\delta(f)$, the score of the rule is given as:

$$s(r) = \frac{\sum_{f:r \in f} \delta(f)/c_f(r)}{|f|} \quad (11)$$

This has the further advantage that we are allowing fragments that were unseen during tuning to be rescored according to previously seen fragment substructures.

To implement this scheme, we select a set of oracle translations for each sentence in the tuning data by evaluating all the candidate translations against the gold standard translation using the F-score (Turian et al., 2003), and selecting those with the highest F_1-measure, with exponent 1. We use GTM, rather than BLEU, because BLEU is not known to work well on a per-sentence level (Lavie et al., 2004) as needed for oracle selection. We then compare all the *target-side* fragments inferred in the translation process for each candidate translation against the fragments that yielded the oracles. There are two relevant parts of the fragments – the internal yields (i.e. the terminal leaves of the fragment) and the substitution sites (i.e. the frontiers where other fragments attach). We score the fragments rooted at the substitution sites separately from the parent fragment. We can uniquely identify the set of fragments that can be rooted at substitution sites by determining the span of the linked source-side derivation.

To compare two fragments, we define an edit distance between them. For a given fragment d, let $r(d)$ be the root of the fragment, let $r(d) \rightarrow rhs1$ be the left subtree of $r(d)$, and let $r(d) \rightarrow rhs2$ be the right subtree. The difference between a candidate fragment d_c and an oracle fragment d_{gs} is given by the equations in Table 1.

These equations define a minimum edit distance between two fragment trees, allowing subfragment order inversion, insertion, and deletion

$$\delta(d_c, d_{gs}) = \begin{cases} 0 & \text{if } d_c = d_{gs} \\ 1 & \text{if } d_c \neq d_{gs} \end{cases} \text{ Base case: } d_c \text{ and } d_{gs} \text{ are unary subtrees or substitution sites} \quad (9)$$

$$\delta(d_c, d_{gs}) = \min \begin{cases} \delta(d_c \rightarrow rhs1, d_{gs} \rightarrow rhs1) + \delta(d_c \rightarrow rhs2, d_{gs} \rightarrow rhs2), \\ \delta(d_c \rightarrow rhs2, d_{gs} \rightarrow rhs1) + \delta(d_c \rightarrow rhs1, d_{gs} \rightarrow rhs2) + 1, \\ \delta(d_c, d_{gs} \rightarrow rhs1) + |y(d_{gs} \rightarrow rhs2)|, \\ \delta(d_c, d_{gs} \rightarrow rhs2) + |y(d_{gs} \rightarrow rhs1)|, \\ \delta(d_c \rightarrow rhs1, d_{gs}) + |y(d_c \rightarrow rhs2)|, \\ \delta(d_c \rightarrow rhs2, d_{gs}) + |y(d_c \rightarrow rhs1)| \end{cases} \quad (10)$$

Table 1: The recursive relation defining the fragment difference between two fragments.

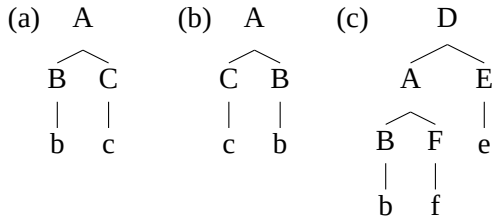

Figure 3: Comparing trees (a) and (b) with our distance metric yields a value of 1. The difference between trees (a) and (c) is 2, and for trees (b) and (c) the distance is 3.

as edit operations. For example, the only difference between trees (a) and (b) in Figure 3 is that their children have been inverted. To compare these trees using our distance metric, we first compute the first argument of the $\min$ function in Equation (10), directly comparing the structure of each immediate subtree. We then compute the second argument, obtaining the cost of performing an inversion, and finally compute the remaining arguments, assessing the cost of allowing each tree to be a direct subtree of the other. The result of this computation is 1, representing the inversion operation required to transform tree (a) into tree (b). If we compare trees (a) and (c) in Figure 3, we obtain a value of 2, given that the minimum operations required to transform tree (a) into tree (c) are inserting an additional subtree at the top level and then substituting the subtree rooted by C for the subtree rooted by F. If we compare tree (b) with tree (c) then the distance is 3, since we are now required to also replace the subtree rooted by C by the one rooted by B.

Since it is not efficient to compute the differences directly, we utilize common substructures and derive a dynamic programming implementation of the recursion. We compare each fragment against the set of oracle fragments for the same source span, and select the lowest cost as the score, assigning the candidate the negative difference between it and the oracle fragment it is most similar to, as in (12):

$$f(\langle d_s, d_t \rangle) = \max_{\langle d_s^o, d_t^o \rangle \in \mathbf{D}^o : d_s^o = d_s} -\delta(d_t, d_t^o) \quad (12)$$

In practice, given the Goodman reduction for DOT, we divide the fragment score by the number of rules in the fragment, and assign the average of those scores for each rule instance across all fragments rescored.

3.2 Normalized Structured Fragment Rescoring

In the structured fragment rescoring scheme, the scores that the fragments are assigned are the unnormalized edit distances between the two fragments. It may be better to normalize the fragment scores, rather than using the minimum number of tree transformations to convert one fragment into the other. We would expect that when comparing larger fragments, on average there would be more transformations needed to change one into the other than when comparing small fragments. However in the previous scheme, small fragments would have higher scores than large fragments, since fewer differences would be observed. The normalized score is given in (13):

$$f(\langle d_s, d_t \rangle) = \max_{\langle d_s^o, d_t^o \rangle \in \mathbf{D}^o : d_s^o = d_s} \log(1 - \delta(d_t, d_t^o)/ \max(|d_t|, |d_t^o|)) \quad (13)$$

Essentially, we are normalizing the edit distance by the maximum edit distance possible, namely the size of the largest fragment of the two being compared.

3.3 Fragment Surface Rescoring

The disadvantage of the minimum tree fragment edit approach is that it explicitly takes the internal

syntactic structure of the fragment into account. In comparing two fragments, they may have the same (or very similar) surface yields, but different internal structures. The previous approach would penalize the candidate fragment, even if its yield is quite close to the oracle. In this rescoring method, we extract the leaves of the candidate and oracle fragments, representing the substitution sites by the source span which their fragments cover. We then compare them using the Damerau-Levenshtein distance $\delta_{dl}(d_c, d_{gs})$ (Damerau, 1964) between the two fragment yields, and score them as in (14):

$$f(\langle d_s, d_t \rangle) = \max_{\langle d_s^o, d_t^o \rangle \in \mathbf{D}^o : d_s^o = d_s} -\delta_{dl}(d_t, d_t^o) \quad (14)$$

In Equation (14) we are selecting the maximal score for $\langle d_s, d_t \rangle$ from its comparison to all the possible corresponding oracle fragments. In this way, we are choosing to score $\langle d_s, d_t \rangle$ against the oracle fragment it is closest to.

4 Experiments

For our pilot experiments, we tested all the rescoring methods in the previous section on Spanish-to-English translation against the relative-frequency baseline. We randomly selected 10,000 sentences from the Europarl corpus (Koehn, 2005), and parsed and aligned the bitext as described in (Tinsley et al., 2009). From the parallel treebank, we extracted a Goodman reduction DOT grammar, as described in (Hearne, 2005), although on an order of magnitude greater amount of training data. Unlike (Bod, 2007), we did not use the unsupervised version of DOT, and did not attempt to scale up our amount of training data to his levels, although in ongoing work we are optimizing our system to be able to handle that amount of training data. To perform the rescoring, we randomly chose an additional 30K sentence pairs from the Spanish-to-English bitext. We rescored the grammar by translating the source side of the 10K training sentence pairs and 10K of the additional sentences, and using the methods in Section 3 to score the fragments derived in the translation process. We then performed the same experiment translating the full 40K-sentence set. Rules in the grammar that were not used during tuning were rescored using a default score defined to be the median of all scores observed.

Our system performs translation by first obtaining the n-best parses for the source sentences and then computing the k-best bilingual derivations for each source parse. In our experiments we used beams of $n = 10,000$ and $k = 5$. We also experimented with different values of α_0 and α_1 in Equation (7). We set these parameters manually, although in future work we will automatically tune them, perhaps using a MERT-like algorithm.

We tested our rescored grammars on a set of 2,000 randomly chosen Europarl sentences, and used a set of 200 randomly chosen sentences as a development test set. [1]

5 Results

Translation quality results can be found in Tables 2 and 3. In these tables, columns labeled i-j indicate that the corresponding system was trained using parameters $\alpha_0 = i$ and $\alpha_1 = j$ in Equation 7. Statistical significance tests for NIST and BLEU were performed using Bootstrap Resampling (Koehn, 2004).

[1] All sentences, including the ones used for training, were limited to a length of at most 20 words.

Table 4: Results on development test set. Rescoring on 40K sentences.

As Table 2 indicates, all three rescoring methods significantly outperform the relative frequency baseline. The unnormalized structured fragment rescoring method performed the best, with the largest improvement of 1.5 BLEU points, a 17.5% relative improvement. We note that the BLEU scores for both the baseline and the experiments are low. This is to be expected, because the grammar is extracted from a very small bitext especially when the heterogeneity of the Europarl corpus is considered. In our analysis, only 32.5 percent of the test sentences had a complete source-side parse, meaning that a lot of structural information is lost contributing to arbitrary target-side ordering. In these experiments we did not use an additional language model. DOT (and many other syntax-based SMT systems) essentially have the target language model encoded within the translation model, since the inferences derived during translations link source structures to target structures, so in principle, no additional language model should be necessary. Furthermore, we only evaluate against a single reference, which also contributes to the lowering of absolute scores. To provide a sanity check against a state-of-the-art system, we trained the Moses phrase-based MT system (Koehn et al., 2007) using our training corpus, using no language model and using uniform feature weights, to provide a fair comparison against our baseline. We used this system to decode our development test set, and as a result we obtained a BLEU score of 10.72, which is comparable to the score obtained by our baseline on the same set.

When we scale up to tuning on 40,000 sentences we see an improvement in BLEU scores as well, as shown in Table 3. When tuning on 40K sentences, we observe an increase of 1.81 BLEU points on the best-performing system, which is a 20.6% improvement over the baseline. We note that rescoring on 20K sentences rescores approximately 275,000 rules out of 655,000 in the grammar, whereas rescoring on 40K sentences rescores approximately 280,000.

To analyze the benefits of the rescored grammar, we set aside a separate development set that we decoded with the grammar trained on 40K sentences. The results are presented in Table 4. The analysis is presented in Section 6.

Interestingly, there is a large difference between the normalized and unnormalized versions of the SFR scoring scheme. Our analysis suggests that the differences are mostly due to numerical issues, namely the difference in magnitude between the NSFR scores and the likelihood scores in the linear combination, and the default value assigned when the NSFR score was zero. In ongoing work, we are working to address these issues.

For most configurations the difference between SFR and FSR was not statistically significant at $p = 0.05$. Our analysis indicated that surface differences tended to co-occur with structural differences. We hypothesize that as we scale up to larger and more ambiguous grammars, the system will infer more derivations with the same yields, rendering a larger difference between the quality of the two scoring mechanisms.

6 Discussion

To analyze the advantages and disadvantages of our approach over the baseline, we closely examined and compared the derivations made on the devset translation by the SFR-scored grammar and the likelihood-scored grammar. Although the BLEU scores are rather low, there were several sentences in which the SFR-scored grammar showed a marked improvement over the baseline. We observed two types of improvements.

The first is where the rescored grammar gave us translations that, while still generally bad, were closer to the gold standard than the baseline translation. For example, the Spanish sentence “Y en tercer lugar , está el problema de la aplicación uniforme del Derecho comunitario .” translates into the gold standard “Thirdly , we have the problem of the uniform application of Community law .” The baseline grammar translates the sentence as “on third place , Transport and Tourism . I are the problems of the implementation standardised is the EU law .” with a GTM F-Score of 0.378,

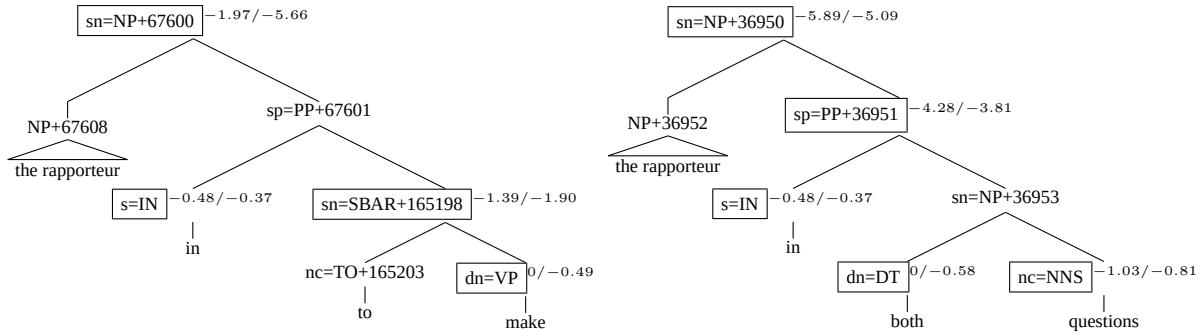

Figure 4: Target side of the highest-scoring translations for a sentence, according to the baseline system (left) and the SFR system (right). Boxed nodes are substitution sites. Scores in superscripts denote the score of the sub-derivation according to the baseline and to the SFR system.

and the rescored grammar outputs the translation "to there in the third place , I are the problem of the implementation standardised is the Community law .", with an F-Score of 0.5. While many of the fragments in the derivations that yielded these two translations differ, the ones we would like to focus on are the fragments that yield the translation of "comunitario". The grammar contains several competing unary fragment pairs for "comunitaro". In the baseline grammar, the pair (`aq=NNP` → `comunitario`, `aq=NNP` → `EU`) has a score of -0.693147, whereas the pair (`aq=NNP` → `comunitario`, `aq=NNP` → `Community`) has a score of -1.38629. In the rescored grammar however, (`aq=NNP` → `comunitario`, `aq=NNP` → `EU`) has a score of -0.762973, whereas (`aq=NNP` → `comunitario`, `aq=NNP` → `Community`) has a score of -0.74399. In effect, the rescoring scheme rescored the word alignment itself. This suggests that in future work, it may be possible to integrate a word aligner or fragment aligner directly into the MT training method.

The other improvement was where the baseline and the SFR-scored grammar output translations of roughly the same quality according to the evaluation measure, yet in terms of human evaluation, the SFR translation was much better than the baseline translation. For instance, our devset contained the Spanish sentence "Estoy de acuerdo con el ponente en dos cuestiones ." The baseline translation given is "I agree with the rapporteur in to make .", and the SFR-scored translation given is "I agree with the rapporteur in both questions .". While both translations have the same GTM score against the gold standard "I agree with the rapporteur on two issues .", clearly, the second one is of far higher quality than the first. As we can see in Figure 4, the derivation over the substring "in both questions" gets a higher score than "in to make" when translated with the rescored grammar. In the baseline, "en dos cuestiones" is not translated as a whole unit – rather, the derivation of "el ponente en dos cuestiones" is decomposed into four subderivations, yielding "el" "ponente" "en" "dos cuestiones", where each of those is translated separately, into "∅" "the rapporteur" "in" and "to make". The SFR-scored grammar, however, outputs a different bilingual derivation. The source is decomposed into five sub-derivations, one for each word, and each word is translated separately. Then, the rescored target fragments set the proper target-side word order and select the target-side words that maximize the score of the subderivation covering the source span. We note that in this example, the score of translating "dos" to "make" was higher than the score of translating "dos" to "both". However, the higher level target fragment that composed the translation of "dos" together with the translation of "cuestiones" yielded a higher score when composing "both questions" rather than "to make".

7 Conclusions and Future Work

The results presented above indicate that augmenting the scoring mechanism with an accuracy-based measure is a promising direction for translation quality improvement. It gives us a statistically significant improvement over the baseline, and our analysis has indicated that the system is indeed making better decisions, moving us a step closer towards the goal of making translation decisions based on the hypothesis of the resulting transla-

tion's accuracy.

Now that we have demonstrated that translation quality can be improved by incorporating a measure of fragment quality into the scoring scheme, our immediate next step is to optimize our system so that we can scale up to significantly larger training and tuning sets, and determine whether the improvements we have noted carry over when the likelihood is computed from more data. Afterwards, we will implement a training scheme to maximize an accuracy-based objective function, for instance, by minimizing the difference between the scores of the highest-scoring derivation and the oracle derivations, in effect maximizing the score of the highest-scoring translation.

The rescoring method presented in this paper need not be limited to DOT. Fragments can be thought of as analogous to phrases in Phrase-Based SMT systems – we could implement a similar rescoring system for phrase-based systems, where we generate several candidate translations for source sentences in a tuning set, and score each phrase used against the phrases used in a set of oracles. More broadly, we could potentially take any statistical MT system, and compare the features of all candidates generated against those of oracle translations, and score those that are closer to the oracle higher than those further away.

Finally, by explicitly framing the translation problem as a search problem, where we are divorcing the inferences in the search space (i.e. the model) from the path we take to find the optimal inference according to some criterion (i.e. the scoring scheme), we can remove some of the variability when comparing two models or scoring mechanisms (Lopez, 2009).

Abstract

Untranslated words still constitute a major problem for Statistical Machine Translation (SMT), and current SMT systems are limited by the quantity of parallel training texts. Augmenting the training data with paraphrases generated by pivoting through other languages alleviates this problem, especially for the so-called "low density" languages. But pivoting requires additional parallel texts. We address this problem by deriving paraphrases monolingually, using distributional semantic similarity measures, thus providing access to larger training resources, such as comparable and unrelated monolingual corpora. We present what is to our knowledge the first successful integration of a collocational approach to untranslated words with an end-to-end, state of the art SMT system demonstrating significant translation improvements in a low-resource setting.

1 Introduction

Phrase-based systems, flat and hierarchical alike (Koehn et al., 2003; Koehn, 2004b; Koehn et al., 2007; Chiang, 2005; Chiang, 2007), have achieved a much better translation coverage than word-based ones (Brown et al., 1993), but untranslated words remain a major problem in SMT. For example, according to Callison-Burch *et al.* (2006), a SMT system with a training corpus of 10,000 words learned only 10% of the vocabulary; the same system learned about 30% with a training corpus of 100,000 words; and even with a large training corpus of nearly 10,000,000 words it only reached about 90% coverage of the source vocabulary. Coverage of higher order n-gram levels is even harder. This problem plays a major part in reducing machine translation quality, as reflected by both automatic measures such as BLEU (Papineni et al., 2002) and human judgment tests. Improving translation coverage accurately is therefore important for SMT systems.

The first solution that might come to mind is to use larger parallel training corpora. However, current state-of-the-art SMT systems cannot learn from non-aligned corpora, while sentence-aligned parallel corpora (bitexts) are a limited resource (See Section 2 for discussion of automatically-compiled bitexts). Another direction might be to make use of non-parallel corpora for training. However, this requires developing techniques to extract alignments or translations from them, and in a sufficiently fast, memory-efficient, and scalable manner. One approach that can, in principle, better exploit both alignments from bitexts and make use of non-parallel corpora is the distributional collocational approach, e.g., as used by Fung and Yee (1998) and Rapp (1999). However, the systems described there are not easily scalable, and require pre-computation of a very large collocation counts matrix. Related attempts propose generating bitexts from comparable and "quasi-comparable" bilingual texts by iteratively bootstrapping documents, sentences, and words (Fung and Cheung, 2004), or by using a maximum entropy classifier (Munteanu and Marcu, 2005). Alignment accuracy remains a challenge for them.

Recent work has proposed augmenting the training data with paraphrases generated by pivoting through other languages (Callison-Burch et al., 2006; Madnani et al., 2007). This indeed alleviates the vocabulary coverage problem, especially for the so-called "low density" languages. However, these approaches still require bitexts where

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 381–390,
Singapore, 6-7 August 2009.

one side contains the original source language.

The paradigm described in this paper involves constructing monolingual distributional profiles (DPs; a.k.a. word association profiles, or co-occurrence vectors) of out-of-vocabulary words and phrases in the source language; then, generating paraphrase candidates from phrases that co-occur in similar contexts, and assigning them similarity scores. The highest ranking paraphrases are used to augment the translation phrase table. The table augmentation idea is similar to Callison-Burch *et al.*'s (Callison-Burch et al., 2006), but our proposed paradigm does not require using a limited resource such as parallel texts in order to generate paraphrases. Moreover, our proposed paradigm can, in principle, achieve large-scale acquisition of paraphrases with high semantic similarity. However, using parallel training texts in pivoting techniques offers the potential advantage of implicit translational knowledge, in the form of sentence alignments, while our approach is unguided in this respect. Therefore, we conducted experiments to find out how these relative advantages play out. We present here, to our knowledge for the first time, positive results of integrating distributional monolingually-derived paraphrases in an end-to-end state-of-the-art SMT system.

In the rest of this paper we discuss related work in Section 2, describe the distributional hypothesis and distributional profiles in Section 3, and present the monolingually-derived paraphrase generation system in Section 4. We report our experiments and results in Section 5, and conclude by discussing the implications and future research directions in Section 6.

2 Related Work

This is not the first to attempt to ameliorate the out-of-vocabulary (OOV) words problem in statistical machine translation, and other natural language processing tasks. This work is most closely related to that of Callison-Burch *et al.* (2006), who also translate source-side paraphrases of the OOV phrases. There, paraphrases are generated from bitexts of various language pairs, by "pivoting": translating the OOV phrases to an additional language (or languages) and back to the source language. The quality of these paraphrases is estimated by marginalizing translation probabilities to and from the additional language side(s) e, as follows: $p(f_2|f_1) = \sum_e p(e|f_1)p(f_2|e)$. A major disadvantage of their approach is that it relies on the availability of parallel corpora in other languages. While this works for English and many European languages, it is far less likely to help when translating from other source languages, for which bitexts are scarce or non-existent. Also, the pivoting approach is inherently noisy (in both the paraphrase candidates' correct sense, and their translational likelihood), and it is likely to fare poorly with out-of-domain translation. One advantage of the bitext-dependent pivoting approach is the use of the additional human knowledge that is encapsulated in the parallel sentence alignment. However, we argue that the ability to use much larger resources for paraphrasing should trump the human knowledge advantage.

More recently, Callison-Burch (2008) has improved performance of this pivoting technique by imposing syntactic constraints on the paraphrases. The limitation of such an approach is the reliance on a good parser (in addition to reliance on bitexts), but a good parser is not available in all languages, especially not in resource-poor languages. Another approach using a pivoting technique augments the human reference translation with paraphrases, creating additional translation "references" (Madnani et al., 2007). Both approaches have shown gains in BLEU score.

Barzilay and McKeown (2001) extract paraphrases from a monolingual parallel corpus, containing multiple translations of the same source. In addition to the parallel corpus usage limitations described above, this technique is further limited by the small size of such materials, which are even scarcer than the resources in the pivoting case.

Dolan *et al.* (2004) explore generating paraphrases by edit-distance and headlines of time- and topic-clustered news articles; they do not address the OOV problem directly, as their focus is sentence-level paraphrases; although they use a standard SMT measure, alignment error rate (AER), they only report results of the alignment quality, and not of an end-to-end SMT system. Much of the previous research largely focused on morphological analysis in order to reduce type sparseness; Callison-Burch *et al.* (2006) list some of the influential work in that direction.

Work that relies on the distributional hypothesis using bilingual comparable corpora (without the need for bitexts), typically uses a seed lexicon for "bridging" source language phrases

with their target languages paraphrases (Fung and Yee, 1998; Rapp, 1999; Diab and Finch, 2000). This approach is sometimes viewed as, or combined with, an information retrieval (IR) approach, and normalizes strength-of-association measures (see Section 3) with IR-related measures such as TF/IDF (Fung and Yee, 1998). To date, reported implementations suffer from scalability issues, as they pre-compute and hold in memory a huge collocation matrix; we know of no report of using this approach in an end-to-end SMT system.

Another approach aiming to reduce OOV rate concentrates on increasing parallel training set size without using more dedicated human translation (Resnik and Smith, 2003; Oard et al., 2003).

3 Collocational Profiles

The distributional hypothesis and distributional profiles. Natural language processing (NLP) applications that assume the distributional hypothesis (Harris, 1940; Firth, 1957) typically keep track of word co-occurrences in *distributional profiles* (a.k.a. *collocation vectors*, or *context vectors*). Each distributional profile DP_u (for some word u) keeps counts of co-occurrence of u with all words within a usually fixed distance from each of its occurrences (a *sliding window*) in some training corpus. More advanced profiles keep "strength of association" (SoA) information between u and each of the co-occurring words, which is calculated from the counts of u, the counts of the other word, their co-occurrence count, and the count of all words in the corpus (corpus size). The information on the other words with respect to u is typically kept in a vector whose dimensions correspond to all words in the training corpus. This is described in Equation (1), where V is the training corpus vocabulary:

$$DP_u = \{< w_i, SoA(u, w_i) > | u, w_i \in V\} \quad \text{for all } i \text{ s.t. } 1 \leq i \leq |V| \tag{1}$$

Semantic similarity between words u and v can be estimated by calculating the similarity (vector distance) between their profiles. Slightly more formally, the distributional hypothesis assumes that if we had access to the hypothetical true (psycholinguistic) semantic similarity function over word pairs, $semsim(u, v)$, then

$$\begin{aligned} &\forall u, v, w \in V, \\ &[semsim(u, v) > semsim(u, w)] \implies \\ &[psim(DP_u, DP_v) > psim(DP_u, DP_w)], \end{aligned} \tag{2}$$

where V is the language vocabulary, DP_{word} is the distributional profile of $word$, and $psim()$ is a 2-place vector similarity function (all further described below). Paraphrasing and other NLP applications that are based on the distributional hypothesis assume entailment in the reverse direction: the right-hand-side of Formula (2) (profile/vector similarity) entails the left-hand-side (semantic similarity).

The sliding window and word association (SoA) measures. Some researchers count *positional* collocations in a sliding window, i.e., the co-counts and SoA measures are calculated per relative position (e.g., for some word/token u, position 1 is the token immediately after u; position -2 is the token preceding the token that precedes u) (Rapp, 1999); other researchers use *non-positional* (which we dub here *flat*) collocations, meaning, they count all token occurrences within the sliding window, regardless of their positions in it relative to u (McDonald, 2000; Mohammad and Hirst, 2006). We use here flat collocations in a 6-token sliding window. Beside simple co-occurrence counts within sliding windows, other SoA measures include functions based on TF/IDF (Fung and Yee, 1998), mutual information (PMI) (Lin, 1998), conditional probabilities (Schuetze and Pedersen, 1997), chi-square test, and the log-likelihood ratio (Dunning, 1993).

Profile similarity measures. A profile similarity function $psim(DP_u, DP_v)$ is typically defined as a two-place function, taking vectors as arguments, each vector representing a distributional profile of some word u and v, respectively, and whose cells contain the SoA of u (or v) with each word ("collocate") in the known vocabulary. Similarity can be (and have been) estimated in several ways, e.g., the cosine coefficient, the Jaccard coefficient, the Dice coefficient, and the City-Block measure. The formula for the cosine function for similarity measure is given in Eq. (3):

$$psim(DP_u, DP_v) = cos(DP_u, DP_v) = \frac{\sum_{w_i \in V} SoA(u, w_i) SoA(v, w_i)}{\sqrt{\sum_{w_i \in V} SoA(u, w_i)^2} \sqrt{\sum_{w_i \in V} SoA(v, w_i)^2}} \quad (3)$$

In principle, any SoA can be used with any profile similarity measure. However, in practice, only some SoA/similarity measure combinations do well, and finding the best combination is still more art than science. Some successful combinations are cos_{CP} (Schuetze and Pedersen, 1997), Lin_{PMI} (Lin, 1998), $City_{LL}$ (Rapp, 1999), and Jensen–Shannon divergence of conditional probabilities (JSD_{CP}). We use here cosine of log-likelihood vectors (McDonald, 2000).

Phrasal distributional profiles. Word DPs can be generalized to phrasal DPs, simply by counting words that co-occur within a sliding window around the target phrase's occurrences (i.e., counting occurrences of words up to 6 words before or after the target phrase). For example, when building a DP for the target phrase *counting words* in the previous sentence, then *simply* is in relative position -2, and *sliding* is in relative position 5. Searching for similar phrasal DPs poses an additional challenge over the word DP case (see Section 4), but there is no additional difficulty in building the phrasal profile itself as described above. In preliminary experiments we found no gain in using phrasal collocates (i.e., count how many times a *phrase* of more than one word co-occurs in a sliding window around the target word/phrase).

4 Searching and Scoring Phrasal Paraphrases

The system design is as follows: upon receiving OOV phrase phr, build distributional profile DP_{phr}. Next, gather contexts: for each occurrence of phr, keep surrounding (left and right) context $L\_\_R$. For each such context, gather paraphrase candidates X which occur between L and R in other locations in the training corpus, i.e., all X such that LXR occur in the corpus. Finally, rank all candidates X, by building distributional profile DP_X and measuring profile similarity between DP_X and DP_{phr}, for each X. Output k-best candidates above a certain similarity score threshold. The rest of this section describes this system in more detail.

Build phrasal profile DP_{phr}. Build a profile of all word collocates, as described in Section 3. Use sliding window of size $MaxPos = 6$. If phr is very frequent (above some threshold of t occurrences), uniformly sample only t occurrences, multiplying the gathered co-counts by factor of $count(phr)/t$. We set $t = 10000$.

Gather context. The challenge in choosing the relevant context is this: if it is very short and/or very frequent (e.g., "the __ is"), then it might not be very informative, in the sense that many words can appear in that context (in this example, practically any noun); however, if it is too long (too specific), then it might not occur enough times elsewhere (or not at all) in the training corpus. Therefore, to balance between these two extremes, we use the following heuristics. Start small: Start with setting the left part of the context L to be a single word/token to the left of phrase phr. If it is stoplisted, append the next word to the left (now having a bigram left context instead of a unigram), and repeat until the left context is not in the stoplist. Repeat similarly for R, the context to the right of phr. Add the resulting $L\_\_R$ context to a context list. We stoplist "promiscuous" words, i.e., those that have more than $StoplistThreshold$ collocates in the training corpus, using the above $MaxPos$ parameter value. We also stoplist bigrams which occur more than t times and comprise solely from stoplisted unigrams.

Gather candidates. For each gathered context in the context list, gather all paraphrase candidate phrases X that connect left hand side context L with right hand side context R, i.e., gather all X such that the sequence LXR occurs in the corpus. In practice, to keep search complexity low, limit X to be up to length $MaxPhraseLen$. Also, to further speed up runtime, we uniformly sample the context occurrences.

