To see how consistent humans can perform the annotation task, we computed the inter-annotator agreement between two annotators on Section 4 of the PropBank corpus. We found that the two annotators assigned the same sense in 86% of the cases. Although not directly comparable, it is interesting to note that this figure is similar to inter-annotator agreement for open-class words reported in previous work (Palmer et al., 2000). In our final data set, all labels were tagged by the same annotator, which we believe makes our annotation reasonably consistent across different instances. Because we annotate running text, not all prepositions have the same number of annotated instances. The numbers for all seven prepositions are shown in Table 3. In our experiments, we use Sections 2 to 4 to train the models, and Section 23 is kept for testing. Although our experiments are limited to three sections of training data, it still allows us to train competitive SRL models. Pradhan *et al.* (2005) have shown that the benefit of using more training data diminishes after a few thousand training instances. We found that the accuracy of our SRL baseline model, which is trained on the 5275 sentences of these three sections, is only an absolute 3.89% lower than the accuracy of the same model when it is trained on twenty sections (71.71% accuracy compared to 75.60% accuracy).

5 Experiments and Results

We evaluate the performance of the joint model on the annotated prepositional phrases in test section 23 and compare the results with the performance of the baseline models and the pipeline models.

Figure 1 shows the classification accuracy of the WSD models for each of the seven prepositions in the test section. The results show that the pipeline model and the joint model perform almost equally, with the joint model performing marginally better in the overall score. The detailed scores are given in Table 4. Both models outperform the baseline classifier for three of the seven prepositions: *at*, *for*, and *to*. For the prepositions *in*, *of*, and *on*, the SRL feature did not affect the WSD classification accuracy significantly. For the preposition *with*, the classification accuracy even dropped by about 6%.

Performing the student's t-test, we found that the improvement for the prepositions *at*, *for*, and *to* is statistical significant ($p < 0.05$), as is the overall improvement. This confirms our hypothesis that the semantic role of the prepositional phrase is a strong hint for the preposition sense. However, our results also show that it is the SRL feature that brings the improvement, not the joint model, because the pipeline and joint model achieve about the same performance.

For the SRL task, we report the classification accuracy over all annotated prepositional phrases in the test section and the F_1 measure for the semantic roles ARGM-LOC and ARGM-TMP. Fig-

Preposition	Baseline	Pipeline	Joint
at	70.83	78.47*	78.47*
for	41.52	49.12*	49.12*
in	62.33	61.74	61.93
of	43.48	43.48	43.48
on	51.85	51.85	52.47
to	58.77	67.11*	66.67*
with	44.78	38.06	38.06
Total	56.54	58.76*	58.84*

Table 4: Classification accuracy of the baseline, pipeline, and joint model on the WSD task in test section 23, statistically significant improvements over the baseline are marked with an (*)

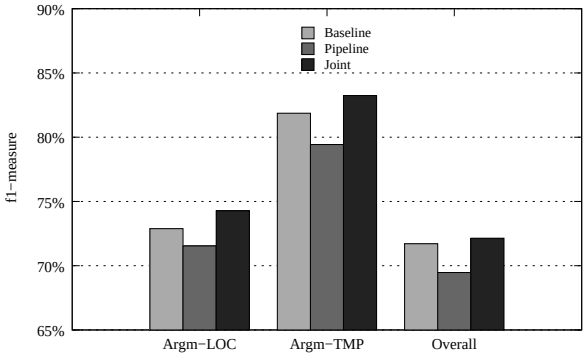

Figure 2: F_1 measure of the SRL models for ARGM-LOC and ARGM-TMP, and overall accuracy on prepositional phrases in test section 23

ure 2 shows the results. The joint model shows a small performance increase of 0.43% over the baseline in the overall accuracy. Adding the preposition sense as a feature, on the other hand, significantly lowers the accuracy by over 2%. For ARGM-LOC and ARGM-TMP, the joint model improves the F_1 measure by about 1.3% each. The improvement of the joint model for these roles is statistically significant ($p \leq 0.05$, student's t-test). Simply adding the preposition sense in the pipeline model again lowers the F_1 measure. The detailed results are listed in Table 5.

Semantic Role	Baseline	Pipeline	Joint
ARGM-LOC(F_1)	72.88	71.54	74.27*
ARGM-TMP(F_1)	81.87	79.43	83.24*
Overall(A)	71.71	69.47	72.14

Table 5: F_1 measure and accuracy of the baseline, pipeline, and joint model on the SRL task in test section 23, statistically significant improvements over the baseline are marked with an (*)

Our SRL experiments show that a pipeline model degrades the performance. The reason is the relatively high degree of noise in the WSD classification and that the pipeline model does not discriminate whether the previous classifier predicts the extra feature with high or low confidence. Instead, the model only passes on the 1-best WSD prediction, which can cause the next classifier to make a wrong classification based on the erroneous prediction of the previous step. In principle, this problem can be mitigated by training the pipeline model on automatically predicted labels using cross-validation, but in our case we found that automatically predicted WSD labels decreased the performance of the pipeline model even more. In contrast, the joint model computes the full probability distribution over the semantic roles and preposition senses. If the noise level in the first classification step is low, the joint model and the pipeline model perform almost identically, as we have seen in the previous WSD experiments. But if the noise level is high, the joint model can still improve while the pipeline model drops in performance. Our experiments show that the joint model is more robust in the presence of noisy features than the pipeline model.

6 Related Work

There is relatively less prior research on prepositions and prepositional phrases in the NLP community. O'Hara and Wiebe (2003) proposed a WSD system to disambiguate function tags of prepositional phrases. An extended version of their work was recently presented in (O'Hara and Wiebe, 2009). Ye and Baldwin (2006) extended their work to a semantic role tagger specifically for prepositional phrases. Their system first classifies the semantic roles of all prepositional phrases and later merges the output with a general SRL system. Ye and Baldwin (2007) used semantic role tags from surrounding tokens as part of the MELB-YB preposition WSD system. They found that the SRL features did not significantly help their classifier, which is different from our findings. Dang and Palmer (2005) showed that semantic role features are helpful to disambiguate verb senses. Their approach is similar to our pipeline WSD model, but they do not present results with automatically predicted semantic roles. Toutanova *et al.* (2008) presented a re-ranking model to jointly learn the semantic roles of multiple constituents in the SRL task. Their work dealt with joint learning in SRL, but it is not directly comparable to ours. The difference is that

Toutanova *et al.* attempt to jointly learn semantic role assignment of *different* constituents for *one* task (SRL), while we attempt to jointly learn *two tasks* (WSD and SRL) for *one* constituent. Because we only look at one constituent at a time, we do not have to restrict ourselves to a re-ranking approach like Toutanova *et al.*, but can calculate the full joint probability distribution of both tasks. Andrew *et al.* (2004) propose a method to learn a joint generative inference model from partially labeled data and apply their method to the problems of word sense disambiguation for verbs and determination of verb subcategorization frames. Their motivation is similar to ours, but they focus on learning from partially labeled data and they investigate different tasks.

None of these systems attempted to jointly learn the semantics of the prepositional phrase and the preposition in a single model, which is the main contribution of our work reported in this paper.

7 Conclusion

We propose a probabilistic model to jointly classify the semantic role of a prepositional phrase and the sense of the associated preposition. We show that learning both tasks together leads to an improvement over competitive, individual models for both subtasks. For the WSD task, we show that the SRL information improves the classification accuracy, although joint learning does not significantly outperform a simpler pipeline model here. For the SRL task, we show that the joint model improves over both the baseline model and the pipeline model, especially for temporal and location arguments. As we only disambiguate the seven most frequent prepositions, potentially more improvement could be gained by including more prepositions into our data set.

Abstract

We report in this paper a way of doing Word Sense Disambiguation (WSD) that has its origin in multilingual MT and that is cognizant of the fact that *parallel corpora, wordnets* and *sense annotated corpora are scarce resources.* With respect to these resources, languages show different levels of readiness; *however a more resource fortunate language can help a less resource fortunate language*. Our WSD method can be applied to a language even when no sense tagged corpora for that language is available. This is achieved by ***projecting wordnet and corpus parameters*** from another language to the language in question. The approach is centered around a novel synset based multilingual dictionary and the empirical observation that within a domain the distribution of senses remains more or less invariant across languages. The effectiveness of our approach is verified by doing parameter projection and then running two different WSD algorithms. The accuracy values of approximately 75% (F1-score) for three languages in two different domains establish the fact that within a domain it is possible to circumvent the problem of scarcity of resources by projecting parameters like sense distributions, corpus-co-occurrences, conceptual distance, *etc.* from one language to another.

1 Introduction

Currently efforts are on in India to build large scale Machine Translation and Cross Lingual Search systems in consortia mode. These efforts are large, in the sense that 10-11 institutes and 6-7 languages spanning the length and breadth of the country are involved. The approach taken for translation is transfer based which needs to tackle the problem of word sense disambiguation (WSD) (Sergei *et. al*., 2003). Since 90s machine learning based approaches to WSD using sense marked corpora have gained ground (Eneko Agirre & Philip Edmonds, 2007). However, the creation of sense marked corpora has always remained a costly proposition. Statistical MT has obviated the need for elaborate resources for WSD, because WSD in SMT happens implicitly through parallel corpora (Brown *et. al*., 1993). But parallel corpora too are a very costly resource.

The above situation brings out the challenges involved in Indian language MT and CLIR. Lack of resources coupled with the multiplicity of Indian languages severely affects the performance of several NLP tasks. In the light of this, we focus on the problem of developing methodologies that *reuse resources*. The idea is to *do the annotation work for one language and find ways of using them for another language.*

Our work on WSD takes place in a multilingual setting involving *Hindi* (national language of India; 500 million speaker base), *Marathi* (20 million speaker base), *Bengali* (185 million speaker base) *and Tamil* (74 million speaker base). The wordnet of Hindi and sense marked corpora of Hindi are used *for all these languages.* Our methodology rests on a novel multilingual dictionary organization and on the idea of "parameter projection" from Hindi to the other languages. Also the domains of interest are *tourism* and *health.*

The roadmap of the paper is as follows. Section 2 describes related work. In section 3 we introduce the parameters essential for domain-specific WSD. Section 4 builds the case for parameter projection. Section 5 introduces the Multilingual Dictionary Framework which plays a key role in parameter projection. Section 6 is the core of the work, where we present parameter projection from one language to another. Section 7 describes two WSD algorithms which combine various parameters for do-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 459–467,
Singapore, 6-7 August 2009.

main-specific WSD. Experiments and results are presented in sections 8 and 9. Section 10 concludes the paper.

2 Related work

Knowledge based approaches to WSD such as Lesk's algorithm (Michael Lesk, 1986), Walker's algorithm (Walker D. & Amsler R., 1986), conceptual density (Agirre Eneko & German Rigau, 1996) and random walk algorithm (Mihalcea Rada, 2005) essentially do Machine Readable Dictionary lookup. However, these are fundamentally *overlap based* algorithms which suffer from overlap sparsity, dictionary definitions being generally small in length.

Supervised learning algorithms for WSD are mostly word specific classifiers, *e.g.*, WSD using SVM (Lee *et. al*., 2004), Exemplar based WSD (Ng Hwee T. & Hian B. Lee, 1996) and decision list based algorithm (Yarowsky, 1994). The requirement of a large training corpus renders these algorithms unsuitable for resource scarce languages.

Semi-supervised and unsupervised algorithms do not need large amount of annotated corpora, but are again word specific classifiers, *e.g.*, semi-supervised decision list algorithm (Yarowsky, 1995) and Hyperlex (Véronis Jean, 2004)). Hybrid approaches like WSD using Structural Semantic Interconnections (Roberto Navigli & Paolo Velardi, 2005) use combinations of more than one knowledge sources (wordnet as well as a small amount of tagged corpora). This allows them to capture important information encoded in wordnet (Fellbaum, 1998) as well as draw syntactic generalizations from minimally tagged corpora.

At this point we state that no single existing solution to WSD completely meets our requirements of **multilinguality, high domain accuracy** and **good performance in the face of not-so-large annotated corpora**.

3 Parameters for WSD

We discuss a number of parameters that play a crucial role in WSD. To appreciate this, consider the following example:

*The river flows through this region to meet the **sea.***

The word *sea* is ambiguous and has three senses as given in the Princeton Wordnet (PWN):

S1: (n) sea (a division of an ocean or a large body of salt water partially enclosed by land)
S2: (n) ocean, sea (anything apparently limitless in quantity or volume)
S3: (n) sea (turbulent water with swells of considerable size) "heavy seas"

Our first parameter is obtained from ***Domain specific sense distributions.*** In the above example, the first sense is more frequent in the tourism domain (verified from manually sense marked tourism corpora). Domain specific sense distribution information should be harnessed in the WSD task.

The second parameter arises from the ***dominance of senses in the domain.*** Senses are expressed by synsets, and we define a dominant sense as follows:

> A synset node in the wordnet hypernymy hierarchy is called *Dominant* if the synsets in the sub-tree below the synset are frequently occurring in the domain corpora.

A few dominant senses in the Tourism domain are *{place, country, city, area}*, *{body of water}*, *{flora, fauna}*, *{mode of transport}* and *{fine arts}*. In disambiguating a word, that sense which belongs to the sub-tree of a domain-specific dominant sense should be given a higher score than other senses. The value of this parameter (θ) is decided as follows:

θ = 1; if the candidate synset is a dominant synset

θ = 0.5; if the candidate synset belongs to the sub-tree of a dominant synset

θ = 0.001; if the candidate synset is neither a dominant synset nor belongs to the sub-tree of a dominant synset.

Our third parameter comes from ***Corpus co-occurrence.*** Co-occurring monosemous words as well as *already disambiguated words* in the context help in disambiguation. For example, the word *river* appearing in the context of *sea* is a monosemous word. The frequency of co-occurrence of *river* with the "water body" sense of *sea* is high in the tourism domain. Corpus co-occurrence is cal-

culated by considering the senses which occur in a window of 10 words around a sense.

Our fourth parameter is based on the ***semantic distance*** between any pair of synsets in terms of the shortest path length between two synsets in the wordnet graph. An edge in the shortest path can be any semantic relation from the wordnet relation repository (*e.g., hypernymy, hyponymy, meronymy, holonymy, troponymy etc.).*

For nouns we do something additional over and above the semantic distance. We take advantage of the deeper hierarchy of noun senses in the wordnet structure. This gives rise to our fifth and final parameter which arises out of the ***conceptual distance*** between a pair of senses. Conceptual distance between two synsets S_1 and S_2 is calculated using Equation (1), motivated by Agirre Eneko & German Rigau (1996).

$$\textit{Conceptual Distance (S1, S2)} = \frac{\text{Length of the path between (S1, S2) in terms of hypernymy hierarchy}}{\text{Height of the lowest common ancestor of S1 and S2 in the wordnet hierarchy}} \quad (1)$$

The conceptual distance is proportional to the path length between the synsets, as it should be. The distance is also inversely proportional to the height of the common ancestor of two sense nodes, because as the common ancestor becomes more and more general the conceptual relatedness tends to get vacuous (e.g., two nodes being related through *entity* which is the common ancestor of EVERYTHING, does not really say anything about the relatedness).

To summarize, our various parameters used for domain-specific WSD are:

Wordnet-dependent parameters

- *belongingness-to-dominant-concept*
- *conceptual-distance*
- s*emantic-distance*

Corpus-dependent parameters

- *sense distributions*
- *corpus co-occurrence*.

In section 7 we show how these parameters are used to come up with a scoring function for WSD.

4 Building a case for Parameter Projection

Wordnet-dependent parameters depend on the graph based structure of Wordnet whereas the ***Corpus-dependent parameters*** depend on various statistics learnt from a sense marked corpora. Both the tasks of (a) constructing a wordnet from scratch and (b) collecting sense marked corpora for multiple languages are tedious and expensive. An important question being addressed in this paper is: *whether the effort required in constructing semantic graphs for multiple wordnets and collecting sense marked corpora can be avoided?* Our findings seem to suggest that by ***projecting relations*** from the wordnet of a language and by ***projecting corpus*** statistics from the sense marked corpora of the language we can achieve this end. Before we proceed to discuss the way to realize parameter projection, we present a novel dictionary which facilitates this task.

5 Synset based multilingual dictionary

Parameter projection as described in section 4 rests on a novel and effective method of storage and use of dictionary in a multilingual setting proposed by Mohanty *et. al*. (2008). For the purpose of current discussion, we will call this multilingual dictionary framework *MultiDict*. One important departure from traditional dictionary is that **synsets are linked, and after that the words inside the synsets are linked.** The basic mapping is thus between synsets and thereafter between the words.

Concepts	**L1 (English)**	**L2 (Hindi)**	**L3 (Marathi)**
04321: a youthful male person	{male child, boy}	{लड़का ladkaa, बालक,baalak बच्चा bachchaa}	{मुलगाmulgaa , पोरगाporgaa , पोरpor }

Table 1: Multilingual Dictionary Framework

Table 1 shows the structure of MultiDict, with one example row standing for the concept of *boy*. The first column is the pivot describing a concept with a unique ID. The subsequent columns show the words expressing the concept in respective languages (in the example table above, *English, Hindi* and *Marathi*). Thus to express the concept *'04321: a youthful male person'*, there are two lexical elements in English, which constitute a *synset.* Correspondingly, the Hindi and Marathi synsets contain 3 words each.

It may be noted that the *central language* whose synsets the synsets of other languages link to is Hindi. This way of linking synsets- more popularly known as the *expansion* approach- has several advantages as discussed in (Mohanty *et. al.*, 2008). One advantage germane to the point of this paper is that the synsets in a particular column automatically inherit the various semantic relations of the Hindi wordnet (Dipak Narayan *et. al., 2000*), which saves the effort involved in reconstructing these relations for multiple languages.

After the synsets are linked, **cross linkages are set up** manually from the words of a synset to the words of a linked synset of the central language. The average number of such links per synset per language pair is approximately 3. These cross-linkages actually solve the problem of *lexical choice* in translating from text of one language to another.

Thus for the Marathi word मुलगा *{mulagaa}* denoting "*a youthful male person",* the correct lexical substitute from the corresponding Hindi synset is लड़का *{ladakaa}* (Figure 1). One might argue that any word within the synset could serve the purpose of translation. However, the exact lexical substitution has to respect native speaker acceptability.

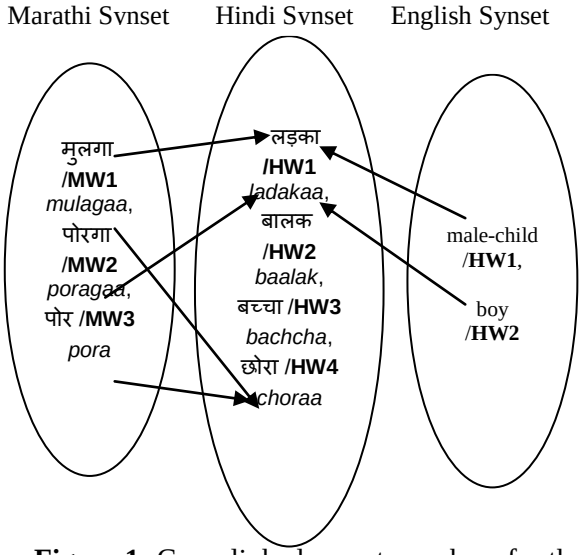

Figure 1: Cross linked synset members for the concept: *a youthful male person*

We put these cross linkages to another use, as described later.

Since it is the MultiDict which is at the heart of parameter projection, we would like to summarize the main points of this section. (1) By linking with the synsets of Hindi, the cost of building wordnets of other languages is partly reduced (semantic relations are inherited). The wordnet parameters of Hindi wordnet now become projectable to other languages. (2) By using the *cross linked words* in the synsets, corpus parameters become projectable (*vide* next section).

6 Parameter projection using MultDict

6.1 *P(Sense|Word)* parameter

Suppose a word (say, ***W***) in language L_1 (say, Marathi) has *k* senses. For each of these *k* senses we are interested in finding the parameter $P(S_i|W)$- which is the probability of sense S_i given the word *W* expressed as:

$$P(S_i|W) = \frac{\#(S_i, W)}{\sum_j \#(S_j, W)}$$

where '#' indicates 'count-of'. Consider the example of two senses of the Marathi word सागर *{saagar}, viz., sea* and *abundance* and the corresponding cross-linked words in Hindi (Figure 2 below):

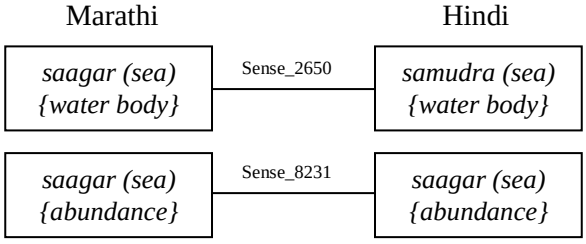

Figure 2: Two senses of the Marathi word सागर *(saagar), viz., {water body}* and *{abundance},* and the corresponding cross-linked words in Hindi[1].

The probability *P({water body}|saagar)* for Marathi is

$$\frac{\#(\{\boldsymbol{water\ body}\}, \boldsymbol{saagar})}{\#(\{\boldsymbol{water\ body}\}, \boldsymbol{saagar}) + \#(\{\boldsymbol{abundance}\}, \boldsymbol{saagar})}$$

We propose that this can be approximated by the counts from Hindi sense marked corpora by replacing *saagar* with the cross linked Hindi words *samudra* and *saagar*, as per Figure 2:

$$\frac{\#(\{\text{water body}\}, \text{samudra})}{\#(\{\text{water body}\}, \text{samudra}) + \#(\{\text{abundance}\}, \text{saagar})}$$

[1] Sense_8231 shows the same word *saagar* for both Marathi and Hindi. This is not uncommon, since Marathi and Hindi are sister languages.

Thus, the following formula is used for calculating the sense distributions of Marathi words using the sense marked Hindi corpus from the same domain:

$$P(S_i|W) = \frac{\#(S_i\ , cross\_linked\_hindi\_word)}{\sum_j\ \#(S_j\ , cross\_linked\_hindi\_word)} \qquad (2)$$

Note that we are not interested in the *exact* sense distribution of the words, but only in the *relative* sense distribution.

To prove that the projected relative distribution is faithful to the actual relative distribution of senses, we obtained the sense distribution statistics of a set of Marathi words from a sense tagged Marathi corpus (we call the sense marked corpora of a language its **self corpora**). These sense distribution statistics were compared with the statistics for these same words obtained by *projecting from* a sense tagged Hindi corpus using Equation (2). The results are summarized in Table 2.

Sr. No	Marathi Word	Synset	P(S|word) as learnt from sense tagged Marathi corpus	P(S|word) as projected from sense tagged Hindi corpus
1	किंमत (kimat)	{ worth }	0.684	0.714
		{ price }	0.315	0.285
2	रस्ता (rasta)	{ roadway }	0.164	0.209
		{road, route}	0.835	0.770
3	ठिकाण (thikan)	{ land site, place}	0.962	0.878
		{ home }	0.037	0.12
4	सागर (saagar)	{water body}	1.00	1.00
		{abundance}	0	0

Table 2: Comparison of the sense distributions of some Marathi words learnt from Marathi sense tagged corpus with those projected from Hindi sense tagged corpus.

The fourth row of Table 2 shows that whenever सागर *(saagar) (sea)* appears in the Marathi tourism corpus there is a 100% chance that it will appear in the *"water body"* sense and 0% chance that it will appear in the sense of *"abundance"*. Column 5 shows that the same probability values are obtained using projections from Hindi tourism corpus. Taking another example, the third row shows that whenever ठिकाण (*thikaan) (place, home)* appears in the Marathi tourism corpus there is a much higher chance of it appearing in the sense of "place" (96.2%) then in the sense of "home" (3.7%). Column 5 shows that the relative probabilities of the two senses remain the same even when using projections from Hindi tourism corpus (i.e. by using the corresponding cross-linked words in Hindi). To quantify these observations, we calculated the average KL divergence and Spearman's correlation co-efficient between the two distributions. The KL divergence is 0.766 and Spearman's correlation co-efficient is 0.299. Both these values indicate that there is a high degree of similarity between the distributions learnt using projection and those learnt from the self corpus.

6.2 Co-occurrence parameter

Similarly, within a domain, the statistics of co-occurrence of senses remain the same across languages. For example, the co-occurrence of the Marathi synsets {आकाश (akash) (sky), अंबर (ambar) (sky)} and {मेघ (megh) (cloud), अभ्र (abhra) (cloud)} in the Marathi corpus remains more or less same as (or proportional to) the co-occurrence between the corresponding Hindi synsets in the Hindi corpus.

Sr. No	Synset	Co-occurring Synset	P(co-occurrence) as learnt from sense tagged Marathi corpus	P(co-occurrence) as learnt from sense tagged Hindi corpus
1	{रोप, रोपटे} {small bush}	{झाड, वृक्ष, तरुवर, द्रुम, तरू, पादप} {tree}	0.125	0.125
2	{मेघ, अभ्र} {cloud}	{आकाश, आभाळ, अंबर} {sky}	0.167	0.154
3	{क्षेत्र, इलाक़ा, इलाका, भूखंड} {geographical area}	{यात्रा, सफ़र} {travel}	0.0019	0.0017

Table 3: Comparison of the corpus co-occurrence statistics learnt from Marathi and Hindi Tourism corpus.

Table 3 shows a few examples depicting similarity between co-occurrence statistics learnt from Marathi tourism corpus and Hindi tourism corpus. Note that we are talking about co-occurrence of synsets and not words. For example, the second row shows that the probability of co-occurrence of the synsets {cloud} and {sky} is almost same in the Marathi and Hindi corpus.

7 Our algorithms for WSD

We describe two algorithms to establish the usefulness of the idea of parameter projection. The first algorithm- called *iterative WSD (IWSD-)* is greedy, and the second based on PageRank algorithm is exhaustive. Both use scoring functions that make use of the parameters detailed in the previous sections.

7.1 Iterative WSD (IWSD)

We have been motivated by the Energy expression in Hopfield network (Hopfield, 1982) in formulating a scoring function for ranking the senses. Hopfield Network is a fully connected bidirectional symmetric network of bi-polar (0/1 or +1/-1) neurons. We consider the asynchronous Hopfield Network. At any instant, a randomly chosen neuron (a) examines the weighted sum of the input, (b) compares this value with a threshold and (c) gets to the state of 1 or 0, depending on whether the input is greater than or less than or equal to the threshold. The assembly of 0/1 states of individual neurons defines a state of the whole network. Each state has associated with it an energy, *E*, given by the following expression

$$E = -\theta_i V_i + \sum_{i=1}^{N} \sum_{j>i}^{N} W_{ij}\, V_i V_j \qquad (3)$$

where, *N* is the total number of neurons in the network, V_i and V_j are the activations of neurons *i* and *j* respectively and W_{ij} is the weight of the connection between neurons *i* and *j*. Energy is a fundamental property of Hopfield networks, providing the necessary machinery for discussing convergence, stability and such other considerations.

The energy expression as given above cleanly separates the influence of self-activations of neurons and that of interactions amongst neurons to the global macroscopic property of energy of the network. This fact has been the primary insight for equation (4) which was proposed to score the most appropriate synset in the given context. The correspondences are as follows:

Neuron	→	*Synset*
Self-activation	→	*Corpus Sense Distribution*
Weight of connection between two neurons	→	*Weight as a function of corpus co-occurrence and Wordnet distance measures between synsets*

$$S^* = \underset{i}{\operatorname{argmax}} \left(\theta_i * V_i + \sum_{j \in \mathrm{J}} W_{ij} * V_i * V_j \right) \quad (4)$$

where,

$\mathrm{J} = Set\ of\ disambiguated\ Words$

$\theta_i = BelongingnessToDominantConcept\ (S_i)$

$V_i = P(S_i \mid word)$

$W_{ij} = CorpusCooccurences\ (S_i, S_j) * 1/WNConceptualDistance(S_i, S_j) * 1/WNSemanticGraphDistance(S_i, S_j)$

The component $\theta_i * V_i$ of the energy due to the self activation of a neuron can be compared to the corpus specific sense of a word in a domain. The other component $w_{ij} * V_i * V_j$ coming from the interaction of activations can be compared to the score of a sense due to its interaction in the form of corpus co-occurrence, conceptual distance, and wordnet-based semantic distance with the senses of other words in the sentence. The first component thus captures the rather *static corpus sense*, whereas the second expression brings in the sentential context.

Algorithm 1: *performIterativeWSD(sentence)*

1. Tag all monosemous words in the sentence.
2. Iteratively disambiguate the remaining words in the sentence in increasing order of their degree of polysemy.
3. At each stage select that sense for a word which maximizes the score given by Equation (4)

Algorithm1: Iterative WSD

IWSD is clearly a greedy algorithm. It bases its decisions on already disambiguated words, and ignores words with higher degree of polysemy. For example, while disambiguating bisemous words, the algorithm uses only the monosemous words.

7.2 Modified PageRank algorithm

Rada Mihalcea (2005) proposed the idea of using PageRank algorithm to find the best combination of senses in a sense graph. The nodes in a sense graph correspond to the senses of all the words in a sentence and the edges depict the strength of interaction between senses. The score of each node in the graph is then calculated using the following recursive formula:

$$score(S_i) = (1-\mathrm{d}) + \mathrm{d} * \sum_{S_j \in In(S_i)} \frac{W_{ij}}{\sum_{S_k \in Out(S_i)} W_{jk}} * Score(S_j)$$

Instead of calculating W_{ij} based on the overlap between the definition of senses S_i and S_j as proposed by Rada Mihalcea (2005), we calculate the edge weights using the following formula:

$$W_{ij} = CorpusCooccurences(S_i, S_j) * 1/WNConceptualDistance(S_i, S_j) * 1/WNSemanticGraphDistance(S_i, S_j) * P(S_i \mid word_i) * P(S_j \mid word_j)$$

$d = damping\ factor\ (typically\ 0.85)$

This formula helps capture the edge weights in terms of the corpus bias as well as the interaction between the senses in the corpus and wordnet. It should be noted that this algorithm is *not greedy*. Unlike IWSD, this algorithm allows all the senses of all words to play a role in the disambiguation process.

8 Experimental Setup:

We tested our algorithm on tourism corpora in 3 languages (*viz.*, Marathi, Bengali and Tamil) and health corpora in 1 language (Marathi) using projections from Hindi. The corpora for both the domains were manually sense tagged. A 4-fold cross validation was done for all the languages in both the domains. The size of the corpus for each language is described in Table 4.

Language	**# of polysemous words (tokens)**	
	Tourism Domain	**Health Domain**
Hindi	50890	29631
Marathi	32694	8540
Bengali	9435	-
Tamil	17868	-

Table 4: Size of manually sense tagged corpora for different languages.

Table 5 shows the number of synsets in MultiDict for each language.

Language	**# of synsets in MultiDict**
Hindi	29833
Marathi	16600
Bengali	10732
Tamil	5727

Table 5: Number of synsets for each language

Algorithm	**Language**					
	Marathi			**Bengali**		
	P %	**R %**	**F %**	**P %**	**R %**	**F %**
IWSD (training on self corpora; no parameter projection)	81.29	80.42	80.85	81.62	78.75	79.94
IWSD (training on Hindi and reusing parameters for another language)	**73.45**	**70.33**	**71.86**	**79.83**	**79.65**	**79.79**
PageRank (training on self corpora; no parameter projection)	79.61	79.61	79.61	76.41	76.41	76.41

Wordnet Baseline	58.07	58.07	58.07	52.25	52.25	52.25

Table 6: Precision, Recall and F-scores of IWSD, PageRank and Wordnet Baseline. Values are reported with and without parameter projection.

9 Results and Discussions

Table 6 shows the results of disambiguation (precision, recall and F-score). We give values for two algorithms in the tourism domain: IWSD and PageRank. In each case figures are given for both with and without parameter projection. The wordnet baseline figures too are presented for the sake of grounding the results.

Note the lines of numbers in bold, and compare them with the numbers in the preceding line. This shows the fall in accuracy value when one tries the parameter projection approach in place of self corpora. For example, consider the F-score as given by *IWSD* for Marathi. It degrades from about 81% to 72% in using parameter projection in place of self corpora. Still, the value is much more than the baseline, *viz.*, the wordnet first sense (a typically reported baseline).

Coming to PageRank for Marathi, the fall in accuracy is about 8%. Appendix A shows the corresponding figure for Tamil with IWSD as 10%. Appendix B reports the fall to be 11% for a different domain- Health- for Marathi (using *IWSD*).

In all these cases, even after degradation the performance is far above the wordnet baseline. This shows that one could trade accuracy with the cost of creating sense annotated corpora.

10 Conclusion and Future Work:

Based on our study for 3 languages and 2 domains, we conclude the following:

(i) Domain specific sense distributions- if obtainable- can be exploited to advantage.

(ii) Since sense distributions remain same across languages, it is possible to create a disambiguation engine that will work even in the absence of sense tagged corpus for some resource deprived language, provided (a) there are aligned and cross linked sense dictionaries for the language in question and another resource rich language, (b) the domain in which disambiguation needs to be performed for the resource deprived language is the same as the domain for which sense tagged corpora is available for the resource rich language.

(iii) Provided the accuracy reduction is not drastic, it may make sense to trade high accuracy for the effort in collecting sense marked corpora.

It would be interesting to test our algorithm on other domains and other languages to conclusively establish the effectiveness of parameter projection for multilingual WSD.

It would also be interesting to analyze the contribution of corpus and wordnet parameters independently.

Abstract

Much NLP research on Multi-Word Expressions (MWEs) focuses on the discovery of new expressions, as opposed to the identification in texts of known expressions. However, MWE identification is not trivial because many expressions allow variation in form and differ in the range of variations they allow. We show that simple rule-based baselines do not perform identification satisfactorily, and present a supervised learning method for identification that uses sentence surface features based on expressions' canonical form. To evaluate the method, we have annotated 3350 sentences from the British National Corpus, containing potential uses of 24 verbal MWEs. The method achieves an F-score of 94.86%, compared with 80.70% for the leading rule-based baseline. Our method is easily applicable to any expression type. Experiments in previous research have been limited to the compositional/non-compositional distinction, while we also test on sentences in which the words comprising the MWE appear but not as an expression.

1 Introduction

Multi-Word Expressions (MWEs) such as 'pull strings', 'make a face' and 'get on one's nerves' are very common in language. Such MWEs can be characterized as being *non-compositional*: the meaning of the expression does not transparently follow from the meaning of the words that comprise it. Much of the work on MWEs in NLP has been in *MWE extraction* – the discovery of new MWEs from a corpus, using statistical and other methods. Identification of *known* MWEs in text has received less attention, but is necessary for many NLP applications, for example in machine translation. The current work deals with the *MWE identification* task: deciding if a sentence contains a use of a known expression.

MWE identification is not as simple as may initially appear, as will be shown by the performance of two rule-based baselines in our experiments. One source of difficulty is variations in expressions' usage in text. Although MWEs generally show less variation than single words, they show enough that it cannot be ignored. In a study on V+NP idioms, Riehemann (2001) found that the idioms' canonical form accounted for 75% of their appearances in a corpus. Additionally, expressions differ considerably in the types of variations they allow, which include passivization, nominalization and addition of modifying words (Moon, 1998).

A second source of difficulty is that expressions consisting of very frequent words will often co-occur in sentences in a non-MWE usage and in similar but distinct expressions.

MWE identification can be modeled as a two step process. Given a sentence and a known expression, step (1) is to decide if the sentence contains a potential use of the expression. This is a relatively simple step based on the appearance in the sentence of the words comprising the MWE. Step (2) is to decide if the potential use is indeed non-compositional. Consider the following sentences with regard to the expression *hit the road*, meaning 'to leave on a journey':

(a) 'At the time, *the road* was long and difficult with few travelers daring to take it.'

(b) 'The headlights of the taxi-van behind us

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 468–477,
Singapore, 6-7 August 2009.

flashed as it *hit* bumps in *the road*.'

(c) 'The bullets were *hitting the road* and I could see them coming towards me a lot faster than I was able to reverse.'

(d) 'Lorry trailers which would have been *hitting the road* tomorrow now stand idle.'

Sentence (a) does not contain a potential use of the expression due to the missing component 'hit'. Each of (b)-(d) does contain a potential use of the expression. In (b) all of the expression components are present, but they do not form an expression. In (c), the words form an expression, but with a compositional (literal) meaning. Only (d) contains a non-compositional use of *hit the road*. The task we address in this paper is to identify whether or not we are in case (d), for a given expression in a given sentence.

To date, most work in MWE identification has focused on manually encoding rules that identify expressions in text. The encodings, usually consisting of regular expressions and syntactic structures, are intended to contain all the necessary information for processing the MWE in text. Being manual, this is time-consuming work and requires expert knowledge of individual expressions. In terms of the above model, such encodings handle both MWE identification steps.

A second approach is to use machine learning methods to learn an expression's behavior from a corpus. Studies taking this approach have focused on distinguishing between compositional and non-compositional uses of an expression (cases (c) and (d) above). As will be detailed in Section 2, existing methods are tailored to an expression's type, and experiment with a single MWE pattern. In addition, the training and test sets they used did not contain non-expression uses as in case (b), which can be quite common in practice.

Our approach is more general. Given a set of sentences with potential MWE uses, we use sentence surface features to create a Support Vector Machine (SVM) classifier for each expression. The classifier is binary and differentiates between non-compositional uses of the expression ((d) above) on the one hand, and compositional and non-expression uses ((b) and (c)) on the other. The experiments and results presented below focus on verbal MWEs, since verbal MWEs are quite common in language use and have also been investigated in related MWE research (e.g., (Cook et al., 2007)). However, the developed features are not specific to a particular type of expression.

The supervised method is compared with two simple rule-based baselines in order to test whether a simple approach is sufficient. In addition, the use of surface features is compared with the use of syntactic features (based on dependency parse trees of the sentences). Averaged over expressions in an independent test set, the supervised classifiers outperform the rule-based baselines, with F-scores of 94.86% (surface features) and 87.77% (syntactic features), compared with 80.70% for the best baseline.

Section 2 reviews previous work. Section 3 discusses the features used for the supervised classifier. Section 4 explains the experimental setting. The results and a discussion are given in sections 5 and 6.

2 Previous Work

2.1 MWE Lexical Encoding

The approach to handling MWEs in early systems was to employ a list of expressions, each with a quasi regular expression that encodes morpho-syntactic variations. One example is Leech et al. (1994) who used this method for automatic part-of-speech tagging for the BNC. Another is a formalism called IDAREX (IDioms And Regular EXpressions) (Breidt et al., 1996).

More recent research emphasizes the integration of MWE lexical entries into existing single word lexicons and grammar systems (Villavicencio et al., 2004; Alegria et al., 2004). There is also an attempt to take advantage of regularities in morpho-syntactic properties across MWE groups, which allows encoding the behavior of the group instead of individual expressions (Villavicencio et al., 2004; Grégoire, 2007). Fellbaum (1998) discusses some difficulties in representing idioms, which are largely figurative in meaning, in WordNet. More recent work (Fellbaum et al., 2006) focuses on German VP idioms.

As already mentioned, one issue with lexical encoding is that it is done manually, making lexicons difficult to create, maintain and extend. The use of regularities among different types of MWEs is one way of reducing the amount of work required. A second issue is that implementations tend to ignore the likelihood and even the possibility of compositional and other interpretations of expressions in text, which can

be common for some expressions. For example, in an MWE identification study, Hashimoto et al. (2006) built an identification system using hand crafted rules for some 100 Japanese idioms. The results showed near perfect performance on expressions without compositional/non-compositional ambiguity but significantly poorer performance on expressions with ambiguity.

2.2 MWE Identification by ML

Katz and Giesbrecht (2006) used a supervised learning method to distinguish between compositional and non-compositional uses of an expression (in German text) by using contextual information in the form of Latent Semantic Analysis (LSA) vectors. LSA vectors of compositional and non-compositional meaning were built from a training set of example sentences and then a nearest neighbor algorithm was applied on the LSA vector of one tested MWE. The technique was tested more thoroughly in Cook et al. (2007).

Cook et al. (2007) devised two unsupervised methods to distinguish between compositional (literal) and non-compositional (idiomatic) tokens of verb-object expressions. The first method is based on an expression's canonical form. In a previous study (Fazly and Stevenson, 2006), the authors came up with a dozen possible syntactic forms for verb-object pairs (based on passivization, determiner, and object pluralization) and used a corpus-based statistical measure to determine the canonical form(s). The method classifies new tokens as idiomatic if they use a canonical form, and literal otherwise.

The second method uses context as well as form. Co-occurrence vectors representing the idiomatic and literal meaning of each expression were computed based on corpus data. Idiomatic-meaning vectors were based on examples matching the expressions' canonical form. Literal meaning vectors were based on examples that did not match the canonical form. New tokens were classified as literal/idiomatic based on their (co-occurrence) vector's cosine similarity to the idiomatic and literal vectors.

(Sporleder and Li, 2009) also attempted to distinguish compositional from non-compositional uses of expressions in text. Their assumption was that if an expression is used literally, but not idiomatically, its component words will be related semantically to several words in the surrounding discourse. For example, when the expression 'play with fire' is used literally, words such as 'smoke, 'burn', 'fire department', and 'alarm' tend to also be used nearby; when it is used idiomatically, they aren't (indeed, other words, e.g., 'danger' or 'risk' appear nearby but they are not close semantically to 'play' or to 'fire'). This property was used to distinguish literal and non-literal instances by measuring the semantic relatedness of an expression's component words to nearby words in the text. If one or more of the expression's components were sufficiently related to enough nearby words, forming a 'lexical chain', the usage was classified as literal. Otherwise it was idiomatic. Two classifiers based on lexical chains were devised. These were compared with a supervised method that trains a classifier for each expression based on surrounding context. The results showed that the supervised classifier method did much better (90% F-score on literal uses) than the lexical chain classifier methods (60% F-score).

In the above studies the focus is on the compositional/non-compositional expression distinction. The sentence data used contains examples of either one or the other. In (Sporleder and Li, 2009) the experimental data included only sentences in which the expressions were in canonical form (allowing for verb inflection). In (Cook et al., 2007) a syntactic parser was used to collect sentences containing the MWEs in the active and passive voice using heuristics. Thus, examples such as the following (from the BNC) would not be included in their sample:

1. *take a chance*: 'While he still had **a chance** of being near Maisie, he would **take** it'.
2. *face the consequences*: '...she did not have to **face**, it appears, **the** possible serious or even fatal **consequences** of her decision'.
3. *make a distinction*: 'Logically, **the distinction** between the two aspects of the theory can and should be **made**'.
4. *break the ice*: '**The ice**, if not **broken**, was beginning to soften a little'.
5. *settle a score*: 'Morrissey had another **score to settle**'.

This means that their experiments have not included all types of sentences that might be encountered in practice when attempting MWE identifi-

cation. Specifically, they would miss many examples in which the MWE words are present but are not used as an expression (case (b) in Section 1). Moreover, their heuristics are tailored to the Verb-Direct Object MWE type. Different heuristics would need to be employed for different MWE types.

In our approach there is no pre-processing stage requiring type-specific knowledge. Specifically, the above examples are used as training sentences in our experiments.

2.3 MWE Extraction

There exists an extensive body of research on MWE extraction (see Wermter and Hahn (2004) for a review), where the only input is a corpus, and the output is a list of MWEs found in it. Most methods collect MWE candidates from the corpus, score them according to some association measure between their components, and accept candidates with scores passing some threshold. The focus of research has been on developing association measures, including statistical, information-theoretic and linguistically motivated measures (e.g., Justeson and Katz (1995), Wermter and Hahn (2006), and Deane (2005)).

3 MWE Identification Method

Our method decides if a potential use of a known expression in a given sentence is non-compositional. The input to the method, for each MWE, is a labeled training set of sentences containing one or more potentially non-compositional uses of the MWE. The output, for each MWE, is a binary classifier, trained on those sentences. Thus, we target step (2) of MWE identification, which is the difficult one.

The learning algorithm used is Support Vector Machine (SVM), which outputs a binary classifier, using Sequential Minimal Optimization (Platt, 1998)[1] in the Weka toolkit[2] (Witten and Frank, 2000).

For training, sentences are converted into feature vectors. Features depend on the assignment of the lexical components of the expression to specific tokens in the sentence. In some cases, there are several tokens in the sentence that match a single component in the expression, and this leads to multiple (potential) assignments. So in the general case a sentence is converted to a set of feature vectors, each corresponding to a single assignment of the MWE's lexical components to sentence tokens.

Training sentences are labeled positive if they contain a non-compositional use of the expression and negative if they do not (i.e., literal and other uses). If the sentence is positive, at least one of the assignments is the true assignment (there may be more than one, e.g., when an expression is used twice in the same sentence). The vector matching the true assignment is labeled positive. The others are labeled negative. If the sentence is negative, all of the vectors are labeled negative.

As mentioned, the output of the method is a distinct binary classifier for each MWE. Although having a single classifier for all expressions would seem advantageous, the wide variation exhibited by MWEs (e.g., for some the passive is common, for other not at all) precludes this option and requires having a separate classifier for each expression.

3.1 Features

Surface features include order and distance, part-of-speech and inflection of an expression's words in a sentence.

Use of surface features is intuitive and relatively cheap. In addition, many studies have shown the importance of order and distance in MWE extraction in English (two recent examples are (Dias, 2003; Deane, 2005)). Thus, we develop a supervised classifier based on surface features.

Many of the surface features make use of an expression's Canonical Form (CF), thus the learning algorithm assumes that it is given such a form. Formally defining the CF is difficult. Indeed, some researchers have concluded that some expressions do not have a CF (Moon, 1998). For our purposes, CF can be informally defined as the most frequent form in which the expression appears. In practice, an approximation of this definition, explained in Section 4, is used.

3.1.1 Surface Features

1. Word Distance: The number of words between the leftmost and rightmost MWE tokens in the sentence.

2. Ordered Gap List: A list of gaps, measured in number of words, between each pair of the

[1] Using the PUK kernel (The Pearson VII function-based Universal Kernel), with parameters omega=1.0 and sigma=1.0.