Rank candidates. For each candidate X, build distributional profile DP_X, and evaluate $psim(DP_{phr}, DP_X)$.

Output k-best candidates. Output k-best paraphrase candidates for phrase phr, in descending order of similarity. We set $k = 20$. Filter out paraphrases with score less than $minScore$.

5 Experiment

We examined the application of the system's paraphrases to handling unknown phrases when translating from English into Chinese (E2C) and from Spanish into English (S2E). For all baselines we used the phrase-based statistical machine translation system Moses (Koehn et al., 2007), with the default model features, weighted in a log-linear framework (Och and Ney, 2002). Feature weights were set with minimum error rate training (Och, 2003) on a development set using BLEU (Papineni et al., 2002) as the objective function. Test results were evaluated using BLEU and TER (Snover et al., 2005). The phrase translation probabilities were determined using maximum likelihood estimation over phrases induced from word-level alignments produced by performing Giza++ training (Och and Ney, 2000) on both source and target sides of the parallel training sets. When the baseline system encountered unknown words in the test set, its behavior was simply to reproduce the foreign word in the translated output.

The paraphrase-augmented systems were identical to the corresponding baseline system, with the exception of additional (paraphrase-based) translation rules, and additional feature(s). Similarly to Callison-Burch *et al.* (2006), we added the following feature:

$$h(e,f) = \begin{cases} psim(DP_{f'}, DP_f) & \text{If phrase table entry } (e,f) \\ & \text{is generated from } (e,f') \\ & \text{using monolingually-} \\ & \text{derived paraphrases.} \\ 1 & \text{Otherwise,} \end{cases} \quad (4)$$

Note that it is possible to construct a new translation rule from f to e via more than one pair of source-side phrase and its paraphrase; e.g., if f_1 is a paraphrase of f, and so is f_2, and both f_1, f_2 translate to the same e, then both lead to the construction of the new rule translating f to e, but with potentially different feature scores.

In order to eliminate this duplicity and leverage over these alternate paths which can be used to increase our confidence level in the new rule, we did the following: For each paraphrase f of some source-side phrases f_i, with respective similarity scores $sim(f_i, f)$, we calculated an aggregate score $asim$ with a "quasi-online-updating" method as follows: $asim_i = (1 - asim_{i-1})sim(f_i, f)$, where $asim_0 = 0$. The aggregate score $asim$ is updated in an "online" fashion with each pair f_i, f as they are processed, but only the final $asim_k$ score is used, after all k pairs have been processed. Simple arithmetics can show that this method is insensitive to the order in which the paraphrases are processed. We only augment the phrase table with a single rule from f to e, and in it are the feature values of the phrase f_i for which the score $sim(f_i, f)$ was the highest.

5.1 English-to-Chinese Translation

For the English-Chinese (E2C) baseline system, we trained on the LCD Sinorama and FBIS tests (LCD2005T10 and LCD2003E14), and segmented the Chinese side with the Stanford Segmenter (Tseng et al., 2005). After tokenization and filtering, this bitext contained 231,586 lines (6.4M + 5.1M tokens). We trained a trigram language model on the Chinese side. We then split the bitext to 32 even slices, and constructed a reduced set of about 29,000 lines (sentences) by using only every eighth slice. The purpose of creating this subset model was to simulate a resource-poor language. See Table 1.

Set	# Tokens Source+Target
E2C 29K	0.8 + 0.6
E2C Full	6.4 + 5.1
bnc+apw	187
S2E 10K	0.3 + 0.3
S2E 20K	0.6 + 0.6
S2E 80K	2.3 + 2.3
wmt09	84
wmt09+acquis	139
wmt09+acquis+afp	402

Table 1: Training set sizes (million tokens).

For development, we used the Chinese-English NIST MT 2005 evaluation set, taking one of the English references as source, and the Chinese source as a single reference translation. We tested the system using the English-Chinese NIST MT evaluation 2008 test set with its four reference translations.

We augmented the E2C baseline models with paraphrases generated as described above, training on the British National Corpus (BNC) v3 (Burnard, 2000) and the first 3 million lines of the English Gigaword v2 APW, totaling 187M terms after tokenization, and number and punctuation removal. We generated paraphrases for phrases up to six tokens in length, and used an ar-

bitrary similarity threshold of $minScore = 0.3$. We experimented with three variants: adding a single additional feature for all paraphrases (*1-6grams*); using only paraphrases of unigrams (*1grams*); and adding two features, one only sensitive to unigrams, and the other only to the rest (*1 + 2-6grams*). All features had the same design as described in Section 5, each had an associated weight (as all other features), and all feature weights in each system, including the baseline, were tuned using a separate minimum error rate training for each system.

Results are shown in Table 2. For the E2C systems, for which we had four reference translations for the test set, we used shortest reference length, and used the NIST-provided script to split the output words to Chinese characters before evaluation. Statistical significance for the BLEU results were calculated using Koehn's (Koehn, 2004) pair-wise bootstrapping test with 95% confidence interval.

On the E2C 29,000-line subset, the augmented system had a significant 1.7 BLEU points gain over its baseline. On the full size model, results were negative. Note that our E2C full size baseline is reasonably strong: Its character-based BLEU score is slightly higher than the JHU-UMD system that participated in the NIST 2008 MT evaluation (constrained training track), although we used a subset of that system's training materials, and a smaller language model. Results there ranged from 15.69 to 30.38 BLEU (ignoring a seeming outlier of 3.93).

5.2 Spanish-to-English Translation

In order to to permit a more direct comparison with the pivoting technique, we also experimented with Spanish to English (S2E) translation, following Callison-Burch *et al.* (2006). For baseline we used the Spanish and English sides of the Europarl multilingual parallel corpus (Koehn, 2005), with the standard training, development, and test sets. We created training subset models of 10,000, 20,000, and 80,000 aligned sentences, as described in Callison-Burch *et al.* (2006). For better comparison with their pivoting system, we used the same 5-gram language model, development and test sets: For development, we used the Europarl dev2006 Spanish and English sides, and for testing we used the Europarl 2006 test set.

We trained the Spanish paraphrase generation system on the Spanish corpora available from

dataset	E2C model	BLEU	TER
29k	baseline	15.21	90.354
29k	1grams	16.87***	90.370
29k	1-6grams	16.54***	90.376
29k	1 + 2-6grams	**16.88*** **	**90.349**
Full	baseline	**22.17**	**90.398**
Full	1grams	21.64***	90.459
Full	1-6grams	21.75	90.421
Full	1 + 2-6grams	21.39***	90.433

Table 2: E2C Results: character-based BLEU and TER scores. All models have one additional feature over baseline, except for the "1 + 2-6" models that have one feature for unigrams and another feature for bigrams to 6-grams. Paraphrases with score $<$ .3 were filtered out. *** = significance test over baseline with $p < 0.0001$, using Koehn's (2004) pair-wise bootstrap resampling test for BLEU with 95% confidence interval.

Table 3: English paraphrases from E2C 29K-bitext systems.

the EACL 2009 Fourth Workshop on Statistical Machine Translation:[1] the Spanish side of the Europarl-v4, news training 2008, and news commentary 2009. We also re-trained adding the JRC-Acquis-v3 corpus[2] to the paraphrase training set, and then adding also the LDC Spanish Gigaword (LDC2006T12) and truncating the resulting corpus after the first 150M lines. We lowercased these training sets, tokenized and removed punctuation marks and numbers, and this resulted in training set sizes as detailed in Table 1. We generated paraphrases for phrases up to four tokens in length, and used two arbitrary similarity thresholds of $minScore = 0.3$ (as in the E2C experiments), and 0.6, for enforcing only higher precision paraphrasing.

We experimented with these variants: a single feature for all paraphrase (*1-4grams*); using only paraphrases of unigrams (*1grams*); and using two features: one only sensitive to unigrams and bigrams, and the other to the rest (*1-2 + 3-4grams*).

Results are shown in Table 4. We used BLEU over lowercased outputs to evaluate all S2E systems, and Koehn's significance test as above.

On the S2E 10,000-line subset, both the *1grams* and *1-4grams* models achieved significant gains of .4 BLEU points over the baseline. We concluded from a manual evaluation of the 10,000-line models that the two major weaknesses of the baseline system were (not surprisingly) number of untranslated (OOV) words / phrases, followed by number of superfluous words / phrases.

On the larger subset models, no system significantly outperformed the baseline. Note that our S2E baselines' scores are higher than those of Callison-Burch *et al.* (2006), since we evaluate lowercased outputs, instead of recased ones.

6 Discussion and Future Work

We have shown that monolingually-derived paraphrases, based on distributional semantic similarity measures over a source-language corpus, can improve the performance of statistical machine translation (SMT) systems. Our proposed method has the advantage of not relying on bitexts in order to generate the paraphrases, and therefore gives access to large amounts of monolingual training data, for which creating bitexts of equivalent size is generally unfeasible. We haven't trained our system on nearly as large a corpus as it can handle, and indeed we see this as a natural next step.

Results support the assumption that a larger monolingual paraphrase training set yields better paraphrases: our S2E *1-4grams* model performed significantly better than baseline when using *wmt09+aquis* for paraphrasing, but when only using *wmt09*, the model had a smaller advantage that did not reach significance. However, for the S2E *1grams* model, there was a slight decrease in performance when switching paraphrasing corpus from *wmt09+aquis* to *wmt09+aquis+afp*. This effect might be due to the genre or unbalanced content of the additional corpus, or perhaps it is the case that in this corpus size, paraphrases of higher-level ngrams benefitted from the additional text much more than paraphrases of unigrams did. The two rightmost columns in Table 5 show that although Spanish monolingual paraphrases for the unigram *baile* improve when using the larger corpus, (e.g., *danza* and *un balie* become the third and fourth top candidates, pushing much worse candidates far down the list), the two top paraphrase candidates remained unchanged. However, for the 4gram *a favor del informe*, antonymous candidates, which are bad and misleading for translation, are pushed down from the top first and third spots by synonymous, better candidates. Table 3 contains additional examples of good and bad top paraphrase candidates, also in English. Paraphrases of phrases seem to be of lower quality than those of unigrams, as can be seen at the bottom of the table.

These results also show that our method is especially useful in settings involving low-density languages or special domains: The smaller subset models, emulating a resource-poor language situation, show higher gains than larger models (which are supersets of the smaller subset models), when augmented with paraphrases derived from the same paraphrase training set. This was validated in two very different language pairs: English to Chinese, and Spanish to English. We believe that larger monolingual training sets for paraphrasing can help languages with richer resources, and we intend to explore this too.

Although the gains in the Spanish-English subsets are somewhat smaller than the pivoting technique reported in Callison-Burch *et al.* (2006), e.g., .7 BLEU for the 10k subset, we take these results as a proof of concept that can yield better

Table 6: S2E translation examples on 10k-bitext systems. Some translation differences are in bold.

gains with larger monolingual training sets. Pivoting techniques (translating back and forth) rely on limited resources (bitexts), and are subject to shifts in meaning due to their inherent double translation step. In contrast, large monolingual resources are relatively easy to collect, and our system involves only a single translation/paraphrasing step per target phrase. Table 5 also shows an exemplar comparison with the pivoting paraphrases used in Callison-Burch *et al.* (2006). It seems that the pivoting paraphrases might suffer more from having frequent function words as top candidates, which might be a by-product of their alignment "promiscuity". However, the top antonymous candidate problem seems to mainly plague the monolingual distributional paraphrases (but improves with larger corpora). See also Table 6.

The paraphrase quality remains an issue with this method (as with all other paraphrasing methods). Some possible ways of improving it, besides using larger corpora, are: using syntactic information (Callison-Burch, 2008), using semantic knowledge such as thesaurus or WordNet to perform word sense disambiguation (WSD) (Resnik, 1999; Mohammad and Hirst, 2006), improving the similarity measure, and refining the similarity threshold. We would like to explore ways of incorporating syntactic knowledge that do not sacrifice coverage as much as in Callison-Burch (2008); incorporating semantic knowledge to disambiguate phrasal senses; using context to help sense disambiguation (Erk and Padó, 2008); and optimizing the similarity threshold for use in SMT, for example on a held-out dataset: too high a threshold reduces coverage, while too low a threshold results in bad paraphrases and translation.

The method presented here is quite general, and therefore different similarity measures, including other corpus-based ones, can be plugged in to generate paraphrases. We are looking into using DPs with word-sense disambiguation: Since it has been shown that similarity is often judged by the semantic distance of the closest senses of the two target words (Mohammad and Hirst, 2006), and that paraphrases generated this way are likely to be of higher quality (Marton et al., 2009), hence it is also likely that the overall performance of an SMT system using them will also improve further.

One potential advantage of using bitexts for paraphrase generation is the usage of implicit human knowledge, i.e., sentence alignments. The concern that not using this knowledge would turn out detrimental to the performance of SMT systems augmented by paraphrases as described here was largely put to rest, as our method improved the tested subset SMT systems' quality.

A Comparison of Model Free versus Model Intensive Approaches to Sentence Compression

Tadashi Nomoto
National Institute of Japanese Literature
10-3 Midori Tachikawa
Tokyo 190-0014 Japan
nomoto@acm.org

Abstract

This work introduces a model free approach to sentence compression, which grew out of ideas from Nomoto (2008), and examines how it compares to a state-of-art model intensive approach known as Tree-to-Tree Transducer, or T3 (Cohn and Lapata, 2008). It is found that a model free approach significantly outperforms T3 on the particular data we created from the Internet. We also discuss what might have caused T3's poor performance.

1 Introduction

While there are a few notable exceptions (Hori and Furui, 2004; Yamagata et al., 2006), it would be safe to say that much of prior research on sentence compression has been focusing on what we might call 'model-intensive approaches,' where the goal is to mimic human created compressions as faithfully as possible, using probabilistic and/or machine learning techniques (Knight and Marcu, 2002; Riezler et al., 2003; Turner and Charniak, 2005; McDonald, 2006; Clarke and Lapata, 2006; Cohn and Lapata, 2007; Cohn and Lapata, 2008; Cohn and Lapata, 2009). Because of this, the question has never been raised as to whether a model free approach – where the goal is not to model what humans would produce as compression, but to provide compressions just as useful as those created by human – will offer a viable alternative to model intensive approaches. This is the question we take on in this paper.[1]

[1]One caveat would be in order. By *model free approach*, we mean a particular approach which does not furnish any parameters or weights that one can train on human created compressions. An approach is said to be *model-intensive* if it does. So as far as the present paper is concerned, we might do equally well with a mention of 'model free' ('model-intensive') replaced with 'unsupervised' ('supervised'), or 'non-trainable' ('trainable').

An immediate benefit of the model-free approach is that we could free ourselves from the drudgery of collecting gold standard data from humans, which is costly and time-consuming. Another benefit is intellectual; it opens up an alternative avenue to addressing the problem of sentence compression hitherto under-explored.

Also breaking from the tradition of previous research on sentence compression, we explore the use of naturally occurring data from the Internet as the gold standard. The present work builds on and takes further an approach called 'Generic Sentence Trimmer' (GST) (Nomoto, 2008), demonstrating along the way that it could be adapted for English with relative ease. (GST was originally intended for Japanese.) In addition, to get a perspective on where we stand with this approach, we will look at how it fares against a state-of-the-art model intensive approach known as 'Tree-to-Tree Transducer' (T3) (Cohn, 2008), on the corpus we created.

2 Approach

Nomoto (2008) discusses a two-level model for sentence compression in Japanese termed 'Generic Sentence Trimmer' (GST), which consists of a component dedicated to producing grammatical sentences, and another to reranking sentences in a way consistent with gold standard compressions. For the convenience's sake, we refer to the generation component as 'GST/g' and the ranking part as 'GST/r.' The approach is motivated largely by the desire to make compressed sentences linguistically fluent, and what it does is to retain much of the syntax of the source sentence as it is, in compression, which stands in contrast to Filippova and Strube (2007) and Filippova and Strube (2008), who while working with dependency structure (as we do), took the issue to be something that can be addressed by selecting and reordering constituents that are deemed relevant.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 391–399,
Singapore, 6-7 August 2009.

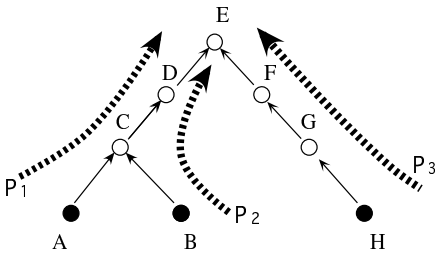

Figure 1: Dependency Structure for 'ABCDEFGH'

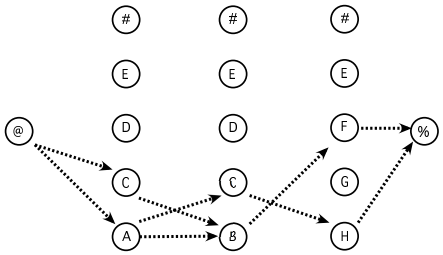

Figure 2: TDP Trellis and POTs.

Getting back to GST, let us consider a sentence,

(1) The bailout plan was likely to depend on private investors to purchase the toxic assets that wiped out the capital of many banks.

Among possible compressions GST/g produces for the sentence are:

(2)

a. The bailout plan was likely to depend on private investors to purchase the toxic assets.

b. The bailout plan was likely to depend on private investors.

c. The bailout plan was likely to depend on investors.

d. The bailout plan was likely.

Notice that they do not differ much from the source sentence (1), except that they get some of the parts chopped off. In the following, we talk about how this could done systematically.

3 Compression with Terminating Dependency Paths

One crucial feature of GST is the notion of *Terminating Dependency Paths* or TDPs, which enables us to factorize a dependency structure into a set of independent fragments. Consider string s = ABCDEFGH with a dependency structure as shown in Figure 1. We begin by locating terminal nodes, i.e., those which have no incoming edges, depicted as filled circles in Figure 1. Next we find a dependency (singly linked) path from each terminal node to the root (labeled E). This would give us three paths p_1 = A-C-D-E, p_2 = B-C-D-E, and p_3 = H-G-F-E (represented by dashed arrows in Figure 1).

Given TDPs, we set out to find a set $\mathcal{T}$ of all suffixes for each TDP, including an empty string, which would look like:

$$\mathcal{T}(p_1) = \{\langle \text{A C D E}\rangle, \langle \text{C D E}\rangle, \langle \text{D E}\rangle, \langle \text{E}\rangle, \langle\rangle\}$$
$$\mathcal{T}(p_2) = \{\langle \text{B C D E}\rangle, \langle \text{C D E}\rangle, \langle \text{D E}\rangle, \langle \text{E}\rangle, \langle\rangle\}$$
$$\mathcal{T}(p_3) = \{\langle \text{G F E}\rangle, \langle \text{F E}\rangle, \langle \text{E}\rangle, \langle\rangle\}$$

Next we combine suffixes, one from each set $\mathcal{T}$, while removing duplicates if any. Combining, for instance, $\langle \text{A C D E}\rangle \in \mathcal{T}(p_1)$, $\langle \text{C D E}\rangle \in \mathcal{T}(p_2)$, and $\langle \text{G F E}\rangle \in \mathcal{T}(p_3)$, would produce {A C D E G F}, which we take to correspond to a string ACDEGF, a short version of s.

As a way of doing this systematically, we put TDPs in a trellis format as in Figure 2, each file representing a TDP, and look for a path across the trellis, which we call 'POT.' It is easy to see that traveling across the trellis (while keeping record of nodes visited), gives you a particular way in which to combine TDPs: thus in Figure 2, we have three POTs, C-B-F, A-C-H, and A-B-F, giving rise to BCDEF, ACDEFGH, and ABCDEF, respectively (where '&' denotes a starting node, '%' an ending node, and '#' an empty string). Note that the POT in effect determines what compression we get.

Take for instance a POT C-B-F. To get to a compression, we first expand C-B-F to get $\{\langle \underline{\text{C}}\ \text{D E}\rangle_1, \langle \underline{\text{B}}\ \text{C D E}\rangle_2, \langle \underline{\text{F}}\ \text{E}\rangle_3\}$ (call it $\mathcal{E}$(C-B-F)). (Note that each TDP is trimmed to start with a node at a corresponding position of the POT.) Next we take a union of TDPs treating them as if they were sets: thus $\bigcup \mathcal{E}(\text{C-B-F}) = \{\text{B C D E F}\}$ = BCDEF.

4 N-Best Search over TDP Trellis

An obvious problem of this approach, however, is that it spawns hundreds of thousands of possible POTs. We would have as many as $5^3 = 125$ of them for the eight-character long string in Figure 1.

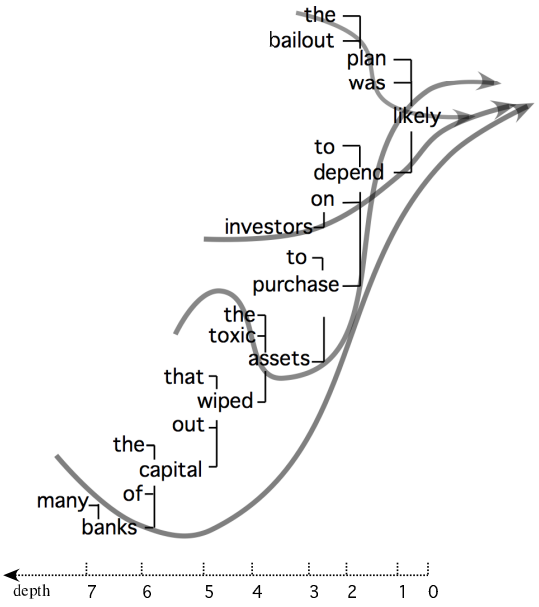

Figure 3: Dependency Structure

What we propose to deal with this problem is to call on a particular ranking scheme to discriminate among candidates we get. Our scheme takes the form of Equation 3 and 4.

$$W(x) = \mathrm{idf}(x) + \exp(-depth(x)) \quad (3)$$

$$S(\mathbf{p}) = \sum_{x_0,\ldots x_n \in \mathcal{E}(\mathbf{p})} W(x_i) \quad (4)$$

$depth(x)$ indicates the distance between x and the root, measured by the number of edges one need to walk across to reach the root from x. Figure 3 shows how the depth is gauged for nodes in a dependency structure. $\mathrm{idf}(x)$ represents the log of the inverse document frequency of x. The equations state that the score S of a POT $\mathbf{p}$ is given as the sum of weights of nodes that comprise $\bigcup \mathcal{E}(\mathbf{p})$.

Despite their being simple, equations 3 and 4 nicely capture our intuition about the way the trimming or compression should work, i.e., that the deeper we go down the tree, or the further away you are from the main clause, the less important information becomes. Putting aside $\mathrm{idf}(x)$ for the moment, we find in Figure 3, $W(assets) > W(capital) > W(banks) > W(many)$. Also depicted in the figure are four TDPs starting with *many*, *the* (preceding *toxic*), *investors*, and *the* (preceding *bailout*).

Finally, we perform a best-first search over the trellis to pick N highest scoring POTs, using Forward DP/Backward A* (Nagata, 1994), with the evaluation function given by Equation 4. We found that the beam search, especially when used with a small width value, does not work as well as the best first search as it tends to produce very short sentences due to its tendency to focus on inner nodes, which generally carry more weights compared to those on the edge. In the experiments described later, we limited the number of candidates to explore at one time to 3,000, to make the search computationally feasible.

Table 1: Drop-me-not rules. A '|' stands for *or*. 'a:b' refers to an element which has both a and b as attributes. Relation names such as *nsubj*, *aux*, *neg*, etc., are from de Marneffe et al. (2006).

R1.	VB	$\Rightarrow$	*nsubj* | *aux* | *neg* | *mark*
R2.	VB	$\Rightarrow$	WDT | WRB
R3.	JJ	$\Rightarrow$	*cop*
R4.	NN	$\Rightarrow$	*det* | *cop*
R5.	NN	$\Rightarrow$	*poss:*WP (='whose')
R6.	$\star$	$\Rightarrow$	*conj* & *cc*

5 'Drop-me-not' Rules

Simply picking a path over the TDP trellis (POT), however, does not warrant the grammaticality of the tree that it generates. Take for instance, a dependency rule, '*likely*←*plan*, *was*, *depend*,' which forms part of the dependency structure for sentence (1). It gives rise to three TDPs, ⟨*plan*, *likely*⟩, ⟨*was*, *likely*⟩, and ⟨*depend*, *likely*⟩. Since we may arbitrarily choose either of the two tokens in each TDP with a complete disregard for a syntagmatic context that each token requires, we may end up with sequences such as '*plan likely*,' '*plan was likely*,' or '*plan likely depend*' (instances of a same token are collapsed into one). This would obviously suggest the need for some device to make the way we pick a path syntagmatically coherent.

The way we respond to the issue is by introducing explicit prohibitions, or 'drop-me-not' rules for POTs to comply with. Some of the major rules are shown in Table 1. A 'drop-me-not' rule (DMN) applies to a local dependency tree consisting of a parent node and its immediate child nodes. The intent of a DMN rule is to prohibit any one of the elements specified on the right hand side of the arrow from falling off in the presence of the head

node; they will be gone only if their head node is.

R1 says that if you have a dependency tree headed by VB with *nsubj*, *aux*, *neg*, or *mark* among its children, they should stay with VB; R2 prohibits against eliminating a WDT or WRB-labeled word in a dependency structure headed by VB; R6 disallows either *cc* or *conj* to drop without accompanying the other, for whatever type the head node assumes.

In Table 2, we find some examples that motivate the kinds of DMN rules we have in Table 1. Note that given the DMNs, the generation of '*was likely depend*,' or '*plan likely depend*' is no longer possible for the sentence in Figure 3.

6 Reranking with CRFs

Pipelining GST/g with CRFs allows us to tap into a host of features found in the sentence that could usefully be exploited toward generating compression, and requires no significant change in the way it is first conceived in Nomoto (2008), in order to make it work for English. It simply involves translating an output by GST/g into the form that allows the use of CRFs; this could be done simply by labeling words included in compression as '1' and those taken out as '0,' which would produce a binary representation of an output generated by GST/g. Given a source sentence $\mathbf{x}$ and a set $G(S)$ of candidate compressions generated by GST/g $-$ represented in binary format $-$ we seek to solve the following,

$$\mathbf{y}^{\star} = \underset{\mathbf{y} \in G(S)}{\operatorname{argmax}}\, p(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}). \tag{5}$$

where $\mathbf{y}^{\star}$ could be found using regular linear-chain CRFs (Lafferty et al., 2001). θ stands for model parameters. In building CRFs, we made use of features representing lexical forms, syntactic categories, dependency relations, TFIDF, whether a given word appears in the title of an article, and the left and right lexical contexts of a word.

7 T3

Cohn and Lapata (2008; 2009) are a recent attempt to bring a machine learning framework known as 'Structured SVM' to bear on sentence compression and could be considered to be among the current state-of-art approaches. Roughly speaking, their approach or what they call 'Tree-to-Tree Transducer' (T3) takes sentence compression to be the problem of classifying the source sentence with its target sentence, where one seeks to find some label $\mathbf{y}$, which represents a compression, for a given source sentence $\mathbf{x}$, that satisfies the following equation,

$$f(\mathbf{x};\mathbf{w}) = \underset{\mathbf{y} \in \mathcal{Y}}{\operatorname{argmax}}\, F(\mathbf{y},\mathbf{x};\mathbf{w}), \tag{6}$$

and

$$F(\mathbf{y},\mathbf{x};\mathbf{w}) = \langle \mathbf{w}, \Psi(\mathbf{y},\mathbf{x}) \rangle, \tag{7}$$

where $\mathbf{w}$, a vector representing model parameters, is determined in such a way that for a target class $\mathbf{y}$ and a prediction $\mathbf{y}'$, $F(\mathbf{x},\mathbf{y};\mathbf{w}) - F(\mathbf{x},\mathbf{y}';\mathbf{w}) > \Delta(\mathbf{y},\mathbf{y}') - \xi$, $\forall \mathbf{y}' \neq \mathbf{y}$; $\Delta(\mathbf{y},\mathbf{y}')$ represents a loss function and ξ a slack variable (Tsochantaridis et al., 2005). $\Psi(\mathbf{y},\mathbf{x})$ represents a vector of features culled from $\mathbf{y}$ and $\mathbf{x}$, and $\langle \cdot,\cdot \rangle$ a dot product.

For each of the rules used to derive a source sentence, T3 makes a decision on how or whether to transform the rule, with reference to $\langle \cdot,\cdot \rangle$, which takes into account such features as the number of terminals, root category, and lengths of frontiers, which eventually leads to a compression via a chart style dynamic programming.

Table 3: RSS item and its source

R *Two bombings rocked Iraq today, killing at least 80 in attacks at a shrine in Karbala and a police recruiting station in Ramadi.*

S *Baghdad, Jan. 5 – Two new suicide bombings rocked Iraq today, killing at least 80 in an attack at a shrine in the Shiite city of Karbala and a police recruiting station in the Sunni city of Ramadi.*

8 Corpus

Parting ways with previous work on sentence compression, which heavily relied on humans to create gold standard references, this work has a particular focus on using data gathered from RSS feeds, which if successful, could open a door to building gold standard data in large quantities rapidly and with little human effort. The primary objective of the present work is to come up with an approach capable of exploiting naturally occurring data as references for compression. So we are interested

Table 2: Examples. $a \Leftarrow_r b$ means that b stands in an r-relation to a.

in finding out how GST compares with T3 from this particular perspective.

We gathered RSS feeds at NYTimes.com over a period of several months, across different sections, including INTERNATIONAL, NATIONAL, NYREGION, BUSINESS, and so forth, out of which we randomly chose 2,000 items for training data and 116 for testing data. For each RSS summary, we located its potential source sentence in the linked page, using a similarity metric known as SoftTFIDF (Cohen et al., 2003).[2] Table 4 gives a rundown on areas items came from and how many of them we collected for each of these areas.

For the ease of reference, we refer to a corpus of the training and test data combined as 'NYT-RSS,' and let 'NYT-RSS(A)' denote the training part of NYT-RSS, and 'NYT-RSS(B)' the testing part.

[2]SoftTFIDF is a hybrid of the TFIDF scheme and an edit-distance model known as Jaro-Winkler(Cohen et al., 2003).