[2] Weka version 3.5.6; www.cs.waikato.ac.nz/ ml/ weka/

expression's tokens in their canonical form order. For example, if the token locations (in canonical form order) are 10, 7 and 3, the ordered gap list would be $(10 \leftrightarrow 7 = 2, 10 \leftrightarrow 3 = 6, 7 \leftrightarrow 3 = 3)$.

3. Word Order: A boolean value indicating whether the expression's word order in the sentence matches the canonical form word order.

4. Word Order Permutation: The permutation of word order relative to the canonical form. For example, the permutation (1,0,2) indicates that component words 1 and 0 have switched order in the sentence.

5. Inflection Ratio: The fraction of words in the expression that have undergone inflection relative to the canonical form.

6. Lexical Values: A list of the tokens in the sentence matching the expression's component words, ordered according to canonical form. For example, if the expression is 'make a distinction', a possible lexical values list is (made,no,distinction) in the sentence 'No possible distinction can be made between the two'.

7. POS Pattern: A boolean value indicating whether the expression's use in the sentence has the same part-of-speech pattern as the canonical form.

Two combinations of surface features are used in the experiments below. The first, named R1, uses all of the above features. The second, R2, uses only Word Distance, Ordered Gap List and Word Order Permutation. Using R2 the learner has only word order and distance information from which to create a classifier.

3.1.2 Syntactic Features

An expression's words may appear unrelated in a sentence, because of distance, order, part-of-speech and other surface variations. However, the words will still be closely related syntactically. Syntactic analysis of the sentence in the form of a dependency parse tree directly gives the syntactic relationships between the expression's components. Thus, we also develop a classifier based on syntactic features.

Dependency Parsing. A dependency parse tree is a directed acyclic graph in which the nodes represent tokens in the sentence and the edges represent syntactic dependencies between the words (e.g., direct-object, prepositional-object, noun-subject etc.). The Stanford Parser[3] (Marneffe et al., 2006) was used.

Minimal Sub-Tree. To compute a syntactic feature, the dependency tree is computed and then the minimal sub-tree containing the expression's tokens is extracted.

The features are:

1. Sub-Tree Distance Sum: The number of edges in the minimal sub-tree. A large number of edges suggests a weaker dependency.

2. Sub-Tree Distance List: A list of the distances of the MWE component nodes from the root of their sub-tree.

3. Descendant Relations List: A list of descendant relations between each pair of MWE component nodes.
   A descendant relation between two nodes exists if there is a directed path from one node (the ancestor) to the other (the descendant). Descendant relations are either direct (parent-child) or indirect. The list consists of the levels of descendant relations between the MWE component nodes, which can be none, indirect or direct.

4. Descendant Direction List: A list of the directions of the descendant relations between each pair of MWE component nodes.
   If there are descendant relations between a pair of nodes, the direction of the dependency, indicating which is the modifying and which the modified node, is important.

5. Sibling Relations List: A list of sibling relations between each pair of MWE component nodes.
   Two nodes are first degree siblings if they share the same parent (which usually means they modify the same word). Two nodes are second degree siblings if they share a common ancestor no more than two edges away, and so on. The list consists of the level of sibling relations for each pair of component

[3] http://www-nlp.stanford.edu/software/lex-parser.shtml

nodes, which can be first, second and third degree.

6. Descendant Type List: A list of the dependency types (e.g., subject, direct object etc.) between each pair of component nodes. If the component nodes are not direct descendants their dependency type is null.

7. Sibling Type List: A list of pairs of dependency types corresponding to the dependencies between a pair of component nodes and their common parent. If the component nodes are not first degree siblings, the type is null.

In the experiments reported below, the classifier using only the syntactic features is denoted by S, and the one using all surface and all syntactic features is denoted by C. We have experimented with additional feature combinations, with no improvement in results.

4 Experimental Method

Canonical form. As described, an expression's canonical form (CF) is used in many of the learning algorithm's features. The CF is taken from Collins COBUILD Advanced Learner's English Dictionary (2003) which is also used as our source for MWEs. COBUILD is an English-English dictionary based on the Bank of English (BOE) corpus (over 520 million words) with approximately 34,000 entries.

Traditional single-word dictionaries are a good source for expressions because they usually list, as part of single-word entries, expressions in which the word is a component. The CF is not explicitly given in COBUILD, so an approximation is the form which appears in the expression's definition. This is a reasonable approximation since the COBUILD authors claim to have selected *typical* uses of the expressions in their definitions.

Each CF also has a matching part-of-speech (POS) pattern, which is a list of the parts-of-speech of the components in the CF. For example, 'walking on air' has the pattern $(Verb, Preposition, Noun)$. COBUILD does not include part-of-speech information for expressions so this information was determined using the British National Corpus (BNC) (BNC, 2001), a (mostly) automatically POS tagged corpus (using the CLAWS tagger). For each MWE, the POS patterns of all instances of the CF in the corpus were counted. The most frequent pattern is the expression's POS pattern.

The expressions. A set of 17 verbal MWEs, the development set, was used for development of the surface and syntactic features described above. All of the development set MWEs had the POS pattern $(Verb, Determiner, Noun)$. Another set of 24 verbal MWEs, the training/test set[4], was then used to test the method. Because the method is not specific to the $(Verb, Determiner, Noun)$ pattern, new POS patterns are included in the training/test set. The training/test set consists of 8 MWEs of the POS pattern $(Verb, Determiner, Noun)$, 7 $(Verb, Preposition, Noun)$ MWEs and and 9 $(Verb, Noun, Preposition)$ MWEs. The list of MWEs was selected randomly from the corresponding POS pattern types. MWEs with a positive or negative percentage of under 5% in their data set were discarded[5]. The MWEs, in their canonical form, are:
Development set:
$(Verb, Determiner, Noun)$ [17]: *break the ice, calls the shots, catch a cold, clear the air, face the consequences, fits the bill, hit the road, make a face, make a distinction, makes an impression, raise the alarm, set an example, sound the alarm, stay the course, take a chance, take the initiative, tie the knot*.
Training/test set:
$(Verb, Determiner, Noun)$ [8]: *changes the subject, get a grip, get the picture, lead the way, makes the grade, sets the scene, take a seat, take the plunge*;
$(Verb, Preposition, Noun)$ [7]: *fall into place, goes to extremes, brought to justice, take to heart, gets on nerves, keep up appearances, comes to light*;
$(Verb, Noun, Preposition)$ [9]: *take aim at, make allowances for, takes advantage of, keep hands off, lay claim to, take care of, make contact with, gives rise to, wash hands of.*

The sentences. As mentioned, the first step of MWE identification is to identify if the sentence contains a potential non-compositional use of the expression. In order to test our method, which targets step (2), a set of such sentences (for each expression) was collected from the BNC corpus and

[4] Using 10-fold cross validation.

[5] Initially there were 20 MWEs in the development set and 30 (10 per group) in the training/test set.

then labeled for use as training/test sentences[6].

The collection method was intended to allow a wide range of variations in expression use. In practice, for each expression sentences containing all of the expression's CF components, in any of their inflections, were collected, but excluding common auxiliary words. So for example, when targeting the MWE 'make an impression' we allowed inflections of 'make' and 'impression' and did not require 'an', to allow for variations such as 'make no impression' and 'make some impression'. For some expressions, sentences were limited to those with a distance of up to 8 words between each expression component. Very long sentences (above 80 words) were discarded. The final set of sentences was then randomly selected.

Given this method, training/test sentences allow non-lexical variations: inflection, word order, part-of-speech, syntactic structure and other non-syntactic transformations. Lexical variations which involve a change in one of the expression's components are not allowed, except for common auxiliary words.

For the development set an average of 97 (40-137) sentences were collected per MWE, giving a total of 1663 sentences, with a micro average of 49% positive labels. For the training/test set there were 139 (73-150) sentences per MWE on average, totaling 3350, with a 40% average positive ratio.

The sentences were manually labeled as positive if they contained a non-compositional use of the MWE and negative if they contained a compositional or non-expression usage. Judgment was based on a single sentence, without wider context.

Baseline methods. Two baseline methods are used to test the intuitive notion that simple rule-based methods are sufficient for MWE identification as well as for comparison with the supervised learning methods.

The first method, CanonicalForm (CF), accepts a sentence use as a non-compositional MWE use if and only if the MWE is in canonical form (there are no intervening words between the MWE components, their order matches canonical-form order, and there is an inflection in at most one component word).

The second method, DistanceOrder (DO), accepts a sentence use if and only if the number of words between the leftmost and rightmost MWE components is less than or equal to 2 (not counting the middle MWE component), and if the order matches the canonical form order.

[6]The PyLucene software package, http://pylucene. osafoundation. org/, was used for building an index to the BNC and for searching.

5 Results

The baseline methods (CF and DO) and the supervised methods (R1,R2,S,C) were run on the development and training/test sets. For the supervised methods, for each MWE we used 10-fold cross-validation[7].

Tables 1 and 2 summarize the results for the development and test sets, respectively. For the development set, average results over all 17 MWEs and over the best 8 MWEs (on R1), a group size comparable to the test set, are shown. For the test set, results over all 24 MWEs and the three MWE types tested are shown.

The tables show average overall accuracy and average precision, recall and F-score on positive instances, where the averages are taken over the results of the individual MWEs (i.e., micro-averaged).

Baselines. Baseline accuracy, (for DO) 82.27% on the development set and 87.2% on the test set (over all groups), is probably insufficient for many NLP applications.

The baselines perform similarly in terms of average accuracy. CF does this with very high precision and low recall, while for DO recall improves at the expense of precision. Looking at individual MWEs reveals that for expressions which allow more variation in terms of intervening words

[7]I.e., we ran 10 experiments where in each experiment we divided the corresponding annotated sentence sets into 90% training sentences and 10% test sentences, and the results reported are the average of the 10 experiments.

Table 2: Test set: Average performance over all MWEs and by group. The best supervised classifier outperforms baselines in all groups. **A**: Accuracy; **P**: Precision; **R**: Recall; **F**: F-Score.

and lexical change, DO outperforms CF. To name a few, *make an impression, raise the alarm, take a chance* and *make allowances for*. For example, for *take a chance* intervening words are quite common, as in: 'I'm taking a real chance on you.', or a change in determiner as in: 'I preferred to take my chances'. Indeed, CF showed poor precision only for MWEs with a common literal usage. Two such MWEs were present in the development set (*break the ice* and *tie the knot*) and two in the test set (*wash hands of* and *keep hands off*).

Baselines versus supervised classifiers. As shown in the tables, R1 outperforms the best baseline in terms of accuracy in both test and development. Moreover, the supervised classifiers are more stable in their accuracy. For the development set the standard deviation of accuracy scores averages 22.58 for CF and DO, and 6.68 for R1, R2, S, and C. For the test set the baselines average 9.07 (Verb-Det-Noun), 11.11 (Verb-Prep-Noun) and 14.26 (Verb-Noun-Prep), and the supervised methods average 4.97 (Verb-Det-Noun), 7.66 (Verb-Prep-Noun) and 7.97. This stability means that the supervised classifiers are able to perform well on MWEs with different behavior. For example, R1 is able to perform well on expressions where order is strict, as DO does (e.g., *make a face*), while also performing well on those where order varies (e.g., *make a distinction*).

Supervised classifiers. R1 and R2, based on surface features, show similar accuracy values, with R1 doing somewhat better in the Verb-Prep-Noun and Verb-Noun-Prep groups. This is due to the Lexical Values feature, which accounts for a change in preposition. A change in preposition (as in 'wash hands *of* some matter' versus 'wash hands *in* the sink') is more significant than a change in determiner in the Verb-Determiner-Noun group. This improves precision on negative instances, which are rejected more precisely based on the preposition value. Nevertheless, the relatively simple features in R2, essentially order and distance, perform quite well.

The F-score result for R1, 94.86, is an improvement over the F-score result of the supervised classifier used in (Sporleder and Li, 2009), 90.15. Although the sentence data is different (our data includes sentences with non-expression uses) the number of sentences used is similar.

S, based on syntactic features, performs worse than R1/2. It shows better accuracy than the baselines in all but the (Verb-Prep-Noun) group and is also more stable. C, a combination of surface and syntactic features, performs better than S and slightly worse than R1/2.

Why do the syntactic features perform worse than surface features? An analysis of the S classifier errors reveals two important causes. First, there is substantial variation in the dependency tree structures of the non-compositional uses of the expressions as output by the parser. Thus, the syntactic feature classifier was more difficult to learn than the surface feature one, requiring a larger training set. This is not surprising, given that many MWEs exhibit an irregular syntactic behavior that might even seem strange at times. For example, in the sentence fragment "and then he came to.", 'came to' is an MWE. A parser might find it difficult to parse the sentence correctly, expecting a noun phrase to follow the 'to'.

Second, as described above, the syntactic features consist of general syntactic relations extracted from the parse tree and not type-specific knowledge. As a result, literal or non-expression uses of the MWE's components, which have a close syntactic relation in a given sentence, appear as non-compositional uses of the expression to the classifier.

6 Discussion

This study has addressed MWE identification: deciding if a potential use of an expression is a non-compositional one. Despite its importance in basic NLP tasks, the problem has been largely overlooked in NLP research, probably due to it presumed simplicity. However, as we have shown, simple methods for MWE identification, such as our baselines, do not perform consistently well across MWEs. This study serves to highlight this point and the need for more sophisticated methods for MWE identification.

We have shown that using a supervised learning method employing surface sentence features based on canonical form, it is possible to improve performance significantly. Unlike previous research, our method is not tailored to specific MWE types, and we did not ignore non-expression uses in our experiments.

Future research should experiment with non-verbal MWEs, since our features are not specific to verbal MWE types. Another direction is a more sophisticated corpus sampling algorithm. The current work ignored MWEs which had an unbalanced training set (usually too few positives). Methods for gathering enough positive instances of such MWEs will be useful for testing the methods proposed here, as well as for general MWE research.

Abstract

In this paper, we present an algorithm for extracting translations of any given multiword expression from parallel corpora. Given a multiword expression to be translated, the method involves extracting a short list of target candidate words from parallel corpora based on scores of normalized frequency, generating possible translations and filtering out common subsequences, and selecting the top-n possible translations using the Dice coefficient. Experiments show that our approach outperforms the word alignment-based and other naive association-based methods. We also demonstrate that adopting the extracted translations can significantly improve the performance of the Moses machine translation system.

1 Introduction

Translation of multiword expressions (MWEs), such as compound words, phrases, collocations and idioms, is important for many NLP tasks, including the techniques are helpful for dictionary compilation, cross language information retrieval, second language learning, and machine translation. (Smadja et al., 1996; Gao et al., 2002; Wu and Zhou, 2003). However, extracting exact translations of MWEs is still an open problem, possibly because the senses of many MWEs are not compositional (Yamamoto and Matsumoto, 2000), i.e., their translations are not compositions of the translations of individual words. For example, the Chinese idiom 坐視不理 should be translated as "*turn a blind eye,*" which has no direct relation with respect to the translation of each constituent (i.e., *"to sit", "to see" and "to ignore"*) at the word level.

Previous SMT systems (e.g., Brown et al., 1993) used a word-based translation model which assumes that a sentence can be translated into other languages by translating each word into one or more words in the target language. Since many concepts are expressed by idiomatic multiword expressions instead of single words, and different languages may realize the same concept using different numbers of words (Ma et al., 2007; Wu, 1997), word alignment based methods, which are highly dependent on the probability information at the lexical level, are not well suited for this type of translation.

To address the above problem, some methods have been proposed for extending word alignments to phrase alignments. For example, Och et al. (1999) proposed the so-called *grow-diag-final* heuristic method for extending word alignments to phrase alignments. The method is widely used and has achieved good results for phrase-based statistical machine translation. (Och et al., 1999; Koehn et al., 2003; Liang et al., 2006). Instead of using heuristic rules, Ma et al. (2008) showed that syntactic information, e.g., phrase or dependency structures, is useful in extending the word-level alignment. However, the above methods still depend on word-based alignment models, so they are not well suited to extracting the translation equivalences of semantically opaque MWEs due to the lack of word level relations between the translational correspondences. Moreover, the aligned phrases are not precise enough to be used in many NLP applications like dictionary compilation, which require high quality translations.

Association-based methods, e.g., the *Dice coefficient*, are widely used to extract translations of MWEs. (Kupiec, 1993; Smadja et al., 1996; Kitamura and Matsumoto, 1996; Yamamoto and Matsumoto, 2000; Melamed, 2001). The advantage of such methods is that association relations are established at the phrase level instead of the lexical level, so they have the potential to resolve the above-mentioned translation problem. However, when applying association-based methods, we have to consider the following complications. The first complication, which we call the *contextual effect*, causes the extracted translation to contain noisy words. For

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 478–486,
Singapore, 6-7 August 2009.

example, translations of the Chinese idiom *兩全其美* (*best of both worlds*) extracted by a naive association-based method may contain noisy collocation words like *difficult*, *try* and *cannot*, which are not part of the translation of the idiom. They are actually translations of its collocation context, such as *難以*(*difficult*), *嘗試*(*try*), and *不能*(*cannot*). This problem arises because naive association methods do not deal with the effect of strongly collocated contexts carefully. If we can incorporate lexical-level information to discount the noisy collocation words, the contextual effect could be resolved.

English (y)	f_y	$f_{x,y}$	Dice(x,y)
quote **out of context**	22	19	0.56
take **out of context**	17	11	0.35
interpret **out of context**	2	2	0.08
out of context	53	32	0.65

Table 1. The Dice coefficient tends to select a common subsequence of translations. (The frequency of *斷章取義*, f_x, is 46.)

The second complication, which we call the *common subsequence problem*, is that the Dice coefficient tends to select the common subsequences of a set of similar translations instead of the full translations. Consider the translations of *斷章取義* (*quote out of context*) shown in the first three rows of Table 1. The Dice coefficient of each translation is smaller than that of the common subsequence "*out of context*" in the last row. If we can tell common subsequence apart from correct translations, the common subsequence problem could be resolved.

In this paper, we propose an improved precision method for extracting MWE translations from parallel corpora. Our method is similar to that of Smadja et al. (1996), except that we incorporate lexical-level information into the association-based method. The algorithm works effectively for various types of MWEs, such as phrases, single words, rigid word sequences (i.e., no gaps) and gapped word sequences. Our experiment results show that the proposed translation extraction method outperforms word alignment-based methods and association-based methods. We also demonstrate that precise translations derived by our method significantly improve the performance of the Moses machine translation system.

The remainder of this paper is organized as follows. Section 2 describes the methodology for extracting translation equivalences of MWEs. Section 3 describes the experiment and presents the results. In Section 4, we consider the application of our results to machine translation. Section 5 contains some concluding remarks.

2 Extracting Translation Equivalences

Our MWE translation extraction method is similar to the two-phase approach proposed by Smadja et al. (1996). The two phases can be briefly described as follows:

Phase 1: Extract candidate words correlated to the given MWE from parallel text.

Phase 2:

1. Generate possible translations for the MWE by combining the candidate words.
2. Select possible translations by the Dice coefficient.

We propose an association function, called the *normalized correlation frequency*, to extract candidate words in the phase 1. This method incorporates lexical-level information with association measure to overcome the *contextual effect*. In phase 2, we also propose a *weighted frequency* function to filter out false common subsequences from possible translations. The filtering step is applied before the translation selecting step of phase 2.

Before describing our extraction method, we define the following important terms used throughout the paper.

Focused corpus (*FC*): This is the corpus created for each targeted MWE. It is a subset of the original parallel corpora, and is comprised of the selected aligned sentence pairs that contain the source MWE and its translations.

Candidate word list (*CW*): A list of extracted candidate words for the translations of the source MWE.

2.1 Selecting Candidate Words

For a source MWE, we try to extract from the *FC* a set of k candidate words *CW* that are highly correlated to the source MWE. We then assume that the target translation is a combination of some words in *CW*. As noted by Smadja et al. (1996), this two-step approach drastically reduces the search space.

However, translations of collocated context words in the source word sequence create noisy candidate words, which might cause incorrect extraction of target translations by naive statistical correlation measures, such as the Dice coef-

ficient used by Smadja et al. (1996). The need to avoid this context effect motivates us to propose a candidate word selection method that uses the normalized correlation frequency as an association measure.

The rationale behind the proposed method is as follows. When counting the word frequency, each word in the target corpus normally contributes a frequency count of one. However, we are only interested in the word counts correlated to a **MWE**. Therefore, intuitively, we define the normalized count of a target word *e* as the translation probability of *e* given the **MWE**.

We explain the concept of normalizing the correlation count in Section 2.1.1 and the computation of the normalized correlation frequency in Section 2.1.2.

2.1.1 Normalizing Correlation Count

We propose an association measure called the *normalized correlation frequency*, which ranks the association strength of target words with the source MWE. For ease of explanation, we use the following notations: let $\mathbf{f}=f_1,f_2,\ldots,f_m$ and $\mathbf{e}=e_1,e_2,\ldots,e_n$ be a pair of parallel Chinese and English sentences; and let $\mathbf{w}=t_1,t_2,\ldots,t_r$ be the Chinese source MWE. Hence, **w** is a subsequence of **f**.

When counting the word frequency, each word in the target corpus normally contributes a frequency count of one. However, since we are interested in the word counts that correlate to **w**, we adopt the concept of the translation model proposed by Brown et al (1993). Each word *e* in a sentence **e** might be generated by some words, denoted as **r**, in the source sentence **f**. If **r** is non-empty the relation between **r** and **w** should fit one of the following cases:

1) All words in **r** belong to **w**, i.e., $\mathbf{r} \subseteq \mathbf{w}$, so we say that *e* is only generated by **w**.
2) No words in **r** belong to **w**, i.e., $\mathbf{r} \subseteq \mathbf{f} - \mathbf{w}$, so we say that *e* is only generated by context words.
3) Some words in **r** belong to **w**, while others are context words.

Intuitively, In Cases 1 and 2, the correlation count of an instance *e* should be 1 and 0 respectively. In Case 3, the normalized count of *e* is the expected frequency generated by **w** divided by the expected frequency generated by **f**. With that in mind, we define the *weighted correlation count*, *wcc*, as follows:

$$wcc(e;\mathbf{e},\mathbf{f},\mathbf{w}) = \frac{\sum_{\forall f_i \in \mathbf{w}} p(e \mid f_i) + \Delta \mid \mathbf{w} \mid}{\sum_{\forall f_j \in \mathbf{f}} p(e \mid f_j) + \Delta \mid \mathbf{f} \mid},$$

where Δ is a very small smoothing factor in case *e* is not generated by any word in **f**. The probability $p(e \mid f)$ is the word translation probability trained by IBM Model 1 on the whole parallel corpus.

The rationale behind the *weighted correlation count*, *wcc*, is that if *e* is part of the translation of **w,** then its association with **w** should be stronger than other words in the context. Hence its *wcc* should be closer to 1. Otherwise, the association is weaker and the *wcc* should be closer to 0.

2.1.2 Normalized Correlation

Once the weighted correlation counts *wcc* is computed for each word in *FC*, we compute the normalized correlation frequency for each word *e* as the total sum of the $wcc(e;\mathbf{e},\mathbf{f},\mathbf{w})$ of all **w** in bilingual sentences (**e**, **f**) in *FC*. The *normalized correlation frequency (ncf)* is defined as follows:

$$ncf(e;\mathbf{w}) = \sum_{i=1}^{n} wcc(e;\mathbf{e}^{(i)},\mathbf{f}^{(i)},\mathbf{w}).$$

We choose the top-n English words ranked by *ncf* as our candidate words and filter out those whose *ncf* is less than a pre-defined threshold. Table 2 shows the candidate words for the Chinese term 斷章取義 (quote/take/interpret out of context) sorted by their *ncf* values. To illustrate the effectiveness *ncf*, we also display candidate words of the term with their Dice values in Tables 3. As shown in the tables, noise words such as *justify, meaning* and *unfair* are ranked lower using *ncf* than using Dice, while correct candidates, such as *out*, *take* and *remark* are ranked higher. We present more experimental results in Section 3.

2.2 Generation and Ranking of Candidate Translations

After determining the candidate words, candidate translations of **w** can be generated by marking the candidate words in each sentence of *FC*. The word sequences marked in each sentence are deemed possible translations. At the same time, the weakly associated function words,

Candidate words *e*	freq	*ncf*(*e*,**w**)
context	54	31.55
out	58	24.58
quote	26	5.84
take	23	4.81
remark	8	1.84
interpret	3	1.38
piecemeal	1	0.98
deliberate	3	0.98

Table 2. Candidate words for the Chinese term *斷章取義* sorted by their global normalized correlation frequencies.

Candidate words *e*	freq	*dice*(*e*,**w**)
context	54	0.0399
quote	26	0.0159
deliberate	3	0.0063
justify	3	0.0034
interpretation	7	0.0032
meaning	3	0.0029
cite	3	0.0025
unfair	4	0.0023

Table 3. Candidate words for the Chinese term *斷章取義* sorted by their Dice coefficient values.

which we fail to select in the candidate word selection stage, should be recovered. The rule is quite simple: if a function word is adjacent to any candidate word, it should be recovered. For example, in the following sentence, the function word *of* would be recovered and added to the marked sequence:

"The financial secretary has been **quoted out** of **context.**
財政司 司長 之 談話 被 **斷章取義.**"

The marked words are shown in boldface.

2.2.1 Generating Possible Translations

Although we have selected a reliable candidate word list, it may still contain some noisy words due to the MWE's collocation context. Consider the following example:

...as **quoted** in the audit report, if **taken out of context...**

In this instance, *quoted* is a false positive; therefore, the marked word sequence **m** "*quoted taken out of context*" is not the correct translation. To avoid such false positives, we include **m** and all its subsequences as possible translations.

quoted taken out of context
quoted taken out of
quoted taken out context
quoted taken of context
quoted out of context
taken out of context
…
quoted out
taken out
quoted
taken
out
context

Table 4. Example subsequences generated of **w** and add them to the candidate translation list.

Table 4 shows the subsequences of **m** in the above example. The generation process is used to increase the coverage of correct translations in the candidate list; otherwise, many correct translations will be lost. However, the process may also trigger the side effect of the common subsequence problem described in Section 1. Since all candidates compete for the best translations by comparing their association strength with **w,** the common subsequences will have an advantage.

2.2.2 Filtering Common Subsequences

To resolve the *common subsequence effect* problem, we evaluate each candidate translation, including its subsequences, by a concept similar to the normalized correlation frequency. As mentioned in Section 1, the Dice coefficient tends to select the common subsequences of some candidates because they have higher frequencies. To avoid this problem, we use the normalized correlation frequency to filter out false common subsequences from the candidate translation list. Here, we also use the weighted correlation count *wcc* to weight the frequency count of a candidate translation. Suppose we have a marked sequence in a sentence, **m,** whose subsequences are generated in the way described in the previous section. If the weighted count of **m** is assigned the score 1, the *weighted count* (*wc*) of a subsequence **t** is then defined as follows:

$$wc(\mathbf{t};\mathbf{e},\mathbf{f},\mathbf{m},\mathbf{w}) = \prod_{\forall e \in \mathbf{m}-\mathbf{t}} (1 - wcc(e;\mathbf{e},\mathbf{f},\mathbf{w})) .$$

The underlying concept of *wc* is that the original marked sequence **m** is supposed to be the most

likely translation of **w** and the weighted count is set to 1. Then, if a subsequence **t** is generated by removing a word *e* from **m**, the weighted count of the subsequence is reduced by multiplying the complement probability of *e* generated by **w**. Note that the weighted correlation count *wcc* is the probability of the word *e* generated by **w**.

After all $wc(\mathbf{t};\mathbf{e},\mathbf{f},\mathbf{m},\mathbf{w})$ in each sentence of the *FC* have been computed, the *weighted frequency* for a sequence **t** can be determined by summing the weighted frequencies over *FC* as follows:

$$wf(\mathbf{t};\mathbf{w}) = \sum_{\forall(\mathbf{e},\mathbf{f})\in FC} wc(\mathbf{t};\mathbf{e},\mathbf{f},\mathbf{m},\mathbf{w}).$$

We compute the *wf* for each candidate translation and then sort the candidate translations by their *wf* values.

Next, we filter out common subsequences based on the following rule: for a sequence **t**, if there is a super-sequence **t'** on the sorted candidate translation list and the *wf* value of **t** is less than that of **t'**, then **t** is assumed be a common subsequence of real translations and removed from the list.

candidate translation list	freq	wf
quote out of context	19	17.55
of context	35	15.45
out of context	32	14.82
quote of context	19	13.32
out	35	11.92
quote	23	11.63
quote out	19	9.42

Table 5. Part of the candidate translation list for the Chinese idiom, *斷章取義*, sorted by the *wf* values.

Table 5 shows an example of the rule's application. The candidate translation list is sorted by the translations' *wf* values. Then, candidates 2-7 are removed because they are subsequences of the first candidate and their *wf* values are smaller than that of the first candidate.

2.3 Selection of Candidate Translations

Having removed the common subsequences of real translations from the candidate translation list of **w**, we can select the best translations by comparing their association strength with **w** for the remaining candidates. The Dice coefficient is a good measure for assessing the association strength and selecting translations from the candidate list. For a candidate translation **t,** the Dice coefficient is defined as follows:

$$Dice(\mathbf{t},\mathbf{w}) = \frac{2p(\mathbf{t},\mathbf{w})}{p(\mathbf{t})+p(\mathbf{w})}.$$

Where $p(\mathbf{t},\mathbf{w})$, $p(\mathbf{t})$, $p(\mathbf{w})$ are probabilities of (**t**,**w**), **t**, **w** derived from the training corpus.

After obtaining the Dice coefficients of the candidate translations, we select the top-n candidate translations as possible translations of **w**.

3 Experiments

In our experiments, we use the Hong Kong Hansard and the Hong Kong News parallel corpora as training data. The training data was preprocessed by Chinese word segmentation to identify words and parsed by Chinese parser to extract MWEs. To evaluate the proposed approach, we randomly extract 309 Chinese MWEs from training data, including dependent word pairs and rigid idioms. We then randomly select 103 of those MWEs as the development set and use the other 206 as the test set. The reference translations of each Chinese MWE are manually extracted from the parallel corpora.

3.1 Evaluation of Word Candidates

To evaluate the method for selecting candidate words, we use the coverage rate, which is defined as follows:

$$coverage = \frac{1}{n}\sum_{\forall \mathbf{w}} \frac{|A_{\mathbf{w}} \cap C_{\mathbf{w}}|}{|A_{\mathbf{w}}|},$$

where *n* is the number of MWEs in the test set, $A_{\mathbf{w}}$ denotes the word set of the reference translations of **w**, and $C_{\mathbf{w}}$ denotes a candidate word list extracted by the system.

Table 6 shows the coverage of our method, NCF, compared with the coverage of the IBM model 1 and the association-based methods MI, Chi-square, and Dice. As we can see, the top-10 candidate words of NCF cover almost 90% of the words in the reference translations. Whereas, the coverage of the association-based methods and IBM model 1 is much lower than 90%. The result implies that the candidate extraction method can extract a more precise candidate set than other methods.

Method	Top10	Top20	Top30
MI	0.514	0.684	0.760
Chi-square	0.638	0.765	0.828
Dice	0.572	0.735	0.803
IBM 1	0.822	0.900	0.948
NCF	0.899	0.962	0.973

Table 6. The coverage rates of the candidate words extracted by the compared methods

Figure 1 shows the curve diagram of the coverage rate of each method. As the figure shows, when the size of the candidate list is increased, the coverage rate of using NCF rises rapidly as *n* increases but levels off after *n*=20. Whereas, the coverage rates of other measures grow much slowly.

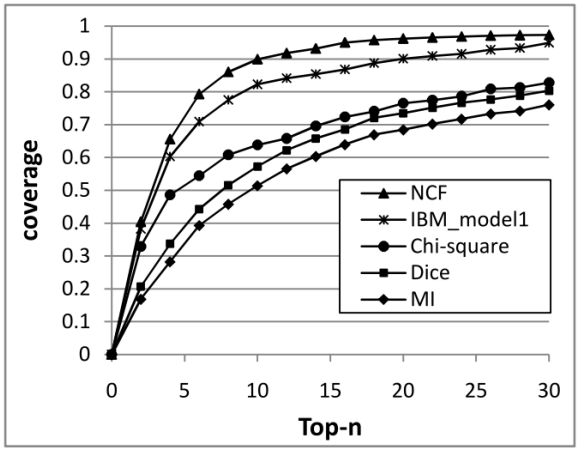

Figure 1. The curve diagram of the coverage of the candidate word list compiled by each method.

From the evaluation of candidate word selection, we find that the *ncf* method, which incorporates lexical-level information into association-based measure, can effectively filter out noisy words and generates a highly reliable list of candidate words for a given MWE.

3.2 Evaluating Extracted Translations

To evaluate the quality of MWE translations extracted automatically, we use the following three criteria:

1) **Translation accuracy:**
   This criterion is used to evaluate the top-n translations of the system. It treats each translation produced as a string and compares the whole string with the given reference translations. If any one of the top-n hypothesis translations is included in the reference translations, it is deemed correct.
2) **WER** (word error rate):
   This criterion compares the top-1 hypothesis translation with the reference translations by computing the edit distance (i.e., the minimum number of substitutions, insertions, and deletions) between the hypothesis translation and the given reference translations.
3) **PER** (position-independent word error rate):
   This criterion ignores the word order and computes the edit distance between the top-1 hypothesis translation and the given reference translations.

We also use the MT task to evaluated our method with other systems. For that, we use the GIZA++ toolkit (Och et al., 2000) to align the Hong Kong Hansard and Hong Kong News parallel corpora. Then, we extract the translations of the given source sequences from the aligned corpus as the baseline. We use the following two methods to extract translations from the aligned results.

1) **Uni-directional alignment**
   We mark all English words that were linked to any constituent of **w** in the parallel Chinese-English aligned corpora. Then, we extract the marked sequences from the corpora and compute the frequency of each sequence. The top-n high frequency sequences are returned as the possible translations of **w**.
2) **Bi-directional alignments**
   We use the *grow-diag-final* heuristic (Och et al., 1999) to combine the Chinese-English and English-Chinese alignments, and then extract the top-n high frequency sequences as described in method 1.

To determine the effect of the *common subsequence filtering method*, FCS, we divide the evaluation of our system into two phases:

1) **NCF+Dice**:
   This system uses the normalized correlation frequency, NCF, to select candidate words as described in Section 2.1. It then extracts candidate translations (described in Section 2.2), but FCS is not used.
2) **NCF+FCS+Dice**:
   This is similar to system 1, but it uses FCS to filter out common subsequences (described in subsection 2.2.2).

Method	WER(%)	PER(%)
Uni-directional	4.84	4.02
Bi-directional	5.84	5.12
NCF+Dice	3.55	3.24
NCF+FCS+Dice	**2.45**	**2.23**

Table 7. Translation error rates of the systems.

Method	Top1	Top2	Top3
Uni-directional	67.5	79.6	83.0
Bi-directional	65.5	77.7	81.1
NCF+Dice	72.8	85.9	88.3
NCF+FCS+Dice	**78.2**	**89.3**	**91.7**

Table 8. Translation accuracy rates of the systems. (%)

Table 7 shows the word error rates for the above systems. As shown in the first and second rows, the translations extracted from *uni-directional* alignments are better than those extracted from *bi-directional* alignments. This means that the *grow-diag-final* heuristic reduces the accuracy rate when extracting MWE translations.

The results in the third row show that the NCF+Dice system outperforms the methods based on GIZA++. In other words, the NCF method can effectively resolve the difficulties of extracting MWE translations discussed in Section 1.

In addition, the fourth row shows that the NCF+FCS+Dice system also outperforms the NCF+Dice system. Thus, the FCS method can resolve the common subsequence problem effectively.

Table 8 shows the translation accuracy rates of each system. The NCF+FCS+Dice system achieves the best translation accuracy. Moreover, it significantly improves the performance of finding MWE translation equivalences.

4 Applying MWE Translations to MT

To demonstrate the usefulness of extracted MWE translations to existing statistical machine translation systems, we use the XML markup scheme provided by the Moses decoder, which allows the specification of translations for parts of a sentence. The procedure for this experiment consists of three steps: (1) the extracted MWE translations are added to the test set with the XML markup scheme, (2) after which the data is input to the Moses decoder to complete the translation task, (3) the results are evaluated using the BLEU metric (Papineni et al., 2002).

	Moses	MWE +Moses
NIST06-sub	23.12	23.49
NIST06	21.57	21.79

Table 9. BLEU scores of the translation results.

4.1 Experimental Settings

To train a translation model for Moses, we use the Hong Kong Hansard and the Hong Kong News parallel corpora as training data (2,222,570 sentence pairs). We also use the same parallel corpora to extract translations of MWEs. The NIST 2008 evaluation data (1,357 sentences, 4 references) is used as development set and NIST 2006 evaluation data (1,664 sentences, 4 references) is used as test set.

4.2 Selection of MWEs

Due to the limitation of the XML markup scheme, we only consider two types of MWEs: continuous bigrams and idioms. Since the goal of this experiment is not focus on extraction of MWEs, simple methods are applied to extract MWEs from the training data: (1) we collect all continuous bigrams from Chinese sentences in the training data and then simply filter out the bigrams by mutual information (MI) with a threshold[1], (2) we also extract all idioms from Chinese sentences of the training data by collecting all 4-syllables words from the training data and filtering out obvious non-idioms, such as determinative-measure words and temporal words by their part-of-speeches, because most Chinese idioms are 4-syllables words.

In total, 33,767 Chinese bigram types and 20,997 Chinese idiom types were extracted from training data; and the top-5 translations of each MWE were extracted by the method described in Section 2. Meanwhile 1,171 Chinese MWEs were added to the translations in the test set. The Chinese words covered by the MWEs in test data set were 2,081 (5.3%).

4.3 Extra Information

When adding the translations to the test data, two extra types of information are required by the Moses decoder. The first type comprises the function words between the translation and its context. For example, if *經貿 合作/economic cooperation* is added to the test data, possible

[1] We set the threshold at 5.

source sentence	... 進入 <MWE>五光十色</MWE> 的社會 ...
Moses	... entered **blinded by the colourful** community ...
MWE+Moses	... entered **the colourful** community ...
reference	... entered **the colorful** society ...
source sentence	... 不希望看到 <MWE>進一步 升級</MWE> 危機 ...
Moses	... do not want to see **an escalation** of crisis ...
MWE+Moses	... do not want to see **a further escalation** of crisis ...
reference	... don 't want to see **the further escalation** of the crisis ...
source sentence	... 廣大 人民 的 <MWE>根本 利益</MWE> ...
Moses	... the people 's **interests** ...
MWE+Moses	... the people of the **fundamental interests** ...
reference	... the **fundamental interests** of the masses ...

Table 10. Examples of improved translation quality with the MWE translation equivalences.

function words, such as '*in*' or '*with*', should be provided for the translation. Because the Moses decoder does not generate function words that are context dependent, it treats a function word as a part of the translation. Therefore, we collect possible function words for each translation from the corpora when the conditional probability is larger than a threshold[2].

The second type of information is the *phrase translation probability* and *lexical weighting*. Computing the phrase translation probability is trivial in the training corpora, but lexical weighting (Koehn et al., 2003) needs lexical-level alignment. For convenience, we assume that each word in an MWE links to each word in the translations. Under this assumption, the lexical weighting is simplified as follows:

$$p_w(\mathbf{f} \mid \mathbf{e}, a) = \prod_{i=1}^{n} \frac{1}{|\{j \mid (i,j) \in a\}|} \sum_{\forall (i,j) \in a} p(f_i \mid e_j)$$
$$\cong \prod_{i=1}^{n} \frac{1}{|\mathbf{e}|} \sum_{\forall e_j \in \mathbf{e}} p(f_i \mid e_j).$$

Then, it is trivial to compute the simplified lexical weighting of each MWE correspondence when the word translation probability table is provided. Here, we use the IBM model 1 to learn the table from the training data.

4.4 Evaluation Results

We trained a model using Moses toolkit (Koehn et al., 2007) on the training data as our baseline system.

Table 9 shows the influence of adding the MWE translations to the test data. In the first row (NIST06-sub), we only consider sentences containing MWE translations for BLEU score evaluation (726 sentences). In the second row, we took the whole NIST 2006 evaluation set into consideration (1,664 sentences). The Chinese words covered by the MWEs in NIST06-sub and NIST06 were 9.9% and 5.3% respectively.

Adding MWE translations to the test data statistically significantly lead to better results than those of the baseline. Significance was tested using a paired bootstrap (Koehn, 2004) with 1000 samples ($p<0.02$). Although the improvement in BLEU score seems small, it is actually reasonably good given that the MWEs account for only 5% of the NIST06 test set. Examples of improved translations are shown in Table 10. There is still room for improvement of the proposed MWE extraction method in order to provide more MWE translation pairs or design a feasible way to incorporate discontinuous bilingual MWEs to the decoder.

5 Conclusions and Future Work

We have proposed a high precision algorithm for extracting translations of multiword expressions from parallel corpora. The algorithm can be used to translate any language pair and any type of word sequence, including rigid sequences and discontinuous sequences. Our evaluation results show that the algorithm can cope with the difficulties caused by *indirect association* and the *common subsequence effects*, leading to significant improvement over the word alignment-based extraction methods used by the state of the art systems and other association-based extraction methods. We also demonstrate that extracted translations significantly improve the

[2] We set the threshold at 0.1.

performance of the Moses machine translation system.

In future work, it would be interesting to develop a machine translation model that can be integrated with the translation acquisition algorithm in a more effective way. Using the normalized-frequency score to help phrase alignment tasks, as the *grow-diag-final* heuristic, would also be interesting direction to explore.

Abstract

Statistical bilingual word alignment has been well studied in the context of machine translation. This paper adapts the bilingual word alignment algorithm to monolingual scenario to extract collocations from monolingual corpus. The monolingual corpus is first replicated to generate a parallel corpus, where each sentence pair consists of two identical sentences in the same language. Then the monolingual word alignment algorithm is employed to align the potentially collocated words in the monolingual sentences. Finally the aligned word pairs are ranked according to refined alignment probabilities and those with higher scores are extracted as collocations. We conducted experiments using Chinese and English corpora individually. Compared with previous approaches, which use association measures to extract collocations from the co-occurring word pairs within a given window, our method achieves higher precision and recall. According to human evaluation in terms of precision, our method achieves absolute improvements of 27.9% on the Chinese corpus and 23.6% on the English corpus, respectively. Especially, we can extract collocations with longer spans, achieving a high precision of 69% on the long-span (>6) Chinese collocations.

1 Introduction

Collocation is generally defined as a group of words that occur together more often than by chance (McKeown and Radev, 2000). In this paper, a collocation is composed of two words occurring as either a consecutive word sequence or an interrupted word sequence in sentences, such as "by accident" or "take … advice". The collocations in this paper include phrasal verbs (e.g. "put on"), proper nouns (e.g. "New York"), idioms (e.g. "dry run"), compound nouns (e.g. "ice cream"), correlative conjunctions (e.g. "either … or"), and the other commonly used combinations in following types: verb+noun, adjective+noun, adverb+verb, adverb+adjective and adjective+preposition (e.g. "break rules", "strong tea", "softly whisper", "fully aware", and "fond of").

Many studies on collocation extraction are carried out based on co-occurring frequencies of the word pairs in texts (Choueka et al., 1983; Church and Hanks, 1990; Smadja, 1993; Dunning, 1993; Pearce, 2002; Evert, 2004). These approaches use association measures to discover collocations from the word pairs in a given window. To avoid explosion, these approaches generally limit the window size to a small number. As a result, long-span collocations can not be extracted[1]. In addition, since the word pairs in the given window are regarded as potential collocations, lots of false collocations exist. Although these approaches used different association measures to filter those false collocations, the precision of the extracted collocations is not high. The above problems could be partially solved by introducing more resources into collocation extraction, such as chunker (Wermter and Hahn, 2004), parser (Lin, 1998; Seretan and Wehrli, 2006) and WordNet (Pearce, 2001).

This paper proposes a novel *monolingual word alignment* (MWA) method to extract collocation of higher quality and with longer spans only from monolingual corpus, without using any additional resources. The difference between MWA and bilingual word alignment (Brown et al., 1993) is that the MWA method works on monolingual parallel corpus instead of bilingual corpus used by bilingual word alignment. The

[1] Here, "span of collocation" means the distance of two words in a collocation. For example, if the span of the collocation (w_1, w_2) is 6, it means there are 5 words interrupting between w_1 and w_2 in a sentence.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 487–495,
Singapore, 6-7 August 2009.

monolingual corpus is replicated to generate a parallel corpus, where each sentence pair consists of two identical sentences in the same language, instead of a sentence in one language and its translation in another language. We adapt the bilingual word alignment algorithm to the monolingual scenario to align the potentially collocated word pairs in the monolingual sentences, with the constraint that a word is not allowed to be aligned with itself in a sentence. In addition, we propose a ranking method to finally extract the collocations from the aligned word pairs. This method assigns scores to the aligned word pairs by using alignment probabilities multiplied by a factor derived from the exponential function on the frequencies of the aligned word pairs. The pairs with higher scores are selected as collocations.

The main contribution of this paper is that the well studied bilingual statistical word alignment method is successfully adapted to monolingual scenario for collocation extraction. Compared with the previous approaches, which use association measures to extract collocations, our method achieves much higher precision and slightly higher recall. The MWA method has the following three advantages. First, it explicitly models the co-occurring frequencies and position information of word pairs, which are integrated into a model to search for the potentially collocated word pairs in a sentence. Second, a new feature, *fertility*, is employed to model the number of words that a word can collocate with in a sentence. Finally, our method can obtain the long-span collocations. Human evaluations on the extracted Chinese collocations show that 69% of the long-span (>6) collocations are correct. Although the previous methods could also extract long-span collocations by setting the larger window size, the precision is very low.