9 Experiments

We ran the Stanford Parser on NYT-RSS to extract dependency structures for sentences involved, to be used with GST/g (de Marneffe et al., 2006; Klein and Manning, 2003). We manually developed 28 DMN rules out of NYT-RSS(A), some of which are presented in Table 1. An alignment between the source sentence and its corresponding gold standard compression was made by SWA or a standard sequence alignment algorithm by Smith and Waterman (1981). Importantly, we set up GST/g and T3 in such a way that they rely on the same set of dependency analyses and alignments when they are put into operation. We trained T3 on NYT-RSS(A) with default settings except for "–epsilon" and "–delete" options which we turned off, as preliminary runs indicated that their use led to a degraded performance (Cohn, 2008). We also set the loss function as was given in the default settings. We trained both GST/r, and T3 on NYT-RSS(A).

We ran GST/g and GST/g+r, i.e., GST/r pipelined with GST/g, varying the compression rate from 0.4 to 0.7. This involved letting GST/g rank candidate compressions by $S(\mathbf{p})$ and then choosing the first candidate to satisfy a given compression rate, whereas GST/g+r was made to output the highest ranking candidate as measured by $p(\mathbf{y} \mid \mathbf{x}; \theta)$, which meets a particular compression rate. It should be emphasized, however, that in T3, varying compression rate is not something the user has control over; so we accepted whatever output

Table 5: Results on NYT-RSS. '*'-marked figures mean that performance of GST/g is different from that of GST/g+r (on the comparable CompR) at 5% significance level according to t-test. The figures indicate average ratings.

Model	CompR	Intelligibility	Rep.
GST/g+r	0.446	2.836	2.612
GST/g	0.469	3.095	2.569
GST/g+r	0.540	2.957	2.767
GST/g	0.562	3.069	3.026*
GST/g+r	0.632	2.931	2.957
GST/g	0.651	3.060	3.259*
GST/g+r	0.729	3.155	3.345
GST/g	0.743	3.328	3.621*
T3	0.353	1.750	1.586
Gold Std.	0.657	4.776	3.931

T3 generated for a given sentence.

Table 5 shows how GST/g, GST/g+r, and T3 performed on NYT-RSS, along with the gold standard, on a scale of 1 to 5. Ratings were solicited from 4 native speakers of English. 'CompR' indicates compression rate. 'Intelligibility' means how well the compression reads; 'representativeness' how well the compression represents its source sentence. Table 6 presents a guideline for rating, describing what each rating should mean, which was also presented to human judges to facilitate evaluation.

The results in Table 5 indicate a clear superiority of GST/g and GST/g+r over T3, while differences in intelligibility between GST/g and GST/g+r were found not statistically significant. What is intriguing, though, is that GST/g produced performance statistically different in representativeness from GST/g+r at 5% level as marked by the asterisk.

Shown in Table 8 are examples of compression created by GST/g+r, GST/g and T3, together with gold standard compressions and relevant source sentences. One thing worth noting about the examples is that T3 keeps inserting out-of-the-source information into compression, which obviously has done more harm than good to compression.

Table 6: Guideline for Rating

MEANING	EXPLANATION	SCORE
very bad	For intelligibility, it means that the sentence in question is rubbish; no sense can be made out of it. As for representativeness, it means that there is no way in which the compression could be viewed as representing its source.	1
poor	Either the sentence is broken or fails to make sense for the most part, or it is focusing on points of least significance in the source.	2
fair	The sentence can be understood, though with some mental effort; it covers some of the important points in the source sentence.	3
good	The sentence allows easy comprehension; it covers most of important points talked about in the source sentence.	4
excellent	The sentence reads as if it were written by human; it gives a very good idea of what is being discussed in the source sentence.	5

10 Why T3 fails

It is interesting and worthwhile to ask what caused T3, heavily clad in ideas from the recent machine learning literature, to fail on NYT-RSS, as opposed to the 'CLwritten' and 'CLspoken' corpora on which T3 reportedly prevailed compared to other approaches (Cohn and Lapata, 2009). The CLwritten corpus comes from written sources in the British National Corpus and the American News Text corpus; the CLspoken corpus comes from transcribed broadcast news stories (cf. Table 7).

We argue that there are some important differences between the NYT-RSS corpus and the CLwritten/CLspoken corpora that may have led to T3's poor record with the former corpus.

The CLwritten and CLspoken corpora were created with a specific purpose in mind: namely to assess the compression-by-deletion approach. So their authors had a very good reason to limit gold standard compressions to those that can be arrived at only through deletion; annotators were carefully instructed to create compression by deleting words from the source sentence in a way that preserves the gist of the original sentence. By contrast, NYT-RSS consists of naturally occurring compressions sampled from live feeds on the Internet, where relations between compression and its source sentence are often not as straightforward. For instance, to arrive at a compression in NYT-RSS in Table 7 involves replacing *race* with *her plans to unseat senator Hillary Rodam Clinton*, which is obviously beyond what is possible with the deletion based approach.

In CLwritten and CLspoken, on the other hand, compressions are constructed out of parts that appear *in verbatim* in the original sentence, as Table 7 shows: thus one may get to the compressions by simply crossing off words from the original sentence.

To see whether there is any significant difference among NYT-RSS, CLwritten and CLspoken, we examined how well gold standard compressions are aligned with source sentences on each of the corpora, using SWA. Table 9 shows what we found. Parenthetical numbers represent how many pairs of compression and source are found in each corpus. A larger score means a tighter alignment between gold standard compression and its source sentence: we find in Table 9 that CLspoken has a source sentence more closely aligned with its compression than CLwritten, whose alignments are more closely tied than NYT-RSS's.

Figure 4 (found in the previous page) shows how SWA alignment scores are distributed over each of the corpora. CLwritten and CLspoken have peaks at around 0, with an almost entire mass of scores concentrating in an area close to or above 0. This means that for the most of the cases in either CLwritten or CLspoken, compression is very similar in form to its source. In contrast, NYT-RSS has a heavy concentration of scores in a stretch between -5 and -10, indicating that for the most of time, the overlap between compression and its source is rather modest compared to CLwritten and CLspoken.

So why does T3 fails on NYT-RSS? Because NYT-RSS contains lots of alignments that are only weakly related: in order for T3 to perform well, the training corpus should be made as free of spurious data as possible, so that most of the alignments are rated over and around 0 by SWA. Our concern is that such data may not happen naturally, as the density distribution of NYT-RSS shows, where the majority of alignments are found far below 0, which could raise some questions about the robustness of T3.

11 Conclusions

This paper introduced the model free approach, GST/g, which works by creating compressions only in reference to dependency structure, and looked at how it compares with a model intensive approach T3 on the data gathered from the Internet. It was found that the latter approach appears to crucially rely on the way the corpus is constructed in order for it to work, which may mean a huge compromise.

Interestingly enough, GST/g came out a winner on the particular corpus we used, even outperform-

ing its CRFs harnessed version, GST/g+r in representativeness. This suggests that we might gain more by improving fluency of GST/g than by focusing on its representativeness, which in any case came close to that of human at 70% compression level. The future work should also look at how the present approach fares on CLwritten and CLspoken, for which T3 was found to be effective.

Natural Language Generation with Tree Conditional Random Fields

Abstract

This paper presents an effective method for generating natural language sentences from their underlying meaning representations. The method is built on top of a *hybrid tree* representation that jointly encodes both the meaning representation as well as the natural language in a tree structure. By using a tree conditional random field on top of the hybrid tree representation, we are able to explicitly model phrase-level dependencies amongst neighboring natural language phrases and meaning representation components in a simple and natural way. We show that the additional dependencies captured by the tree conditional random field allows it to perform better than directly inverting a previously developed hybrid tree semantic parser. Furthermore, we demonstrate that the model performs better than a previous state-of-the-art natural language generation model. Experiments are performed on two benchmark corpora with standard automatic evaluation metrics.

1 Introduction

One of the ultimate goals in the field of natural language processing (NLP) is to enable computers to converse with humans through human languages. To achieve this goal, two important issues need to be studied. First, it is important for computers to capture the meaning of a natural language sentence in a meaning representation. Second, computers should be able to produce a human-understandable natural language sentence from its meaning representation. These two tasks are referred to as semantic parsing and natural language generation (NLG), respectively.

In this paper, we use corpus-based statistical methods for constructing a natural language generation system. Given a set of pairs, where each pair consists of a natural language (NL) sentence and its formal meaning representation (MR), a learning method induces an algorithm that can be used for performing language generation from other previously unseen meaning representations.

A crucial question in any natural language processing system is the representation used. Meaning representations can be in the form of a tree structure. In Lu et al. (2008), we introduced a *hybrid tree* framework together with a probabilistic generative model to tackle semantic parsing, where tree structured meaning representations are used. The hybrid tree gives a natural joint tree representation of a natural language sentence and its meaning representation.

A joint generative model for natural language and its meaning representation, such as that used in Lu et al. (2008) has several advantages over various previous approaches designed for semantic parsing. First, unlike most previous approaches, the generative approach models a simultaneous generation process for both NL and MR. One elegant property of such a joint generative model is that it allows the modeling of both semantic parsing and natural language generation within the same process. Second, the generative process proceeds as a recursive top-down Markov process in a way that takes advantage of the tree structure of the MR. The hybrid tree generative model proposed in Lu et al. (2008) was shown to give state-of-the-art accuracy in semantic parsing on benchmark corpora.

While semantic parsing with hybrid trees has been studied in Lu et al. (2008), its inverse task – NLG with hybrid trees – has not yet been explored. We believe that the properties that make the hybrid trees effective for semantic parsing also make them effective for NLG. In this paper, we develop systems for the generation task by building

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 400–409,
Singapore, 6-7 August 2009.

on top of the generative model introduced in Lu et al. (2008) (referred to as the LNLZ08 system).

We first present a baseline model by directly "inverting" the LNLZ08 system, where an NL sentence is generated word by word. We call this model the *direct inversion model*. This model is unable to model some long range global dependencies over the entire NL sentence to be generated. To tackle several weaknesses exhibited by the baseline model, we next introduce an alternative, novel model that performs generation at the phrase level. Motivated by conditional random fields (CRF) (Lafferty et al., 2001), a different parameterization of the conditional probability of the hybrid tree that enables the model to encode some longer range dependencies amongst phrases and MRs is used. This novel model is referred to as the *tree* CRF*-based model*.

Evaluation results for both models are presented, through which we demonstrate that the tree CRF-based model performs better than the direct inversion model. We also compare the tree CRF-based model against the previous state-of-the-art model of Wong and Mooney (2007). Furthermore, we evaluate our model on a dataset annotated with several natural languages other than English (Japanese, Spanish, and Turkish). Evaluation results show that our proposed tree CRF-based model outperforms the previous model.

2 Related Work

There have been substantial earlier research efforts on investigating methods for transforming MR to their corresponding NL sentences. Most of the recent systems tackled the problem through the architecture of chart generation introduced by Kay (1996). Examples of such systems include the chart generator for Head-Driven Phrase Structure Grammar (HPSG) (Carroll et al., 1999; Carroll and Oepen, 2005; Nakanishi et al., 2005), and more recently for Combinatory Categorial Grammar (CCG) (White and Baldridge, 2003; White, 2004). However, most of these systems only focused on surface realization (inflection and ordering of NL words) and ignored lexical selection (learning the mappings from MR domain concepts to NL words).

The recent work by Wong and Mooney (2007) explored methods for generation by inverting a system originally designed for semantic parsing. They introduced a system named WASP^{-1} that employed techniques from statistical machine translation using Synchronous Context-Free Grammar (SCFG) (Aho and Ullman, 1972). The system took in a linearized MR tree as input, and translated it into a natural language sentence as output. Unlike most previous systems, their system integrated both lexical selection and surface realization in a single framework. The performance of the system was enhanced by incorporating models borrowed from PHARAOH (Koehn, 2004). Experiments show that this new hybrid system named WASP^{-1}++ gives state-of-the-art accuracies and outperforms the direct translation model obtained from PHARAOH, when evaluated on two corpora. We will compare our system's performance against that of WASP^{-1}++ in Section 5.

3 The Hybrid Tree Framework and the LNLZ08 System

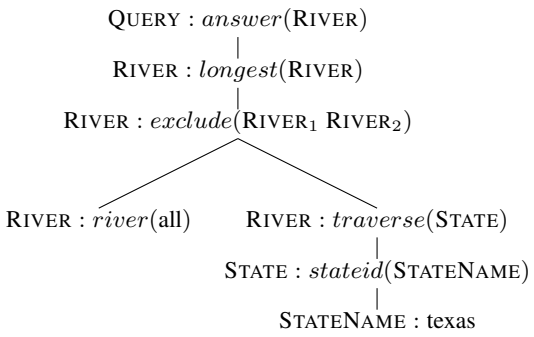

Figure 1: An example MR paired with its NL sentence.

Following most previous works in this area (Kate et al., 2005; Ge and Mooney, 2005; Kate and Mooney, 2006; Wong and Mooney, 2006; Lu et al., 2008), we consider MRs in the form of tree structures. An example MR and its corresponding natural language sentence are shown in Figure 1. The MR is a tree consisting of nodes called MR productions. For example, the node "QUERY : $answer$(RIVER)" is one MR production. Each MR production consists of a semantic category ("QUERY"), a function symbol ("$answer$") which can be optionally omitted, as well as an argument list which possibly contains

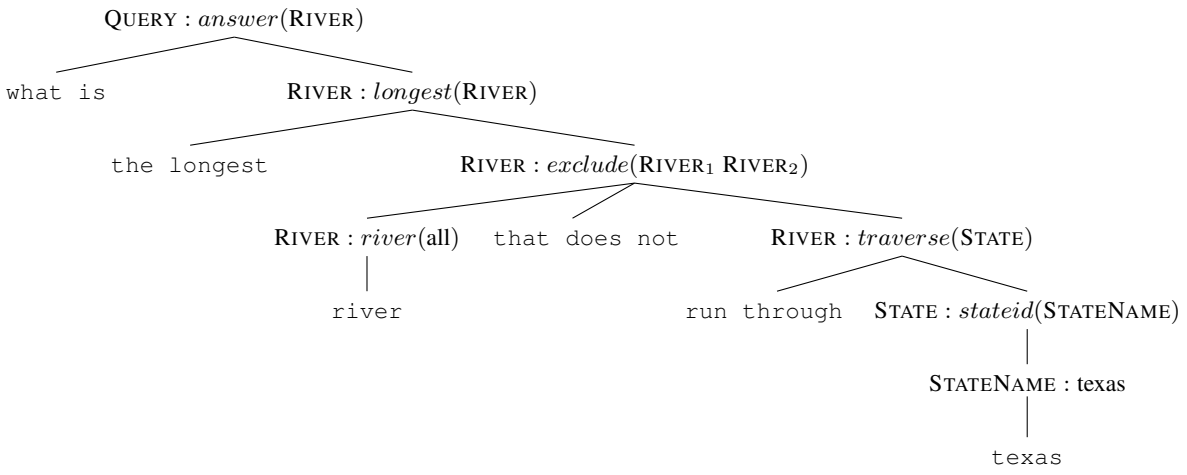

Figure 2: One possible hybrid tree $\mathcal{T}_1$

child semantic categories ("RIVER").

Now we give a brief overview of the hybrid tree framework and the LNLZ08 system that was presented in Lu et al. (2008). The training corpus required by the LNLZ08 system contains example pairs $\mathbf{d}^{(i)} = (\widehat{\mathbf{m}}^{(i)}, \widehat{\mathbf{w}}^{(i)})$ for $i = 1 \ldots N$, where each $\widehat{\mathbf{m}}^{(i)}$ is an MR, and each $\widehat{\mathbf{w}}^{(i)}$ is an NL sentence. The system makes the assumption that the entire training corpus is generated from an underlying generative model, which is specified by the parameter set Ω.

The parameter set Ω includes the following: the MR model parameter $\rho(m_j|m_i, \arg_k)$ which models the generation of an MR production m_j from its parent MR production m_i as its k-th child, the emission parameter $\theta(t|m_i, \Lambda)$ that is responsible for generation of an NL word or a semantic category t from the MR production m_i (the parent of t) under the context Λ (such as the token to the left of the current token), and the pattern parameter $\phi(r|m_i)$, which models the selection of a *hybrid pattern* r that defines globally how the NL words and semantic categories are interleaved given a parent MR production m_i. All these parameters are estimated from the corpus during the training phase. The list of possible hybrid patterns is given in Table 1 (at most two child semantic categories are allowed – MR productions with more child semantic categories are transformed into those with two).

In the table, m refers to the MR production, the symbol **w** denotes an NL word sequence and is optional if it appears inside []. The symbol $\mathcal{Y}$ and $\mathcal{Z}$ refer to the first and second semantic category under the MR production m respectively.

# RHS	Hybrid Pattern	# Patterns
0	$m \rightarrow$ **w**	1
1	$m \rightarrow$ [**w**]$\mathcal{Y}$[**w**]	4
2	$m \rightarrow$ [**w**]$\mathcal{Y}$[**w**]$\mathcal{Z}$[**w**]	8
	$m \rightarrow$ [**w**]$\mathcal{Z}$[**w**]$\mathcal{Y}$[**w**]	8

Table 1: The list of possible hybrid patterns, [] denotes optional

The generative process recursively creates MR productions as well as NL words at each generation step in a top-down manner. This process results in a *hybrid tree* for each MR-NL pair. The list of children under each MR production in the hybrid tree forms a *hybrid sequence*. One example hybrid tree for the MR-NL pair given in Figure 1 is shown in Figure 2. In this hybrid tree $\mathcal{T}_1$, the list of children under the production RIVER : $longest$(RIVER) forms the hybrid sequence "`the longest` RIVER : $exclude$(RIVER$_1$ RIVER$_2$)". The yield of the hybrid tree is exactly the NL sentence. The MR can also be recovered from the hybrid tree by recording all the internal nodes of the tree, subject to the reordering operation required by the hybrid pattern.

To illustrate, consider the generation of the hybrid tree $\mathcal{T}_1$ shown in Figure 2. The model first generates an MR production from its parent MR production (empty as the MR production is the root in the MR). Next, it selects a hybrid pattern $m \rightarrow \mathbf{w}\mathcal{Y}$ from the predefined list of hybrid patterns, which puts a constraint on the set of all allowable hybrid sequences that can be generated: the hybrid sequence must be an NL word sequence

followed by a semantic category. Finally, actual NL words and semantic categories are generated from the parent MR production. Now the generation for one level is complete, and the above process repeats at the newly generated MR productions, until the complete NL sentence and MR are both generated.

Mathematically, the above generative process yields the following formula that models the joint probability for the MR-NL pair, assuming the context Λ for the emission parameter is the preceding word or semantic category (*i.e.*, the bigram model is assumed, as discussed in Lu et al. (2008)):

$$\begin{aligned} & p\big(\mathcal{T}_1(\widehat{\mathbf{w}}, \widehat{\mathbf{m}})\big) \\ &= \rho(\textsc{Query} : answer(\textsc{River}) | -, \arg_1) \\ &\times \phi(m \rightarrow \mathbf{w}\mathcal{Y} | \textsc{Query} : answer(\textsc{River})) \\ &\times \theta(\texttt{what} | \textsc{Query} : answer(\textsc{River}), \texttt{BEGIN}) \\ &\times \theta(\texttt{is} | \textsc{Query} : answer(\textsc{River}), \texttt{what}) \\ &\times \theta(\textsc{River} | \textsc{Query} : answer(\textsc{River}), \texttt{is}) \\ &\times \theta(\texttt{END} | \textsc{Query} : answer(\textsc{River}), \textsc{River}) \\ &\times \rho(\textsc{River} : longest(\textsc{River}) | \\ &\textsc{Query} : answer(\textsc{River}), \arg_1) \times \ldots \end{aligned} \quad (1)$$

where $\mathcal{T}_1(\widehat{\mathbf{w}}, \widehat{\mathbf{m}})$ denotes the hybrid tree $\mathcal{T}_1$ which contains the NL sentence $\widehat{\mathbf{w}}$ and MR $\widehat{\mathbf{m}}$.

For each MR-NL pair in the training set, there can be potentially many possible hybrid trees associated with the pair. However, the correct hybrid tree is completely unknown during training. The correct hybrid tree is therefore treated as a hidden variable. An efficient inside-outside style algorithm (Baker, 1979) coupled with further dynamic programming techniques is used for efficient parameter estimation.

During the testing phase, the system makes use of the learned model parameters to determine the most probable hybrid tree given a new natural language sentence. The MR contained in that hybrid tree is the output of the system. Dynamic programming techniques similar to those of training are also employed for efficient decoding.

The generative model used in the LNLZ08 system has a natural symmetry, allowing for easy transformation from NL to MR, as well as from MR to NL. This provides the starting point for our work in "inverting" the LNLZ08 system to generate natural language sentences from the underlying meaning representations.

4 Generation with Hybrid Trees

The task of generating NL sentences from MRs can be defined as follows. Given a training corpus consisting of MRs paired with their NL sentences, one needs to develop algorithms that learn how to effectively "paraphrase" MRs with natural language sentences. During testing, the system should be able to output the most probable NL "paraphrase" for a given new MR.

The LNLZ08 system models $p(\mathcal{T}(\widehat{\mathbf{w}}, \widehat{\mathbf{m}}))$, the joint generative process for the hybrid tree containing both NL and MR. This term can be rewritten in the following way:

$$p(\mathcal{T}(\widehat{\mathbf{w}}, \widehat{\mathbf{m}})) = p(\widehat{\mathbf{m}}) \times p\left(\mathcal{T}(\widehat{\mathbf{w}}, \widehat{\mathbf{m}}) | \widehat{\mathbf{m}}\right) \quad (2)$$

In other words, we reach an alternative view of the joint generative process as follows. We choose to generate the complete MR $\widehat{\mathbf{m}}$ first. Given $\widehat{\mathbf{m}}$, we generate hybrid sequences below each of its MR production, which gives us a complete hybrid tree $\mathcal{T}(\widehat{\mathbf{w}}, \widehat{\mathbf{m}})$. The NL sentence $\widehat{\mathbf{w}}$ can be constructed from this hybrid tree exactly.

We define an operation $yield(\mathcal{T})$ which returns the NL sentence as the yield of the hybrid tree $\mathcal{T}$. Given an MR $\widehat{\mathbf{m}}$, we find the most probable NL sentence $\widehat{\mathbf{w}}^*$ as follows:

$$\widehat{\mathbf{w}}^* = yield\Big(\operatorname*{argmax}_{\mathcal{T}} p(\mathcal{T} | \widehat{\mathbf{m}})\Big) \quad (3)$$

In other words, we first find the most probable hybrid tree $\mathcal{T}$ that contains the provided MR $\widehat{\mathbf{m}}$. Next we return the yield of $\mathcal{T}$ as the most probable NL sentence.

Different assumptions can be made in the process of finding the most probable hybrid tree. We first describe a simple model which is a direct inversion of the LNLZ08 system. This model, as a baseline model, generates a complete NL sentence word by word. Next, a more sophisticated model that exploits NL phrase-level dependencies is built that tackles some weaknesses of the simple baseline model.

4.1 Direct Inversion Model

Assume that a pre-order traversal of the MR $\widehat{\mathbf{m}}$ gives us the list of MR productions $m_1, m_2, \ldots, m_S$, where S is the number of MR productions in $\widehat{\mathbf{m}}$. Based on the independence assumption made by the LNLZ08 system, each MR production independently generates a hybrid

sequence. Denote the hybrid sequence generated under the MR production m_s as h_s, for $s = 1, \ldots, S$. We call the list of hybrid sequences $\mathbf{h} = \langle h_1, h_2, \ldots, h_S \rangle$ a *hybrid sequence list* associated with this particular MR. Thus, our goal is to find the optimal hybrid sequence list $\mathbf{h}^*$ for the given MR $\widehat{\mathbf{m}}$, which is formulated as follows:

$$\mathbf{h}^* = \langle h_1^*, \ldots, h_S^* \rangle = \underset{h_1,\ldots,h_S}{\operatorname{argmax}} \prod_{s=1}^{S} p(h_s|m_s) \quad (4)$$

The optimal hybrid sequence list defines the optimal hybrid tree whose yield gives the optimal NL sentence.

Due to the strong independence assumption introduced by the LNLZ08 system, the hybrid tree generation process is in fact highly decomposable. Optimization of the hybrid sequence list $\langle h_1, \ldots, h_S \rangle$ can be performed individually since they are independent of one another. Thus, mathematically, for $s = 1, \ldots, S$, we have:

$$h_s^* = \underset{h_s}{\operatorname{argmax}}\, p(h_s|m_s) \quad (5)$$

The LNLZ08 system presented three models for the task of transforming NL to MR. In this inverse task, for generation of a hybrid sequence, we choose to use the bigram model (model II). We choose this model mainly due to its stronger ability in modeling dependencies between adjacent NL words, which we believe to be quite important in this NL generation task. With the bigram model assumption, the optimal hybrid sequence that can be generated from each MR production is defined as follows:

$$\begin{aligned} h_s^* &= \underset{h_s}{\operatorname{argmax}}\, p(h_s|m_s) \\ &= \underset{h_s}{\operatorname{argmax}} \left\{ \phi(r|m_s) \times \prod_{j=1}^{|h_s|+1} \theta(t_j|m_s, t_{j-1}) \right\} \end{aligned} \quad (6)$$

where t_i is either an NL word or a semantic category with $t_0 \equiv$ BEGIN and $t_{|h_s|+1} \equiv$ END, and r is the hybrid pattern that matches the hybrid sequence h_s, which is equivalent to $t_1, \ldots, t_{|h_s|}$.

Equivalently, we can view the problem in the log-space:

$$\begin{aligned} h_s^* = \underset{h_s}{\operatorname{argmin}} \Bigg\{ & -\log \phi(r|m_s) \\ & + \sum_{j=1}^{|h_s|+1} -\log \theta(t_j|m_s, t_{j-1}) \Bigg\} \end{aligned} \quad (7)$$

Note the term $-\log \phi(r|m_s)$ is a constant for a particular MR production m_s and a particular hybrid pattern r. This search problem can be equivalently cast as the shortest path problem which can be solved efficiently with Dijkstra's algorithm (Cormen et al., 2001). We define a set of states. Each state represents a single NL word or a semantic category, including the special symbols BEGIN and END. A directed path between two different states t_u and t_v is associated with a distance measure $-\log \theta(t_v|m_s, t_u)$, which is non-negative. The task now is to find the shortest path between BEGIN and END[1]. The sequence of words appearing in this path is simply the most probable hybrid sequence under this MR production m_s. We build this model by directly inverting the LNLZ08 system, and this model is therefore referred to as the *direct inversion model*.

A major weakness of this baseline model is that it encodes strong independence assumptions during the hybrid tree generation process. Though shown to be effective in the task of transforming NL to MR, such independence assumptions may introduce difficulties in this NLG task. For example, consider the MR shown in Figure 1. The generation steps of the hybrid sequences from the two adjacent MR productions QUERY : $answer$(RIVER) and RIVER : $longest$(RIVER) are completely independent of each other. This may harm the fluency of the generated NL sentence, especially when a transition from one hybrid sequence to another is required. In fact, due to such an independence assumption, the model always generates the same hybrid sequence from the same MR production, regardless of its context such as parent or child MR productions. Such a limitation points to the importance of better utilizing the tree structure of the MR for this NLG task. Furthermore, due to the bigram assumption, the model is unable to capture longer range dependencies amongst the words or semantic categories in each hybrid sequence.

To tackle the above issues, we explore ways of relaxing various assumptions, which leads to an

[1] In addition, we should make sure that the generated hybrid sequence $t_0 \ldots t_{|h_s|+1}$ is a valid hybrid sequence that comply with the hybrid pattern r. For example, the MR production STATE : loc_1(RIVER) can generate the following hybrid sequence "BEGIN have RIVER END" but not this hybrid sequence "BEGIN have END". This can be achieved by finding the shortest path from BEGIN to RIVER, which then gets concatenated to the shortest path from RIVER to END.

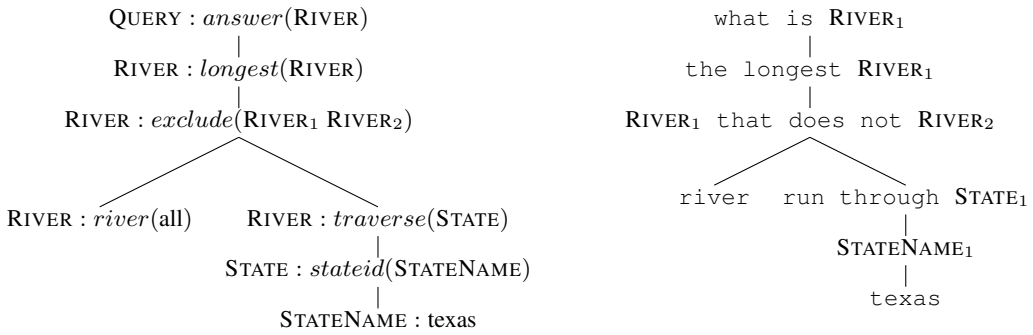

Figure 3: An MR (left) and its associated hybrid sequences (right)

alternative model as discussed next.

4.2 Tree CRF-Based Model

Based on the belief that using known phrases usually leads to better fluency in the NLG task (Wong and Mooney, 2007), we explore methods for generating an NL sentence at phrase level rather than at word level. This is done by generating hybrid sequences as complete objects, rather than sequentially one word or semantic category at a time, from MR productions.

We assume that each MR production can generate a complete hybrid sequence below it from a finite set of possible hybrid sequences. Each such hybrid sequence is called a *candidate hybrid sequence* associated with that particular MR production. Given a set of candidate hybrid sequences associated with each MR production, the generation task is to find the optimal hybrid sequence list $\mathbf{h}^*$ for a given MR $\widehat{\mathbf{m}}$:

$$\mathbf{h}^* = \underset{\mathbf{h}}{\operatorname{argmax}}\, p(\mathbf{h}|\widehat{\mathbf{m}}) \tag{8}$$

Figure 3 shows a complete MR, as well as a possible tree that contains hybrid sequences associated with the MR productions. For example, in the figure the MR production RIVER : $traverse$(STATE) is associated with the hybrid sequence `run through` STATE$_1$. Each MR production can be associated with potentially many different hybrid sequences. The task is to determine the most probable list of hybrid sequences as the ones appearing on the right of Figure 3, one for each MR production.