In the remainder of this paper, Section 2 describes the MWA model for collocation extraction. Section 3 describes the initial experimental results. In Section 4, we propose a method to improve the MWA models. Further experiments are shown in Sections 5 and 6, followed by a discussion in Section 7. Finally, the conclusions are presented in Section 8.

2 Collocation Extraction With Monolingual Word Alignment Method

2.1 Monolingual Word Alignment

Given a bilingual sentence pair, a source language word can be aligned with its corresponding target language word. Figure 1 shows an example of Chinese-to-English word alignment.

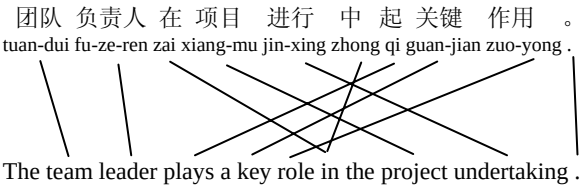

Figure 1. Bilingual word alignment

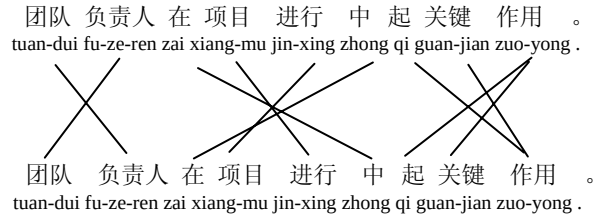
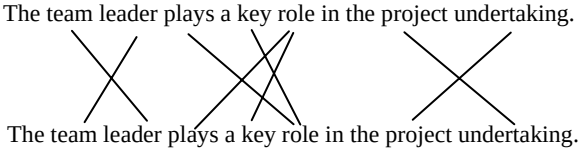
In Figure 1, a word in one language is aligned with its counterpart in the other language. For examples, the Chinese word "团队/tuan-dui" is aligned with its English translation "team", while the Chinese word "负责人/fu-ze-ren" is aligned with its English translation "leader".

In the Chinese sentence in Figure 1, there are some Chinese collocations, such as (团队/tuan-dui, 负责人/fu-ze-ren). There are also some English collocations in the English sentence, such as (team, leader). We separately illustrate the collocations in the Chinese sentence and the English sentence in Figure 2, where the collocated words are aligned with each other.



(a) Collocations in the Chinese sentence



(b) Collocations in the English sentence

Figure 2. Word alignments of collocations in sentence

Comparing the alignments in Figures 1 and 2, we can see that the task of monolingual collocations construction is similar to that of bilingual word alignment. In a bilingual sentence pair, a source word is aligned with its corresponding target word, while in a monolingual sentence, a word is aligned with its collocates. Therefore, it is reasonable to regard collocation construction as a task of aligning the collocated words in monolingual sentences.

Statistical bilingual word alignment method, which has been well studied in the context of machine translation, can extract the aligned bilingual word pairs from a bilingual corpus. This paper adapts the bilingual word alignment algorithm to monolingual scenario to align the collocated words in a monolingual corpus.

Given a sentence with l words $S = \{w_1, ..., w_l\}$, the word alignments $A = \{(i, a_i) \mid i \in [1, l]\}$ can be obtained by maximizing the word alignment probability of the sentence, according to Eq. (1).

$$A = \arg\max_{\forall A'} p(A' \mid S) \quad (1)$$

Where $(i, a_i) \in A$ means that the word w_i is aligned with the word w_{a_i}.

In a monolingual sentence, a word never collocates with itself. Thus the alignment set is denoted as $A = \{(i, a_i) \mid i \in [1, l] \,\&\, a_i \neq i\}$.

We adapt the bilingual word alignment model, IBM Model 3 (Brown et al., 1993), to monolingual word alignment. The probability of the alignment sequence is calculated using Eq. (2).

$$p(A \mid S) \propto \prod_{i=1}^{l} n(\phi_i \mid w_i) \prod_{j=1}^{l} t(w_j \mid w_{a_j}) d(j \mid a_j, l) \quad (2)$$

Where ϕ_i denotes the number of words that are aligned with w_i. Three kinds of probabilities are involved:

- Word collocation probability $t(w_j \mid w_{a_j})$, which describes the possibility of w_j collocating with w_{a_j};
- Position collocation probability $d(j, a_j, l)$, which describes the probability of a word in position a_j collocating with another word in position j;
- Fertility probability $n(\phi_i \mid w_i)$, which describes the probability of the number of words that a word w_i can collocate with (refer to subsection 7.1 for further discussion).

Figure 3 shows an example of word alignment on the English sentence in Figure 2 (b) with the MWA method. In the sentence, the 7th word "role" collocates with both the 4th word "play" and the 6th word "key". Thus, $t(w_4 \mid w_7)$ and $t(w_6 \mid w_7)$ describe the probabilities that the word "role" collocates with "play" and "key",

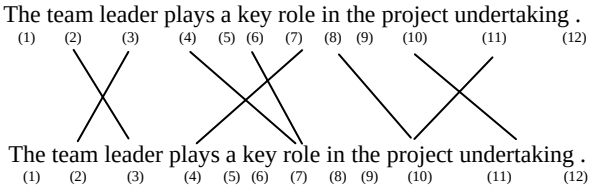


Figure 3. Results of MWA method

respectively. $d(4 \mid 7,12)$ and $d(6 \mid 7,12)$ describe the probabilities that the word in position 7 collocates with the words in position 4 and 6 in a sentence with 12 words. For the word "role", ϕ_7 is 2, which indicates that the word "role" collocates with two words in the sentence.

To train the MWA model, we implement a MWA tool for collocation extraction, which uses similar training methods for bilingual word alignment, except that a word can not be aligned to itself.

2.2 Collocation Extraction

Given a monolingual corpus, we use the trained MWA model to align the collocated words in each sentence. As a result, we can generate a set of aligned word pairs on the corpus. According to the alignment results, we calculate the frequency for two words aligned in the corpus, denoted as $freq(w_i, w_j)$. In our method, we filtered those aligned word pairs whose frequencies are lower than 5. Based on the alignment frequency, we estimate the alignment probabilities for each aligned word pair as shown in Eq. (3) and (4).

$$p(w_i \mid w_j) = \frac{freq(w_i, w_j)}{\sum_{w'} freq(w', w_j)} \quad (3)$$

$$p(w_j \mid w_i) = \frac{freq(w_i, w_j)}{\sum_{w'} freq(w_i, w')} \quad (4)$$

With alignment probabilities, we assign scores to the aligned word pairs and those with higher scores are selected as collocations, which are estimated as shown in Eq. (5).

$$\bar{p}(w_i, w_j) = \frac{p(w_i \mid w_j) + p(w_j \mid w_i)}{2} \quad (5)$$

3 Initial Experiments

In this experiment, we used the method as described in Section 2 for collocation extraction. Since our method does not use any linguistic information, we compared our method with the

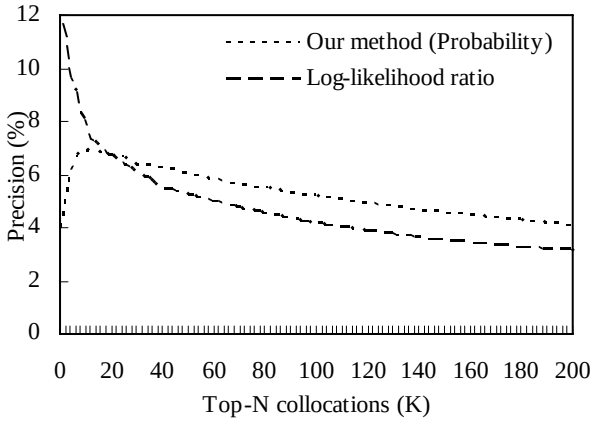

Figure 4. Precision of collocations

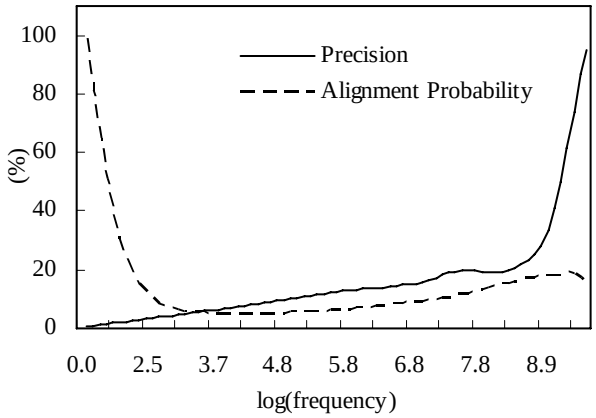

Figure 5. Frequency vs. precision/alignment probability

baseline methods without using linguistic knowledge. These baseline methods take all co-occurring word pairs within a given window as collocation candidates, and then use association measures to rank the candidates. Those candidates with higher association scores are extracted as collocations. In this paper, the window size is set to [-6, +6].

3.1 Data

The experiments were carried out on a Chinese corpus, which consists of one year (2004) of the Xinhua news corpus from LDC[2], containing about 28 millions of Chinese words. Since punctuations are rarely used to construct collocations, they were removed from the corpora. To automatically estimate the precision of extracted collocations on the Chinese corpus, we built a gold set by collecting Chinese collocations from handcrafted collocation dictionaries, containing 56,888 collocations.

3.2 Results

The precision is automatically calculated against the gold set according to Eq. (6).

$$precision = \frac{\#(C_{\text{Top}-N} \bigcap C_{\text{gold}})}{\#(C_{\text{Top}-N})} \qquad (6)$$

Where $C_{\text{Top-}N}$ and C_{gold} denote the top collocations in the N-best list and the collocations in the gold set, respectively.

We compared our method with several baseline methods using different association measures[3]: co-occurring frequency, log-likelihood ratio, chi-square test, mutual information, and t-test. Among them, the log-likelihood ratio measure achieves the best performance. Thus, in this paper, we only show the performance of the log-likelihood ratio measure.

Figure 4 shows the precisions of the top N collocations as N steadily increases with an increment of 1K, which are extracted by our method and the baseline method using log-likelihood ratio as the association measure.

The absolute precision of collocations is not high in the figure. For example, among the top 200K collocations, about 4% of the collocations are correct. This is because our gold set contains only about 57K collocations. Even if all collocations in the gold set are included in the 200K-best list, the precision is only 28%. Thus, it is more useful to compare precision curves for collocations in the N-best lists extracted by different methods. In addition, since this gold set only includes a small number of collocations, the precision curves of our method and the baseline method are getting closer, as N increases. For example, when N is set to 200K, our method and the baseline method achieved precisions of 4.09% and 3.12%, respectively. And when N is set to 400K, they achieved 2.78% and 2.26%, respectively. For convenience of comparison, we set N up to 200K in the experiments.

From the results, it can also be seen that, among the N-best lists with N less than 20K, the precision of the collocations extracted by our method is lower than that of the collocations extracted by the baseline, and became higher when N is larger than 20K.

In order to analyze the possible reasons, we investigated the relationships among the frequencies of the aligned word pairs, the alignment

[2] Available at: http://www.ldc.upenn.edu/Catalog/CatalogEntry.jsp?catalogId=LDC2007T03

[3] The definitions of these measures can be found in Manning and Schütze (1999).

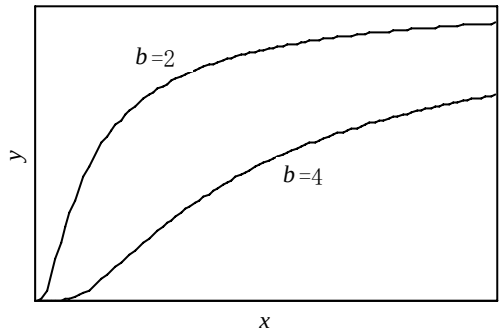

Figure 6. $y = e^{-b/x}$

probabilities, and precisions of collocations, which are shown in Figure 5. From the figure, we can see (1) that the lower the frequencies of the aligned word pairs are, the higher the alignment probabilities are; and (2) that the precisions of the aligned word pairs with lower frequencies is lower. According to the above observations, we conclude that it is the word pairs with lower frequencies but higher probabilities that caused the lower precision of the top 20K collocations extracted by our method.

4 Improved MWA Method

According to the analysis in subsection 3.2, we need to penalize the aligned word pairs with lower frequencies. In order to achieve the above goal, we need to refine the alignment probabilities by using a penalization factor derived from a function on the frequencies of the aligned word pairs. This function $y = f(x)$ should satisfy the following two conditions, where x represents the log function of frequencies.

(1) The function is monotonic. When x is set to a smaller number, y is also small. This results in the penalization on the aligned word pairs with lower frequencies.
(2) When $x \to \infty$, y is set to 1. This means that we don't penalize the aligned word pairs with higher frequencies.

According to the above descriptions, we propose to use the exponential function in Eq. (7).

$$y = e^{-b/x} \tag{7}$$

Figure 6 describes this function. The constant b in the function is used to adjust the shape of the line. The line is sharp with b set to a small number, while the line is flat with b set to a larger number. In our case, if b is set to a larger number, we assign a larger penalization weight to those aligned word pairs with lower frequencies.

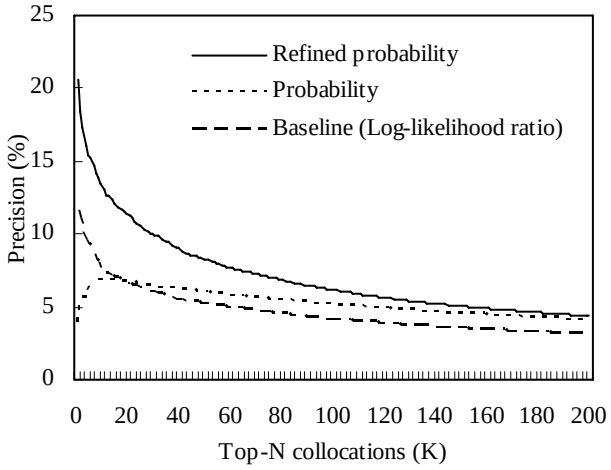

Figure 7. Precision of collocations extracted by the improved method

According to the above discussion, we can use the following measure to assign scores to the aligned words pairs generated by the MWA method.

$$\overline{p}_r(w_i, w_j) = \frac{p(w_i \mid w_j) + p(w_j \mid w_i)}{2} \times e^{-\frac{b}{\log(freq(w_i, w_j))}} \tag{8}$$

Where w_i and w_j are two aligned words. $p(w_i|w_j)$ and $p(w_j|w_i)$ are alignment probabilities as shown in Eq. (3) and (4). $\log(freq(w_i, w_j))$ is the log function of the frequencies of the aligned word pairs (w_i, w_j).

5 Evaluation on Chinese corpus

We used the same Chinese corpus described in Section 3 to evaluate the improved method as shown in Section 4. In the experiments, b was tuned by using a development set and set to 25.

5.1 Precision

In this section, we evaluated the extracted collocations in terms of precision using both automatic evaluation and human evaluation.

Automatic Evaluation

Figure 7 shows the precisions of the collocations in the N-best lists extracted by our method and the baseline method against the gold set in Section 3. For our methods, we used two different measures to rank the aligned word pairs: alignment probabilities in Eq. (5) and refined

		Our method	Baseline
True		569	290
False	A	25	16
	B	5	4
	C	240	251
	D	161	439

Table 1. Manual evaluation of the top 1K Chinese collocations. The precisions of our method and the baseline method are 56.9% and 29.0%, respectively.

alignment probabilities in Eq. (8). From the results, it can be seen that with the refined alignment probabilities, our method achieved the highest precision on the N-best lists, which greatly outperforms the best baseline method. For example, in the top 1K list, our method achieves a precision of 20.6%, which is much higher than the precision of the baseline method (11.7%). This indicates that the exponential function used to penalize the alignment probabilities plays a key role in demoting most of the aligned word pairs with low frequencies.

Human Evaluation

In automatic evaluation, the gold set only contains collocations in the existing dictionaries. Some collocations related to specific corpora are not included in the set. Therefore, we selected the top 1K collocations extracted by our improved method to manually estimate the precision. During human evaluation, the true collocations are denoted as "**True**" in our experiments. The false collocations were further classified into the following classes.

A: The candidate consists of two words that are semantically related, such as (医生 doctor, 护士 nurse).

B: The candidate is a part of the multi-word (≥3) collocation. For example, (自我 self, 机制 mechanism) is a part of the three-word collocation (自我 self, 约束 regulating, 机制 mechanism).

C: The candidates consist of the adjacent words that frequently occur together, such as (他 he, 说 say) and (很 very, 好 good).

D: Two words in the candidates have no relationship with each other, but occur together frequently, such as (北京 Beijing, 月 month) and (和 and, 为 for).

Table 1 shows the evaluation results. Our method extracted 569 true collocations, which

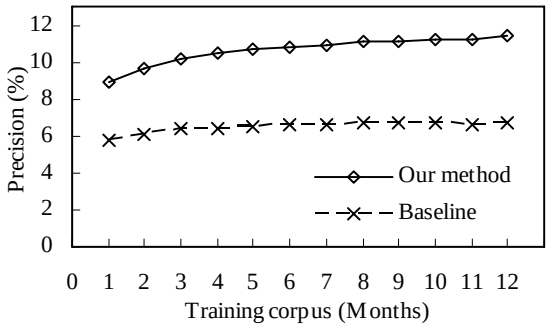

Figure 8. Corpus size vs. precision

are much more than those extracted by the baseline method. Further analysis shows that, in addition to extracting short-span collocations, our method extracted collocations with longer spans as compared with the baseline method. For example, (处于 in, 状态 state) and (由于 because, 因此 so) are two long-span collocations. Among the 1K collocations, there are 48 collocation candidates whose spans are larger than 6, which are not covered by the baseline method since the window size is set to 6. And 33 of them are true collocations, with a higher precision of 69%.

Classes C and D account for the most part of the false collocations. Although the words in these two classes co-occur frequently, they can not be regarded as collocations. And we also found out that the errors in class D produced by the baseline method are much more than that of those produced by our method. This indicates that our MWA method can remove much more noise from the frequently occurring word pairs.

In Class A, the two words are semantically related and occur together in the corpus. These kinds of collocations can not be distinguished from the true collocations by our method without additional resources.

Since only bigram collocations were extracted by our method, the multi-word (≥3) collocations were split into bigram collocations, which caused the error collocations in Class B[4].

Corpus size vs. precision

Here, we investigated the effect of the corpus size on the precision of the extracted collocations. We evaluated the precision against the gold set as shown in the automatic evaluation. First, the whole corpus (one year of newspaper) was split into 12 parts according to the published months. Then we calculated the precisions as the training

[4] Since only a very small faction of collocations contain more than two words, a few error collocations belong to Class B.

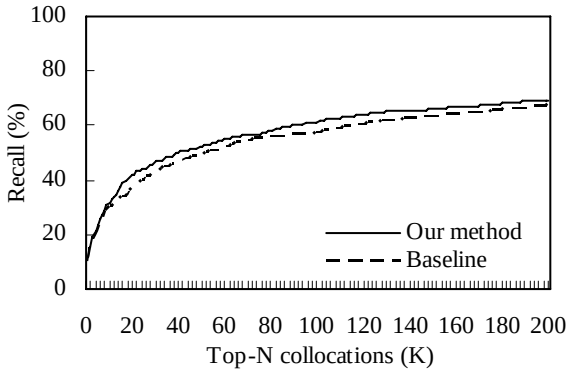

Figure 9. Recall on the Chinese corpus

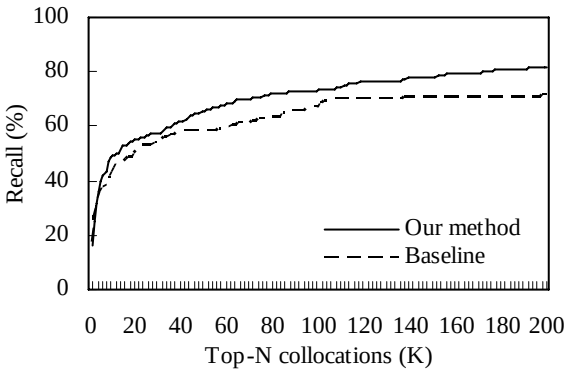

Figure 10. Recall on the English corpus

corpus increases part by part. The top 20K collocations were selected for evaluation.

Figure 8 shows the experimental results. The precision of collocations extracted by our method is obviously higher than that of collocations extracted by the baseline method. When the size of the training corpus became larger, the difference between our method and the baseline method also became bigger. When the training corpus contains more than 9 months of corpora, the precision of collocations extracted by the baseline method did not increase anymore. However, the precision of collocations extracted by our method kept on increasing. This indicates the MWA method can extract more true collocations of higher quality when it is trained with larger size of training data.

5.2 Recall

Recall was evaluated on a manually labeled subset of the training corpus. The subset contains 100 sentences that were randomly selected from the whole corpus. The sentence average length is 24. All true collocations (660) were labeled manually. The recall was calculated according to Eq. (9).

$$recall = \frac{\#(C_{\text{Top}-N} \bigcap C_{\text{subset}})}{\#(C_{\text{subset}})} \qquad (9)$$

Here, $C_{\text{Top-}N}$ denotes the top collocations in the N-best list and C_{subset} denotes the true collocations in the subset.

Figure 9 shows the recalls of collocations extracted by our method and the baseline method on the labeled subset. The results show that our method can extract more true collocations than the baseline method.

		Our method	Baseline
True		591	355
False	A	11	4
	B	19	20
	C	200	136
	D	179	485

Table 2. Manual evaluation of the top 1K English collocations. The precisions of our method and the baseline method are 59.1% and 35.5%, respectively.

In our experiments, the baseline method extracts about 20 millions of collocation candidates, while our method only extracts about 3 millions of collocation candidates[5]. Although the collocations of our method are much less than that of the baseline, the experiments show that the recall of our method is higher. This again proved that our method has the stronger ability to distinguish true collocations from false collocations.

6 Evaluation on English corpus

We also manually evaluated the proposed method on an English corpus, which is a subset randomly extracted from the British National Corpus[6]. The English corpus contains about 20 millions of words.

6.1 Precision

We estimated the precision of the top 1K collocations. Table 2 shows the results. The classification of the false collocations is the same as that in Table 1. The results show that our methods outperformed the baseline method using log-

[5] We set the threshold to 7.88 with a confidence level of $\alpha = 0.005$ (cf. page 174 of Chapter 5 in (McKeown and Radev, 2000) for more details).

[6] Available at: http://www.hcu.ox.ac.uk/BNC/

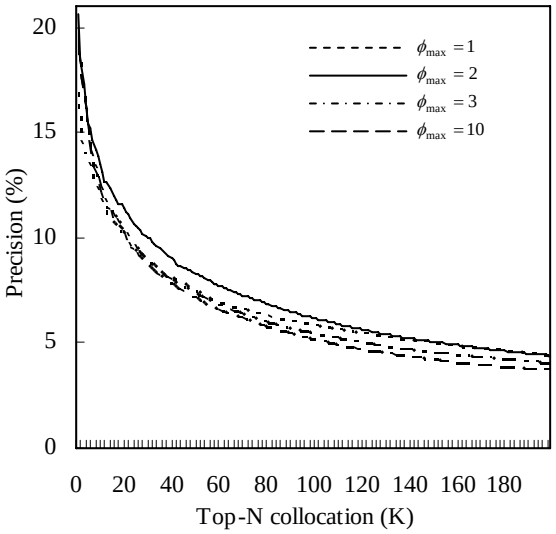

Figure 11. Fertility vs. precision

likelihood ratio. And the distribution of the false collocations is similar to that on the Chinese corpus.