To make better use of the tree structure of MR, we take the approach of modeling the conditional distribution using a log-linear model. Following the conditional random fields (CRF) framework (Lafferty et al., 2001), we can define the probability of the hybrid sequence list given the complete MR $\widehat{\mathbf{m}}$, as follows:

$$p(\mathbf{h}|\widehat{\mathbf{m}}) = \frac{1}{Z(\widehat{\mathbf{m}})} \exp\left(\sum_{i \in V} \sum_{k} \mu_k g_k(h_i, \widehat{\mathbf{m}}, i) + \sum_{(i,j) \in E} \sum_{k} \lambda_k f_k(h_i, h_j, \widehat{\mathbf{m}}, i, j) \right) \tag{9}$$

where V is the set of all the vertices in the tree, and E is the set of the edges in the tree, consisting of parent-child pairs. The function $Z(\widehat{\mathbf{m}})$ is the normalization function. Note that the dependencies among the features here form a tree, unlike the sequence models used in Lafferty et al. (2001). The function $f_k(h_i, h_j, \widehat{\mathbf{m}}, i, j)$ is a feature function of the entire MR tree $\widehat{\mathbf{m}}$ and the hybrid sequences at vertex i and j. These features are usually referred to as the edge features in the CRF framework. The function $g_k(h_i, \widehat{\mathbf{m}}, i)$ is a feature function of the hybrid sequence at vertex i and the entire MR tree. These features are usually referred to as the vertex features. The parameters λ_k and μ_k are learned from the training data.

In this task, we are given only MR-NL pairs and do not have the hybrid tree corresponding to each MR as training data. Now we describe how the set of candidate hybrid sequences for each MR production is obtained as well as how the training data for this model is constructed. After the joint generative model is learned as done in Lu et al. (2008), we first use a Viterbi algorithm to find the optimal hybrid tree for each MR-NL pair in the training set. From each optimal hybrid tree, we extract the hybrid sequence h_i below each MR production m_i. Using this process on the training MR-NL pairs, we can obtain a set of candidate

hybrid sequences that can be associated with each MR production. The optimal hybrid tree generated by the Viterbi algorithm in this way is considered the "correct" hybrid tree for the MR-NL pair and is used as training data. While this does not provide hand-labeled training data, we believe the hybrid trees generated this way form a high quality training set as both the MR and NL are available when Viterbi decoding is performed, guaranteeing that the generated hybrid tree has the correct yield.

There exist several advantages of such a model over the simple generative model. First, this model allows features that specifically model the dependencies between neighboring hybrid sequences in the tree to be used. In addition, the model can efficiently capture long range dependencies between MR productions and hybrid sequences since each hybrid sequence is allowed to depend on the entire MR tree.

For features, we employ four types of simple features, as presented below. Note that the first three types of features are vertex features, and the last are edge features. Examples are given based on Figure 3. All the features are indicator functions, *i.e.*, a feature takes value 1 if a certain combination is present, and 0 otherwise. The last three features explicitly encode information from the tree structure of MR.

Hybrid sequence features : one hybrid sequence together with the associated MR production. For example:

$$g_1 : \langle \texttt{run through } \textsc{State}_1, \textsc{River} : traverse(\textsc{State}) \rangle ;$$

Two-level hybrid sequence features : one hybrid sequence, its associated MR production, and the parent MR production. For example:

$$g_2 : \langle \texttt{run through } \textsc{State}_1, \textsc{River} : traverse(\textsc{State}), \textsc{River} : exclude(\textsc{River}_1, \textsc{River}_2) \rangle ;$$

Three-level hybrid sequence features : one hybrid sequence, its associated MR production, the parent MR production, and the grandparent MR production. For example:

$$g_3 : \langle \texttt{run through } \textsc{State}_1, \textsc{River} : traverse(\textsc{State}), \textsc{River} : exclude(\textsc{River}_1, \textsc{River}_2), \textsc{River} : longest(\textsc{River}) \rangle ;$$

Adjacent hybrid sequence features : two adjacent hybrid sequences, together with their associated MR productions. For example:

$$f_1 : \langle \texttt{run through } \textsc{State}_1, \textsc{River}_1 \texttt{ that does not } \textsc{River}_2, \textsc{River} : traverse(\textsc{State}), \textsc{River} : exclude(\textsc{River}_1, \textsc{River}_2) \rangle .$$

For training, we use the feature forest model (Miyao and Tsujii, 2008), which was originally designed as an efficient algorithm for solving maximum entropy models for data with complex structures. The model enables efficient training over packed trees that potentially represent exponential number of trees. The tree conditional random fields model can be effectively represented using the feature forest model. The model has also been successfully applied to the HPSG parsing task.

To train the model, we run the Viterbi algorithm on the trained LNLZ08 model and perform convex optimization using the feature forest model. The LNLZ08 model is trained using an EM algorithm with time complexity $O(MN^3D)$ per EM iteration, where M and N are respectively the maximum number of MR productions and NL words for each MR-NL pair, and D is the number of training instances. The time complexity of the Viterbi algorithm is also $O(MN^3D)$. For training the feature forest, we use the Amis toolkit (Miyao and Tsujii, 2002) which utilizes the GIS algorithm. The time complexity for each iteration of the GIS algorithm is $O(MK^2D)$, where K is the maximum number of candidate hybrid sequences associated with each MR production. Finally, the time complexity for generating a natural language sentence from a particular MR is $O(MK^2)$.

5 Experiments

In this section, we present the results of our systems when evaluated on two standard benchmark corpora. The first corpus is GEOQUERY, which contains Prolog-based MRs that can be used to query a US geographic database (Kate et al., 2005). Our task for this domain is to generate NL sentences from the formal queries. The second corpus is ROBOCUP. This domain contains MRs which are instructions written in a formal language called CLANG. Our task for this domain is to generate NL sentences from the coaching advice written in CLANG.

Table 4: Results on the GEOQUERY-250 corpus with 4 natural languages.

The GEOQUERY domain contains 880 instances, while the ROBOCUP domain contains 300 instances. The average NL sentence length for the two corpora are 7.57 and 22.52 respectively. Following the evaluation methodology of Wong and Mooney (2007), we performed 4 runs of the standard 10-fold cross validation and report the averaged performance in this section using the standard automatic evaluation metric BLEU (Papineni et al., 2002) and NIST (Doddington, 2002)[2]. The BLEU and NIST scores of the WASP^{-1}++ system reported in this section are obtained from the published paper of Wong and Mooney (2007). Note that to make our experimental results directly comparable to Wong and Mooney (2007), we used the identical training and test data splits for the 4 runs of 10-fold cross validation used by Wong and Mooney (2007) on both corpora.

Our system has the advantage of always producing an NL sentence given any input MR, even if there exist unseen MR productions in the input MR. We can achieve this by simply skipping those unseen MR productions during the generation process. However, in order to make a fair comparison against WASP^{-1}++, which can only generate NL sentences for 97% of the input MRs, we also do not generate any NL sentence in the case of observing an unseen MR production. All the evaluations discussed in this section follow this evaluation methodology, but we notice that empirically our system is able to achieve higher BLEU/NIST scores if we allow generation for those MRs that include unseen MR productions.

[2]We used the official evaluation script (version 11b) provided by http://www.nist.gov/.

5.1 Comparison between the two models

We compare the performance of our two models in Table 2. From the table, we observe that the tree CRF-based model outperforms the direct inversion model on both domains. This validates our earlier belief that some long range dependencies are important for the generation task. In addition, while the direct inversion model performs reasonably well on the ROBOCUP domain, it performs substantially worse on the GEOQUERY domain where the sentence length is shorter. We note that the evaluation metrics are strongly correlated with the cumulative matching n-grams between the output and the reference sentence (n ranges from 1 to 4 for BLEU, and 1 to 5 for NIST). The direct inversion model fails to capture the transitional behavior from one phrase to another, which makes it more vulnerable to n-gram mismatch, especially when evaluated on the GEOQUERY corpus where phrase-to-phrase transitions are more frequent. On the other hand, the tree CRF-based model does not suffer from this problem, mainly due to its ability to model such dependencies between neighboring phrases. Sample outputs from the two models are shown in Figure 4.

Reference:	`what is the largest state bordering texas`
Direct inversion model:	`what the largest states border texas`
Tree CRF-based model:	`what is the largest state that borders texas`
Reference:	`if DR2C7 is true then players 2 , 3 , 7 and 8 should pass to player 4`
Direct inversion model:	`if DR2C7 , then players 2 , 3 7 and 8 should ball to player 4`
Tree CRF-based model:	`if the condition DR2C7 is true then players 2 , 3 , 7 and 8 should pass to player 4`

Figure 4: Sample outputs from the two models, for GEOQUERY domain (top) and ROBOCUP domain (bottom) respectively.

5.2 Comparison with previous model

We also compare the performance of our tree CRF-based model against the previous state-of-the-art system WASP^{-1}++ in Table 3. Our tree CRF-based model achieves better performance on both corpora. We are unable to carry out statistical significance tests since the detailed BLEU and NIST scores of the cross validation runs of WASP^{-1}++ as reported in the published paper of Wong and Mooney (2007) are not available.

The results confirm our earlier discussions: the dependencies between the generated NL words are important and need to be properly modeled. The WASP^{-1}++ system uses a log-linear model which incorporates two major techniques to attempt to model such dependencies. First, a back-off language model is used to capture dependencies at adjacent word level. Second, a technique that merges smaller translation rules into a single rigid rule is used to capture dependencies at phrase level (Wong, 2007). In contrast, the proposed tree CRF-based model is able to explicitly and flexibly exploit phrase-level features that model dependencies between adjacent phrases. In fact, with the hybrid tree framework, the better treatment of the tree structure of MR enables us to model some crucial dependencies between the complete MR tree and generated NL phrases. We believe that this property plays an important role in improving the quality of the generated sentences in terms of fluency, which is assessed by the evaluation metrics.

Furthermore, WASP^{-1}++ employs minimum error rate training (Och, 2003) to directly optimize the evaluation metrics. We have not done so but still obtain better performance. In future, we plan to explore ways to directly optimize the evaluation metrics in our system.

5.3 Experiments on different languages

Following the work of Wong and Mooney (2007), we also evaluated our system's performance on a subset of the GEOQUERY corpus with 250 instances, where sentences of 4 natural languages (English, Japanese, Spanish, and Turkish) are available. The evaluation results are shown in Table 4. Our tree CRF-based model achieves better performance on this task compared to WASP^{-1}++. We are again unable to conduct statistical significance tests for the same reason reported earlier.

6 Conclusions

In this paper, we presented two novel models for the task of generating natural language sentences from given meaning representations, under a hybrid tree framework. We first built a simple direct inversion model as a baseline. Next, to address the limitations associated with the direct inversion model, a tree CRF-based model was introduced. We evaluated both models on standard benchmark corpora. Evaluation results show that the tree CRF-based model performs better than the direct inversion model, and that the tree CRF-based model also outperforms WASP^{-1}++, which was a previous state-of-the-art system reported in the literature.

Acknowledgments

The authors would like to thank Seung-Hoon Na for his suggestions on the presentation of this paper, Yuk Wah Wong for answering various questions related to the WASP^{-1}++ system, and the anonymous reviewers for their thoughtful comments on this work.

Perceptron Reranking for CCG Realization

Michael White and **Rajakrishnan Rajkumar**

{mwhite,raja}@ling.osu.edu

Abstract

This paper shows that discriminative reranking with an averaged perceptron model yields substantial improvements in realization quality with CCG. The paper confirms the utility of including language model log probabilities as features in the model, which prior work on discriminative training with log linear models for HPSG realization had called into question. The perceptron model allows the combination of multiple n-gram models to be optimized and then augmented with both syntactic features and discriminative n-gram features. The full model yields a state-of-the-art BLEU score of 0.8506 on Section 23 of the CCGbank, to our knowledge the best score reported to date using a reversible, corpus-engineered grammar.

1 Introduction

In this paper, we show how discriminative training with averaged perceptron models (Collins, 2002) can be used to substantially improve surface realization with Combinatory Categorial Grammar (Steedman, 2000, CCG). Velldal and Oepen (2005) and Nakanishi et al. (2005) have shown that discriminative training with log-linear (maximum entropy) models is effective in realization ranking with Head-Driven Phrase Structure Grammar (Pollard and Sag, 1994, HPSG). Here we show that averaged perceptron models also perform well for realization ranking with CCG. Averaged perceptron models are very simple, just requiring a decoder and a simple update function, yet despite their simplicity they have been shown to achieve state-of-the-art results in Treebank and CCG parsing (Huang, 2008; Clark and Curran, 2007a) as well as on other NLP tasks.

Along the way, we address the question of whether it is beneficial to incorporate n-gram log probabilities as baseline features in a discriminatively trained realization ranking model. On a limited domain corpus, Velldal & Oepen found that including the n-gram log probability of each candidate realization as a feature in their log-linear model yielded a substantial boost in ranking performance; on the Penn Treebank (PTB), however, Nakanishi et al. found that including an n-gram log prob feature in their model was of no benefit (with the use of bigrams instead of 4-grams suggested as a possible explanation). With these mixed results, the utility of n-gram baseline features for PTB-scale discriminative realization ranking has been unclear. In our particular setting, the question is: Do n-gram log prob features improve performance in broad coverage realization ranking with CCG, where factored language models over words, part-of-speech tags and supertags have previously been employed (White et al., 2007; Espinosa et al., 2008)?

We answer this question in the affirmative, confirming the results of Velldal & Oepen, despite the differences in corpus size and kind of language model. We show that including n-gram log prob features in the perceptron model is highly beneficial, as the discriminative models we tested without these features performed worse than the generative baseline. These findings are in line with Collins & Roark's (2004) results with incremental parsing with perceptrons, where it is suggested that a generative baseline feature provides the perceptron algorithm with a much better starting point for learning. We also show that discriminative training allows the combination of multiple n-gram models to be optimized, and that the best model augments the n-gram log prob features with both syntactic features and discriminative n-gram features. The full model yields a state-of-the-art BLEU (Papineni et al., 2002) score of 0.8506 on Section 23 of the CCGbank, which is to our knowledge the best score reported to date

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 410–419,
Singapore, 6-7 August 2009.

using a reversible, corpus-engineered grammar.

The paper is organized as follows. Section 2 reviews previous work on broad coverage realization with OpenCCG. Section 3 describes our approach to realization reranking with averaged perceptron models. Section 4 presents our evaluation of the perceptron models, comparing the results of different feature sets. Section 5 compares our results to those obtained by related systems and discusses the difficulties of cross-system comparisons. Finally, Section 6 concludes with a summary and discussion of future directions for research.

2 Background

2.1 Surface Realization with CCG

CCG (Steedman, 2000) is a unification-based categorial grammar formalism which is defined almost entirely in terms of lexical entries that encode sub-categorization information as well as syntactic feature information (e.g. number and agreement). Complementing function application as the standard means of combining a head with its argument, type-raising and composition support transparent analyses for a wide range of phenomena, including right-node raising and long distance dependencies. An example syntactic derivation appears in Figure 1, with a long-distance dependency between *point* and *make*. Semantic composition happens in parallel with syntactic composition, which makes it attractive for generation.

OpenCCG is a parsing/generation library which works by combining lexical categories for words using CCG rules and multi-modal extensions on rules (Baldridge, 2002) to produce derivations. Surface realization is the process by which logical forms are transduced to strings. OpenCCG uses a hybrid symbolic-statistical chart realizer (White, 2006) which takes logical forms as input and produces sentences by using CCG combinators to combine signs. Edges are grouped into equivalence classes when they have the same syntactic category and cover the same parts of the input logical form. Alternative realizations are ranked using integrated n-gram or perceptron scoring, and pruning takes place within equivalence classes of edges. To more robustly support broad coverage surface realization, OpenCCG greedily assembles fragments in the event that the realizer fails to find a complete realization.

To illustrate the input to OpenCCG, consider the semantic dependency graph in Figure 2. In

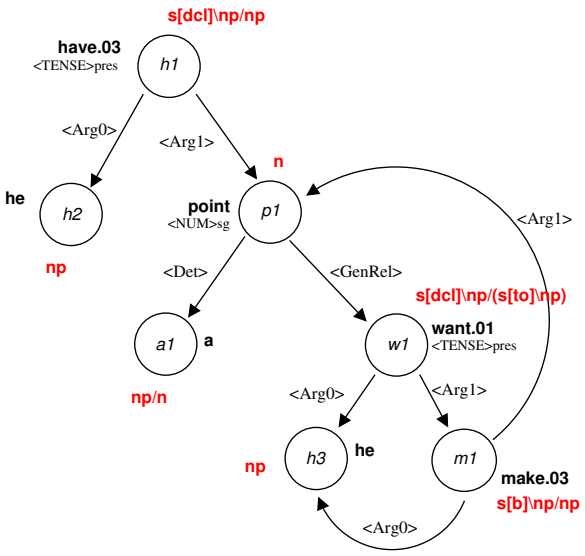

Figure 2: Semantic dependency graph from the CCGbank for *He has a point he wants to make [. . .]*, along with gold-standard supertags (category labels)

the graph, each node has a lexical predication (e.g. **make.03**) and a set of semantic features (e.g. ⟨NUM⟩sg); nodes are connected via dependency relations (e.g. ⟨ARG0⟩). (Gold-standard supertags, or category labels, are also shown; see Section 2.4 for their role in hypertagging.) Internally, such graphs are represented using Hybrid Logic Dependency Semantics (HLDS), a dependency-based approach to representing linguistic meaning (Baldridge and Kruijff, 2002). In HLDS, each semantic head (corresponding to a node in the graph) is associated with a nominal that identifies its discourse referent, and relations between heads and their dependents are modeled as modal relations.

2.2 Realization from an Enhanced CCGbank

Our starting point is an enhanced version of the CCGbank (Hockenmaier and Steedman, 2007)—a corpus of CCG derivations derived from the Penn Treebank—with Propbank (Palmer et al., 2005) roles projected onto it (Boxwell and White, 2008). To engineer a grammar from this corpus suitable for realization with OpenCCG, the derivations are first revised to reflect the lexicalized treatment of coordination and punctuation assumed by the multi-modal version of CCG that is implemented in OpenCCG (White and Rajkumar, 2008). Further changes are necessary to support semantic dependencies rather than surface syntactic ones; in

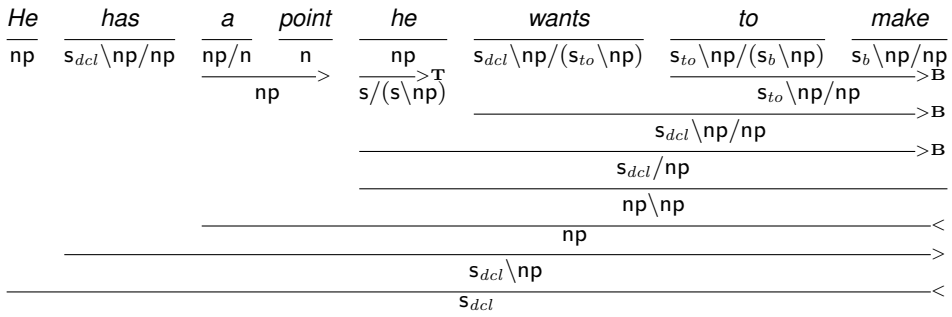

Figure 1: Syntactic derivation from the CCGbank for *He has a point he wants to make [. . .]*

particular, the features and unification constraints in the categories related to semantically empty function words such complementizers, infinitival-*to*, expletive subjects, and case-marking prepositions are adjusted to reflect their purely syntactic status.

In the second step, a grammar is extracted from the converted CCGbank and augmented with logical forms. Categories and unary type changing rules (corresponding to zero morphemes) are sorted by frequency and extracted if they meet the specified frequency thresholds. A separate transformation then uses a few dozen generalized templates to add logical forms to the categories, in a fashion reminiscent of (Bos, 2005). As shown in Figure 2, numbered semantic roles are taken from PropBank when available, and more specific relations are introduced in the categories for closed-class items such as determiners.

After logical form insertion, the extracted and augmented grammar is loaded and used to parse the sentences in the CCGbank according to the gold-standard derivation. If the derivation can be successfully followed, the parse yields a logical form which is saved along with the corpus sentence in order to later test the realizer. Currently, the algorithm succeeds in creating logical forms for 98.85% of the sentences in the development section (Sect. 00) of the converted CCGbank, and 97.06% of the sentences in the test section (Sect. 23). Of these, 95.99% of the development LFs are semantic dependency graphs with a single root, while 95.81% of the test LFs have a single root. The remaining cases, with multiple roots, are missing one or more dependencies required to form a fully connected graph. Such missing dependencies usually reflect remaining inadequacies in the logical form templates.

An error analysis of OpenCCG output by Rajkumar et al. (2009) recently revealed that out of 2331 named entities (NEs) annotated by the BBN corpus (Weischedel and Brunstein, 2005), 238 were not realized correctly. For example, multi-word NPs like *Texas Instruments Japan Ltd.* were realized as *Japan Texas Instruments Ltd.* Accordingly, inspired by Hogan et al.'s (2007)'s Experiment 1, Rajkumar et al. used the BBN corpus NE annotation to collapse certain classes of NEs. But unlike Hogan et al.'s experiment where all the NEs annotated by the BBN corpus were collapsed, Rajkumar et al. chose to collapse into single tokens only NEs whose exact form can be reasonably expected to be specified in the input to the realizer. For example, while some quantificational or comparatives phrases like *more than $ 10,000* are annotated as MONEY in the BBN corpus, Rajkumar et al. only collapse *$_10,000* into an atomic unit, with *more than* handled compositionally according to the semantics assigned to it by the grammar. Thus, after transferring the BBN annotations to the CCGbank corpus, Rajkumar et al. (partially) collapsed NEs which are CCGbank constituents according to the following rules: (1) completely collapse the PERSON, ORGANIZATION, GPE, WORK OF ART major class type entitites; (2) ignore phrases like *three decades later*, which are annotated as DATE entities; and (3) collapse all phrases with POS tags CD or NNP(S) or lexical items % or $, ensuring that all prototypical named entities are collapsed.

It is worth noting that improvements in our corpus-based grammar engineering process—including a more precise treatment of punctuation, better named entity handling and the addition of catch-all logical form templates—have resulted in a 13.5 BLEU point improvement in our baseline realization scores on Section 00 of the CCGbank, from a score of 0.6567 in (Espinosa et al., 2008) to 0.7917 in (Rajkumar et al., 2009), contributing greatly to the state-of-the-art results reported

in Section 4. A further 4.5 point improvement is obtained from the use of named entity classes in language modeling and hypertagging (Rajkumar et al., 2009), as described next, and from our perceptron reranking model, described in Section 3.

2.3 Factored Language Models

As in (White et al., 2007; Rajkumar et al., 2009), we use factored language models (Bilmes and Kirchhoff, 2003) over words, part-of-speech tags and supertags[1] to score partial and complete realizations. The trigram models were created using the SRILM toolkit (Stolcke, 2002) on the standard training sections (02–21) of the CCGbank, with sentence-initial words (other than proper names) uncapitalized. While these models are considerably smaller than the ones used in (Langkilde-Geary, 2002; Velldal and Oepen, 2005), the training data does have the advantage of being in the same domain and genre. The models employ interpolated Kneser-Ney smoothing with the default frequency cutoffs. The best performing model interpolates three component models using rank-order centroid weights: (1) a word trigram model; (2) a word model with semantic classes replacing named entities; and (3) a trigram model that chains a POS model with a supertag model, where the POS model (P) conditions on the previous two POS tags, and the supertag model (S) conditions on the previous two POS tags as well as the current one, as shown below:

$$p^{PS}(\vec{F}_i \mid \vec{F}_{i-2}^{i-1}) = p(P_i \mid P_{i-2}^{i-1})p(S_i \mid P_{i-2}^{i}) \quad (1)$$

Training data for the semantic class–replaced model was created by replacing (collapsed) words with their NE classes, in order to address data sparsity issues caused by rare words in the same semantic class. For example, the Section 00 sentence *Pierre_Vinken , 61 years old , will join the board as a nonexecutive director Nov._29 .* becomes *PERSON , DATE:AGE DATE:AGE old , will join the ORG_DESC:OTHER as a nonexecutive PER_DESC DATE:DATE DATE:DATE .* During realization, word forms are generated, but are then replaced by their semantic classes for scoring using the semantic class–replaced model, similar to Oh and Rudnicky (2002).

Note that the use of supertags in the factored language model to score possible realizations is distinct from the prediction of supertags for lexical category assignment: the former takes the words in the local context into account (as in supertagging for parsing), while the latter takes features of the logical form into account. This latter process we call hypertagging, to which we now turn.

2.4 Hypertagging

A crucial component of the OpenCCG realizer is the *hypertagger* (Espinosa et al., 2008), or supertagger for surface realization, which uses a maximum entropy model to assign the most likely lexical categories to the predicates in the input logical form, thereby greatly constraining the realizer's search space.[2] Figure 2 shows gold-standard supertags for the lexical predicates in the graph; such category labels are predicted by the hypertagger at run-time. As in recent work on using supertagging in parsing, the hypertagger operates in a multitagging paradigm (Curran et al., 2006), where a variable number of predictions are made per input predicate. Instead of basing category assignment on linear word and POS context, however, the hypertagger predicts lexical categories based on contexts within a directed graph structure representing the logical form (LF) of the sentence to be realized. The hypertagger generalizes Bangalore and Rambow's (2000) method of using supertags in generation by using maximum entropy models with a larger local context.

During realization, the hypertagger returns a β-best list of supertags in order of decreasing probability. Increasing the number of categories returned clearly increases the likelihood that the most-correct supertag is among them, but at a corresponding cost in chart size. Accordingly, the hypertagger begins with a highly restrictive value for β, and backs off to progressively less-restrictive values if no complete realization can be found using the set of supertags returned. Clark and Curran (2007b) have shown this iterative relaxation strategy to be highly effective in CCG parsing.

3 Perceptron Reranking

As Collins (2002) observes, perceptron training involves a simple, on-line algorithm, with few iterations typically required to achieve good performance. Moreover, *averaged* perceptrons—which

[1] With CCG, supertags (Bangalore and Joshi, 1999) are lexical categories considered as fine-grained syntactic labels.

[2] The approach has been dubbed *hypertagging* since it operates at a level "above" the syntax, moving from semantic representations to syntactic categories.

Input: training examples (x_i, y_i)
Initialization: set $\overline{\alpha} = 0$, or use optional input model
Algorithm:
for $t = 1 \ldots T, i = 1 \ldots N$
$z_i = \text{argmax}_{y \in \text{GEN}(x_i)} \Phi(x_i, y) \cdot \overline{\alpha}$
if $z_i \neq y_i$
$\overline{\alpha} = \overline{\alpha} + \Phi(x_i, y_i) - \Phi(x_i, z_i)$
Output: $\overline{\alpha} = \sum_{t=1}^{T} \sum_{i=1}^{N} \overline{\alpha}_{ti} / TN$

Figure 3: Averaged perceptron training algorithm

approximate voted perceptrons, a maximum-margin method with attractive theoretical properties—seem to work remarkably well in practice, while adding little further complexity. Additionally, since features only take on non-zero values when they appear in training items requiring updates, perceptrons integrate feature selection with, and often produce quite small models, especially when starting with a good baseline.

The generic averaged perceptron training algorithm appears in Figure 3. In our case, the algorithm trains a model for reranking the n-best realizations generated using our existing factored language model for scoring, with the oracle-best realization considered the correct answer. Accordingly, the input to the algorithm is a list of pairs (x_i, y_i), where x_i is a logical form, GEN(x_i) are the n-best realizations for x_i, and y_i is the oracle-best member of GEN(x_i). The oracle-best realization is determined using a 4-gram precision metric (approximating BLEU) against the reference sentence.

We have followed Huang (2008) in using oracle-best targets for training, rather than gold standard ones, in order to better approximate test conditions during training. However, following Clark & Curran (2007a), during training we seed the realizer with the gold-standard supertags, augmenting the hypertagger's β-best list, in order to ensure that the n-best realizations are generally of high quality; consequently, the gold standard realization (i.e., the corpus sentence) usually appears in the n-best list.[3] In addition, we use a hypertagger trained on all the training data, to improve hypertagger performance, while excluding the current training section (in jack-knifed fashion) from the word-based parts of the language model, in order to make the language model scores more realistic. It remains for future work to determine whether using a different compromise between ensuring high-quality training data and remaining faithful to the test conditions would yield better results.

Since realization of the n-best lists for training is the most time-consuming part of the process, in our current implementation we perform this step once, generating event files along the way containing feature vectors for each candidate realization. The event files are used to calculate the frequency distribution for the features, and minimum cutoffs are chosen to trim the feature alphabet to a reasonable size. Training then takes place by iterating over the event files, ignoring features that do not appear in the alphabet. As Figure 3 indicates, training consists of calculating the top-ranked realization according to the current model $\overline{\alpha}$, and performing an update when the top-ranked realization does not match the oracle-best realization. Updates to the model add the feature vector $\Phi(x_i, y_i)$ for the missed oracle-best realization, and subtract the feature vector $\Phi(x_i, z_i)$ for the mistakenly top-ranked realization. The final model averages the models across the T iterations over the training data, and N test cases within each iteration.

Note that while training the perceptron model involves n-best reranking, realization with the resulting model can be viewed as forest rescoring, since scoring of all partial realizations is integrated into the realizer's beam search. In future work, we intend to investigate saving the realizer's packed charts, rather than event files, and integrating the unpacking of the charts with the perceptron training algorithm.

The features we employ in our perceptron models are of three kinds. First, as in the log-linear models of Velldal & Oepen and Nakanishi et al., we incorporate the log probability of the candidate realization's word sequence according to our factored language model as a single feature in the perceptron model. Since our language model linearly interpolates three component models, we also include the log prob from each component language model as a feature, so that the combination of these components can be optimized.

Second, we include syntactic features in our

[3] As in Clark & Curran's approach, we use a single β value during training, rather than iteratively loosening the β value; the chosen β value determines the size of the discrimation space.

Feature Type	Example
LexCat + Word	$\mathsf{s/s/np}$ + before
LexCat + POS	$\mathsf{s/s/np}$ + IN
Rule	$\mathsf{s}_{dcl} \rightarrow \mathsf{np}\ \mathsf{s}_{dcl}\backslash\mathsf{np}$
Rule + Word	$\mathsf{s}_{dcl} \rightarrow \mathsf{np}\ \mathsf{s}_{dcl}\backslash\mathsf{np}$ + bought
Rule + POS	$\mathsf{s}_{dcl} \rightarrow \mathsf{np}\ \mathsf{s}_{dcl}\backslash\mathsf{np}$ + VBD
Word-Word	$\langle$company, $\mathsf{s}_{dcl} \rightarrow \mathsf{np}\ \mathsf{s}_{dcl}\backslash\mathsf{np}$, bought$\rangle$
Word-POS	$\langle$company, $\mathsf{s}_{dcl} \rightarrow \mathsf{np}\ \mathsf{s}_{dcl}\backslash\mathsf{np}$, VBD$\rangle$
POS-Word	$\langle$NN, $\mathsf{s}_{dcl} \rightarrow \mathsf{np}\ \mathsf{s}_{dcl}\backslash\mathsf{np}$, bought$\rangle$
Word + Δ_w	$\langle$bought, $\mathsf{s}_{dcl} \rightarrow \mathsf{np}\ \mathsf{s}_{dcl}\backslash\mathsf{np}\rangle$ + d_w
POS + Δ_w	$\langle$VBD, $\mathsf{s}_{dcl} \rightarrow \mathsf{np}\ \mathsf{s}_{dcl}\backslash\mathsf{np}\rangle$ + d_w
Word + Δ_p	$\langle$bought, $\mathsf{s}_{dcl} \rightarrow \mathsf{np}\ \mathsf{s}_{dcl}\backslash\mathsf{np}\rangle$ + d_p
POS + Δ_p	$\langle$VBD, $\mathsf{s}_{dcl} \rightarrow \mathsf{np}\ \mathsf{s}_{dcl}\backslash\mathsf{np}\rangle$ + d_p
Word + Δ_v	$\langle$bought, $\mathsf{s}_{dcl} \rightarrow \mathsf{np}\ \mathsf{s}_{dcl}\backslash\mathsf{np}\rangle$ + d_v
POS + Δ_v	$\langle$VBD, $\mathsf{s}_{dcl} \rightarrow \mathsf{np}\ \mathsf{s}_{dcl}\backslash\mathsf{np}\rangle$ + d_v

Table 1: Basic and dependency features from Clark & Curran's (2007b) normal form model; distances are in intervening words, punctuation marks and verbs, and are capped at 3, 3 and 2, respectively

model by implementing Clark & Curran's (2007b) normal form model in OpenCCG.[4] The features of this model are listed in Table 1; they are integer-valued, representing counts of occurrences in a derivation. These syntactic features are quite comparable to the dominance-oriented features in the union of the Velldal & Oepen and Nakanishi et al. models, except that our feature set does not include grandparenting, which has been found to have limited utility in CCG parsing. Our syntactic features also include ones that measure the distance between headwords in terms of intervening words, punctuation marks or verbs; these features generalize the ones in Nakanishi et al.'s model. Note that in contrast to parsing, in realization distance features are non-local, since different partial realizations in the same equivalence class typically differ in word order; as we are working in a reranking paradigm though, the non-local nature of these features is unproblematic.

Third, we include discriminative n-gram features in our model, following Roark et al.'s (2004) approach to discriminative n-gram modeling for speech recognition. By discriminative n-gram features, we mean features counting the occurrences of each n-gram that is scored by our factored language model, rather than a feature whose value is the log prob determined by the language model. As Roark et al. note, discriminative training with n-gram features has the potential to learn to negatively weight n-grams that appear in some of the GEN(x_i) candidates, but which never appear in the naturally occurring corpus used to train a standard, generative language model. Since our factored language model considers words, semantic classes, part-of-speech tags and supertags, our n-gram features represent a considerable generalization of the sequence-oriented features in Velldal & Oepen's model, which never contain more than one word and do not include semantic classes.

[4] We have omitted Clark & Curran's root features, since the category we use for the full stop ensures that it must appear at the root of any complete derivation.

Model	#Alph-feats	#Feats	Acc	Time
full-model	2402173	576176	96.40%	08:53
lp-ngram	1127437	342025	94.52%	05:19
lp-syn	1274740	291728	85.03%	05:57

4 Evaluation

4.1 Experimental Conditions

For the experiments reported below, we used a lexico-grammar extracted from Sections 02–21 of our enhanced CCGbank, a hypertagging model incorporating named entity class features, and a trigram factored language model over words, named entity classes, part-of-speech tags and supertags, as described in the preceding section. BLEU scores were calculated after removing the underscores between collapsed NEs.

Events were generated for each training section separately. As already noted, the hypertagger and POS/supertag language model was trained on all the training sections, while separate word-based models were trained excluding each of the training sections in turn. Event files for 26530 training sentences with complete realizations were generated in 7 hours and 16 minutes on a cluster using one commodity server per section, with an average n-best list size of 18.2. Perceptron models were trained on single machines; details for three of the models appear in Table 2. The complete set of models is listed in Table 3.

4.2 Results

Realization results on the development section are given in Table 4. As the first block of rows after the baseline shows, of the models incorporating a single kind of feature, only the one with the n-gram log prob features beats the baseline BLEU

Model	Description
baseline-w3	No perceptron (3g wd only)
baseline	No perceptron
syn-only-nodist	All syntactic features except distance
ngram-only	Just ngram features
syn-only	Just syntactic features
lp-only	Just log prob features
lp-ngram	Log prob + Ngram features
lp-syn	Log prob + Syntactic features
full-model	Log prob + Ngram +Syntactic features

Table 3: Legend for Experimental Conditions

score, with the other models falling well below the baseline (though faring better than the trigram-word LM baseline). This result confirms the importance of including n-gram log prob features in discriminative realization ranking models, in line with Velldal & Oepen's findings, and contra those of Nakanishi et al., even though it was Nakanishi et al. who experimented with the Penn Treebank corpus, while Velldal & Oepen's experiments were on a much smaller, limited domain corpus. The second block of rows shows that both the discriminative n-gram features and the syntactic features provide a substantial boost when used with the n-gram log prob features, with the syntactic features yielding a more than 3 BLEU point gain. The final row shows that the full model works best, though the boosts provided by the syntactic and discriminative n-gram features are clearly not independent. The BLEU point trends are mirrored in the percentage of exact match realizations, which goes up by more than 10% from the baseline. The percentage of complete (i.e., non-fragmentary) realizations, however, goes down; we expect that this is due to the time taken up by our current naive method of feature extraction, which does not cache the features calculated for partial realizations. Realization results on the standard test section appear in Table 5, confirming the gains made by the full model over the baseline.[5]

We calculated statistical significance for the main results on the development section using bootstrap random sampling.[6] After re-sampling 1000 times, significance was calculated using a paired t-test (999 d.f.). The results indicated that lp-only exceeded the baseline, lp-ngram and lp-syn exceeded lp-only, and the full model exceeded lp-syn, with $p < 0.0001$ in each case.

[5]Note that the baseline for Section 23 uses 4-grams and a filter for balanced punctuation (White and Rajkumar, 2008), unlike the other reported configurations, which would explain the somewhat smaller increase seen with this section.

[6]Scripts for running these tests are available at `http://projectile.sv.cmu.edu/research/public/tools/bootStrap/tutorial.htm`

4.3 Examples

Table 6 presents four examples where the full model improves upon the baseline. Example sentence wsj_0020.10 in Table 6 is a case where the perceptron successfully weights the component ngram models, as the lp-ngram model and those that build on it get it right. Note that here, the modifier ordering in *small video-viewing* is not specified in the logical form and either ordering is possible syntactically. In wsj_0024.2, number agreement between the conjoined subject noun phrase and verb is obtained only with the full model. This suggests that the full model is more robust to cases where the grammar is insufficiently precise (number agreement is enforced by the grammar in only the simplest cases). Example wsj_0034.9 corrects a VP ordering mismatch, where the corpus sentence is clearly preferred to the one where *into oblivion* is shifted to the end. Finally, wsj_0047.13 corrects an animacy mismatch on the *wh*-pronoun, in large part due to the high negative weight assigned to the discriminative n-gram feature PERSON_,_which. Note that the full model still differs from the original sentence in its placement of the adverb *reportedly*, choosing the arguably more natural position following the auxiliary.

4.4 Comparison to Other Systems

Table 7: PTB Section 23 BLEU scores and exact match percentages in the NLG literature (Nakanishi et al.'s results are for sentences of length 20 or less)

most similar systems to ours are those of Nakanishi et al. (2005) and Hogan et al. (2007), as they both involve chart realizers for reversible grammars engineered from the Penn Treebank. While direct comparisons across systems cannot really be made when inputs vary in their semantic depth and specificity, we observe that our all-sentences BLEU score of 0.8506 exceeds that of Hogan et al., who report a top score of 0.6882 (though with coverage near 100%), and also surpasses Nakanishi et al.'s score of 0.7733, despite their results being limited to sentences of length 20 or less (with 91% coverage). Velldal & Oepen's (2005) system is also closely related, as noted in the introduction, but as their experiments are on a limited domain corpus, their results cannot be compared at all meaningfully.

5 Related Work and Discussion

As alluded to above, realization systems cannot be easily compared, even on the same corpus, when their inputs are not the same. This point is dramatically illustrated in Langkilde-Geary's (2002) system, where a BLEU score of 0.514 is reported for minimally specified inputs on PTB Section 23, while a score of 0.757 is reported for the 'Permute, no dir' case (which perhaps most closely resembles our inputs), and a score of 0.924 is reported for the most fully specified inputs; note, however, that in the latter case word order is determined by sibling order in the inputs, an assumption not commonly made. As another example, Guo et al. (2008) report a competitive result of 0.7440 (with 100% coverage) using a dependency-based approach; however, their inputs, like those of Hogan et al., include more surface syntactic information than ours, as they specify case-marking prepositions, *wh*-pronouns and complementizers. In a recent experiment to assess the impact of input specificity, we found that including predicates for all prepositions in our logical forms boosted our baseline results by more than 3 BLEU points, with complete realizations found in more than 90% of the test cases, indicating that generating from a more surfacy input is indeed an easier task than generating from a deeper representation. Given the current lack of consensus on realizer input specificity, we believe it is important to keep in mind that within-system comparisons (such as those in the preceding section) are the ones that should be given the most credence.

Returning to our cross-system comparison, it is perhaps surprising that Callaway (2005) reports the best PTB BLEU score to date, 0.9321, with 98.5% coverage, using a purely symbolic, handcrafted grammar augmented to handle the most frequent coverage issues for the PTB. While Callaway's inputs are unordered, word order is often determined by positional features (e.g. `front`) or by the type of modification (e.g. `describer` vs. `qualifier`), and parts-of-speech are included for lexical items. Additionally, in contrast to our approach, Callaway makes use of a generation-only grammar, rather than a reversible one, and his approach is less well-suited to producing n-best

outputs. Nevertheless, his high scores do suggest the potential for precise grammar engineering to improve realization quality.

While we have yet to perform a thorough error analysis, our impression is that although the current set of syntactic features substantially improves clausal constituent ordering, a variety of disfluent cases remain. More thorough investigations of features for constituent ordering in English have been performed by Ringger et al. (2004), Filippova and Strube (2009) and Zhong and Stent (2009), all of whom develop classifiers for determining linear order. In future work, we plan to investigate whether features inspired by these approaches can be usefully integrated into our perceptron reranker.

Also related to the present work is discriminative training in syntax-based MT (Turian et al., 2007; Watanabe et al., 2007; Blunsom et al., 2008; Chiang et al., 2009). Not surprisingly, since MT is a harder problem than surface realization, syntax-based MT systems have made use of less precise grammars and more impoverished (target-side) feature sets than those tackling realization ranking. With progress on discriminative training with large numbers of features in syntax-based MT, the features found to be useful for high-quality surface realization may become increasingly relevant for MT as well.

6 Conclusions

In this paper, we have shown how discriminative reranking with an averaged perceptron model can be used to achieve substantial improvements in realization quality with CCG. Using a comprehensive feature set, we have also confirmed the utility of including language model log probabilities as features in the model, which prior work on discriminative training with log linear models for HPSG realization had called into question. The perceptron model allows the combination of multiple n-gram models to be optimized and then augmented with both syntactic features and discriminative n-gram features, inspired by related work in discriminative parsing and language modeling for speech recognition. The full model yields a state-of-the-art BLEU score of 0.8506 on Section 23 of the CCGbank, to our knowledge the best score reported to date using a reversible, corpus-engineered grammar, despite our use of deeper, less specific inputs. Finally, the perceptron model paves the way for exploring the utility of richer feature spaces in statistical realization, including the use of linguistically-motivated and non-local features, a topic which we plan to investigate in future work.

Multi-Document Summarisation Using Generic Relation Extraction

Abstract

Experiments are reported that investigate the effect of various source document representations on the accuracy of the sentence extraction phase of a multi-document summarisation task. A novel representation is introduced based on generic relation extraction (GRE), which aims to build systems for relation identification and characterisation that can be transferred across domains and tasks without modification of model parameters. Results demonstrate performance that is significantly higher than a non-trivial baseline that uses *tf*idf*-weighted words and at least as good as a comparable but less general approach from the literature. Analysis shows that the representations compared are complementary, suggesting that extraction performance could be further improved through system combination.

1 Introduction

The goal of summarisation is to take an information source, extract content from it, and present the most important content in a condensed form (Mani, 2001). The field of automatic summarisation (Mani, 2001; Spärck Jones, 2007) aims to create tools that address various summarisation tasks with minimal human intervention. Extractive approaches to automatic summarisation create representations of the source document that are generally based on an easily identified text sub-unit such as sentences or paragraphs. These representations are then used to identify representative or otherwise important snippets of text to place in the summary.

Following Spärck Jones (2007), summarisation systems can be characterised with respect to their approach to three main sub-tasks: 1) interpretation, 2) transformation and 3) generation. The input consists of the source document (or a collection of source documents in the case of multi-document summarisation). The first step (interpretation) creates a representation of the source document by performing some level of interpretation. A simple approach here represents sentences by their tokens (i.e., as an unordered bag-of-words). The next step (transformation) is the compaction step where the source representation is converted into the summary representation, e.g. by identifying sentences whose words are most representative of the full text. Finally, in the last step (generation), the output summary is created. In the case of sentence extraction, this includes various operations to maximise coherence such as ensuring that entity references are comprehensible and arranging the sentences in a sensible order.

The current work investigates several representations of source documents. In particular, an approach from the literature based on atomic events (Filatova and Hatzivassiloglou, 2004) is compared to a novel approach based on generic relation extraction (GRE), which aims to build systems for relation identification and characterisation that can be transferred across domains and tasks without modification of model parameters (Hachey, 2009). The various representations are substituted in the interpretation phase of a multi-document summarisation task and used as the basis for extracting sentences to be placed in the summary. System summaries are compared by calculating term overlap with reference summaries created by human analysts.

2 Motivation

In seminal work on automatic summarisation, Luhn (1958) introduces a representation based on content words. These are defined as non-function words from the source document that are neither too frequent nor too infrequent. Luhn uses frequency to weight content words and ex-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 420–429,
Singapore, 6-7 August 2009.

tracts sentences with the highest combined content scores to form the summary. Subsequent work adapted the *tf*idf* weighting scheme, where term frequency (*tf*) is combined with inverse document frequency (*idf*), an inverse measure of term occurrence across documents that serves to downweight common words (Spärck Jones, 1972). In modern work, *tf*idf* representations are often used as simple but non-trivial baselines. The problem is that these shallow features often break down where underlying linguistic content needs to be compared rather than just surface structure.

The use of representations based on information extraction (IE) has been suggested as one approach to capturing deeper semantic information. This is based on the notion that IE definitions of types for entities, relations and events provide a level of abstraction that is appropriate for automatic summarisation. Several approaches in the literature have explored the use of IE-based representations for extractive summarisation: McKeown et al. (1998) incorporate patient characteristic templates for matching potential treatments to specific patients in a medical summarisation system; White and Cardie (2002) incorporate a bootstrapped IE system based on Autoslog (Riloff, 1996) for filling event templates; and Harabagiu and Maiorano (2002) incorporate a hybrid approach that uses conventional supervised IE techniques for known topics and a more general approach based on WordNet for unknown topics.[1] The problem with these systems is that they all use supervised approaches to IE that require that the IE templates be known in advance and additionally require significant investment in writing extraction rules or in annotating data for training. Where more general techniques are used, they still require domain-specific resources, e.g. White and Cardie (2002) bootstrapping approach still requires that the extraction templates be known in advance and Harabagiu and Maiorano (2002) approach depends on the WordNet lexical database, for which coverage is not guaranteed for arbitrary domains.

Filatova and Hatzivassiloglou (2004) introduce methods using more general IE representations that are not based on supervised learning. Given a named entity recogniser, the representation is automatically derived and consists of $<Ent, Connector, Ent>$ event triples, where connectors are verbs or action nouns that occur in between the two NEs. Thus, the approach aims to perform a generic IE task that the authors refer to as atomic event extraction. This representation is shown to outperform a *tf*idf* baseline on a multi-document summarisation task. As we will see in Section 4.3 below, Filatova and Hatzivassiloglou's approach has three main shortcomings. First, it focuses exclusively on simple atomic events (i.e., entity mention pairs with an intervening verbal connector), meaning that it will not be able to address tasks where relations are at least as important as events (e.g., biographical summarisation). Second, it relies on exact matching between connectors, which is not capable of capturing latent semantic similarities (e.g., between 'work for' and 'employed by'). Third, its performance is subject to the coverage of WordNet, which is used to identify action nouns.

Generic relation extraction (GRE) aims to build systems that can be transferred across domains and tasks without modification of model parameters (Hachey, 2009). For relation identification (i.e., extraction of relation forming entity mention pairs), this is achieved by using general rule-based approaches and, for relation characterisation (i.e., assignment of types to relation mentions), this is achieved by using unsupervised machine learning. Hachey (2009) introduces a GRE approach that addresses the shortcomings of the atomic event approach mentioned above. First, it models a type of IE that includes relations. Second, it uses a connector model based on latent Dirichlet allocation (Blei et al., 2003), which provides a mechanism for capturing latent semantic similarities between connectors. Third, it does not rely on domain-specific resource like WordNet. The GRE models used here do rely on dependency parsing. However, they still generalise across formal domains as the relation identification and characterisation systems, developed on news data, achieve comparable performance when applied directly to a relation extraction task in the biomedical domain (see Hachey (2009) for details). Furthermore, grammatical relations obtained from dependency parsing provide a means for constraining relation identification and supplying more linguistically meaningful features for relation characterisation.

[1] Comparable approaches using IE in the context of abstractive–as opposed to extractive–summarisation include work by DeJong (1982), Hahn and Reimer (1999), White et al. (2001) and Saggion and Lapalme (2002).

	c_1	c_2	c_3	c_4	c_5
t_1	1	1	0	1	1
t_2	1	0	0	1	0
t_3	0	1	0	0	1
t_4	1	0	1	1	1

Table 1: Text × concept matrix for set cover approach to automatic summarisation (Filatova and Hatzivassiloglou, 2004).

3 Algorithm for Set Cover Extraction

For the sake of comparison, the current evaluation adopts the Filatova and Hatzivassiloglou (2004) summarisation framework. This defines an extraction approach based on a mapping between *textual* units and *concepts*. To illustrate, consider the matrix in Table 1 where rows represent textual units (e.g., sentences, paragraphs) and columns represent concepts (e.g., words, events, relations) in the input text. Each concept is either absent or present in a given textual unit. Additionally, each concept has a weight associated with it. Looking at the problem in this way makes it natural to formulate it as follows: *the summary should select textual units such that there is maximal coverage of the salient conceptual units*.[2] This is essentially the maximum coverage problem, which has been shown to be reducible to the set covering problem, for which there are approximation algorithms in the literature that run in polynomial time or better (Hochbaum, 1997; Bienstock and Iyengar, 2004).

Filatova and Hatzivassiloglou define several greedy algorithms that can be parametrised in terms of the general SUMMARISE function in Figure 1, which takes the text × concept matrix D and the maximum summary length k as input. The SUMMARISE function first initialises the summary $\mathcal{S}$ to the empty set. Then it enters a loop that continues until the summary reaches the desired length. Within the loop, a text unit is extracted and added to the summary after which the text × concept matrix is updated The output of the algorithm is a set $\mathcal{S}$ comprising the text units that make up the summary. For the experiments reported here, the text units t are sentences and LENGTH(t_i) returns the count of word tokens in sentence t_i.

```
SUMMARISE : D, k
1  S ← {}
2  while Σ_{t_i∈S} LENGTH(t_i) < k
3        t_j ← EXTRACT(D)
4        S ← S ∪ t_j
5        D ← UPDATE(D, t_j)
6  return S
```

Figure 1: Generalised function for Filatova and Hatzivassiloglou (2004) approach to extractive summarisation.

```
EXTRACT: D
1  c_j ← arg max_{c_j∈cols(D)} Σ_{t_i∈rows(D)} D[t_i, c_j]
2  t_k ← arg max_{t_k∈rows(D)&D[t_k,c_j]>0} SCORE(D, t_k)
3  return t_k
```

```
UPDATE: D, t_i
1  for each c_j ∈ cols(D)
2        if D[t_i, c_j] > 0
3              for each t_k ∈ rows(D)
4                    D[t_k, c_j] ← 0
5  D ← DELETE(D, t_i)
6  return D
```

Figure 2: Extraction and update functions for Filatova and Hatzivassiloglou (2004) modified adaptive algorithm.

Figure 2 contains the EXTRACT and UPDATE functions used here.[3] The EXTRACT function first identifies the concept c_j not yet covered in the summary that has the highest overall weight in the text × concept matrix D. Then it selects the text unit t_k with the highest score from among the text units that contain concept c_j. The SCORE function is the sum of concept weights for the given text unit, i.e.:

$$\text{SCORE} : D, t_i \mapsto \textbf{return} \sum_{c_j \in cols(D)} D[t_i, c_j] \quad (1)$$

The UPDATE function in Figure 2 aims to minimise redundancy in the summary by globally maximising the number of conceptual units covered in the output. In addition to removing the row representing the extracted text unit from the text × concept matrix D, it iterates through the remaining text units and assigns zero weights to all concepts that are covered by the extracted text unit.

[2] While not considered in the current experiments, a more discourse-oriented approach could be derived within the set cover framework by down-weighting conceptual units that occur e.g. in portions of the source documents that describe background information, where text segments containing background information could be identified using a sentence-level rhetorical status classifier like that developed by Teufel and Moens (2002).

[3] The EXTRACT and UPDATE functions in Figure 2 correspond to Filatova and Hatzivassiloglou (2004) modified adaptive algorithm and were found in preliminary experiments to be the better than the simple greedy and adaptive greedy algorithms (see Hachey (2009) for details).

Figure 3: Example sentence and various representations of sentence content.

4 Models

Figure 3 contains an example sentence and its representations corresponding to the various models of sentence content explored here.[4] These are described in detail in the rest of this section.

4.1 Baseline *tf*idf* Representation (TF)

The baseline model represents sentences as *tf*idf*-weighted bags-of-words (*TF*). Document frequencies for terms are derived from the same resource used by Filatova and Hatzivassiloglou (2004)–a frequency list compiled from a large sample of web pages. Term weighting is calculated using *tf*idf* as:

$$w(i,j) = \sqrt{(1 + \log(tf_{i,j})) * \log\left(\frac{N}{df_i}\right)} \quad (2)$$

where $tf_{i,j}$ is the number of times term i occurs in sentence j and df_i is the number of documents in which term i occurs. An example sentence and its *tf*idf* representation can be seen in Figure 3.

[4]The sentence was selected from document set d47 (from the data set described in Section 5.1 below), which contains articles about Neil Bush and his role in the collapse of Silverado Savings and Loan during the U.S. Savings and Loan crisis of the 1980s and 1990s.

4.2 Event Representation (EV)

We also compare to Filatova and Hatzivassiloglou (2004) atomic events (*EV*). This consists of $<Ent_i, Connector_j, Ent_k>$ event triples, where *connectors* are verbs or action nouns (i.e., nouns that are hyponyms of event or activity in WordNet) that occur in between the two entity mentions. Given a named entity recogniser and a lexical resource (WordNet), these are derived automatically from the text as follows. In the first step, all pairs of entity mentions that occur together in a sentence are identified. Next, the algorithm characterises the entity mention pairs using the connector words from the intervening context and discards pairs without an intervening connector word.

Event triple weighting is calculated by combining entity pair and connector weights as:

$$w_{ev}(i,j,k) = w_{ne}(i,k) * w_{cn}(j,i,k) \quad (3)$$

where $w_{ne}(i,k)$ is the weight of the entity pair $<i,k>$ consisting of entities i and k and $w_{cn}(j,i,k)$ is the weight of connector j in the context of entity pair $<i,j>$. $w_{ne}(i,k)$ is calculated as the normalised entity pair count, i.e.:

$$w_{ne}(i,k) = \frac{C_{ne}(<i,k>)}{C_{ne}(<*,*>)} \quad (4)$$

where $C_{ne}(<i,k>)$ is the count of mentions of entity pair $<i,k>$[5] and $C_{ne}(<*,*>)$ is the total count of entity mention pairs. And, $w_{cn}(j,i,k)$ is calculated as the normalised count of connector j in the context of the entity pair, i.e.:

$$w_{cn}(j,i,k) = \frac{C_{cn}^{<i,k>}(j)}{C_{cn}^{<i,k>}(*)} \quad (5)$$

where $C_{cn}^{<i,k>}(j)$ is the count of occurrences of connector j in the context of entity pair $<i,k>$ and $C_{cn}^{<i,k>}(*)$ is the total count of connectors in the context of entity pair $<i,k>$. An example sentence and its *event* representation can be seen in Figure 3. Event triples generated include <PER_bush,worked,ORG_amoco> and <PER_bush,started,ORG_jnb>.

Some erroneous event triples are also generated. The first error has to do with the fact that entities

[5]Coreference between entity mentions is computed by exact string match after removing punctuation, converting to all lower case, and prefixing the entity type. For example, the entity mention string "JNB" with type ORGANISATION is normalised to ORG_jnb.

include named entities identified in the preprocessing as well as the ten most frequent nouns in the document set. In the example sentence from Figure 3, the most frequent nouns include 'oil' but not 'negotiator' or 'company'. Therefore, 'oil' is labelled as an entity and extracted in a number of triples such as <PER_bush,worked, XFN_oil> (as opposed to <PER_bush, worked,XFN_negotiator>). Another problem illustrated by the example sentence has to do with the noisy nature of the surface-level approach to identifying entity mention pairs and connectors which tends to generate many false positive events, e.g. <ORG_amoco,started, ORG_jnb>. If the algorithm was constrained based on the underlying grammatical structure, it should be able to identity that the arguments of 'worked' are 'Bush' and 'Amoco' (i.e., <PER_bush,worked,ORG_amoco>) and that 'worked' does not describe an event involving 'Amoco' and 'JNB'.

4.3 Relation Representation (RL)

The focus of the current evaluation is a novel representation based on generic relation extraction (GRE). As mentioned above, GRE is a minimally supervised approach to the relation extraction task that aims to build systems for relation identification and characterisation that can be transferred across domains and tasks without modification of model parameters. Relation mentions are identified by taking pairs of entity mentions that have either 1) no more than two intervening words in the surface order of the sentence or 2) no more than one edge intervening on the shortest path through a dependency parse (see Hachey (2009) for details and experiments comparing different window configurations). This is stricter than the Filatova and Hatzivassiloglou approach in that entity mentions have to occur much closer or be connected by a single dependency relation. At the same time, it is less strict in the sense that an action- or event-denoting word is not required in the context, which makes it a more general model of IE.

Relation *connectors* are derived from a model of relation types based on latent Dirichlet allocation (Blei et al., 2003) that incorporates word, entity and dependency path features from the context of a relation-forming entity mention pair (see Hachey (2009) for details). This outputs a topic distribution for each entity mention pair that corresponds to the type of relation that is described. This representation 1) models a type of generic IE that includes relations, 2) uses a connector model that abstracts away from surface-level event descriptors used by Filatova and Hatzivassiloglou (2004) and 3) does not rely on domain-specific resources like WordNet.[6] For the purpose of comparison, relation triples are weighted in the same way as event triples using Equations 3 and 4 above. However, the connector pair weighting is modified to use the distribution over topics given by the LDA output.[7]

Relation triples generated for the example sentence in Figure 3 include <ORG_amoco, rd94,LOC_denver> and <ORG_amoco, rd505,LOC_denver>, where the connectors (i.e., rd94 and rd505) are identifiers that index particular topics from the LDA output. Here, rd94 and rd505 index topics that correspond to *located-in* relations so the respective triples both describe *located-in* relations between Amoco and Denver. Relation triples generated for the example sentence also include <XFN_oil, rd92,ORG_jnb> and <XFN_oil,rd712, ORG_jnb>. These are erroneous for the same reason as some of the event triples above (i.e., due to the noise inherent in the approach to identifying nominal entity mentions by identifying the ten most frequent nouns in the document set).

4.4 Entity Pair Representations (EE, ER)

Finally, we investigate the performance of representations that do not model event or relation type information. These are identical to the EV and RL representations above, except they are $<Ent, Ent>$ 2-tuples instead of $<Ent, Connector, Ent>$ 3-tuples. That is, entity pairs are included here provided that they meet the relation mention identification constraints. They are weighted using the normalised entity pair count (Equation 4 above). Relation-based entity pairs generated for the example sentence in Figure 3 include <LOC_denver,ORG_amoco> and <ORG_jnb,XFN_oil>.

[6] The GRE representation here does rely on dependency parsing, however, Hachey (2009) shows that it is still directly portable between the news and biomedical domains without modification of model parameters.

[7] Distributions for entity mention pairs tend to have a long uniform tail and only a few topics with higher probability. In converting to a weighting scheme, topic representations here are converted to a sparse representation where all topics in the uniform tail are removed.

5 Experimental Setup

5.1 Data

The experiments here use the multi-document summarisation data from the 2001 Document Understanding Conference (DUC),[8] which is the same data used by Filatova and Hatzivassiloglou (2004). This comprises 30 test document sets, each of which include approximately 10 news stories. Each document set is collected by a human and focuses on a particular topic. Example topics include the nomination of Clarence Thomas to the American Supreme Court, Neil Bush's role in the collapse of Silverado Savings and Loan and the Exxon Valdez oil spill. Gold standard summaries are provided for each document set for summary lengths of 50, 100, 200 and 400 words. This helps to ensure that the systems are not over-tuned to specific summary lengths. For each summary task (i.e., all 120 document set $\times$ summary length combinations), there are three distinct gold standard summaries created by different human analysts.

Pre-processing includes sentence boundary identification, segmentation of words (tokenisation), labelling words with part-of-speech tags, identification of noninflected base word forms (lemmatisation) from the LT-TTT tools (Grover et al., 2000). It also includes dependency parsing using Minipar (Lin, 1998) and automatic named entity recognition using the C&C tagger (Curran and Clark, 2003) trained on the data from the MUC-7 shared task (Chinchor, 1998). Weights for the various IE-based representations are calculated over each input document set.