6.2 Recall

We used the method described in subsection 5.2 to calculate the recall. 100 English sentences were labeled manually, obtaining 205 true collocations. Figure 10 shows the recall of the collocations in the N-best lists. From the figure, it can be seen that the trend on the English corpus is similar to that on the Chinese corpus, which indicates that our method is language-independent.

7 Discussion

7.1 The Effect of Fertility

In the MWA model as described in subsection 2.1, ϕ_i denotes the number of words that can align with w_i. Since a word only collocates with a few other words in a sentence, we should set a maximum number for ϕ, denote as $\phi_{\max}$.

In order to set $\phi_{\max}$, we examined the true collocations in the manually labeled set described in subsection 5.2. We found that 78% of words collocate with only one word, and 17% of words collocate with two words. In sum, 95% of words in the corpus can only collocate with at most two words. According to the above observation, we set $\phi_{\max}$ to 2.

In order to further examine the effect of $\phi_{\max}$ on collocation extraction, we used several different $\phi_{\max}$ in our experiments. The comparison

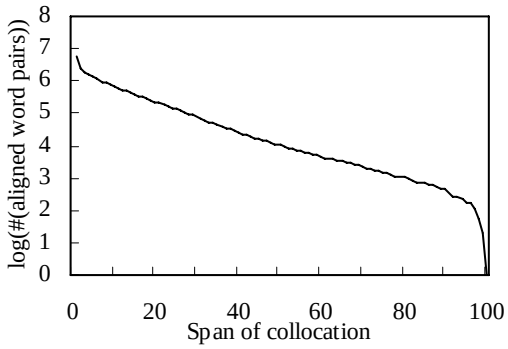

Figure 12. Distribution of spans

results are shown in Figure 11. The highest precision is achieved when $\phi_{\max}$ is set to 2. This result verifies our observation on the corpus.

7.2 Span of Collocation

One of the advantages of our method is that long-span collocations can be reliably extracted. In this subsection, we investigate the distribution of the span of the aligned word pairs. For the aligned word pairs occurring more than once, we calculated the average span as shown in Eq. (10).

$$AveSpan(w_i, w_j) = \frac{\sum_{s \in corpus} Span(w_i, w_j; s)}{freq(w_i, w_j)} \quad (10)$$

Where, $Span(w_i, w_j; s)$ is the span of the words w_i and w_j in the sentence s; $AveSpan(w_i, w_j)$ is the average span.

The distribution is shown in Figure 12. It can be seen that the number of the aligned word pairs decreased exponentially as the average span increased. About 17% of the aligned word pairs have spans longer than 6. According to the human evaluation result for precision in subsection 5.1, the precision of the long-span collocations is even higher than that of the short-span collocations. This indicates that our method can extract reliable collocations with long spans.

8 Conclusion

We have presented a monolingual word alignment method to extract collocations from monolingual corpus. We first replicated the monolingual corpus to generate a parallel corpus, in which each sentence pair consists of the two identical sentences in the same language. Then we adapted the bilingual word alignment algorithm to the monolingual scenario to align the

potentially collocated word pairs in the monolingual sentences. In addition, a ranking method was proposed to finally extract the collocations from the aligned word pairs. It scores collocation candidates by using alignment probabilities multiplied by a factor derived from the exponential function on the frequencies. Those with higher scores are selected as collocations. Both Chinese and English collocation extraction experiments indicate that our method outperforms previous approaches in terms of both precision and recall. For example, according to the human evaluations on the Chinese corpus, our method achieved a precision of 56.9%, which is much higher than that of the baseline method (29.0%). Moreover, we can extract collocations with longer span. Human evaluation on the extracted Chinese collocations shows that 69% of the long-span (>6) collocations are correct.

Abstract

The recently introduced online confidence-weighted (CW) learning algorithm for binary classification performs well on many binary NLP tasks. However, for multi-class problems CW learning updates and inference cannot be computed analytically or solved as convex optimization problems as they are in the binary case. We derive learning algorithms for the multi-class CW setting and provide extensive evaluation using nine NLP datasets, including three derived from the recently released New York Times corpus. Our best algorithm outperforms state-of-the-art online and batch methods on eight of the nine tasks. We also show that the confidence information maintained during learning yields useful probabilistic information at test time.

1 Introduction

Online learning algorithms such as the Perceptron process one example at a time, yielding simple and fast updates. They generally make few statistical assumptions about the data and are often used for natural language problems, where high dimensional feature representations, e.g., bags-of-words, demand efficiency. Most online algorithms, however, do not take into account the unique properties of such data, where many features are extremely rare and a few are very frequent.

Dredze, Crammer and Pereira (Dredze et al., 2008; Crammer et al., 2008) recently introduced confidence weighted (CW) online learning for binary prediction problems. CW learning explicitly models classifier weight uncertainty using a multivariate Gaussian distribution over weight vectors. The learner makes online updates based on its confidence in the current parameters, making larger changes in the weights of infrequently observed features. Empirical evaluation has demonstrated the advantages of this approach for a number of binary natural language processing (NLP) problems.

In this work, we develop and test multi-class confidence weighted online learning algorithms. For binary problems, the update rule is a simple convex optimization problem and inference is analytically computable. However, neither is true in the multi-class setting. We discuss several efficient online learning updates. These update rules can involve one, some, or all of the competing (incorrect) labels. We then perform an extensive evaluation of our algorithms using nine multi-class NLP classification problems, including three derived from the recently released New York Times corpus (Sandhaus, 2008). To the best of our knowledge, this is the first learning evaluation on these data. Our best algorithm outperforms state-of-the-art online algorithms and batch algorithms on eight of the nine datasets.

Surprisingly, we find that a simple algorithm in which updates consider only a single competing label often performs as well as or better than multi-constraint variants if it makes multiple passes over the data. This is especially promising for large datasets, where the efficiency of the update can be important. In the true online setting, where only one iteration is possible, multi-constraint algorithms yield better performance.

Finally, we demonstrate that the label distributions induced by the Gaussian parameter distributions resulting from our methods have interesting properties, such as higher entropy, compared to those from maximum entropy models. Improved label distributions may be useful in a variety of learning settings.

2 Problem Setting

In the multi-class setting, instances from an input space $\mathcal{X}$ take labels from a finite set $\mathcal{Y}$, $|\mathcal{Y}| = K$.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 496–504,
Singapore, 6-7 August 2009.

We use a standard approach (Collins, 2002) for generalizing binary classification and assume a feature function $\boldsymbol{f}(\boldsymbol{x}, y) \in \mathbb{R}^d$ mapping instances $\boldsymbol{x} \in \mathcal{X}$ and labels $y \in \mathcal{Y}$ into a common space.

We work in the online framework, where learning is performed in rounds. On each round the learner receives an input $\boldsymbol{x}_i$, makes a prediction $\hat{y}_i$ according to its current rule, and then learns the true label y_i. The learner uses the new example $(\boldsymbol{x}_i, y_i)$ to modify its prediction rule. Its goal is to minimize the total number of rounds with incorrect predictions, $|\{i : y_i \neq \hat{y}_i\}|$.

In this work we focus on linear models parameterized by weights $\boldsymbol{w}$ and utilizing prediction functions of the form $h_{\boldsymbol{w}}(\boldsymbol{x}) = \arg\max_z \boldsymbol{w} \cdot \boldsymbol{f}(\boldsymbol{x}, z)$. Note that since we can choose $\boldsymbol{f}(\boldsymbol{x}, y)$ to be the vectorized Cartesian product of an input feature function $\boldsymbol{g}(\boldsymbol{x})$ and y, this setup generalizes the use of unique weight vectors for each element of $\mathcal{Y}$.

3 Confidence Weighted Learning

Dredze, Crammer, and Pereira (2008) introduced online confidence weighted (CW) learning for binary classification, where $\mathcal{X} = \mathbb{R}^d$ and $\mathcal{Y} = \{\pm 1\}$. Rather than using a single parameter vector $\boldsymbol{w}$, CW maintains a distribution over parameters $\mathcal{N}(\boldsymbol{\mu}, \Sigma)$, where $\mathcal{N}(\boldsymbol{\mu}, \Sigma)$ the multivariate normal distribution with mean $\boldsymbol{\mu} \in \mathbb{R}^d$ and covariance matrix $\Sigma \in \mathbb{R}^{d \times d}$. Given an input instance $\boldsymbol{x}$, a Gibbs classifier draws a weight vector $\boldsymbol{w}$ from the distribution and then makes a prediction according to the sign of $\boldsymbol{w} \cdot \boldsymbol{x}$.

This prediction rule is robust if the example is classified correctly with high-probability, that is, for some confidence parameter $.5 \leq \eta < 1$, $\Pr_{\boldsymbol{w}}[y(\boldsymbol{w} \cdot \boldsymbol{x}) \geq 0] \geq \eta$. To learn a binary CW classifier in the online framework, the robustness property is enforced at each iteration while making a minimal update to the parameter distribution in the KL sense:

$$
\begin{aligned}
(\boldsymbol{\mu}_{i+1}, \Sigma_{i+1}) = & \\
& \arg\min_{\boldsymbol{\mu}, \Sigma} \mathrm{D}_{\mathrm{KL}}\left(\mathcal{N}(\boldsymbol{\mu}, \Sigma) \,\|\, \mathcal{N}(\boldsymbol{\mu}_i, \Sigma_i)\right) \\
& \text{s.t. } \Pr_{\boldsymbol{w}}[y_i(\boldsymbol{w} \cdot \boldsymbol{x}_i) \geq 0] \geq \eta
\end{aligned} \tag{1}
$$

Dredze et al. (2008) showed that this optimization can be solved in closed form, yielding the updates

$$\boldsymbol{\mu}_{i+1} = \boldsymbol{\mu}_i + \alpha_i \Sigma_i \boldsymbol{x}_i \tag{2}$$

$$\Sigma_{i+1} = \left(\Sigma_i^{-1} + \beta_i \boldsymbol{x}_i \boldsymbol{x}_i^T\right)^{-1} \tag{3}$$

for appropriate α_i and β_i.

For prediction, they use the Bayesian rule

$$\hat{y} = \arg\max_{z \in \{\pm 1\}} \Pr_{\boldsymbol{w} \sim \mathcal{N}(\boldsymbol{\mu}, \Sigma)}[z(\boldsymbol{x} \cdot \boldsymbol{w}) \geq 0] \ ,$$

which for binary labels is equivalent to using the mean parameters directly, $\hat{y} = \mathrm{sign}(\boldsymbol{\mu} \cdot \boldsymbol{x})$.

4 Multi-Class Confidence Weighted Learning

As in the binary case, we maintain a distribution over weight vectors $\boldsymbol{w} \sim \mathcal{N}(\boldsymbol{\mu}, \Sigma)$. Given an input instance $\boldsymbol{x}$, a Gibbs classifier draws a weight vector $\boldsymbol{w} \sim \mathcal{N}(\boldsymbol{\mu}, \Sigma)$ and then predicts the label with the maximal score, $\arg\max_z (\boldsymbol{w} \cdot \boldsymbol{f}(\boldsymbol{x}, z))$. As in the binary case, we use this prediction rule to define a robustness condition and corresponding learning updates.

We generalize the robustness condition used in Crammer et al. (2008). Following the update on round i, we require that the ith instance is correctly labeled with probability at least $\eta < 1$. Among the distributions that satisfy this condition, we choose the one that has the minimal KL distance from the current distribution. This yields the update

$$
\begin{aligned}
(\boldsymbol{\mu}_{i+1}, \Sigma_{i+1}) = & \\
& \arg\min_{\boldsymbol{\mu}, \Sigma} \mathrm{D}_{\mathrm{KL}}\left(\mathcal{N}(\boldsymbol{\mu}, \Sigma) \,\|\, \mathcal{N}(\boldsymbol{\mu}_i, \Sigma_i)\right) \\
& \text{s.t. } \Pr[y_i \,|\, \boldsymbol{x}_i, \boldsymbol{\mu}, \Sigma] \geq \eta \ ,
\end{aligned} \tag{4}
$$

where

$$
\begin{aligned}
& \Pr[y \,|\, \boldsymbol{x}, \boldsymbol{\mu}, \Sigma] = \\
& \Pr_{\boldsymbol{w} \sim \mathcal{N}(\boldsymbol{\mu}, \Sigma)}\left[y = \arg\max_{z \in \mathcal{Y}} (\boldsymbol{w} \cdot \boldsymbol{f}(\boldsymbol{x}, z))\right] \ .
\end{aligned}
$$

Due to the $\max$ operator in the constraint, this optimization is not convex when $K > 2$, and it does not permit a closed form solution. We therefore develop approximations that can be solved efficiently. We define the following set of events for a general input $\boldsymbol{x}$:

$$
\begin{aligned}
A_{r,s}(\boldsymbol{x}) &\stackrel{\text{def}}{=} \{\boldsymbol{w} : \boldsymbol{w} \cdot \boldsymbol{f}(\boldsymbol{x}, r) \geq \boldsymbol{w} \cdot \boldsymbol{f}(\boldsymbol{x}, s)\} \\
B_r(\boldsymbol{x}) &\stackrel{\text{def}}{=} \{\boldsymbol{w} : \boldsymbol{w} \cdot \boldsymbol{f}(\boldsymbol{x}, r) \geq \boldsymbol{w} \cdot \boldsymbol{f}(\boldsymbol{x}, s) \ \ \forall s\} \\
&= \bigcap_{s \neq r} A_{r,s}(\boldsymbol{x})
\end{aligned}
$$

We assume the probability that $\boldsymbol{w} \cdot \boldsymbol{f}(\boldsymbol{x}, r) = \boldsymbol{w} \cdot \boldsymbol{f}(\boldsymbol{x}, s)$ for some $s \neq r$ is zero, which

holds for non-trivial distribution parameters and feature vectors. We rewrite the prediction $\hat{y} = \arg\max_r \Pr[B_r(\boldsymbol{x})]$, and the constraint from Eq. (4) becomes

$$\Pr[B_{y_i}(\boldsymbol{x})] \geq \eta \,. \tag{5}$$

We focus now on approximating the event $B_{y_i}(\boldsymbol{x})$ in terms of events $A_{y_i,r}$. We rely on the fact that the level sets of $\Pr[A_{y_i,r}]$ are convex in $\boldsymbol{\mu}$ and Σ. This leads to convex constraints of the form $\Pr[A_{y_i,r}] \geq \gamma$.

Outer Bound: Since $B_r(\boldsymbol{x}) \subseteq A_{r,s}(\boldsymbol{x})$, it holds trivially that $\Pr[B_{y_i}(\boldsymbol{x})] \geq \eta \Rightarrow \Pr[A_{y_i,r}] \geq \eta, \forall r \neq y_i$. Thus we can replace the constraint $\Pr[B_{y_i}(\boldsymbol{x})] \geq \eta$ with $\Pr[A_{y_i,r}] \geq \eta$ to achieve an outer bound. We can simultaneously apply *all* of the pairwise constraints to achieve a tighter bound:

$$\Pr[A_{y_i,r}] \geq \eta \quad \forall r \neq y_i$$

This yields a convex approximation to Eq. (4) that may improve the objective value at the cost of violating the constraint. In the context of learning, this means that the new parameter distribution will be close to the previous one, but may not achieve the desired confidence on the current example. This makes the updates more conservative.

Inner Bound: We can also consider an inner bound. Note that $B_{y_i}(\boldsymbol{x})^c = (\cap_r A_{y_i,r}(\boldsymbol{x}))^c = \cup_r A_{y_i,r}(\boldsymbol{x})^c$, thus the constraint $\Pr[B_{y_i}(\boldsymbol{x})] \geq \eta$ is equivalent to

$$\Pr[\cup_r A_{y_i,r}(\boldsymbol{x})^c] \leq 1 - \eta \,,$$

and by the union bound, this follows whenever

$$\sum_r \Pr[A_{y_i,r}(\boldsymbol{x})^c] \leq 1 - \eta \,.$$

We can achieve this by choosing non-negative $\zeta_r \geq 0$, $\sum_r \zeta_r = 1$, and constraining

$$\Pr[A_{y_i,r}(\boldsymbol{x})] \geq 1 - (1-\eta)\,\zeta_r \quad \text{for} \quad r \neq y_i \,.$$

This formulation yields an inner bound on the original constraint, guaranteeing its satisfaction while possibly increasing the objective. In the context of learning, this is a more aggressive update, ensuring that the current example is robustly classified even if doing so requires a larger change to the parameter distribution.

Algorithm 1 Multi-Class CW Online Algorithm

Input: Confidence parameter η
Feature function $\boldsymbol{f}(\boldsymbol{x}, y) \in \mathbb{R}^d$
Initialize: $\boldsymbol{\mu}_1 = \mathbf{0}$, $\Sigma_1 = I$
for $i = 1, 2 \ldots$ **do**
Receive $\boldsymbol{x}_i \in \mathcal{X}$
Predict ranking of labels $\hat{y}_1, \hat{y}_2, \ldots$
Receive $y_i \in \mathcal{Y}$
Set $\boldsymbol{\mu}_{i+1}, \Sigma_{i+1}$ by approximately solving Eq. (4) using one of the following:
Single-constraint update (Sec. 5.1)
Exact many-constraint update (Sec. 5.2)
Seq. many-constraint approx. (Sec. 5.2)
Parallel many-constraint approx. (Sec. 5.2)
end for
Output: Final $\boldsymbol{\mu}$ and Σ

Discussion: The two approximations are quite similar in form. Both replace the constraint $\Pr[B_{y_i}(\boldsymbol{x})] \geq \eta$ with one or more constraints of the form

$$\Pr[A_{y_i,r}(\boldsymbol{x})] \geq \eta_r \,. \tag{6}$$

To achieve an outer bound we choose $\eta_r = \eta$ for any set of $r \neq y_i$. To achieve an inner bound we use all $K-1$ possible constraints, setting $\eta_r = 1 - (1-\eta)\,\zeta_r$ for suitable ζ_r. A simple choice is $\zeta_r = 1/(K-1)$.

In practice, η is a learning parameter whose value will be optimized for each task. In this case, the outer bound (when all constraints are included) and inner bound (when $\zeta_r = 1/(K-1)$) can be seen as equivalent, since for any fixed value of $\eta^{(\text{in})}$ for the inner bound we can choose

$$\eta^{(\text{out})} = 1 - \frac{1-\eta^{(\text{in})}}{K-1} \,,$$

for the outer bound and the resulting η_r will be equal. By optimizing η we automatically tune the approximation to achieve the best compromise between the inner and outer bounds. In the following, we will therefore assume $\eta_r = \eta$.

5 Online Updates

Our algorithms are online and process examples one at a time. Pseudo-code for our approach is given in algorithm 1. We approximate the prediction step by ranking each label y according to the score given by the mean weight vector, $\boldsymbol{\mu} \cdot \boldsymbol{f}(\boldsymbol{x}_i, y)$. Although this approach is Bayes optimal for binary problems (Dredze et al., 2008),

it is an approximation in general. We note that more accurate inference can be performed in the multi-class case by sampling weight vectors from the distribution $\mathcal{N}(\boldsymbol{\mu}, \Sigma)$ or selecting labels sensitive to the variance of prediction; however, in our experiments this did not improve performance and required significantly more computation. We therefore proceed with this simple and effective approximation.

The update rule is given by an approximation of the type described in Sec. 4. All that remains is to choose the constraint set and solve the optimization efficiently. We discuss several schemes for minimizing KL divergence subject to one or more constraints of the form $\Pr[A_{y_i,r}(\boldsymbol{x})] \geq \eta$. We start with a single constraint.

5.1 Single-Constraint Updates

The simplest approach is to select the single constraint $\Pr[A_{y_i,r}(\boldsymbol{x})] \geq \eta$ corresponding to the highest-ranking label $r \neq y_i$. This ensures that, following the update, the true label is more likely to be predicted than the label that was its closest competitor. We refer to this as the $k = 1$ update.

Whenever we have only a single constraint, we can reduce the optimization to one of the closed-form CW updates used for binary classification. Several have been proposed, based on linear approximations (Dredze et al., 2008) and exact formulations (Crammer et al., 2008). For simplicity, we use the `Variance` method from Dredze et al. (2008), which did well in our initial evaluations. This method leads to the following update rules. Note that in practice Σ is projected to a diagonal matrix as part of the update; this is necessary due to the large number of features that we use.

$$\boldsymbol{\mu}_{i+1} = \boldsymbol{\mu}_i + \alpha_i \Sigma_i \boldsymbol{g}_{i,y_i,r} \tag{7}$$

$$\Sigma_{i+1} = \left(\Sigma_i^{-1} + 2\alpha_i \phi \boldsymbol{g}_{i,y_i,r} \boldsymbol{g}_{i,y_i,r}^\top\right)^{-1} \tag{8}$$

$$\boldsymbol{g}_{i,y_i,r} = \boldsymbol{f}(\boldsymbol{x}_i, y_i) - \boldsymbol{f}(\boldsymbol{x}_i, r) \quad \phi = \Phi^{-1}(\eta)$$

The scale α_i is given by $\max(\gamma_i, 0)$, where γ_i is equal to

$$\frac{-(1 + 2\phi m_i) + \sqrt{(1 + 2\phi m_i)^2 - 8\phi(m_i - \phi v_i)}}{4\phi v_i}$$

and

$$m_i = \boldsymbol{\mu}_i \cdot \boldsymbol{g}_{i,y_i,r} \qquad v_i = \boldsymbol{g}_{i,y_i,r}^\top \Sigma_i \boldsymbol{g}_{i,y_i,r} \,.$$

These rules derive directly from Dredze et al. (2008) or Figure 1 in Crammer et al. (2008); we simply substitute $y_i = 1$ and $\boldsymbol{x}_i = \boldsymbol{g}_{i,y_i,r}$.

5.2 Many-Constraints Updates

A more accurate approximation can be obtained by selecting multiple constraints. Analogously, we choose the $k \leq K-1$ constraints corresponding to the labels $r_1, \ldots, r_k \neq y_i$ that achieve the highest predicted ranks. The resulting optimization is convex and can be solved by a standard Hildreth-like algorithm (Censor & Zenios, 1997). We refer to this update as `Exact`. However, `Exact` is expensive to compute, and tends to over-fit in practice (Sec. 6.2). We propose several approximate alternatives.

Sequential Update: The Hildreth algorithm iterates over the constraints, updating with respect to each until convergence is reached. We approximate this solution by making only a single pass:

- Set $\boldsymbol{\mu}_{i,0} = \boldsymbol{\mu}_i$ and $\Sigma_{i,0} = \Sigma_i$.
- For $j = 1, \ldots, k$, set $(\boldsymbol{\mu}_{i,j}, \Sigma_{i,j})$ to the solution of the following optimization:

$$\min_{\boldsymbol{\mu},\Sigma} \mathrm{D}_{\mathrm{KL}}\left(\mathcal{N}(\boldsymbol{\mu}, \Sigma) \,\|\, \mathcal{N}\left(\boldsymbol{\mu}_{i,j-1}, \Sigma_{i,j-1}\right)\right)$$
$$\text{s.t. } \Pr\left[A_{y_i,r_j}(\boldsymbol{x})\right] \geq \eta$$

- Set $\boldsymbol{\mu}_{i+1} = \boldsymbol{\mu}_{i,k}$ and $\Sigma_{i+1} = \Sigma_{i,k}$.

Parallel Update: As an alternative to the Hildreth algorithm, we consider the simultaneous algorithm of Iusem and Pierro (1987), which finds an exact solution by iterating over the constraints in parallel. As above, we approximate the exact solution by performing only one iteration. The process is as follows.

- For $j = 1, \ldots, k$, set $(\boldsymbol{\mu}_{i,j}, \Sigma_{i,j})$ to the solution of the following optimization:

$$\min_{\boldsymbol{\mu},\Sigma} \mathrm{D}_{\mathrm{KL}}\left(\mathcal{N}(\boldsymbol{\mu}, \Sigma) \,\|\, \mathcal{N}(\boldsymbol{\mu}_i, \Sigma_i)\right)$$
$$\text{s.t. } \Pr\left[A_{y_i,r_j}(\boldsymbol{x})\right] \geq \eta$$

- Let $\boldsymbol{\lambda}$ be a vector, $\lambda_j \geq 0$, $\sum_j \lambda_j = 1$.
- Set $\boldsymbol{\mu}_{i+1} = \sum_j \lambda_j \boldsymbol{\mu}_{i,j}$, $\Sigma_{i+1}^{-1} = \sum_j \lambda_j \Sigma_{i,j}^{-1}$.

In practice we set $\lambda_j = 1/k$ for all j.

6 Experiments

6.1 Datasets

Following the approach of Dredze et al. (2008), we evaluate using five natural language classification tasks over nine datasets that vary in difficulty, size, and label/feature counts. See Table 1 for an overview. Brief descriptions follow.

Task	*Instances*	*Features*	*Labels*	*Bal.*
20 News	18,828	252,115	20	Y
Amazon 7	13,580	686,724	7	Y

Table 2: A comparison of $k = \infty$ updates. While the two approximations (sequential and parallel) are roughly the same, the exact solution over-fits.

Amazon Amazon product reviews. Using the data of Dredze et al. (2008), we created two domain classification datasets from seven product types (apparel, books, dvds, electronics, kitchen, music, video). *Amazon 7* includes all seven product types and *Amazon 3* includes books, dvds, and music. Feature extraction follows Blitzer et al. (2007) (bigram features and counts).

20 Newsgroups Approximately 20,000 newsgroup messages, partitioned across 20 different newsgroups.[1] This dataset is a popular choice for binary and multi-class text classification as well as unsupervised clustering. We represent each message as a binary bag-of-words.

Enron Automatic sorting of emails into folders.[2] We selected two users with many email folders and messages: `farmer-d` (*Enron A*) and `kaminski-v` (*Enron B*). We used the ten largest folders for each user, excluding non-archival email folders such as "inbox," "deleted items," and "discussion threads." Emails were represented as binary bags-of-words with stop-words removed.

NY Times To the best of our knowledge we are the first to evaluate machine learning methods on the New York Times corpus. The corpus contains 1.8 million articles that appeared from 1987 to 2007 (Sandhaus, 2008). In addition to being one of the largest collections of raw news text, it is possibly the largest collection of publicly released annotated news text, and therefore an ideal corpus for large scale NLP tasks. Among other annotations, each article is labeled with the desk that produced the story (Financial, Sports, etc.) (*NYTD*), the online section to which the article was posted (*NYTO*), and the section in which the article was printed (*NYTS*). Articles were represented as bags-of-words with feature counts (stop-words removed).

Reuters Over 800,000 manually categorized newswire stories (RCV1-v2/ LYRL2004). Each article contains one or more labels describing its general topic, industry, and region. We performed topic classification with the four general topics: corporate, economic, government, and markets. Details on document preparation and feature extraction are given by Lewis et al. (2004).

6.2 Evaluations

We first set out to compare the three update approaches proposed in Sec. 5.2: an exact solution and two approximations (sequential and parallel). Results (Table 2) show that the two approximations perform similarly. For every experiment the CW parameter η and the number of iterations (up to 10) were optimized using a single randomized iteration. However, sequential converges faster, needing an average of 4.33 iterations compared to 7.56 for parallel across all datasets. Therefore, we select sequential for our subsequent experiments.

The exact method performs poorly, displaying the lowest performance on almost every dataset. This is unsurprising given similar results for binary CW learning Dredze et al. (2008), where exact updates were shown to over-fit but converged after a single iteration of training. Similarly, our exact implementation converges after an average of 1.25 iterations, much faster than either of the approximations. However, this rapid convergence appears to come at the expense of accuracy. Fig. 1 shows the accuracy on Amazon 7 test data after each training iteration. While both sequential and parallel improve with several iterations, exact de-

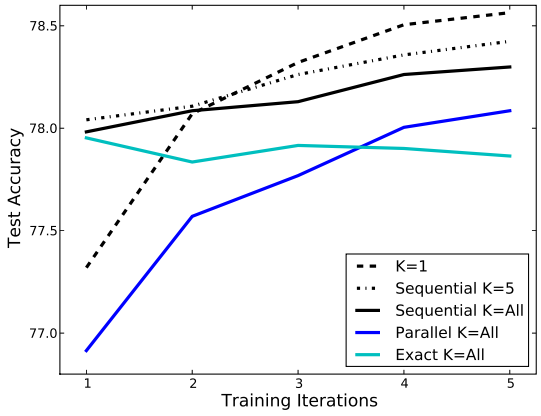

Figure 1: Accuracy on test data after each iteration on the Amazon 7 dataset.

grades after the first iteration, suggesting that it may over-fit to the training data. The approximations appear to smooth learning and produce better performance in the long run.

6.3 Relaxing Many-Constraints

While enforcing many constraints may seem optimal, there are advantages to pruning the constraints as well. It may be time consuming to enforce dozens or hundreds of constraints for tasks with many labels. Structured prediction tasks often involve exponentially many constraints, making pruning mandatory. Furthermore, many real world datasets, especially in NLP, are noisy, and enforcing too many constraints can lead to over-fitting. Therefore, we consider the impact of reducing the constraint set in terms of both reducing run-time and improving accuracy.

We compared using all constraints ($k = \infty$) with using 5 constraints ($k = 5$) for the sequential update method (Table 3). First, we observe that $k = 5$ performs better than $k = \infty$ on nearly every dataset: fewer constraints help avoid over-fitting and once again, simpler is better. Additionally, $k = 5$ converges faster than $k = \infty$ in an average of 2.22 iterations compared with 4.33 iterations. Therefore, reducing the number of constraints improves both speed and accuracy. In comparing $k = 5$ with the further reduced $k = 1$ results, we observe the latter improves on seven of the nine methods. This surprising result suggests that CW learning can perform well even without considering more than a single constraint per example. However, $k = 1$ exceeds the performance of multiple constraints only through repeated training iterations. $k = 5$ CW learning converges faster — 2.22 iterations compared with 6.67 for $k = 1$ — a desirable property in many resource restricted settings. (In the true online setting, only a single iteration may be possible.) Fig. 1 plots the performance of $k = 1$ and $k = 5$ CW on test data after each training iteration. While $k = 1$ does better in the long run, it lags behind $k = 5$ for several iterations. In fact, after a single training iteration, $k = 5$ outperforms $k = 1$ on eight out of nine datasets. Thus, there is again a tradeoff between faster convergence ($k = 5$) and increased accuracy ($k = 1$). While the $k = 5$ update takes longer per iteration, the time required for the approximate solutions grows only linearly in the number of constraints. The evaluation in Fig. 1 required 3 seconds for the first iteration of $k = 1$, 10 seconds for $k = 5$ and 11 seconds for one iteration of all 7 constraints. These differences are insignificant compared to the cost of performing multiple iterations over a large dataset. We note that, while both approximate methods took about the same amount of time, the exact solution took over 4 minutes for its first iteration.

Finally, we compare CW methods with several baselines in Table 3. Online baselines include Top-1 Perceptron (Collins, 2002), Top-1 Passive-Aggressive (PA), and k-best PA (Crammer & Singer, 2003; McDonald et al., 2004). Batch algorithms include Maximum Entropy (default configuration in McCallum (2002)) and support vector machines (LibSVM (Chang & Lin, 2001) for one-against-one classification and multiclass (MC) (Crammer & Singer, 2001)). Classifier parameters (C for PA/SVM and maxent's Gaussian prior) and number of iterations (up to 10) for the online methods were optimized using a single randomized iteration. On eight of the nine datasets, CW improves over all baselines. In general, CW provides faster and more accurate multiclass predictions.

7 Error and Probabilistic Output

Our focus so far has been on accuracy and speed. However, there are other important considerations for selecting learning algorithms. Maximum entropy and other probabilistic classification algorithms are sometimes favored for their probability scores, which can be useful for integration with other learning systems. However, practition-

Table 3: A comparison of CW learning ($k = 1, 5, \infty$ with sequential updates) with several baseline algorithms. CW learning achieves the best performance eight out of nine times. Statistical significance (McNemar) is measured against *all* baselines ($*$ indicates 0.05 and $**$ 0.001) or against online baselines († indicates 0.05 and †† 0.001).

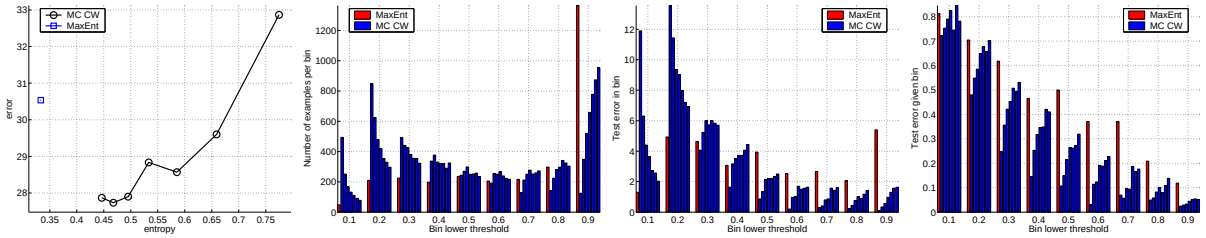

Figure 2: **First panel:** Error versus prediction entropy on Enron B. As CW converges (right to left) error and entropy are reduced. **Second panel:** Number of test examples per prediction probability bin. The red bars correspond to maxent and the blue bars to CW, with increasing numbers of epochs from left to right. **Third panel:** The contribution of each bin to the total test error. **Fourth panel:** Test error conditioned on prediction probability.

ers have observed that maxent probabilities can have low entropy and be unreliable for estimating prediction confidence (Malkin & Bilmes, 2008). Since CW also produces label probabilities — and does so in a conceptually distinct way — we investigate in this section some empirical properties of the label distributions induced by CW's parameter distributions and compare them with those of maxent.

We trained maxent and CW $k = 1$ classifiers on the Enron B dataset, optimizing parameters as before (maxent's Gaussian prior and CW's η). We estimated the label distributions from our CW classifiers after each iteration and on every test example $\boldsymbol{x}$ by Gibbs sampling weight vectors $\boldsymbol{w} \sim \mathcal{N}(\boldsymbol{\mu}, \Sigma)$, and for each label y counting the fraction of weight vectors for which $y = \arg\max_z \boldsymbol{w} \cdot \boldsymbol{f}(\boldsymbol{x}, z)$. Normalizing these counts yields the label distributions $\Pr[y|\boldsymbol{x}]$. We denote by $\hat{y}$ the predicted label for a given $\boldsymbol{x}$, and refer to $\Pr[\hat{y}|\boldsymbol{x}]$ as the prediction probability.

The leftmost panel of Fig. 2 plots each method's prediction error against the normalized entropy of the label distribution $-\left(\frac{1}{m}\sum_i \sum_z \Pr[z|\boldsymbol{x}_i] \log\left(\Pr[z|\boldsymbol{x}_i]\right)\right) / \log(K)$. Each CW iteration (moving from right to left in the plot) reduces both error and entropy. From our maxent results we make the common observation that maxent distributions have (ironically) low entropy. In contrast, while CW accuracy exceeds maxent after its second iteration, normalized entropy remains high. Higher entropy suggests a distribution over labels that is less peaked and potentially more informative than those from maxent. We found that the average probability assigned to a correct prediction was 0.75 for CW versus 0.83 for maxent and for an incorrect prediction was 0.44 for CW versus 0.56 for maxent.

Next, we investigate how these probabilities relate to label accuracy. In the remaining panels, we binned examples according to their prediction probabilities $\Pr[\hat{y}|\boldsymbol{x}] = \max_y \Pr[y|\boldsymbol{x}]$. The second panel of Fig. 2 shows the numbers of test examples with $\Pr[\hat{y}|\boldsymbol{x}] \in [\theta, \theta + 0.1)$ for $\theta = 0.1, 0.2 \ldots 0.9$. (Note that since there are 10

classes in this problem, we must have $\Pr[\hat{y}|\boldsymbol{x}] \geq 0.1$.) The red (leftmost) bar corresponds to the maximum entropy classifier, and the blue bars correspond, from left to right, to CW after each successive training epoch.

From the plot we observe that the maxent classifier assigns prediction probability greater than 0.9 to more than 1,200 test examples out of 3,000. Only 50 examples predicted by maxent fall in the lowest bin, and the rest of examples are distributed nearly uniformly across the remaining bins. The large number of examples with very high prediction probability explains the low entropy observed for the maximum entropy classifier.

In contrast, the CW classifier shows the opposite behavior after one epoch of training (the leftmost blue bar), assigning low prediction probability (less than 0.3) to more than 1,200 examples and prediction probability of at least 0.9 to only 100 examples. As CW makes additional passes over the training data, its prediction confidence increases and shifts toward more peaked distributions. After seven epochs fewer than 100 examples have low prediction probability and almost 1,000 have high prediction probability. Nonetheless, we note that this distribution is still less skewed than that of the maximum entropy classifier.

Given the frequency of high probability maxent predictions, it seems likely that many of the high probability maxent labels will be wrong. This is demonstrated in the third panel, which shows the contribution of each bin to the total test error. Each bar reflects the number of mistakes per bin divided by the size of the complete test set (3,000). Thus, the sum of the heights of the corresponding bars in each bin is proportional to test error. Much of the error of the maxent classifier comes not only from the low-probability bins, due to their inaccuracy, but also from the highest bin, due to its very high population. In contrast, the CW classifiers see very little error contribution from the high-probability bins. As training progresses, we see again that the CW classifiers move in the direction of the maxent classifier but remain essentially unimodal.

Finally, the rightmost panel shows the conditional test error given bin identity, or the fraction of test examples from each bin where the prediction was incorrect. This is the pointwise ratio between corresponding values of the previous two histograms. For both methods, there is a monotonically decreasing trend in error as prediction probability increases; that is, the higher the value of the prediction probability, the more likely that the prediction it provides is correct. As CW is trained, we see an increase in the conditional test error, yet the overall error decreases (not shown). This suggests that as CW is trained and its overall accuracy improves, there are more examples with high prediction probability, and the cost for this is a relative increase in the conditional test error per bin. The maxent classifier produces an extremely large number of test examples with very high prediction probabilities, which yields relatively high conditional test error. In nearly all cases, the conditional error values for the CW classifiers are smaller than the corresponding values for maximum entropy. These observations suggest that CW assigns probabilities more conservatively than maxent does, and that the (fewer) high confidence predictions it makes are of a higher quality. This is a potentially valuable property, e.g., for system combination.

8 Conclusion

We have proposed a series of approximations for multi-class confidence weighted learning, where the simple analytical solutions of binary CW learning do not apply. Our best CW method outperforms online and batch baselines on eight of nine NLP tasks, and is highly scalable due to the use of a single optimization constraint. Alternatively, our multi-constraint algorithms provide improved performance for systems that can afford only a single pass through the training data, as in the true online setting. This result stands in contrast to previously observed behaviors in non-CW settings (McDonald et al., 2004). Additionally, we found improvements in both label entropy and accuracy as compared to a maximum entropy classifier. We plan to extend these ideas to structured problems with exponentially many labels and develop methods that efficiently model label correlations. An implementation of CW multi-class algorithms is available upon request from the authors.

Abstract

This paper explores two classes of model adaptation methods for Web search ranking: Model Interpolation and error-driven learning approaches based on a boosting algorithm. The results show that model interpolation, though simple, achieves the best results on all the open test sets where the test data is very different from the training data. The tree-based boosting algorithm achieves the best performance on most of the closed test sets where the test data and the training data are similar, but its performance drops significantly on the open test sets due to the instability of trees. Several methods are explored to improve the robustness of the algorithm, with limited success.

1 Introduction

We consider the task of ranking Web search results, i.e., a set of retrieved Web documents (URLs) are ordered by relevance to a query issued by a user. In this paper we assume that the task is performed using a *ranking model* (also called *ranker* for short) that is learned on labeled training data (e.g., human-judged query-document pairs). The ranking model acts as a function that maps the feature vector of a query-document pair to a real-valued score of relevance.

Recent research shows that such a learned ranker is superior to classical retrieval models in two aspects (Burges et al., 2005; 2006; Gao et al., 2005). First, the ranking model can use arbitrary features. Both traditional criteria such as TF-IDF and BM25, and non-traditional features such as hyperlinks can be incorporated as features in the ranker. Second, if large amounts of high-quality human-judged query-document pairs were available for model training, the ranker could achieve significantly better retrieval results than the traditional retrieval models that cannot benefit from training data effectively. However, such training data is not always available for many search domains, such as non-English search markets or person name search.

One of the most widely used strategies to remedy this problem is model adaptation, which attempts to adjust the parameters and/or structure of a model trained on one domain (called the *background* domain), for which large amounts of training data are available, to a different domain (the *adaptation* domain), for which only small amounts of training data are available. In Web search applications, domains can be defined by query types (e.g., person name queries), or languages, etc.

In this paper we investigate two classes of model adaptation methods for Web search ranking: Model Interpolation approaches and error-driven learning approaches. In model interpolation approaches, the adaptation data is used to derive a domain-specific model (also called in-domain model), which is then combined with the background model trained on the background data. This appealingly simple concept provides fertile ground for experimentation, depending on the level at which the combination is implemented (Bellegarda, 2004). In error-driven learning approaches, the background model is adjusted so as to minimize the ranking errors the model makes on the adaptation data (Bacchiani et al., 2004; Gao et al. 2006). This is arguably more powerful than model interpolation for two reasons. First, by defining a proper error function, the method can optimize more directly the measure used to assess the final quality of the Web search system, e.g., *Normalized Discounted Cumulative Gain* (Javelin & Kekalainen, 2000) in this study. Second, in this framework, the model can be adjusted to be as fine-grained as necessary. In this study we developed a set of error-driven learning methods based on a boosting algorithm where, in an incremental manner, not only each feature weight could be

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 505–513,
Singapore, 6-7 August 2009.

changed separately, but new features could be constructed.

We focus our experiments on the robustness of the adaptation methods. A model is robust if it performs reasonably well on unseen test data that could be significantly different from training data. Robustness is important in Web search applications. Labeling training data takes time. As a result of the dynamic nature of Web, by the time the ranker is trained and deployed, the training data may be more or less out of date. Our results show that the model interpolation is much more robust than the boosting-based methods. We then explore several methods to improve the robustness of the methods, including regularization, randomization, and using shallow trees, with limited success.

2 Ranking Model and Quality Measure in Web Search

This section reviews briefly a particular example of rankers, called LambdaRank (Burges et al., 2006), which serves as the baseline ranker in our study.

Assume that training data is a set of input/output pairs ($\mathbf{x}$, y). $\mathbf{x}$ is a feature vector extracted from a query-document pair. We use approximately 400 features, including dynamic ranking features such as term frequency and BM25, and statistic ranking features such as PageRank. y is a human-judged relevance score, 0 to 4, with 4 as the most relevant.

LambdaRank is a neural net ranker that maps a feature vector $\mathbf{x}$ to a real value y that indicates the relevance of the document given the query (relevance score). For example, a linear LambdaRank simply maps $\mathbf{x}$ to y with a learned weight vector $\mathbf{w}$ such that $y = \mathbf{w} \cdot \mathbf{x}$. (We used nonlinear LambdaRank in our experiments). LambdaRank is particularly interesting to us due to the way $\mathbf{w}$ is learned. Typically, $\mathbf{w}$ is optimized w.r.t. a cost function using numerical methods if the cost function is smooth and its gradient w.r.t. $\mathbf{w}$ can be computed easily. In order for the ranker to achieve the best performance in document retrieval, the cost function used in training should be the same as, or as close as possible to, the measure used to assess the quality of the system. In Web search, *Normalized Discounted Cumulative Gain* (NDCG) (Jarvelin and Kekalainen, 2000) is widely used as quality measure. For a query, NDCG is computed as

$$\mathcal{N}_i = N_i \sum_{j=1}^{L} \frac{2^{r(j)} - 1}{\log(1+j)}, \qquad (1)$$

where $r(j)$ is the relevance level of the j-th document, and the normalization constant N_i is chosen so that a perfect ordering would result in $\mathcal{N}_i = 1$. Here L is the ranking truncation level at which NDCG is computed. The $\mathcal{N}_i$ are then averaged over a query set. However, NDCG, if it were to be used as a cost function, is either flat or discontinuous everywhere, and thus presents challenges to most optimization approaches that require the computation of the gradient of the cost function.

LambdaRank solves the problem by using an implicit cost function whose gradients are specified by rules. These rules are called *λ-functions*. Burges et al. (2006) studied several λ-functions that were designed with the NDCG cost function in mind. They showed that LambdaRank with the best λ-function outperforms significantly a similar neural net ranker, RankNet (Burges et al., 2005), whose parameters are optimized using the cost function based on cross-entropy.

The superiority of LambdaRank illustrates the key idea based on which we develop the model adaptation methods. We should always adapt the ranking models in such a way that the NDCG can be optimized as directly as possible.

3 Model Interpolation

One of the simplest model interpolation methods is to combine an in-domain model with a background model at the model level via linear interpolation. In practice we could combine more than two in-domain/background models. Letting *Score*(q, d) be a ranking model that maps a query-document pair to a relevance score, the general form of the interpolation model is

$$Score(q,d) = \sum_{i=1}^{N} \alpha_i Score_i(q,d), \qquad (2)$$

where the α's are interpolation weights, optimized on validation data with respect to a predefined objective, which is NDCG in our case. As mentioned in Section 2, NDCG is not easy to optimize, for which we resort to two solutions, both of which achieve similar results in our experiments.

The first solution is to view the interpolation model of Equation (2) as a linear neural net ranker where each component model $Score_i(.)$ is defined as a feature function. Then, we can use the LambdaRank algorithm described in Section 2 to find the optimal weights.