5.2 Evaluation

The evaluation uses Rouge[9] to determine which representation selects content that overlaps most with human summaries. Rouge estimates the coverage of appropriate concepts (Lin, 2004) in a summary by comparing it to several human-created reference summaries. Rouge-1 does so by computing recall based on macro-averaged unigram overlap. Rouge-SU4 does so by calculating skip-bigram overlap where bigrams are allowed to be composed of non-contiguous words (with as many as four words intervening). Rouge-SU4 also includes unigrams to decrease the chances of zero scores where there is no skip-bigram overlap.

The configuration is based on comparisons between Rouge and human judgements of content coverage (Lin, 2004), which suggest that Rouge-1 and Rouge-SU4 with stemming and removal of stop words are good measures for evaluating multi-document summarisation tasks, consistently achieving Pearson's correlation scores above 0.72 and as high as 0.9 for longer summaries. Paired Wilcoxon signed ranks tests across document sets are used to check for significant differences between systems. The paired Wilcoxon signed ranks test is a non-parametric analogue of the paired t test. The null hypothesis is that the two populations from which the scores are sampled are identical.

1	50	100	200	400
TF	0.0797	0.1113	0.1742	0.2467
EV	**0.1360**	**0.1776**	0.2315	**0.3019**
RL	**0.1360**	0.1766	**0.2412**	0.3014

SU4	50	100	200	400
TF	0.0173	0.0259	0.0442	0.0693
EV	**0.0376**	**0.0494**	0.0692	**0.0950**

Table 2: Comparison of Rouge scores for the *tf*idf* (*TF*), *event* (*EV*) and *relation* (*RL*).

6 Results

Can extractive summarisation be improved using representations based on generic information extraction? Table 2 contains results for *tf*idf* (*TF*), *event* (*EV*) and *relation* (*RL*) representations. Columns contain results for different lengths of summary (50, 100, 200 and 400 words). The best representation for each summary length is in bold and representations that are statistically distinguishable from the best (i.e., $p \leq 0.05$) are underlined. The results demonstrate unambiguously that the *event* and *relation* representations outperform the *tf*idf* representation, with strongly significant p-values less than 0.001 for both Rouge measures and all summary lengths. The *event* and *relation* representations are indistinguishable for both Rouge measures and all summary lengths.

[8] http://www-nlpir.nist.gov/projects/duc/index.html

[9] Rouge stands for recall-oriented understudy for gisting evaluations. While current versions also compute precision and f-score of system summaries, the evaluation here uses recall alone, which is sufficient when the length of the summaries being compared is the same. Rouge can be obtained from http://haydn.isi.edu/ROUGE/.

1	50	100	200	400
ER	**0.1497**	**0.1929**	**0.2527**	**0.3123**
EE	0.1442	0.1705	0.2288	0.3061

SU4	50	100	200	400
ER	**0.0419**	**0.0537**	**0.0786**	**0.1008**
EE	0.0364	0.0447	0.0643	0.0963

Table 3: Comparison of Rouge scores for entity pairs based on relations (*ER*) and events (*EE*).

How does entity pair identification for generic relations compare to entity pair identification for atomic events? Table 3 contains results for the representations described in Section 4.4. Rows correspond to entity pair identification for relations (*ER*) and events (*EE*).[10] Results suggest that the entity pair model based on GRE data outperforms the entity pair model based on atomic events, at least for medium sized summaries of 100 and 200 words where *ER* is significantly better than *EE* for both Rouge measures.

How do the event and relation representations perform with respect to corresponding entity pair representations? The scores for the entity pair representations reported in Table 3 are statistically indistinguishable from those for corresponding *relation* and *event* representations in Table 2 above. This appears to be a mixed result for both the *relation* representation introduced here and the Filatova and Hatzivassiloglou *event* representation. And, while GRE is shown to have a positive effect on Rouge scores when compared to atomic events, the same cannot be said of approaches to characterising relation and event types. However, as the correlation analysis (Section 7.1 below) demonstrates, RL and ER do not necessarily perform well on the same document sets. This suggests that they are actually complementary to some degree, meaning that a combined system based on both representations would outperform RL and ER on their own.

[10] In contrast to the results for the *tf*idf*, *relation* and *event* representations which use the modified adaptive algorithm described above, results for entity pair representations use a simplified version of the EXTRACT function that picks the text unit that has the highest score. This performed significantly better than the modified adaptive algorithm ($p \leq 0.01$) for all summary lengths for *ER* and was indistinguishable for *EE*. See Hachey (2009) for details.

7 Analysis and Comparison

7.1 Complementarity

Figure 4 contains results for a correlation analysis comparing the various representations. This also includes a comparison to the human upper bound (*HU*), computed by leave-one-out cross validation. Cells in the matrix contain the correlations values measured across document set Rouge-SU4 scores[11] using Spearman's ρ rank correlation coefficient (r_S). Here, high values mean that two representations tend to perform well on the same document sets such that an ordering of document sets by Rouge scores is similar for the representations being compared. In the figure, correlation strength is represented by shading where light-toned squares indicate strong correlation (and the darkest squares indicate weak negative correlation). For example, the upper left cell contains r_S between the TF and EV representations. The four squares correspond to r_S values of -0.085, 0.199, 0.245 and 0.267 respectively for summaries of 50, 100, 200 and 400 words.

The analysis illustrates a number of interesting points. First, it demonstrates that none of the representations correlate highly with the human upper bound, meaning that the automatic systems do not necessarily do well on the document sets that may be considered easier as measured by human agreement using Rouge. This suggests that task difficulty does not need to be considered as a possible underlying cause of correlation between the automatic systems. The analysis also illustrates that there is no clear and consistent relationship between summary length and correlation values. Some cells suggest that correlation may have a monotonic linear relationship increasing with length (e.g., TF*EV) while others seem to suggest inverse linear (e.g., TF*RL), quadratic (e.g., EV*HU) and invariant (e.g., EV*EE) relationships with length.

Looking at correlation between automatic systems (i.e., TF, EV, RL, EE and ER), correlation values closer to zero suggest that the systems do well on different document sets and that a combined system might therefore be better. By this reasoning, the largest gains would come from combining TF with any other representation. Among the other automatic systems, the *relation*

[11] Correlation across document set Rouge-1 scores shows similar trends.

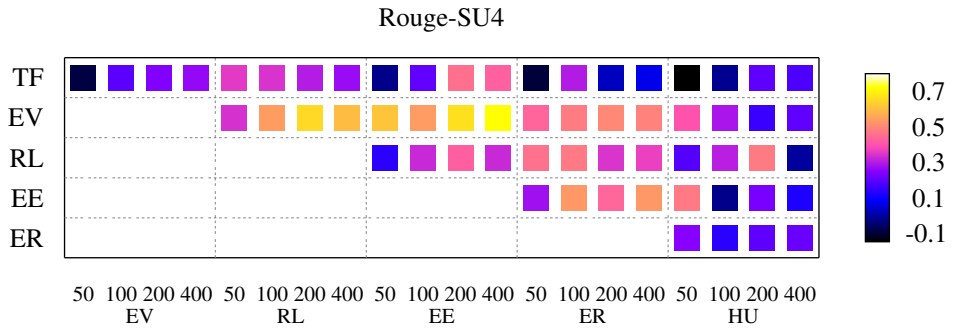

Figure 4: Comparison of representations using Spearman's r_s. Row and column labels correspond to *tf*idf* (*TF*), *event* (*EV*), *relation* (*RL*), *event entity pair* (*EE*), *relation entity pair* (*ER*) and human (*HU*) representations. Lighter toned squares indicate stronger correlation.

representation (RL) shows moderately high potential for combination with its corresponding entity pair representation (ER) with Spearman's r_S values in the range from 0.348 to 0.476. This suggests that ER should not necessarily be considered a simpler representation of the same information captured by RL when comparing results. The *event* representation (EV), by contrast, shows the strongest correlation of any comparison with its corresponding entity pair representation (EE) with r_S values in the range from 0.541 to 0.725.

7.2 Error Analysis

Four document sets were considered for error analysis. These were selected to cover different relative rankings of representations. Rows in Table 4 give the document set ID and list the representations in order of their Rouge-SU4 scores. Inspection of the corresponding document sets suggests that the different approaches compared here are appropriate for different types of summary tasks. Specifically, it suggests that *relation* and *event* representations perform poorly on summarisation tasks that are oriented towards sentiment, description or analysis. However, they do well on document sets that are oriented towards factual information typical of information extraction tasks (though current representations do not capture date, time or numeric information). This supports the notion from the previous section that the different representations evaluated here are complementary.

The document set (d06) for the summaries in Figure 5 illustrates a case where the *relation* and *event* representations perform well with respect

Set	Rank 1	Rank 2	Rank 3
d15	TF (0.046)	RL (0.035)	EV (0.023)
d39	TF (0.033)	EV (0.024)	RL (0.014)
d06	RL (0.094)	EV (0.060)	TF (0.016)
d53	RL (0.078)	TF (0.035)	EV (0.020)

Table 4: DUC 2001 document sets chosen for error analysis and corresponding Rouge-SU4 scores.

to *tf*idf*. The gold standard summary describes a beating event, addressing the basic facts of the Rodney King beating by Los Angeles police as well as the political aftermath which consists primarily of an investigation and a summary of related police brutality events. The difference in performance seems to be due to the fact that relations and events are central to all aspects of this summary and the *relation* and *event* representations clearly do better than *tf*idf* at capturing this information. This summary also illustrates an unintended side-effect of the *relation* representation where the generic relation identification algorithm finds relations between components of lexical compounds or multi-word phrases. The representation for the third sentence in the *RL* summary, for example, includes a relation between `ORG_police` and `XFN_chief` in addition to true positive relations e.g. between `ORG_police` and `PER_darylgates` and false positive relations e.g. between `PER_tombradley` and `ORG_police`.

7.3 Comparison to Supervised Extraction

Related work by Wong et al. (2008) also compares representations for sentence extraction on

TF (0.016) (20/29)	**[S1]** Mr. Williams likened the report to the Knapp Commission, a 1970s blue-ribbon study that exposed widespread corruption in the New York Police Department and led to significant improvements there. **[S2]** "There's no doubt in our mind that the only reason they stopped Joe Morgan was because he is black and he was the first black who happened to come by," said William Barnes, one of the attorneys representing the former ballplayer. **[S3]** Joseph McNamara, retired chief of San Jose's department and now a fellow at Stanford University's Hoover Institution, said he has been getting calls all summer from **[END]** cities around the country about racism and brutality in their departments.
EV (0.060) (9/29)	**[S1]** A high-ranking commission appointed after the beating, under the chairmanship of Mr Warren Christopher, a lawyer and former deputy secretary of state, concluded that the Los Angeles police department got results, in terms of arrests, but had developed a 'siege mentality that alienates the officer from the community'. **[S2]** The images of Los Angeles police swinging nightsticks at King as he lay on the ground, played repeatedly on national news programs, were burned into the national conscience and led to widespread calls for investigation of police brutality. **[S3]** Besides recommending that Mr Gates should go, the Christopher commission urged a policy **[END]** of community policing with more foot patrols, as well as measures to discipline racist police officers and to improve the investigation of complaints about police brutality.
RL (0.094) (3/29)	**[S1]** Mr. Gates opposed the Police Corps because its members would not be professionals. **[S2]** Shortly after Rodney King's beating, a news program on ABC illustrating police brutality showed a still photo of police using a martial-arts weapon against a person being arrested, but there was no mention that the episode involved Operation Rescue. **[S3]** The report was issued yesterday by a commission appointed by Mayor Tom Bradley and Police Chief Daryl Gates in the wake of the videotaped beating March 3 of a black motorist, Rodney King, by Los Angeles police. **[S4]** Investigations have been launched by the FBI, the Los **[END]** Angeles County district attorney's office and the Long Beach Police Department.
HU (0.400) (15/29)	The most important of the many cases of police brutality reported in southern California 1989-1992, was the beating of Rodney King by four Los Angeles officers on March 3, 1991. An investigating commission outlined steps for improvement of the police department and called for the resignation of Chief Gates. Gates did not resign until the following year after the acquittal of the four officers caused massive rioting. Other cases of police brutality arose in Minneapolis, Chicago and Kansas City. Operation Rescue claimed that its non-violent anti-abortion demonstrators were seriously injured by excessive police tactics in more than **[END]** 50 cities.

Figure 5: Example system and *human* (*HU*) summaries where *relation* (*RL*) and *event* (*EV*) representations perform well with respect to the *tf*idf* (*TF*) representation: Police Brutality Document Set (d06).

the DUC 2001 data. However, it uses supervised machine learning (probabilistic support vector machines) to derive a salience function while we focus on unsupervised approaches that can be ported to new domains and tasks without annotation or training. Interestingly, Wong et al.'s results suggest that adding events to a word-based feature set increases the precision of supervised sentence extraction but reduces the recall. By contrast, the current results and analysis provide evidence that word and generic IE-based representations are complementary when using unsupervised salience functions for sentence extraction.

The Wong et al. (2008) paper also provides useful results for comparison to state-of-the art. On the 200 word summarisation task, Wong et al. report Rouge-1 scores of 0.352 and 0.344 respectively for word-based and event-based representations. On the same task, our unsupervised approach achieves Rouge-1 scores of 0.174, 0.232, 0.229, 0.241 and 0.253 respectively for the *tf*idf*, *event*, *event entity pair*, *relation* and *relation entity pair* representations. Wong et al.'s best overall score is 0.396 using a representation that combines surface, content and relevance features.

8 Conclusion

Experiments were presented that compare the effect of various source document representations on the accuracy of automatic summarisation. This serves as an extrinsic evaluation of generic relation extraction, a domain-neutral and fully portable approach to relation identification and characterisation. Results demonstrate that GRE is an effective representation for sentence extraction for multi-document summarisation. Performance for the *relation* representation is significantly better than a non-trivial *tf*idf* baseline across the range of summary lengths explored. Performance is also at least as good as a comparable but less general representation based on event extraction. Correlation analysis suggests that different representations are complementary due to the fact that they perform well on different document sets. Error analysis supports this conclusion, suggesting that the *relation* and *event* representations perform poorly on summarisation tasks that are oriented towards e.g. sentiment, description or analysis while they perform well on tasks that focus on fact-oriented information.

Language Models Based on Semantic Composition

Jeff Mitchell and **Mirella Lapata**
School of Informatics, University of Edinburgh

jeff.mitchell@ed.ac.uk, mlap@inf.ed.ac.uk

Abstract

In this paper we propose a novel statistical language model to capture long-range semantic dependencies. Specifically, we apply the concept of semantic composition to the problem of constructing predictive history representations for upcoming words. We also examine the influence of the underlying semantic space on the composition task by comparing spatial semantic representations against topic-based ones. The composition models yield reductions in perplexity when combined with a standard n-gram language model over the n-gram model alone. We also obtain perplexity reductions when integrating our models with a structured language model.

1 Introduction

Statistical language modeling plays an important role in many areas of natural language processing including speech recognition, machine translation, and information retrieval. The prototypical use of language models is to assign probabilities to sequences of words. By invoking the chain rule, these probabilities are generally estimated as the product of conditional probabilities $P(w_i|h_i)$ of a word w_i given the history of preceding words $h_i \equiv w_1^{i-1}$. In theory, the history could span any number of words up to w_i such as sentences or even a paragraphs. In practice, however, it has proven challenging to deal with the combinatorial growth in the number of possible histories which in turn impacts reliable parameter estimation. A simple and effective strategy is to truncate the chain rule to include only the n-1 preceding words (n is often set within the range of 3–5). The simplification reduces the number of free parameters. However, low values of n impose an artificially local horizon to the language model, and compromise its ability to capture long-range dependencies, such as syntactic relationships, semantic or thematic constraints.

The literature offers many examples of how to overcome this limitation, essentially by allowing the modulation of probabilities by dependencies which extend to words beyond the n-gram horizon. Cache language models (Kuhn and de Mori, 1992) increase the probability of words observed in the history, e.g., by some factor which decays exponentially with distance. Trigger models (Rosenfeld, 1996) go a step further by allowing arbitrary word pairs to be incorporated into the cache. Structured language models (e.g., Roark (2001)) go beyond the representation of history as a linear sequence of words to capture the syntactic constructions in which these words are embedded.

It is also possible to build representations of history which are semantic rather than syntactic (Bellegarda (2000; Coccaro and Jurafsky (1998; Gildea and Hofmann (1999)). In this approach, estimates for the probabilities of upcoming words are derived from a comparison of their semantic content with the content of the history so far. The semantic representations, in this case, are vectors derived from the distributional properties of words in a corpus, based on the insight that words which are semantically similar will be found in similar contexts (Harris, 1968; Firth, 1957). Although the the construction of a semantic representation for the history is crucial to this approach, the underlying vector-based models are primarily designed to represent isolated words rather than word sequences. Ideally, we would like to *compose* the meaning of the history out of its constituent parts. This is by no means a new idea. Much work in linguistic theory (Partee, 1995; Montague, 1974) has been devoted to compositionality, the process of determining the meaning of complex expressions from simpler ones. Previous work either ignores this issue (e.g., Bellegarda (2000)) or simply com-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 430–439,
Singapore, 6-7 August 2009.

putes the centroid of the vectors representing the history (e.g., Coccaro and Jurafsky (1998)). This is motivated primarily by mathematical convenience rather than by empirical evidence.

In our earlier work (Mitchell and Lapata, 2008) we formulated composition as a function of two vectors and introduced a variety of models based on addition and multiplication. In this paper we apply vector composition to the problem of constructing predictive history representations for language modeling. Besides integrating composition with language modeling, a task which is novel to our knowledge, our approach also serves as a valuable testbed of our earlier framework which we originally evaluated on a small scale verb-subject similarity task. We also investigate how the choice of the underlying semantic representation interacts with the choice of composition function by comparing a spatial model that represents words as vectors in a high-dimensional space against a probabilistic model that represents words as topic distributions.

Our results show that the proposed composition models yield reductions in perplexity when combined with a standard n-gram model over the n-gram model alone. We also show that with an appropriate composition function spatial models outperform the more sophisticated topic models. Finally, we obtain further perplexity reductions when our models are integrated with a structured language model, indicating that the two approaches to language modeling are complementary.

2 Background

2.1 Distributional Models of Semantics

The insight that words with similar meanings will tend to be distributed in similar contexts has given rise to a number of approaches that construct semantic representations from corpora. Broadly speaking, these models come in two flavors. *Semantic space* models represent the meaning of words in terms of vectors, with the vector components being derived from the distributional statistics of those words. Essentially, these models provide a simple procedure for constructing spatial representations of word meaning. *Topic models*, in contrast, impose a probabilistic model onto those distributional statistics, under the assumption that hidden topic variables drive the process that generates words. Both approaches represent the meanings of words in terms of an n-dimensional series of values, but whereas the semantic space model treats those values as defining a vector with spatial properties, the topic model treats them as a probability distribution.

A simple and popular (McDonald, 2000; Bullinaria and Levy, 2007; Lowe, 2000) way to construct a semantic space model is to associate each vector component with a particular context word, and assign it a value based on the strength of its co-occurrence with the target (i.e., the word for which a semantic representation is being constructed). For example, in Mitchell and Lapata (2008) we used the 2,000 most frequent content words in a corpus as their contexts, and defined co-occurrence in terms of the context word being present in a five word window on either side of the target word. We calculated the ratio of the probability of the context word given the target word to the overall probability of the context word and use these values as their vector components. This procedure has the benefits of simplicity and also of being largely free of any additional theoretical assumptions over and above the distributional approach to semantics. This is not to say that more sophisticated approaches have not been developed or that they are not useful. Much work has been devoted to enriching semantic space models with syntactic information (e.g., Grefenstette (1994; Padó and Lapata (2007)), selectional preferences (Erk and Padó, 2008) or with identifying optimal ways of defining the vector components (e.g., Bullinaria and Levy (2007)).

The semantic space discussed thus far is based on word co-occurrence statistics. However, the statistics of how words are distributed across the documents also carry useful semantic information. Latent Semantic Analysis (LSA, Landauer and Dumais (1997) utilizes precisely this distributional information to uncover hidden semantic factors by means of dimensionality reduction. Singular value decomposition (SVD, Berry et al. (1994)) is applied to a word-document co-occurrence matrix which is factored into a product of a number of other matrices; one of them represents words in terms of the semantic factors and another represents documents in terms of the same factors. The algebraic relation between these matrices can be used to show that any document vector is a linear combination of the vectors representing the words it contains. Thus, within this paradigm it is nat-

ural to treat multi-word structures as a "pseudo-document" and represent them via linear combinations of word vectors.

Due to its generality, LSA has proven a valuable analysis tool with a wide range of applications. However, the SVD procedure is somewhat ad-hoc lacking a sound statistical foundation. Probabilistic Latent Semantic Analysis (pLSA, Hofmann (2001)) casts the relationship between documents and words in terms of a generative model based on a set of hidden topics. Documents are represented by distributions over topics and topics are distributions over words. Thus the mixture of topics in any document determines its vocabulary. Maximum likelihood estimation of these distributions over a word-document matrix has a comparable effect to SVD in LSA: a set of hidden semantic factors, in this case topics, are extracted and documents and words are represented by these topics.

Latent Dirichlet Allocation (Griffiths et al., 2007; Blei et al., 2003) enhances further the mathematical foundation of this approach. Whereas pLSA treats each document as a separate, independent mixture of topics, LDA assumes that the topic distributions of documents are generated by a Dirichlet distribution. Thus, LDA is a probabilistic model of the whole document collection. In this model the process of generating a document can be described as follows:

1. draw a multinomial distribution θ from a Dirichlet distribution parametrized by α
2. for each word in a document:
   (a) draw a topic z_k from the multinomial distribution characterized by θ
   (b) draw a word from a multinomial distribution conditioned on the topic z_k and word probabilities β

Under this model, constructing a representation for a multi-word sequence amounts to estimating the topic proportions for that sequence.[1] Structure here arises from the mathematical form of the model, as opposed to any linguistic assumptions.

Without anticipating our results too much, we should point out that several features of the LDA model are likely to affect the representation of multi-word sequences. Firstly, it is a top-down generative model (the topic proportions for a document are first selected and then this drives the generation of words) as opposed to a bottom-up constructive process (words modulate each other to produce a complex representation of their combination). Secondly, the top level Dirichlet distribution is likely to lead to documents being dominated by a small number of topics, producing sparse vectors. And lastly, the assumption that words are generated independently means the interaction between them is not modeled.

[1] Estimating the posterior distribution $P(\theta, z|\mathbf{w}, \alpha, \beta)$ of the hidden variables given an observed collection of documents $\mathbf{w}$ is intractable in general; however, a variety of approximate inference algorithms have been proposed in the literature (e.g., Blei et al. (2003; Griffiths et al. (2007)).

2.2 Language Modeling using Semantic Representations

A common approach to embedding semantic representations within language modeling is to measure the semantic similarity between an upcoming word and its history and use it to modify the probabilities from an n-gram model. In this way, the n-gram's sensitivity to short-range dependencies is enriched with information about longer-range semantic coherence. Much of previous work has taken this approach (Bellegarda, 2000; Coccaro and Jurafsky, 1998; Wandmacher and Antoine, 2007), whilst relying on LSA to provide semantic representations for individual words. Some authors (Coccaro and Jurafsky, 1998; Wandmacher and Antoine, 2007) use the geometric notion of a vector centroid to construct representations of history, whereas others (Bellegarda, 2000; Deng and Khundanpur, 2003) use the idea of a "pseudo-document", which is derived from the algebraic relation between documents and words assumed within LSA. They all derive $P(w_i|h_i)$, the probability of an upcoming word given its history, from the cosine similarity measure which must be somehow normalized in order to yield well-formed probability estimates.

The approach of Gildea and Hofmann (1999) overcomes this difficulty by using representations constructed with pLSA, which have a direct probabilistic interpretation. As a result, the probability of an upcoming word given the history can be derived naturally and directly, avoiding the need for ad-hoc transformations. In constructing their representation of history, Gildea and Hofmann (1999) use an online Expectation Maximization process, which derives from the probabilistic basis of pLSA, to update the history with new words.

Extensions on the basic semantic language

models sketched above involve representing the history by multiple LSA models of varying granularity in an attempt to capture topic, subtopic, and local information (Zhang and Rudnicky, 2002); incorporating syntactic information by building the semantic space over words and their syntactic annotations (Kanejiya et al., 2004); and treating the LSA similarity as a feature in a maximum entropy language model (Deng and Khundanpur, 2003).

3 Composition Models

The problem of vector composition has received relatively little attention within natural language processing. Attempts to use tensor products (Smolensky, 1990; Clark et al., 2008; Widdows, 2008) as a means of binding one vector to another face major computational difficulties as their dimensionality grows exponentially with the number of constituents being composed. To overcome this problem, other techniques (Plate, 1995) have been proposed in which the binding of two vectors results in a vector which has the same dimensionality as its components. Crucially, the success of these methods depends on the assumption that the vector components are randomly distributed. This is problematic for modeling language which has regular structure.

Given the above considerations, in Mitchell and Lapata (2008) we introduce a general framework for studying vector composition, which we formulate as a function f of two vectors $\mathbf{u}$ and $\mathbf{v}$:

$$\mathbf{h} = f(\mathbf{u}, \mathbf{v}) \tag{1}$$

where $\mathbf{h}$ denotes the composition of $\mathbf{u}$ and $\mathbf{v}$. Different composition models arise, depending on how f is chosen. Our earlier work (Mitchell and Lapata, 2008) explored two broad classes of models based on additive and multiplicative functions.

Additive models are the most common method of vector combination in the literature. They have been applied to a wide variety of tasks including document coherence (Foltz et al., 1998), essay grading (Landauer and Dumais, 1997), modeling selectional restrictions (Kintsch, 2001), and notably language modeling (Coccaro and Jurafsky, 1998; Wandmacher and Antoine, 2007):

$$h_i = u_i + v_i \tag{2}$$

Vector addition (or averaging, which is equivalent under the cosine similarity measure) is a computationally efficient composition model as it does not increase the dimensionality of the resulting vector. However, the idea of averaging is somewhat counterintuitive from a linguistic perspective. Composition of simple elements onto more complex ones must allow the construction of novel meanings which go beyond those of the individual elements (Pinker, 1994).

In Mitchell and Lapata (2008) we argue that composition models based on multiplication address this problem:

$$h_i = u_i \cdot v_i \tag{3}$$

Whereas the addition of vectors 'lumps their content together', multiplication picks out the content relevant to their combination by scaling each component of one with the strength of the corresponding component of the other. This argument is appealing, especially if one is interested in explaining how the meaning of a verb is modulated by its subject. Here, we also develop a complementary, probabilistic argument for the validity of this model.

Let us assume that semantic vectors are based on components defined as the ratio of the conditional probability of a context word given the target word to the overall probability of the context word.

$$v_i = \frac{p(context_i|target)}{p(context_i)} \tag{4}$$

These vectors represent the distributional properties of a given target word in terms of the strength of its co-occurrence with a set of context words. Dividing through by the overall probability of each context word prevents the vectors being dominated by the most frequent context words, which will often also have the highest conditional probabilities.

Let us assume vectors $\mathbf{u}$ and $\mathbf{v}$ represent target words w_1 and w_2. Now, when we compose these vectors using the multiplicative model and the components definition in (4), we obtain:

$$h_i = v_i \cdot u_i = \frac{p(c_i|w_1)}{p(c_i)} \frac{p(c_i|w_2)}{p(c_i)} \tag{5}$$

And by Bayes' theorem:

$$h_i = \frac{p(w_1|c_i)p(w_2|c_i)}{p(w_1)p(w_2)} \tag{6}$$

Assuming w_1 and w_2 are independent and applying Bayes' theorem again, h_i becomes:

$$h_i \approx \frac{p(w_1 w_2|c_i)}{p(w_1 w_2)} = \frac{p(c_i|w_1 w_2)}{p(c_i)} \tag{7}$$

By comparing to (4), we can see that the expression on the right hand side gives us something akin to the vector components we would expect when our target is the co-occurrence of w_1 and w_2. Thus, for the multiplicative model, the combined vector h_i can be thought of as an approximation to a vector representing the distributional properties of the phrase $w_1 w_2$.

If multiplication results in a vector which is something like the representation of w_1 *and* w_2, then addition produces a vector which is more like the representation of w_1 *or* w_2. Suppose we were unsure whether a word token x was an instance of w_1 or of w_2. It would be reasonable to express the probabilities of context words around this token in terms of the probabilities for w_1 and w_2, assuming complete uncertainty between them:

$$p(c_i|x) = \frac{1}{2}p(c_i|w_1) + \frac{1}{2}p(c_i|w_2) \tag{8}$$

Therefore, we could represent x with a vector, based on these probabilities, having the components:

$$x_i = \frac{1}{2}\frac{p(c_i|w_1)}{p(c_i)} + \frac{1}{2}\frac{p(c_i|w_2)}{p(c_i)} \tag{9}$$

Which is exactly the vector averaging approach to semantic composition. As more vectors are combined, vector addition will lead to greater generality rather than greater specificity. The multiplicative approach, on the other hand, picks out the components of the constituents that are relevant to the combination, and represents more faithfully the properties of their conjunction.

As an aside, we should point out that our earlier work (Mitchell and Lapata, 2008) introduced several other models, additive and multiplicative, besides the ones discussed here. We selected the additive model as a baseline and also due to its overwhelming popularity in the language modeling literature. The multiplicative model presented above performed best in our evaluation study (i.e., predicting *verb-subject* similarity).

4 Language Modeling

Estimating Probabilities In language modeling our aim is to derive probabilities, $p(w|h)$, given the semantic representations of word, w, and its history, h, based on the assumption that probable words should be semantically coherent with the history. Semantic coherence is commonly measured via the cosine of the angle between two vectors:

$$sim(\mathbf{w},\mathbf{h}) = \frac{\mathbf{w}\cdot\mathbf{h}}{|\mathbf{w}||\mathbf{h}|} \tag{10}$$

$$\mathbf{w}\cdot\mathbf{h} = \sum_i w_i h_i \tag{11}$$

where $\mathbf{w}\cdot\mathbf{h}$ is the dot product of $\mathbf{w}$ and $\mathbf{h}$. Coccaro and Jurafsky (1998) utilize this measure in their approach to language modeling. Unfortunately, they find it necessary to resort to a number of ad-hoc mechanisms to turn the cosine similarities into useful probabilities. The primary problem with the cosine measure is that, although its values lie between 0 and 1, they do not sum to 1, as probabilities must. Thus, some form of normalization is required. A further problem concerns the fact that such a measure takes no account of the underlying frequency of w, which is crucial for a probabilistic model. For example, *encephalon* and *brain* are roughly synonymous, and may be equally similar to some context, but *brain* may nonetheless be much more likely, as it is generally more common.

An ideal measure would take account of the underlying probabilities of the elements involved and produce values that sum to 1. Our approach is to modify the dot product (equation (11)) on which the cosine measure is based. Assuming that our vector components are given by equation (4), the dot product becomes:

$$\mathbf{w}\cdot\mathbf{h} = \sum_i \frac{p(c_i|w)}{p(c_i)}\frac{p(c_i|h)}{p(c_i)} \tag{12}$$

which we modify to derive probabilities as follows:

$$p(w|h) = p(w)\sum_i \frac{p(c_i|w)}{p(c_i)}\frac{p(c_i|h)}{p(c_i)}p(c_i) \tag{13}$$

This expression now weights the sum with the independent probabilities of the context words and the word to be predicted. That this is indeed a valid probability can be seen by the fact it is equivalent to $\sum_i p(w|c_i)p(c_i|h)$. However, in constructing a representation of the history h, it is more convenient to work with equation (13) as it is based on vector components and can be readily used with the composition models presented in Mitchell and Lapata (2008).

Equation (13) allows us to derive probabilities from vectors representing a word and its prior history. We must also construct a representation of

the history up to the nth word of a sentence. To do this, we combine, via some (additive or multiplicative) function f, the vector representing that word with the vector representing the history up to $n-1$ words:

$$\mathbf{h}_n = f(\mathbf{w}_n, \mathbf{h}_{n-1}) \tag{14}$$

$$\mathbf{h}_1 = \mathbf{w}_1 \tag{15}$$

One issue that must be resolved in implementing equation (14) is that the history vector should remain correctly normalized. In other words, the products $h_i \cdot p(c_i)$ must themselves be a valid distribution over context words. So, after each vector composition the history vector is normalized as follows:

$$h_i = \frac{\hat{h}_i}{\sum_j \hat{h}_j \cdot p(c_i)} \tag{16}$$

Equations (13)–(16) define a language model that incorporates vector composition. To generate probability estimates, it requires a set of word vectors whose components are based on the ratio of probabilities described by equation (4).

Our discussion thus far has assumed a spatial semantic space model similar to that employed in Mitchell and Lapata (2008). However, there is no reason why the vectors should not be constructed by some other means. As mentioned earlier, in the LDA topic model, words are represented as distributions over topics. These distributions are essentially components of a vector $\mathbf{v}$ corresponding to the target word for which we wish to construct a semantic representation. Analogously to equation (4), we convert these probabilities to ratios of probabilities:

$$v_i = \frac{p(topic_i|target)}{p(topic_i)} \tag{17}$$

Integrating with Other Language Models The models defined above are based on little more than semantic coherence. As such they will be only weakly predictive, since they largely ignore word order, which n-gram models primarily exploit. The simplest means to integrate semantic information with a standard language model involves combining two probability estimates as a weighted sum:

$$p(w|h) = \lambda_1 p_1(w|h) + (1-\lambda) p_2(w|h) \tag{18}$$

Linear interpolation is guaranteed to produce valid probabilities, and has been used, for example, to integrate structured language models with n-gram models (Roark, 2001). However, it will work best when the models being combined are roughly equally predictive and have complementary strengths and weaknesses. If one model is much weaker than the other, linear interpolation will typically produce a model of intermediate strength (i.e., worse than the better model), with the weaker model contributing a form of smoothing at best.

Therefore, based on equation (13), we express our semantic probabilities as the product of the unigram probability, $p(w)$, and a semantic component, Δ, which determines the factor by which this probability should be scaled up or down given the context in which it occurs.

$$p(w|h) = p(w) \cdot \Delta(w,h) \tag{19}$$

$$\Delta(w,h) = \sum_i \frac{p(c_i|w)}{p(c_i)} \frac{p(c_i|h)}{p(c_i)} p(c_i) \tag{20}$$

Thus, it seems reasonable to integrate the n-gram model by replacing the unigram probabilities with the n-gram versions.[2]

$$\hat{p}(w_n) = p(w_n|w_{n-2}^{n-1}) \cdot \Delta(w_n, h) \tag{21}$$

To obtain a true probability estimate we normalize $\hat{p}(w_n)$ by dividing through the sum of all word probabilities:

$$p(w_n|w_{n-2}^{n-1}, h) = \frac{\hat{p}(w_n)}{\sum_w \hat{p}(w)} \tag{22}$$

In integrating our semantic model with an n-gram model, we allow the latter to handle short range dependencies and have the former handle the longer dependencies outside the n-gram window. For this reason, the history h used by the semantic model in the prediction of w_n only includes words up to w_{n-3} (i.e., only words outside the n-gram).

We also integrate our models with a structured language model (Roark, 2001). However, in this case we use linear interpolation (equation (18)) because the models are roughly equally predictive and also because linear interpolation is widely used when structured language models are combined with n-grams and other information sources. This approach also has the benefit of allowing the

[2] Equation (21) can also be expressed as $p(w_n|w_{n-2}^{n-1}, h) \approx \frac{p(w_n|w_{n-2}^{n-1}) p(w_n|h)}{p(w_n)}$, Which is equivalent to assuming that h is conditionally independent of w_{n-2}^{n-1} (Gildea and Hofmann, 1999).

models to be combined without out the need to renormalize the probabilities. In the case of the structured language model, normalizing across the whole vocabulary would be prohibitive.

5 Experimental Setup

In this section we discuss our experimental design for assessing the performance of the models presented above. We give details on our training procedure and parameter estimation, and present the methods used for comparison with our approach.

Method Following previous work (e.g., Bellegarda (2000)) we integrated our compositional language models with a standard n-gram model (see equation (21)). We experimented with additive and multiplicative composition functions, and two semantic representations (LDA and the simpler semantic space model), resulting in four compositional models. In addition, we compared our models against a state of the art structured language model in order to assess the extent to which the information provided by the semantic representation is complementary to syntactic structure. Our experiments used Roark's (2001) grammar-based language model. Similarly to standard language models, it computes the probability of the next word based upon the previous words of the sentence. This is done by computing a subset of all possible grammatical relations for the prior words and then estimating the probability of the next grammatical structure and the probability of seeing the next word given each of the prior grammatical relations. When estimating the probability of the next word, the model conditions on the two prior heads of constituents, thereby using information about word triples (like a trigram model).

All our models were evaluated by computing perplexity on the test set. Roughly, this quantifies the degree of unpredictability in a probability distribution, such that a fair k-sided dice would have a perplexity of k. More precisely, perplexity is the reciprocal of the geometric average of the word probabilities and a lower score indicates better predictions.

Parameter Estimation The compositional language models were trained on the BLLIP corpus, a collection of texts from the Wall Street Journal (years 1987–89). The training corpus consisted of 38,521,346 words. We used a development corpus of 50,006 words and a test corpus of similar size. All words were converted to lowercase and numbers were replaced with the symbol $\langle$num$\rangle$. A vocabulary of 20,000 words was chosen and the remaining tokens were replaced with $\langle$unk$\rangle$.

Following Mitchell and Lapata (2008), we constructed a simple semantic space based on co-occurrence statistics from the BLLIP training set. We used the 2,000 most frequent word types as contexts and a symmetric five word window. Vector components were defined as in equation (4). Contrary to our earlier work, we did not lemmatize the corpus before constructing the vectors as in the context of language modeling this was not appropriate. We also trained the LDA model on BLLIP, using Blei et al.'s (2003) implementation.[3] We experimented with different numbers of topics on the development set (from 10 to 200) and report results on the test set with 100 topics. In our experiments, the hyperparameter α was initialized to 0.5, and the β word probabilities were initialized randomly.

We integrated our compositional models with a trigram model which we also trained on BLLIP. The model was built using the SRILM toolkit (Stolcke, 2002) with backoff and Good-Turing smoothing. Ideally, we would have liked to train Roark's (2001) parser on the same data as that used for the semantic models. However, this would require a gold standard treebank several times larger than those currently available. Following previous work on structured language modeling (Roark, 2001; Charniak, 2001; Chelba and Jelinek, 1998), we therefore trained the parser on sections 2–21 of the Penn Treebank containing 936,017 words. Note that Roark's (2001) parser produces prefix probabilities for each word of a sentence which we converted to conditional probabilities by dividing each current probability by the previous one.

6 Results

Table 1 shows perplexity results when the compositional models are combined with an n-gram model. With regard to the simple semantic space model (SSM) we observe that both additive and multiplicative approaches to constructing history are successful in reducing perplexity over the n-gram baseline, with the multiplicative model outperforming the additive one. This confirms the

Model	Perplexity
n-gram	78.72
n-gram+Add$_{\text{SSM}}$	76.65
n-gram + Multiply$_{\text{SSM}}$	75.01
n-gram+Add$_{\text{LDA}}$	76.60
n-gram+Multiply$_{\text{LDA}}$	123.93
parser	173.35
n-gram + parser	75.22
n-gram + parser + Add$_{\text{SSM}}$	73.45
n-gram + parser + Multiply$_{\text{SSM}}$	71.32
n-gram + parser + Add$_{\text{LDA}}$	71.58
n-gram + parser + Multiply$_{\text{LDA}}$	87.93

Table 1: Perplexities for n-gram, composition and structured language models, and their combinations; subscripts $_{\text{SSM}}$ and $_{\text{LSA}}$ refer to the semantic space and LDA models, respectively.

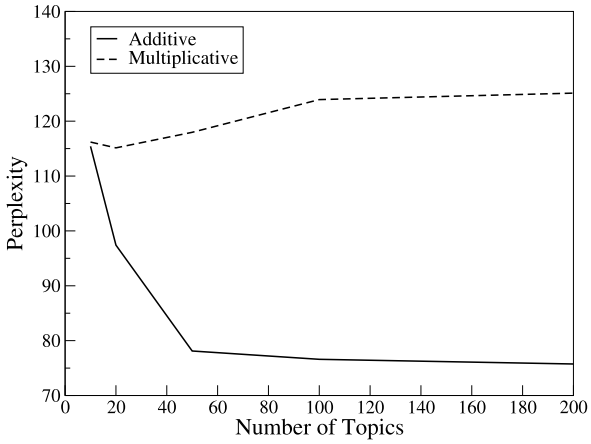

Figure 1: Perplexity versus Number of Topics for the LDA models using additive and multiplicative composition functions.

hypothesis that for this type of semantic space the multiplicative vector combination function produces representations which have a sounder probabilistic basis.

The results for the LDA model are also reported in the table. This model reduces perplexity with an additive composition function, but performs worse than the n-gram with a multiplicative function. For comparison, Figure 1 plots the perplexity of the combined LDA and n-gram models against the number of topics. Increasing the number of topics produces higher dimensional representations which ought to be richer, more detailed and therefore more predictive. While this is true for the additive model, a greater number of topics actually increases the perplexity of the multiplicative model, indicating it has become less predictive.

We compared these perplexity reductions against those obtained with a structured language model. Following Roark (2001), we combined the structured language model with a trigram model using linear interpolation (the weights were optimized on the development set). This model (n-gram + parser) performs comparably to our best compositional model (n-gram + Multiply$_{\text{SSM}}$). While both models incorporate long range dependencies, the parser is trained on a hand annotated treebank, whereas the compositional model uses raw text, albeit from a larger corpus. Interestingly, when interpolating the trigram with the parser *and* the compositional models, we obtain additional perplexity reductions. This suggests that the semantic models are encoding useful predictive information about long range dependencies, which is distinct from and potentially complementary to the parser's syntactic information about such dependencies. Note that the semantic space multiplicative model yields the highest perplexity reduction in this suite of experiments followed by the LDA additive model.

7 Conclusions

In this paper we advocated the use of vector composition models for language modeling. Using semantic representations of words outside the n-gram window, we enhanced a trigram model with longer range dependencies. We compared composition models based on addition and multiplication and examined the influence of the underlying semantic space on the composition task. Our results indicate that the multiplicative composition function produced the most predictive representations with a simple semantic space. Interestingly, its effect in the LDA setting was detrimental. Increasing the representational power of the LDA model, by using a greater number of topics, rendered the multiplicative model less predictive.

These results, together with the basic mathematical structure of the LDA model, suggest that it may not be well suited to forming representations for word sequences. In particular, the assumption that words are generated independently within documents prevents the interactions between words being modeled. This assumption, along with the Dirichlet prior on document distributions tends to lead to highly sparse word vec-

tors, with a typical word being strongly associated with only one or two topics. Multiplication of a number of these vectors generally produces a vector in which most of these associations have been obliterated by the sparse components, resulting in a representation with little predictive power.

These shortcomings arise from the mathematical formulation of LDA, which is not directed at modeling the semantic interaction between words. An interesting future direction would be to optimize the vector components of the probabilistic model over a suitable training corpus, in order to derive a vector model of semantics adapted specifically to the task of composition. We also plan to investigate more sophisticated composition models that take syntactic structure into account. Our results on interpolating the compositional models with a parser indicate that there is substantial mileage to be gained by combining syntactic and semantic dependencies.

Acknowledgements We are grateful to Brian Roark for making his parser available to us. Thanks to Frank Keller and Victor Lavrenko for insightful comments and suggestions. Abstract

Word sense disambiguation is typically phrased as the task of labeling a word in context with the best-fitting sense from a sense inventory such as WordNet. While questions have often been raised over the choice of sense inventory, computational linguists have readily accepted the best-fitting sense methodology despite the fact that the case for discrete sense boundaries is widely disputed by lexical semantics researchers. This paper studies *graded word sense assignment*, based on a recent dataset of graded word sense annotation.

1 Introduction

The task of automatically characterizing word meaning in text is typically modeled as word sense disambiguation (WSD): given a list of senses for target lemma w, the task is to pick the best-fitting sense for a given occurrence of w. The list of senses is usually taken from an online dictionary or thesaurus. However, clear cut sense boundaries are sometimes hard to define, and the meaning of words depends strongly on the context in which they are used (Cruse, 2000; Hanks, 2000). Some researchers in lexical semantics have suggested that word meanings lie on a continuum between i) clear cut cases of ambiguity and ii) vagueness where clear cut boundaries do not hold (Tuggy, 1993). Certainly, it seems that a more complex representation of word sense is needed with a softer, graded representation of meaning rather than a fixed listing of senses (Cruse, 2000).

A recent annotation study ((Erk et al., 2009), hereafter **GWS**) marked a target word in context with graded ratings (on a scale of 1-5) on senses from WordNet (Fellbaum, 1998). Table 1 shows an example of a sentence with the target word in bold, and with the annotator judgments given to each sense. The study found that annotators made ample use of the intermediate ratings on the scale, and often gave high ratings to more than one WordNet sense for the same occurrence. It was found that the annotator ratings could not easily be transformed to categorial judgments by making more coarse-grained senses. If human word sense judgments are best viewed as graded, it makes sense to explore models of word sense that can predict graded sense assignments.

In this paper we look at the issue of graded applicability of word sense from the point of view of automatic *graded word sense assignment*, using the GWS graded word sense dataset. We make three primary contributions. Firstly, we propose evaluation metrics that can be used on graded word sense judgments. Some of these metrics, like Spearman's ρ, have been used previously (McCarthy et al., 2003; Mitchell and Lapata, 2008), but we also introduce new metrics based on the traditional precision and recall. Secondly, we investigate how two classes of models perform on the task of graded word sense assignment: on the one hand classical WSD models, on the other hand prototype-based vector space models that can be viewed as simple one-class classifiers. We study supervised models, training on traditional WSD data and evaluating against a graded scale. Thirdly, the evaluation metrics we use also provides a novel analysis of annotator performance on the GWS dataset.

2 Related Work

WSD has to date been a task where word senses are viewed as having clear cut boundaries. However, there are indications that word meanings do not behave in this way (Kilgarriff, 2006). Researchers in the field of WSD have acknowledged these problems but have used existing lexical resources in the hope that useful applications can be built with them. However, there is no consensus on which

inventory is suitable for which application, other than cross-lingual applications where the inventory can be determined from parallel data (Carpuat and Wu, 2007; Chan et al., 2007). For monolingual applications however it is less clear whether current state-of-the-art WSD systems for tagging text with dictionary senses are able to have an impact on applications.

One way of addressing the problem of low inter-annotator agreement and system performance is to create an inventory that is coarse-grained enough for humans and computers to do the job reliably (Ide and Wilks, 2006; Hovy et al., 2006; Palmer et al., 2007). Such coarse-grained inventories can be produced manually from scratch (Hovy et al., 2006) or by automatically relating (McCarthy, 2006) or clustering (Navigli, 2006; Navigli et al., 2007) existing word senses. While the reduction in polysemy makes the task easier, we do not know which are the right distinctions to retain. In fact, fine-grained distinctions may be more useful than coarse-grained ones for some applications (Stokoe, 2005). Furthermore, Hanks (2000) goes further and argues that while the ability to distinguish coarse-grained senses is indeed desirable, subtler and more complex representations of word meaning are necessary for text understanding.

In this paper, instead of focusing on issues of granularity we try to predict graded judgments of word sense applicability, using a recent dataset with graded annotation (Erk et al., 2009). Our hope is that models which can mimic graded human judgments on the same task should better reflect the underlying phenomena of word meaning compared to a system that focuses on making clear cut distinctions. Also, we hope that such models might prove more useful in applications. There is one existing study of graded sense assignment (Ramakrishnan et al., 2004). It tries to estimate a probability distribution over senses by converting all of WordNet into a huge Bayesian Network, and reports improvements in a Question Answering task. However, it does not test its prediction against human annotator data.

We concentrate on supervised models in this paper since they generally perform better than their unsupervised or knowledge-based counterparts (Navigli, 2009). We compare them against a baseline model which simply uses the training data to obtain a probability distribution over senses regardless of context, since marginal distributions are highly skewed making a prior distribution very informative (Chan and Ng, 2005; Lapata and Brew, 2004).

Along with standard WSD models, we evaluate vector space models that use the training data to locate a word sense in semantic space. Word sense and vector space models have been related in two ways. On the one hand, vector space models have been used for inducing word senses (Schütze, 1998; Pantel and Lin, 2002). The different meanings of a word are obtained by clustering vectors. The clusters must then be mapped to an inventory if a standard WSD dataset is used for evaluation. In contrast, we use sense tagged training data with the aim of building models of given word senses, rather than clustering occurrences into word senses. The second way in which word sense and vector space models have been related is to assign disambiguated feature vectors to WordNet concepts (Pantel, 2005; Patwardhan and Pedersen, 2006). However those works do not use sense-tagged data and are not aimed at WSD, rather the applications are to insert new concepts into an ontology and to measure the relatedness of concepts.

We are not concerned in this paper with arguing for or against any particular sense inventory. WordNet has been criticized for being overly fine-grained (Navigli et al., 2007; Ide and Wilks, 2006), we are using it here because it is the sense inventory used by Erk et al. (2009). That annotation study used it because it is sufficiently fine-grained to allow for the examination of subtle distinctions between usages and because it is publicly available

3 Data

In this paper, we use a subset of the GWS dataset (Erk et al., 2009) where three annotators supplied ordinal judgments of the applicability of WordNet (v3.0) senses on a 5 point scale: 1 – *completely different*, 2 – *mostly different*, 3 – *similar*, 4 – *very similar* and 5 – *identical*. Table 1 shows a sample annotation. The sentences that we use from the GWS dataset were originally extracted from the English SENSEVAL-3 lexical sample task (Mihalcea et al., 2004) (hereafter SE-3) and SemCor (Miller et al., 1993). [1] For 8 lemmas, 25 sentences were randomly sampled from SemCor and 25 randomly sampled from SE-3, giving a total of 50 sentences per lemma. The lemmas, their PoS and number of senses from WordNet are shown in table 2.

The annotation study found that annotators made ample use of the intermediate levels of applicability (2-4), and they often gave positive ratings (3-5) to more than one sense for a single occurrence. The example in Table 1 is one such case. An analysis of the annotator ratings found that they could not easily be explained in categorial terms by making more coarse-grained senses because senses that were not positively correlated often had high ratings for the same instance.

The GWS dataset contains a sequence of judgments for each occurrence of a target word in a sentence context: one judgment for each WordNet sense of the target word. To obtain a single judgment for each sense in each sentence we use the average judgment from the three annotators. As models typically assign values between 0 and 1, we normalize the annotator judgments from the GWS dataset to fall into the same range by using $normalized\_judgment = (judgment - 1.0)/4.0$. This maps an original judgment of 5 to a normalized judgment of 1.0, it maps an original 1 to 0.0, and intermediate judgments are mapped accordingly.

As the GWS dataset is too small to accommodate both training and testing of a supervised model, we use all the data from GWS for testing our models, and train our models on traditional word sense annotation data. We use as training data all sentences from SemCor and the training portion of SE-3 that are not included in GWS. The quantity of training data available is shown in the last two columns of table 2.

4 Evaluating Graded Word Sense Assignment

This section discusses measures for evaluating system performance for the case where gold judgments are graded rather than categorial.

Correlation. The standard method for comparing a list of graded gold judgments to a list of graded predicted judgments is by testing for correlation. In our case, as we cannot assume a normal distribution of the judgments, a non-parametric test such as Spearman's ρ will be appropriate. Spearman's ρ uses the formula of Pearson's coefficient, defined as

$$\rho(X, Y) = \frac{cov(X, Y)}{\sigma_X \sigma_Y}$$

Pearson's coefficient computes the correlation of two random variables X and Y as their covariance divided by the product of their standard deviations. In the computation of Spearman's ρ, values are transformed to rankings before the formula is applied. [2] As Spearman's ρ compares the rankings of two sets of judgments, it abstracts from the absolute values of the judgments. It is useful to have a measure that abstracts from absolute values of judgments and magnitude of difference because the GWS dataset contains annotator judgments on a fixed scale, and it is quite possible that human judges will differ in how they use such a scale.

Each judgment in the gold-standard can be represented as a 4-tuple ⟨lemma, sense_no, sentence_no, gold_judgment⟩. For example, ⟨add.v,

[1] The GWS data also contains data from the English Lexical Substitution Task (McCarthy and Navigli, 2007) but we do not use that portion of the data for these experiments.

[2] Mitchell and Lapata (2008) note that Spearman's ρ tends to yield smaller coefficients than its parametric counterparts such as Pearson's coefficient.

1, 1, 0.8⟩ is the first sentence for target *add.v*, first WordNet sense, with a (normalized) judgment of 0.8. Likewise, each prediction by the model can be represented as a 4-tuple ⟨lemma, sense_no, sentence_no, predicted_judgment⟩. We write G for the set of gold tuples, A for the set of assigned tuples, L for the set of lemmas, S_ℓ for the set of sense numbers that exist for lemma ℓ, and T for the set of sentence numbers (there are 50 sentences for each lemma). We write $G|_{lemma=\ell}$ for the gold set restricted to those tuples with lemma ℓ, and analogously for other set restrictions and for A. There are several possibilities for measuring correlation:

by lemma: for each lemma $\ell \in L$, compute correlation between $G|_{lemma=\ell}$ and $A|_{lemma=\ell}$

by lemma+sense: for each lemma ℓ and each sense number $i \in S_\ell$, compute correlation between $G|_{lemma=\ell,senseno=i}$ and $A|_{lemma=\ell,senseno=i}$

by lemma+sentence: for each lemma ℓ and sentence number $t \in T$, compute correlation between $G|_{lemma=\ell,sentence=t}$ and $A|_{lemma=\ell,sentence=t}$

Comparison by lemma tests for the consistent use of judgments for the same target lemma. A comparison by lemma+sense ranks all occurrences of the same target lemma by how strongly they evoke a given word sense. A comparison by lemma+sentence ranks different senses by how strongly they apply to a given target lemma occurrence. In reporting correlation by lemma (by lemma+sense, by lemma+sentence), we average over all lemmas (lemma+sense, lemma+sentence combinations), and we report the percentage of lemmas (combinations) for which the correlation was significant. We report averaged correlation by lemma rather than one overall correlation over all judgments in order not to give more weight to lemmas with more senses.

Divergence. Another possibility for measuring the performance of a graded sense assignment model is to use Jensen/Shannon divergence (J/S), which is a symmetric version of Kullback/Leibler divergence. Given two probability distributions p, q, the Kullback/Leibler divergence of q from p is

$$D(p||q) = \sum_x p(x) \log \frac{p(x)}{q(x)}$$

and their J/S is

$$JS(p,q) = \frac{1}{2}\big(D(p||\frac{p+q}{2}) + D(q||\frac{p+q}{2})$$

We will use J/S for an evaluation by lemma+sentence: for each lemma $\ell \in L$ and sentence number $t \in T$, we normalize $G|_{lemma=\ell,sentence=t}$, the set of judgments for senses of ℓ in t, by the sum of sense judgments for ℓ and t. We do the same for $A|_{lemma=\ell,sentence=t}$. Then we compute J/S. In doing so, we are not trying to interpret $G|_{lemma=\ell,sentence=t}$ as some kind of probability distribution over senses, rather we use J/S as a measure that abstracts from absolute judgments but not from the magnitude of differences between judgments.

Precision and Recall. We have discussed a measure that abstracts from both absolute judgments and magnitude of differences (Spearman's ρ), and a measure that abstracts from absolute judgments but not the magnitude of differences (J/S). What is still missing is a measure that tests to what degree a model conforms to the absolute judgments given by the human annotators.

To obtain a measure for performance in predicting absolute gold judgments, we generalize precision and recall. In the categorial case, precision is defined as $P = \frac{\text{true positives}}{\text{true positives+false positives}}$, true positives divided by system-assigned positives, and recall is $R = \frac{\text{true positives}}{\text{true positives+false negatives}}$, true positives divided by gold positives. Writing $\text{gold}_{\ell,i,t}$ for the judgment j associated with lemma ℓ and sense number i for sentence t in the gold data (i.e., $\langle \ell, i, t, j\rangle \in G$), and analogously $\text{assigned}_{\ell,i,t}$, we extend precision and recall to the graded case as follows:

$$P_\ell = \frac{\sum_{i \in S_\ell, t \in T} \min(\text{gold}_{\ell,i,t}, \text{assigned}_{\ell,i,t})}{\sum_{i \in S_\ell, t \in T} \text{assigned}_{\ell,i,t}}$$

and

$$R_\ell = \frac{\sum_{i \in S_\ell, t \in T} \min(\text{gold}_{\ell,i,t}, \text{assigned}_{\ell,i,t})}{\sum_{i \in S_\ell, t \in T} \text{gold}_{\ell,i,t}}$$

where ℓ is a lemma. We compute precision and recall by lemma, then macro-average them in order not to give more weight to lemmas that have more senses. The formula for F-score as the harmonic mean of precision and recall remains unchanged: $F = 2\,P\,R/(P+R)$.

If the data is categorial, the graded precision and recall measures coincide with "classical" precision

Cx/2	until, IN, soft, JJ, remaining, VBG, ingredient, NNS
Cx/50	for, IN, sweet-sour, NN, sauce, NN, ..., to, TO, a, DT, boil, NN
Ch	OA, OA/ingredient/NNS

Table 3: Sample features for *add* in BNC occurrence *For sweet-sour sauce, cook onion in oil until soft.* ***Add*** *remaining ingredients and bring to a boil.* Cx/2 (Cx/50): context of size 2 (size 50) either side of the target. Ch: children of target.

and recall, which can be seen as follows. Graded sense assignment is represented by assigning each sense a score between 0.0 and 1.0. The categorial case can be represented in the same way, the difference being that one single sense will receive a score of 1.0 while all other senses get a score of 0.0. With this representation for categorial sense assignment, consider a fixed token t of lemma ℓ. $\sum_{i \in S_\ell} \min(\text{assigned}_{\ell,i,t}, \text{gold}_{\ell,i,t})$ will be 1 if the assigned sense is the gold sense, and 0 otherwise.

5 Models for Graded Word Sense Assignment

In this section we discuss the computational models for graded word sense that are tested in this paper.

Single-best-sense WSD. The first model that we test is a standard WSD model that assigns, to each test occurrence of a target word, a single best-fitting word sense. The system thus attributes a confidence score of 1 to the assigned sense and a confidence score of 0 for all other senses for that sentence. We refer to it as ***WSD/single***. The model uses standard features: lemma and part of speech in a narrow context window (2 words either side) and a wide context window (50 words either side), as well as dependency labels leading to parent, children, and siblings of the target word, and lemmas and part of speech of parent, child, and sibling nodes. Table 3 shows sample model features for an occurrence of *add* in the British National Corpus (BNC) (Leech, 1992). The model uses a maximum entropy learner[3], training one binary classifier per sense. (With n-ary classifiers, the model's performance is slightly worse.) The model is thus not highly optimized, but fairly standard.

WSD confidence level as judgment. Our second model is the same WSD system as above, but we use it to predict a judgment for each sense of a target occurrence, taking the confidence level returned by each sense-specific binary classifier as the predicted judgment. We refer to this model as ***WSD/conf***.

Word senses as points in semantic space. The results of the GWS annotation study raise the question of how word senses are best conceptualized, given that annotators assigned graded judgments of applicability of word senses, and given that they often combined high judgments for multiple word senses. One way of modeling these findings is to view word senses as prototypes, where some uses of a word will be typical examples of a given sense, for some uses the sense will clearly not apply, and to some uses the sense will be borderline applicable.

We use a very simple model of word senses as prototypes, representing them as points in a semantic space. Graded sense applicability judgments can then be modeled using vector similarity. The dimensions of the vector space are the features of the WSD system above (including dimensions like *Cx2/until*, *Cx2/IN*, *Ch/OA/ingredient/NNS* for the example in Table 3), and the coordinates are raw feature counts. We compute a single vector for each sense s, the centroid of all training occurrences that have been labeled with s. The predicted judgment for a test sentence and sense s is then the similarity of the sentence's vector to the centroid vector for s, computed using *cosine*. We call this model ***Prototype***. Like instance-based learners (Daelemans and den Bosch, 2005), the *Prototype* model measures the distance between feature vectors in space. Unlike instance-based learners, it only uses data from a single category for training.

As it is to be expected that the vectors in this space will be very sparse, we also test a variant of the *Prototype* model with Schütze-style second-order vectors (Schütze, 1998), called ***Prototype/2***. Given a (first-order) feature vector, we compute a second-order vector as the centroid of vectors for all lemma features (omitting stopwords) in the first-order vector. For the feature vector in Table 3, this is the centroid of vectors $\vec{sweet\text{-}sour}$, $\vec{sauce}$, ..., $\vec{boil}$. We compute the vectors $\vec{sweet\text{-}sour}$ etc. as dependency vectors (Padó and Lapata, 2007) [4] over a Minipar parse (Lin, 1993) of the BNC.

[3] http://maxent.sourceforge.net/

[4] We use the DV package, http://www.nlpado.de/~sebastian/dv.html, to compute the vector space.

We transform raw co-occurrence counts in the BNC-based vectors using pointwise mutual information (PMI), a common transformation function (Mitchell and Lapata, 2008). [5]

Another way of motivating the use of vector space models of word sense is by noting that we are trying to predict graded sense assignment by training on traditional word sense annotated data, where each target word occurrence is typically marked with a single word sense. Traditional word sense annotation, when used to predict GWS judgments, will contain spurious negative data: suppose a human annotator is annotating an occurrence of target word t and views senses s_1, s_2 and s_3 as somewhat applicable, with sense s_1 applying most clearly. Then if the annotation guidelines ask for the best-fitting sense, the annotator should only assign s_1. The occurrence is recorded as having sense s_1, but not senses s_2 and s_3. This, then, constitutes spurious negative data for senses s_2 and s_3. The simple vector space model of word sense that we use implements a radical solution to this problem of spurious negative data: it only uses positive data for a single sense, thus forgoing competition between categories. It is to be expected that not using competition between categories will hurt the vector space model's performance, but this design gives us the chance to compare two model classes that use opposing strategies with respect to spurious negative data: the WSD models fully trust the negative data, while the vector space models ignore it.

6 Experiments

This section reports on experiments for the task of graded word sense assignment. As data, we use the GWS dataset described in Sec. 3. We test the models discussed in Sec. 5, evaluating with the methods described in Sec. 4.

To put the models' performance into perspective, we first consider the human performance on the task, shown in Table 4. The first three lines of the table show the performance of each annotator evaluated against the average of the other two. The fourth line averages over the previous three lines to provide an average human ceiling for the task. In the correlation of rankings by lemma, correlation is statistically significant for all lemmas at $p \leq 0.01$. For correlation by lemma+sense and by lemma+sentence, the percentage of pairs with significant correlation is lower: 73.6 of lemma/sense pairs and 29.0 of lemma/sentence pairs reach significance at $p \leq 0.05$. For $p \leq 0.01$, the percentage is 58.3 and 12.2, respectively. The higher ρ but lower proportion of significant values for lemma+sentence pairs compared to lemma+sense is due to the fact that there are far fewer datapoints (sample size) for each calculation of ρ (#senses for lemma+sentence vs 50 sentences for lemma+sense).

At 0.131, J/S for Annotator 1 is considerably lower than for Annotators 2 and 3. [6] In terms of precision and recall, Annotator 1 again differs from the other two. At 87.5, her recall is higher than her precision (50.6), while the other annotators have considerably higher precision (75.5 and 82.4) than recall (62.4 and 52.3). This indicates that Annotator 1 tended to assign higher ratings throughout, an impression that is confirmed by Table 6. The left two columns show average ratings for each annotator over all senses of all tokens (normalized to values between 0.0 and 1.0 as described in Sec. 3). The three annotators differ widely in their average ratings, which range from 0.285 for Ann.3 to 0.540 for Ann.1.

Standard WSD. We tested the performance of the *WSD/single* model on a standard WSD task, using the same training and testing data as in our subsequent experiments, as described in section 3. [7] The model's accuracy when trained and tested on SemCor was A=77.0%, with a most frequent sense baseline of 63.5%. When trained and tested on SE-3, the model achieved A=53.0% against a baseline of 44.0%. When trained and tested on SemCor plus SE-3, the model reached an accuracy 58.2%, with a baseline of 56.0%. So on the combined dataset, the baseline is the average of the baselines on the individual datasets, while the model's performance falls below the average performance on the individual datasets.

WSD models for graded sense assignment. Table 5 shows the performance of different models in the task of graded word sense assignment. The first line in Table 5 lists results for the maximum entropy model when used to assign a single best sense. The second line lists the results for

[5] We also tested PMI transformation for the first-order vectors, but will not report the results here as they were worse across the board than without PMI.

[6] Low J/S implies a closer agreement between two sets of judgments.

[7] Note that this constitutes less training data than in the SE-3 task.

Table 5: Evaluation: computational models, and baseline. $*$, $**$: percentage significant at $p \leq 0.05$, $p \leq 0.01$

the same maximum entropy model when classifier confidence is used as predicted judgment. The last line shows the baseline, an adaptation of the most frequent sense baseline to the graded case. For this baseline, we computed the relative frequency of each sense in the training corpus and used this relative frequency as the prediction for each test sentence and sense combination. The *WSD/single* model remains below the baseline in all evaluations except correlation by lemma+sense, where no rank-based correlation could be computed for the baseline because it always assigns the same judgment for a given sense. *WSD/conf* shows a performance slightly above the baseline in all evaluation measures. Table 6 lists average ratings, averaged over all lemmas, senses, and occurrences, for each model in the two right-hand columns.

***Prototype* models.** Lines 3-6 in Tables 5 and 6 show results for *Prototype* variants. While each *Prototype* and *Prototype/2* model only sees positive data annotated for a single sense, the variants with */N* (lines 5 and 6) make very limited use of information coming from all senses of a given lemma. They normalize judgments for each sentence, with

$$\text{assigned}^{norm}_{\ell,i,t} = \frac{\text{assigned}_{\ell,i,t}}{\sum_{j \in S_\ell} \text{assigned}_{\ell,j,t}}$$

Line 3 evaluates the *Prototype* model with first-order vectors. Its correlation with the gold data is somewhat lower than that of *WSD/conf* in almost all cases. [8] The *Prototype* model deviates strongly from both *WSD/conf* and baseline in having a very good recall, at 78.3, with lower precision at 58.4, for an overall F-score that is 16 points higher than that of *WSD/conf*. Both *Prototype* and *Prototype/2* have average ratings (Table 6) far above those of the WSD models and of the */N* variants. The second-order vector model *Prototype/2* has relatively low correlation by lemma+sense, while correlation by lemma+sentence shows the best performance of all models (along with *Prototype/2N*). Its correlation by lemma+sentence is similar to the lowest correlation by lemma+sentence achieved by a human annotator. In terms of J/S, this model also shows the best performance along with *WSD/conf* and *Prototype/2N*. Both */N* variants achieve very high correlation by lemma. Correlation by lemma+sense for the */N* models is between those of *Prototype* and *WSD/conf*. The correlation by lemma+sentence is the same with or without normalization, as normalization does not change the ranking of senses of an individual sentence. While *Prototype* has higher recall than precision, normalization turns it into a model with even higher precision than *WSD/conf* but even lower recall.

Discussion

Human performance. The evaluation of human annotators in Table 4 provides a novel analysis of the GWS dataset over and above that by Erk et al.

[8] The reason why the average ρ for correlation by lemma+sense is the same for *Prototype* and *WSD/single* while the significance percentage differs greatly is that the *Prototype* shows negative correlation for some of the senses.

Ann.	avg	Model	avg
Ann.1	0.540	*WSD/single*	0.163
Ann.2	0.345	*WSD/conf*	0.173
Ann.3	0.285	*Prototype*	0.558
		Prototype/N	0.143
		Prototype/2	0.375
		Prototype/2N	0.143
		baseline	0.167

Table 6: Average judgment for individual annotators (transformed) and average rating for models

(2009). Human annotators show very strong correlation of their rankings by lemma. They also had strong agreement on rankings by lemma+sense, which ranks occurrences of a lemma by how strongly they evoke a given sense. The relatively low precision and recall in Table 4 confirm that different annotators use the 5-point scale in different ways. A comparison of precision and recall between the annotators reflects the fact that Annotator 1 tended to give considerably higher ratings than the other two, which is also apparent in the average ratings in Table 6. Given the relatively low F-score achieved by human annotators, judgments by additional annotators could make the GWS dataset more useful, in that the average judgments would not be influenced so strongly by idiosyncrasies in the use of the 5-point scale. (Psycholinguistic experiments using fixed scales typically elicit judgments from 10 or more participants per item.)

Evaluation measures. Given the degree of differences in the absolute values of the human annotator judgments (Table 4), a rank-based evaluation of graded sense assignment models, complemented by J/S to evaluate the magnitude of differences between ratings, seems most appropriate to the data. Rankings by lemma+sense and by lemma+sentence are especially interesting for their potential use in systems that might use graded sense assignment as part of a larger pipeline. Still, the new graded precision and recall measures allow for a more fine-grained analysis of the performance of models, showing fundamental differences in the behavior of *WSD/conf* and the *Prototype* model. Graded precision and recall could become even more informative measures with a gold set containing judgments of more annotators, since then the absolute gold judgments would be more reliable.

Standard WSD models and vector space models. The results in Table 5 reflect the compromise between the advantage of having competition between categories and the disadvantage of spurious negative data: *WSD/conf*, *Prototype/N* and *Prototype/2N* achieve the highest correlation by lemma, and high precision, while *Prototype* has much better recall for an overall higher F-score. However, as Table 6 shows, *Prototype* tends to assign high ratings across the board, leading to high recall. The much lower average ratings of the */N* models explain their higher precision and lower recall: they overshoot less and undershoot more. The improvement in correlation for the */N* models also indicates that *Prototype* assigns some sentences high ratings for all senses, impacting rankings by lemma and by lemma+sense.

The comparison of *Prototype* and *Prototype/2* gives us a chance to study effects of feature sparseness. *Prototype/2*, using second-order vectors that should be much less sparse, yields better rankings than *Prototype*. The average ratings of model *Prototype/2* (Table 6) are lower than those of *Prototype* (and closer to human average ratings), resulting in higher precision and lower recall. One possible reason for the high average ratings of *Prototype* is that in sparser (and shorter) vectors, matches in dimensions for high-frequency, relatively uninformative context items have greater impact.

It is interesting to see that *WSD/conf* performs slightly above the sense frequency baseline in all evaluations, since this is a very familiar picture from standard WSD.

Prototype/2N shows the overall most favorable performance in terms of correlation as it i) pays minimal attention to the negative data ii) uses normalization to avoid overshooting and iii) compensates for sparse data by using second order vectors. For J/S, *WSD/conf*, *Prototype/2*, *Prototype/2N* and the sense frequency baseline just outperform the score of the lowest-scoring of the three annotators. In terms of F-score, *Prototype* shows results very close to human performance. Interestingly, the *Prototype* model resembles Annotator 1 in its precision and recall, while *WSD/conf* more resembles Annotators 2 and 3. None of the models come close to human performance in ranking by lemma+sense, which requires an identification of the "typical" occurrence of a given sense. The low ratings in correlation by lemma+sense indicate that the models might be limited by the lack of training data for many of the rarer senses. In fu-

ture work, we will test how the frequency of senses in the training data affects the different models.

7 Conclusion

In this paper we have done a first study on modeling graded annotator judgments on sense applicability. We have discussed evaluation measures for models of graded sense assignment, including new extensions of precision and recall to the graded case. A combination of rank-based correlation at the level of lemmas, senses, and sentences, Jensen/Shannon divergence, and precision and recall provided a nuanced picture of the strengths and weaknesses of different models. We have tested two types of models: on the one hand a standard binary WSD model using classifier confidence as predicted judgments, and on the other hand several vector space models which compute a prototype vector for each sense in semantic space. These two types of model differ strongly in their behavior. The WSD model shows a similar behavior as the baseline, with high precision but low recall, while the unnormalized version of the vector space model has higher recall at lower precision. The results show both the benefits of having competition between categories, for improved rank-based correlation and precision, and the problem of spurious negative data in the training set arising from the best-sense methodology.

The last two correlation measures, by lemma+sense and by lemma+sentence, yield maybe the most insight into the question of the usability of a computational model for graded word sense assignment: a graded word sense assignment model that is a component of a larger system could provide useful sense information either by ranking occurrences by how strongly they evoke a sense, or by ranking senses by how strongly they apply to a given occurrence. There is room for improvement however as system performance is well below that of humans. In the future we plan to investigate features that are more informative for making graded judgments. Second, the vector space model we used was very simple; it might be worthwhile to test more sophisticated one-class classifiers (Marsland, 2003; Schölkopf et al., 2000).

Abstract

The sense of a preposition is related to the semantics of its dominating prepositional phrase. Knowing the sense of a preposition could help to correctly classify the semantic role of the dominating prepositional phrase and vice versa. In this paper, we propose a joint probabilistic model for word sense disambiguation of prepositions and semantic role labeling of prepositional phrases. Our experiments on the PropBank corpus show that jointly learning the word sense and the semantic role leads to an improvement over state-of-the-art individual classifier models on the two tasks.

1 Introduction

Word sense disambiguation (WSD) and semantic role labeling (SRL) are two key components in natural language processing to find a semantic representation for a sentence. Semantic role labeling is the task of determining the constituents of a sentence that represent semantic arguments with respect to a predicate and labeling each with a semantic role. Word sense disambiguation tries to determine the correct meaning of a word in a given context. Ambiguous words occur frequently in normal English text.

One word class which is both frequent and highly ambiguous is preposition. The different senses of a preposition express different relations between the preposition complement and the rest of the sentence. Semantic roles and word senses offer two different inventories of "meaning" for prepositional phrases (PP): semantic roles distinguish between different verb complements while word senses intend to fully capture the preposition semantics at a more fine-grained level. In this paper, we use the semantic roles from the PropBank corpus and the preposition senses from the Preposition Project (TPP). Both corpora are explained in more detail in the following section. The relationship between the two inventories (PropBank semantic roles and TPP preposition senses) is not a simple one-to-one mapping, as we can see from the following examples:

- She now lives with relatives [in_{sense1} *Alabama.*]$_{\text{ARGM-LOC}}$
- The envelope arrives [in_{sense1} *the mail.*]$_{\text{ARG4}}$
- [In_{sense5} *separate statements*]$_{\text{ARGM-LOC}}$ the two sides said they want to have "further discussions."

In the first two examples, the sense of the preposition *in* is annotated as sense 1 ("surrounded by or enclosed in"), following the definitions of the TPP, but the semantic roles are different. In the first example the semantic role is a locative adjunctive argument (ARGM-LOC), while in the second example it is ARG4 which denotes the "end point or destination" of the arriving action[1]. In the first and third example, the semantic roles are the same, but the preposition senses are different, i.e., sense 1 and sense 5 ("inclusion or involvement").

Preposition senses and semantic roles provide two different views on the semantics of PPs. Knowing the semantic role of the PP could be helpful to successfully disambiguate the sense of the preposition. Likewise, the preposition sense could provide valuable information to classify the semantic role of the PP. This is especially so for the semantic roles ARGM-LOC and ARGM-TMP, where we expect a strong correlation with spatial and temporal preposition senses respectively.

In this paper, we propose a probabilistic model for joint inference on preposition senses and semantic roles. For each prepositional phrase that

[1]http://verbs.colorado.edu/framesets/arrive-v.html

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 450–458,
Singapore, 6-7 August 2009.

has been identified as an argument of the predicate, we jointly infer its semantic role and the sense of the preposition that is the lexical head of the prepositional phrase. That is, our model maximizes the *joint probability* of the semantic role and the preposition sense.

Previous research has shown the benefit of jointly learning semantic roles of *multiple constituents* (Toutanova et al., 2008; Koomen et al., 2005). In contrast, our joint model makes predictions for a *single constituent*, but *multiple tasks* (WSD and SRL) .

Our experiments show that adding the SRL information leads to statistically significant improvements over an independent, state-of-the-art WSD classifier. For the SRL task, we show statistically significant improvements of our joint model over an independent, state-of-the-art SRL classifier for locative and temporal adjunctive arguments, even though the overall improvement over all semantic roles is small. To the best of our knowledge, no previous research has attempted to perform preposition WSD and SRL of prepositional phrases in a joint learning approach.

The remainder of this paper is structured as follows: First, we give an introduction to the WSD and SRL task. Then, in Section 3, we describe the individual and joint classifier models. The details of the data set used in our experiments are given in Section 4. In Section 5, we present experiments and results. Section 6 summarizes related work, before we conclude in the final section.

2 Task Description

This section gives an introduction to preposition sense disambiguation and semantic role labeling of prepositional phrases.

2.1 Preposition Sense Disambiguation

The task of word sense disambiguation is to find the correct meaning of a word, given its context. Most prior research on word sense disambiguation has focused on disambiguating the senses of nouns, verbs, and adjectives, but not on prepositions. Word sense disambiguation can be framed as a classification task. For each preposition, a classifier is trained on a corpus of training examples annotated with preposition senses, and tested on a set of unseen test examples.

To perform WSD for prepositions, it is necessary to first find a set of suitable sense classes. We adopt the sense inventory from the Preposition Project (TPP) (Litkowski and Hargraves, 2005) that was also used in the SemEval 2007 preposition WSD task (Litkowski and Hargraves, 2007). TPP is an attempt to create a comprehensive lexical database of English prepositions that is suitable for use in computational linguistics research. For each of the over 300 prepositions and phrasal prepositions, the database contains a set of sense definitions, which are based on the Oxford Dictionary of English. Every preposition has a set of fine-grained senses, which are grouped together into a smaller number of coarse-grained senses. In our experiments, we only focus on coarse-grained senses since better inter-annotator agreement can be achieved on coarse-grained senses, which also results in higher accuracy of the trained WSD classifier.

2.2 Semantic Role Labeling

The task of semantic role labeling in the context of PropBank (Palmer et al., 2005) is to label tree nodes with semantic roles in a syntactic parse tree.

The PropBank corpus adds a semantic layer to parse trees from the Wall Street Journal section of the Penn Treebank II corpus (Marcus et al., 1993). There are two classes of semantic roles: core arguments and adjunctive arguments. Core arguments are verb sense specific, i.e., their meaning is defined relative to a specific verb sense. They are labeled with consecutive numbers ARG0, ARG1, etc. ARG0 usually denotes the AGENT and ARG1 the THEME of the event. Besides the core arguments, a verb can have a number of adjunctive arguments that express more general properties like time, location, or manner. They are labeled as ARGM plus a functional tag, e.g., LOC for locative or TMP for temporal modifiers. Prepositional phrases can appear as adjunctive arguments or core arguments.

The standard approach to semantic role labeling is to divide the task into two sequential sub-tasks: *identification* and *classification*. During the identification phase, the system separates the nodes that fill some semantic roles from the rest. During the classification phase, the system assigns the exact semantic roles for all nodes that are identified as arguments. In this paper, we focus on the classification phase. That is, we assume that prepositional phrases that are semantic arguments have been identified correctly and concentrate on the

task of determining the semantic role of prepositional phrases. The reason is that argument identification mostly relies on syntactic features, like the path from the constituent to the predicate (Pradhan et al., 2005). Consider, for example, the phrase *in the dark* in the sentence: "We are in the dark", he said. The phrase is clearly not an argument to the verb *say*. But if we alter the syntactic structure of the sentence appropriately (while the sense of the preposition *in* remains unchanged), the same phrase suddenly becomes an adjunctive argument: In the dark, he said "We are". On the other hand, we can easily find examples, where *in* has a different sense, but the phrase always fills some semantic role:

- In a separate manner, he said ...
- In 1998, he said ...
- In Washington, he said ...

This illustrates that the preposition sense is independent of whether the PP is an argument or not. Thus, a joint learning model for argument identification and preposition sense is unlikely to perform better than the independent models.

3 Models

This section describes the models for preposition sense disambiguation and semantic role labeling.

We compare three different models for each task: First, we implement an independent model that only uses task specific features from the literature. This serves as the *baseline model*. Second, we extend the baseline model by adding the most likely prediction of the other task as an additional feature. This is equivalent to a *pipeline model* of classifiers that feeds the prediction of one classification step into the next stage. Finally, we present a *joint model* to determine the preposition sense and semantic role that maximize the joint probability.

3.1 WSD model

Our approach to building a preposition WSD classifier follows that of Lee and Ng (2002), who evaluated a set of different knowledge sources and learning algorithms for WSD. However, in this paper we use maximum entropy models[2] (instead of support vector machines (SVM) reported in (Lee and Ng, 2002)), because maximum entropy models output probability distributions, unlike SVM. This property is useful in the joint model, as we will see later. Maxent models have been successfully applied to various NLP tasks and achieve state-of-the-art performance. There are two training parameters that have to be adjusted for maxent models: the number of training iterations and the Gaussian smoothing parameter. We find optimal values for both parameters through 10-fold cross-validation on the training set.

For every preposition, a baseline maxent model is trained using a set of features reported in the state-of-the-art WSD system of Lee and Ng (2002). These features encode three knowledge sources:

- Part-of-speech (POS) of surrounding words
- Single words in the surrounding context
- Local collocations

For *part-of-speech features*, we include the POS tags of surrounding tokens from the same sentence within a window of seven tokens around the target prepositions. All tokens (i.e., all words and punctuation symbols) are considered. We use the Penn Treebank II POS tag set.

For the knowledge source *single words in the surrounding context*, we consider all words from the same sentence. The input sentence is tokenized and all tokens that do not contain at least one alphabetical character (such as punctuation symbols and numbers) and all words that appear on a stopword list are removed. The remaining words are converted to lower case and replaced by their morphological root form. Every unique morphological root word contributes one binary feature, indicating whether or not the word is present in the context. The position of a word in the sentence is ignored in this knowledge source.

The third knowledge source, *local collocations*, encodes position-specific information of words within a small window around the target preposition. For this knowledge source, we consider unigrams, bigrams, and trigrams from a window of seven tokens. The position of the target preposition inside the n-gram is marked with a special character '_'. Words are converted to lower case, but no stemming or removal of stopwords is performed. If a token falls outside the sentence, it is replaced by the empty token symbol *nil*.

During testing, the maxent model computes the

[2]Zhang Le's Maximum Entropy Modeling Toolkit, http://homepages.inf.ed.ac.uk/s0450736/maxent_toolkit.html

conditional probability of the sense, given the feature representation of the surrounding context c. The classifier outputs the sense that receives the highest probability:

$$\hat{s} = \underset{s}{\operatorname{argmax}}\, P(s|\Psi(c)) \quad (1)$$

where $\Psi(\cdot)$ is a feature map from the surrounding context to the feature representation.

To ensure that our model is competitive, we tested our system on the data set from the SemEval 2007 preposition WSD task (Litkowski and Hargraves, 2007). Our baseline classifier achieved a coarse-grained accuracy of 70.7% (micro-average) on the official test set. This would have made our system the second best system in the competition, behind the MELB-YB system (Ye and Baldwin, 2007).

We also investigate the effect of the semantic role label by adding it as a feature to the baseline model. This pipeline model is inspired by the work of Dang and Palmer (2005) who investigated the role of SRL features in verb WSD. We add the semantic role of the prepositional phrase dominating the preposition as a feature to the WSD model. During training, the PropBank gold SRL label is used. During testing, we rely on the baseline SRL model (to be introduced in the next subsection) to predict the semantic role of the prepositional phrase. This is equivalent to first performing semantic role labeling and adding the output as a feature to the WSD classifier. In earlier experiments, we found that training on gold SRL labels gave better results than training on automatically predicted SRL labels (using cross-validation). Note that our approach uses automatically assigned SRL labels during testing, while the system of Dang and Palmer (2005) only uses gold SRL labels.

3.2 SRL model

Our semantic role labeling classifier is also based on maxent models. It has been shown that maximum entropy models achieve state-of-the-art results on SRL (Xue and Palmer, 2004; Toutanova et al., 2008). Again, we find optimal values for the training parameters through 10-fold cross-validation on the training set.

By treating SRL as a classification problem, the choice of appropriate features becomes a key issue. Features are encoded as binary-valued functions. During testing, the maxent model computes the conditional probability $P(a|t, p, v)$ of the argument label a, given the parse tree t, predicate p, and constituent node v. The classifier outputs the semantic role with the highest probability:

$$\hat{a} = \underset{a}{\operatorname{argmax}}\, P(a|t, p, v) \quad (2)$$

$$= \underset{a}{\operatorname{argmax}}\, P(a|\Phi(t, p, v)) \quad (3)$$

where $\Phi(\cdot, \cdot, \cdot)$ is a feature map to an appropriate feature representation.

Baseline Features (Gildea and Jurafsky, 2002)	
pred	predicate lemma
path	path from constituent to predicate
ptype	syntactic category (NP, PP, etc.)
pos	relative position to the predicate
voice	active or passive voice
hw	syntactic head word of the phrase
sub-cat	rule expanding the predicate's parent
Advanced Features (Pradhan et al., 2005)	
hw POS	POS of the syntactic head word
PP hw/POS	head word and POS of the rightmost NP child if the phrase is a PP
first/last word	first/last word and POS in the constituent
parent ptype	syntactic category of the parent node
parent hw/POS	head word and POS of the parent
sister ptype	phrase type of left and right sister
sister hw/POS	head word and POS of left and right sister
temporal	temporal key words present
partPath	partial path predicate
proPath	projected path without directions
Feature Combinations (Xue and Palmer, 2004)	
pred & ptype	predicate and phrase type
pred & hw	predicate and head word
pred & path	predicate and path
pred & pos	predicate and relative position

Table 1: SRL features for the baseline model

For our baseline SRL model, we adopt the features used in other state-of-the-art SRL systems, which include the seven baseline features from the original work of Gildea and Jurafsky (2002), additional features taken from Pradhan *et al.* (2005), and feature combinations which are inspired by the system in Xue and Palmer (2004). Table 1 lists the features we use for easy reference.

In the pipeline model, we investigate the usefulness of the preposition sense as a feature for SRL by adding the preposition lemma concatenated with the sense number (e.g., *on_1*) as a feature. During training, the gold annotated preposition sense is used. During testing, the sense is automatically tagged by the baseline WSD model. This is equivalent to first running the WSD classifier for all prepositions, and adding the output preposition sense as a feature to our baseline SRL

system.

3.3 Joint Inference Model

The two previous models seek to maximize the probability of the semantic role and the preposition sense individually, thus ignoring possible dependencies between the two. Instead of maximizing the individual probabilities, we would like to maximize the *joint probability* of the semantic role and the preposition sense, given the parse tree, predicate, constituent node, and surrounding context.

$$\widehat{(a,s)} = \underset{(a,s)}{\operatorname{argmax}} P(a,s|t,p,v,c) \qquad (4)$$

We assume that the probability of the semantic role is already determined by the syntactic parse tree t, the predicate p, and the constituent node v, and is conditionally independent of the remaining surrounding context c given t, p, and v. Likewise, we assume that the probability of the preposition sense is conditionally independent of the parse tree t, predicate p, and constituent v, given the surrounding context c and the semantic role a. This assumption allows us to factor the joint probability into an SRL and a WSD component:

$$\widehat{(a,s)} = \underset{(a,s)}{\operatorname{argmax}} P(a|t,p,v) \times P(s|c,a) \qquad (5)$$

$$= \underset{(a,s)}{\operatorname{argmax}} P(a|\Phi(t,p,v)) \times P(s|\Psi(c,a)) \qquad (6)$$

We observe that the first component in our joint model corresponds to the baseline SRL model and the second component corresponds to the WSD pipeline model. Because our maxent models output a complete probability distribution, we can combine both components by multiplying the probabilities. Theoretically, the joint probability could be factored in the other way, by first computing the probability of the preposition sense and then conditioning the SRL model on the predicted preposition sense. However, in our early experiments, we found that this approach gave lower classification accuracy.

During testing, the classifier seeks to find the tuple of semantic role and preposition sense that maximizes the joint probability. For every semantic role, the classifier computes its probability given the SRL features, and multiplies it by the probability of the most likely preposition sense, given the context and the semantic role. The tuple that receives the highest joint probability is the final output of the joint classifier.

Semantic Role	Total	Training	Test
ARG0	28	15	13
ARG1	374	208	166
ARG2	649	352	297
ARG3	111	67	44
ARG4	177	91	86
ARGM-ADV	141	101	40
ARGM-CAU	31	23	8
ARGM-DIR	28	19	9
ARGM-DIS	29	9	20
ARGM-EXT	61	42	19
ARGM-LOC	954	668	286
ARGM-MNR	316	225	91
ARGM-PNC	115	78	37
ARGM-PRD	1	1	0
ARGM-REC	1	0	1
ARGM-TMP	838	563	275
Total	3854	2462	1392

Table 2: Number of annotated prepositional phrases for each semantic role

4 Data Set

The joint model uses the probability of a preposition sense, given the semantic role of the dominating prepositional phrase. To estimate this probability, we need a corpus which is annotated with both preposition senses and semantic roles. Unfortunately, PropBank is not annotated with preposition senses. Instead, we manually annotated the seven most frequent prepositions in four sections of the PropBank corpus with their senses from the TPP dictionary. According to Jurafsky and Martin (2008), the most frequent English prepositions are: *of*, *in*, *for*, *to*, *with*, *on* and *at* (in order of frequency). Our counts on Sections 2 to 21 of PropBank revealed that these top 7 prepositions account for about 65% of all prepositional phrases that are labeled with semantic roles.

The annotation proceeds in the following way. First, we automatically extract all sentences which have one of the prepositions as the lexical head of a prepositional phrase. The position of the preposition is marked in the sentence. By only considering prepositional phrases, we automatically exclude occurrences of the word *to* before infinitives and instances of particle usage of prepositions, such as phrasal verbs. The extracted prepositions are manually tagged with their senses from the TPP dictionary. Idiomatic usage of prepositions like *for example* or *in fact*, and complex preposition constructions that involve more than one word (e.g., *because of*, *instead of*, etc.) are excluded by the annotators and compiled into a stoplist.

We annotated 3854 instances of the top 7 prepo-

Preposition	Total	Training	Test
at	404	260	144
for	478	307	171
in	1590	1083	507
of	97	51	46
on	408	246	162
to	532	304	228
with	345	211	134
Total	3854	2462	1392

sitions in Sections 2 to 4 and 23 of the PropBank corpus. The data shows a strong correlation between semantic roles and preposition senses that express a spatial or temporal meaning. For the preposition *in*, 90.8% of the instances that appear inside an ARGM-LOC are tagged with sense 1 ("surrounded by or enclosed in") or sense 5 ("inclusion or involvement"). 94.6% of the instances that appear inside an ARGM-TMP role are tagged with sense 2 ("period of time"). Our counts furthermore show that about one third of the annotated prepositional phrases fill core roles and that ARGM-LOC and ARGM-TMP are the most frequent roles. The detailed breakdown of semantic roles is shown in Table 2.