An alternative solution is to view interpolation weight estimation as a multi-dimensional optimization problem, with each model as a

dimension. Since NCDG is not differentiable, we tried in our experiments the numerical algorithms that do not require the computation of gradient. Among the best performers is the Powell Search algorithm (Press et al., 1992). It first constructs a set of N virtual directions that are conjugate (i.e., independent with each other), then it uses *line search* N times, each on one virtual direction, to find the optimum. Line search is a one-dimensional optimization algorithm. Our implementation follows the one described in Gao et al. (2005), which is used to optimize the averaged precision.

The performance of model interpolation depends to a large degree upon the quality and the size of adaptation data. First of all, the adaptation data has to be "rich" enough to suitably characterize the new domain. This can only be achieved by collecting more in-domain data. Second, once the domain has been characterized, the adaptation data has to be "large" enough to have a model reliably trained. For this, we developed a method, which attempts to augment adaptation data by gathering similar data from background data sets.

The method is based on the *k-nearest-neighbor* (kNN) algorithm, and is inspired by Bishop (1995). We use the small in-domain data set *D1* as a seed, and expand it using the large background data set *D2*. When the relevance labels are assigned by humans, it is reasonable to assume that queries with the lowest information entropy of labels are the least noisy. That is, for such a query most of the URLs are labeled as highly relevant/not relevant documents rather than as moderately relevance/not relevant documents.

Due to computational limitations of kNN-based algorithms, a small subset of queries from *D1* which are least noisy are selected. This data set is called *S1*. For each sample in *D2*, its 3-nearest neighbors in *S1* are found using a cosine-similarity metric. If the three neighbors are within a very small distance from the sample in *D2*, and one of the labels of the nearest neighbors matches exactly, the training sample is selected and is added to the expanded set *E2*, in its own query. This way, *S1* is used to choose training data from *D2*, which are found to be close in some space.

This process effectively creates several data points in close neighborhood of the points in the original small data set *D1*, thus expanding the set, by jittering each training sample a little. This is equivalent to training with noise (Bishop, 1995), except that the training samples used are actual queries judged by a human. This is found to increase the NDCG in our experiments.

1 Set $F_0(\mathbf{x})$ be the background ranking model
2 **for** $m = 1$ **to** M **do**

4 $\quad (h_m, \beta_m) = \underset{h,\beta}{\operatorname{argmin}} \sum_{i=1}^{N} \left[y_i' - \beta h(\mathbf{x}_i)\right]^2$
5 $\quad F_m(\mathbf{x}) = F_{m-1}(\mathbf{x}) + \beta_m h(\mathbf{x})$

Figure 1. The generic boosting algorithm for model adaptation

4 Error-Driven Learning

Our error-drive learning approaches to ranking modeling adaptation are based on the Stochastic Gradient Boosting algorithm (or the boosting algorithm for short) described in Friedman (1999). Below, we follow the notations in Friedman (2001).

Let adaptation data (also called *training data* in this section) be a set of input/output pairs $\{\mathbf{x}_i, y_i\}$, $i = 1 \ldots N$. In error-driven learning approaches, model adaptation is performed by adjusting the background model into a new in-domain model $F: x \rightarrow y$ that minimizes a loss function $L(y, F(\mathbf{x}))$ over all samples in training data

$$F^* = \underset{F}{\operatorname{argmin}} \sum_{i=1}^{N} L(y_i, F(\mathbf{x}_i)). \quad (3)$$

We further assume that $F(\mathbf{x})$ takes the form of additive expansion as

$$F(\mathbf{x}) = \sum_{m=0}^{M} \beta_m h(\mathbf{x}; \mathbf{a}_m), \quad (4)$$

where $h(\mathbf{x}; \mathbf{a})$ is called *basis function*, and is usually a simple parameterized function of the input $\mathbf{x}$, characterized by parameters $\mathbf{a}$. In what follows, we drop $\mathbf{a}$, and use $h(\mathbf{x})$ for short. In practice, the form of h has to be restricted to a specific function family to allow for a practically efficient procedure of model adaptation. β is a real-valued coefficient.

Figure 1 is the generic algorithm. It starts with a base model F_0, which is a background model. Then for $m = 1, 2, \ldots, M$, the algorithm takes three steps to adapt the base model so as to best fit the adaptation data: (1) compute the residual of the current base model (line 3), (2) select the optimal basis function (line 4) that best fits the residual, and (3) update the base model by adding the optimal basis function (line 5). The two model adaptation algorithms that will be described below follow the same 3-step adaptation procedure. They only differ in the choice of h. In the LambdaBoost algorithm (Section 4.1) h

1 Set $F_0(\mathbf{x})$ to be the background ranking model
2 **for** $m = 1$ **to** M **do**
3 compute residuals according to Equation (5)
4 select best h_m (with its best β_m), according to *LS*, computed by Equations (8) and (9)
5 $F_m(\mathbf{x}) = F_{m-1}(\mathbf{x}) + \upsilon\beta_m h(\mathbf{x})$

Figure 2. The LambdaBoost algorithm for model adaptation.

is defined as a single feature, and in LambdaSMART (Section 4.2), h is a regression tree.

Now, we describe the way residual is computed, the step that is identical in both algorithms. Intuitively, the residual, denoted by y' (line 3 in Figure 1), measures the amount of errors (or loss) the base model makes on the training samples. If the loss function in Equation (3) is differentiable, the residual can be computed easily as the negative gradient of the loss function. As discussed in Section 2, we want to directly optimize the NDCD, whose gradient is approximated via the λ-function. Following Burges et al. (2006), the gradient of a training sample $(\mathbf{x}_i, y_i)$, where $\mathbf{x}_i$ is a feature vector representing the query-document pair (q_i, d_i), w.r.t. the current base model is computed by marginalizing the λ-functions of all document pairs, (d_i, d_j), of the query, q_i, as

$$y_i' = \sum_{j \neq i} \Delta\text{NDCG} \cdot \frac{\partial C_{ij}}{\partial o_{ij}}, \quad (5)$$

where ΔNDCG is the NDCG gained by swapping those two documents (after sorting all documents by their current scores); $o_{ij} \equiv s_i - s_j$ is the difference in ranking scores of d_i and d_j given q_i; and C_{ij} is the cross entropy cost defined as

$$C_{ij} \equiv C(o_{ij}) = s_j - s_i + \log(1 + \exp(s_i - s_j)). \quad (6)$$

Thus, we have

$$\frac{\partial C_{ij}}{\partial o_{ij}} = \frac{-1}{1 + \exp(o_{ij})}. \quad (7)$$

This λ-function essentially uses the cross entropy cost to smooth the change in NDCG obtained by swapping the two documents. A key intuition behind the λ-function is the observation that NDCG does not treat all pairs equally; for example, it costs more to incorrectly order a pair, where the irrelevant document is ranked higher than a highly relevant document, than it does to swap a moderately relevant/not relevant pair.

4.1 The LambdaBoost Algorithm

In LambdaBoost, the basis function h is defined as a single feature (i.e., an element feature in the feature vector $\mathbf{x}$). The algorithm is summarized in Figure 2. It iteratively adapts a background model to training data using the 3-step procedure, as in Figure 1. Step 1 (line 3 in Figure 2) has been described.

Step 2 (line 4 in Figure 2) finds the optimal basis function h, as well as its optimal coefficient β, that best fits the residual according to the least-squares (LS) criterion. Formally, let h and β denote the candidate basis function and its optimal coefficient. The LS error on training data is $LS(h;\beta) = \sum_{i=0}^{N}(y_i' - \beta h)^2$, where y_i' is computed as Equation (5). The optimal coefficient of h is estimated by solving the equation $\partial \sum_{i=1}^{N}(y_i' - \beta h2/\partial\beta=0$. Then, β is computed as

$$\beta = \frac{\sum_{i=1}^{N} y_i' h(\mathbf{x}_i)}{\sum_{i=1}^{N} h(\mathbf{x}_i)}. \quad (8)$$

Finally, given its optimal coefficient β, the optimal LS loss of h is

$$LS(h;\beta) = \sum_{i=1}^{N} y_i' \times y_i' - \frac{(\sum_{i=1}^{N} y_i' h(\mathbf{x}_i))^2}{\sum_{i=1}^{N} h^2(\mathbf{x}_i)}. \quad (9)$$

Step 3 (line 5 in Figure 2) updates the base model by adding the chosen optimal basis function with its optimal coefficient. As shown in Step 2, the optimal coefficient of each candidate basis function is computed when the basis function is evaluated. However, adding the basis function using its optimal efficient is prone to overfitting. We thus add a shrinkage coefficient $0 < \upsilon < 1$ – the fraction of the optimal line step taken. The update equation is thus rewritten in line 5 in Figure 2.

Notice that if the background model contains all the input features in $\mathbf{x}$, then LambdaBoost does not add any new features but adjust the weights of existing features. If the background model does not contain all of the input features, then LambdaBoost can be viewed as a feature selection method, similar to Collins (2000), where at each iteration the feature that has the largest impact on reducing training loss is selected and added to the background model. In either case, LambdaBoost adapts the background model by adding a model whose form is a (weighted) linear combination of input features. The property of linearity makes LambdaBoost robust and less likely to overfit in Web search applications. But this also limits the adaptation capacity. A simple method that allows us to go beyond linear adaptation is to define h as nonlinear terms of the input features, such as regression trees in LambdaSMART.

4.2 The LambdaSMART Algorithm

LambdaSMART was originally proposed in Wu et al. (2008). It is built on MART (Friedman, 2001) but uses the λ-function (Burges et a., 2006) to

1 Set $F_0(\mathbf{x})$ to be the background ranking model
2 **for** $m = 1$ **to** M **do**
3 compute residuals according to Equation (5)
4 create a L-terminal node tree, $h_m \equiv \{R_{lm}\}_{l=1\ldots L}$
5 **for** $l = 1$ **to** L **do**
6 compute the optimal β_{lm} according to Equation (10), based on approximate Newton step.
7 $F_m(\mathbf{x}) = F_{m-1}(x) + \upsilon \sum_{l=1\ldots L} \beta_{lm} 1(x \in R_{lm})$

Figure 3. The LambdaSMART algorithm for model adaptation.

compute gradients. The algorithm is summarized in Figure 3. Similar to LambdaBoost, it takes M rounds, and at each boosting iteration, it adapts the background model to training data using the 3-step procedure. Step 1 (line 3 in Figure 3) has been described.

Step 2 (lines 4 to 6) searches for the optimal basis function h to best fit the residual. Unlike LambdaBoost where there are a finite number of candidate basis functions, the function space of regression trees is infinite. We define h as a regression tree with L terminal nodes. In line 4, a regression tree is built using Mean Square Error to determine the best split at any node in the tree. The value associated with a leaf (i.e., terminal node) of the trained tree is computed first as the residual (computed via λ-function) for the training samples that land at that leaf. Then, since each leaf corresponds to a different mean, a one-dimensional Newton-Raphson line step is computed for each leaf (lines 5 and 6). These line steps may be simply computed as the derivatives of the LambdaRank gradients w.r.t. the model scores s_i. Formally, the value of the l-th leaf, β_{ml}, is computed as

$$\beta_{ml} = \frac{\sum_{x \in R_{lm}} y_i'}{\sum_{x \in R_{lm}} w_i}, \quad (10)$$

where y_i' is the residual of training sample i, computed in Equation (5), and w_i is the derivative of y_i', i.e., $w_i = \partial y_i' / \partial F(\mathbf{x}_i)$.

In Step 3 (line 7), the regression tree is added to the current base model, weighted by the shrinkage coefficient $0 < \upsilon < 1$.

Notice that since a regression tree can be viewed as a complex feature that combines multiple input features, LambdaSMART can be used as a feature generation method. LambdaSMART is arguably more powerful than LambdaBoost in that it introduces new complex features and thus adjusts not only the parameters but also the structure of the background model[1]. However, one problem of trees is their high variance. Often a small change in the data can result in a very different series of splits. As a result, tree-based ranking models are much less robust to noise, as we will show in our experiments. In addition to the use of shrinkage coefficient $0 < \upsilon < 1$, which is a form of model regularization according to Hastie, et al., (2001), we will explore in Section 5.3 other methods of improving the model robustness, including randomization and using shallow trees.

5 Experiments

5.1 The Data

We evaluated the ranking model adaptation methods on two Web search domains, namely (1) a name query domain, which consists of only person name queries, and (2) a Korean query domain, which consists of queries that users submitted to the Korean market.

For each domain, we used two in-domain data sets that contain queries sampled respectively from the query log of a commercial Web search engine that were collected in two non-overlapping periods of time. We used the more recent one as *open test* set, and split the other into three non-overlapping data sets, namely training, validation and *closed test* sets, respectively. This setting provides a good simulation to the realistic Web search scenario, where the rankers in use are usually trained on early collected data, and thus helps us investigate the robustness of these model adaptation methods.

The statistics of the data sets used in our person name domain adaptation experiments are shown in Table 1. The names query set serves as the adaptation domains, and Web-1 as the background domain. Since Web-1 is used to train a background ranker, we did not split it to train/valid/test sets. We used 416 input features in these experiments.

For cross-domain adaptation experiments from non-Korean to Korean markets, Korean data serves as the adaptation domain, and English, Chinese, and Japanese data sets as the background domain. Again, we did not split the data sets in the background domain to train/valid/test sets. The statistics of these data sets are shown in Table 2. We used 425 input features in these experiments.

[1] Note that in a sense our proposed LambdaBoost algorithm is the same as LambdaSMART, but using a single feature at each iteration, rather than a tree. In particular, they share the trick of using the Lambda gradients to learn NDCG.

Table 4. Open test results on Names-2-Test.

In each domain, the in-domain training data is used to train in-domain rankers, and the background data for background rankers. Validation data is used to learn the best training parameters of the boosting algorithms, i.e., M, the total number of boosting iterations, υ, the shrinkage coefficient, and L, the number of leaf nodes for each regression tree (L=1 in LambdaBoost). Model performance is evaluated on the closed/open test sets.

All data sets contain samples labeled on a 5-level relevance scale, 0 to 4, with 4 as most relevant and 0 as irrelevant. The performance of rankers is measured through NDCG evaluated against closed/open test sets. We report NDCG scores at positions 1, 3 and 10, and the averaged NDCG score (Ave-NDCG), the arithmetic mean of the NDCG scores at 1 to 10. Significance test (i.e., t-test) was also employed.

5.2 Model Adaptation Results

This section reports the results on two adaptation experiments. The first uses a large set of Web data, Web-1, as background domain and uses the name query data set as adaptation data. The results are summarized in Tables 3 and 4. We compared the three model adaptation methods against two baselines: (1) the background ranker (Row 1 in Tables 3 and 4), a 2-layer LambdaRank model with 15 hidden nodes and a learning rate of 10^{-5} trained on Web-1; and (2) the In-domain Ranker (Row 2), a 2-layer LambdaRank model with 10 hidden nodes and a learning rate of 10^{-5} trained on Names-1-Train. We built two interpolated rankers. The 2-way interpolated ranker (Row 3) is a linear combination of the two baseline rankers, where the interpolation weights were optimized on Names-1-Valid. To build the 3-way interpolated ranker (Row 4), we linearly interpolated three rankers. In addition to the two baseline rankers, the third ranker is trained on an augmented training data, which was created using the kNN method described in Section 3.

In LambdaBoost (Row 5) and LambdaSMART (Row 6), we adapted the background ranker to name queries by boosting the background ranker with Names-1-Train. We trained LambdaBoost with the setting M = 500, υ = 0.5, optimized on Names-1-Valid. Since the background ranker uses all of the 416 input features, in each boosting iteration, LambdaBoost in fact selects one existing feature in the background ranker and adjusts its weight. We trained LambdaSMART with M = 500, L = 20, υ = 0.5, optimized on Names-1-Valid.

We see that the results on the closed test set (Table 3) are quite different from the results on the open test set (Table 4). The in-domain ranker outperforms the background ranker on the closed test set, but underperforms significantly the background ranker on the open test set. The interpretation is that the training set and the closed test set are sampled from the same data set and are very similar, but the open test set is a very different data set, as described in Section 5.1. Similarly, on the closed test set, LambdaSMART outperforms LambdaBoost with a big margin due to its superior adaptation capacity; but on the open test set their performance difference is much smaller due to the instability of the trees in LambdaSMART, as we will investigate in detail later. Interestingly, model interpolation, though simple, leads to the two best rankers on the open test set. In particular, the 3-way interpolated ranker outperforms the two baseline rankers

significantly (i.e., p-value < 0.05 according to t-test) on both the open and closed test sets.

The second adaptation experiment involves data sets from several languages (Table 2). 2-layer LambdaRank baseline rankers were first built from Korean, English, Japanese, and Chinese training data and tested on Korean test sets (Tables 5 and 6). These baseline rankers then serve as in-domain ranker and background rankers for model adaptation. For model interpolation (Tables 7 and 8), Rows 1 to 4 are three 2-way interpolated rankers built by linearly interpolating
each of the three background rankers with the in-domain ranker, respectively. Row 4 is a 4-way interpolated ranker built by interpolating the in-domain ranker with the three background rankers. For LambdaBoost (Tables 9 and 10) and LambdaSMART (Tables 11 and 12), we used the same parameter settings as those in the name query experiments, and adapted the three background rankers, to the Korean training data, Kokr-1-Train.

The results in Tables 7 to 12 confirm what we learned in the name query experiments. There are three main conclusions. (1) Model interpolation is an effective method of ranking model adaptation. E.g., the 4-way interpolated ranker outperforms other ranker significantly. (2) LambdaSMART is the best performer on the closed test set, but its performance drops significantly on the open test set due to the instability of trees. (3) LambdaBoost does not use trees. So its modeling capacity is weaker than LambdaSMART (e.g., it always underperforms LambdaSMART significantly on the closed test sets), but it is more robust due to its linearity (e.g., it performs similarly to LambdaSMART on the open test set).

5.3 Robustness of Boosting Algorithms

This section investigates the robustness issue of the boosting algorithms in more detail. We compared LambdaSMART with different values of L (i.e., the number of leaf nodes), and with and without randomization. Our assumptions are (1) allowing more leaf nodes would lead to deeper trees, and as a result, would make the resulting ranking models less robust; and (2) injecting randomness into the basis function (i.e. regression tree) estimation procedure would improve the robustness of the trained models (Breiman, 2001; Friedman, 1999). In LambdaSMART, the randomness can be injected at different levels of tree construction. We found that the most effective method is to introduce the randomness at the node level (in Step 4 in Figure 3). Before each node split, a subsample of the training data and a subsample of the features are drawn randomly. (The sample rate is 0.7). Then, the two randomly selected subsamples, instead of the full samples, are used to determine the best split.

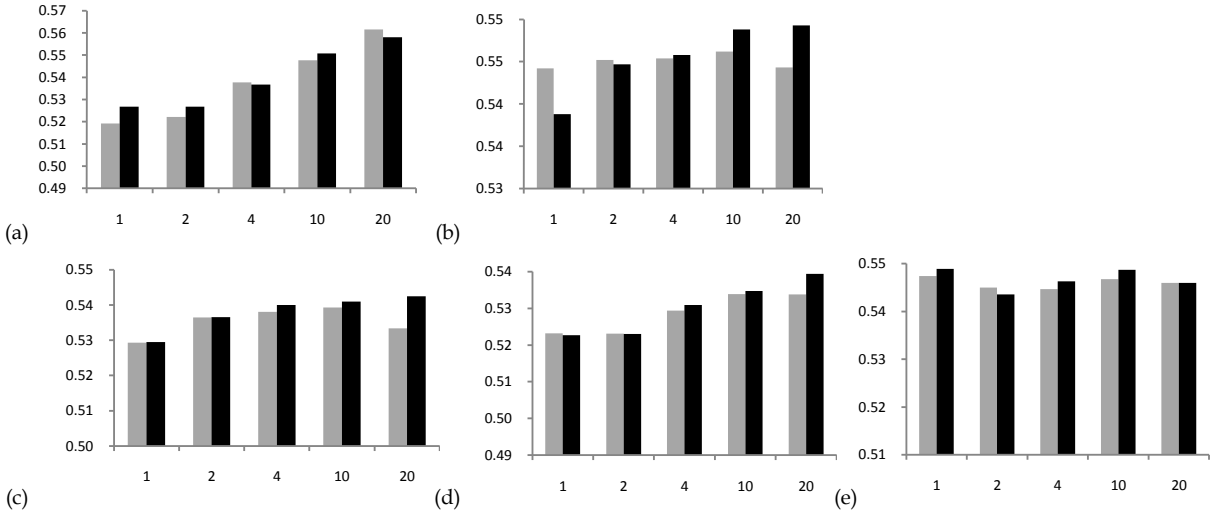

Figure 4. AveNDCG results (*y*-axis) of LambdaSMART with different values of *L* (*x*-axis), where *L*=1 is LambdaBoost; (a) and (b) are the results on closed and open tests using Names-1-Train as adaptation data, respectively; (d), (e) and (f) are the results on the Korean open test set, using background models trained on Web-En, Web-Ja, and Web-Cn data sets, respectively.

We first performed the experiments on name queries. The results on the closed and open test sets are shown in Figures 4 (a) and 4 (b), respectively. The results are consistent with our assumptions. There are three main observations. First, the gray bars in Figures 4 (a) and 4 (b) (boosting without randomization) show that on the closed test set, as expected, NDCG increases with the value of *L*, but the correlation does not hold on the open test set. Second, the black bars in these figures (boosting with randomization) show that in both closed and open test sets, NDCG increases with the value of *L*. Finally, comparing the gray bars with their corresponding black bars, we see that randomization consistently improves NDCG on the open test set, with a larger margin of gain for the boosting algorithms with deeper trees ($L > 5$).

These results are very encouraging. Randomization seems to work like a charm. Unfortunately, it does not work well enough to help the boosting algorithm beat model interpolation on the open test sets. Notice that all the LambdaSMART results reported in Section 5.2 use randomization with the same sampling rate of 0.7. We repeated the comparison in the cross-domain adaptation experiments. As shown in Figure 4, results in 4 (c) and 4 (d) are consistent with those on names queries in 4 (b). Results in 4 (f) show a visible performance drop from LambdaBoost to LambdaSMART with $L = 2$, indicating again the instability of trees.

6 Conclusions and Future Work

In this paper, we extend two classes of model adaptation methods (i.e., model interpolation and error-driven learning), which have been well studied in statistical language modeling for speech and natural language applications (e.g., Bacchiani et al., 2004; Bellegarda, 2004; Gao et al., 2006), to ranking models for Web search applications.

We have evaluated our methods on two adaptation experiments over a wide variety of datasets where the in-domain datasets bear different levels of similarities to their background datasets. We reach different conclusions from the results of the open and close tests, respectively. Our open test results show that in the cases where the in-domain data is dramatically different from the background data, model interpolation is very robust and outperforms the baseline and the error-driven learning methods significantly; whereas our close test results show that in the cases where the in-domain data is similar to the background data, the tree-based boosting algorithm (i.e. LambdaSMART) is the best performer, and achieves a significant improvement over the baselines. We also show that these different conclusions are largely due to the instability of the use of trees in the boosting algorithm. We thus explore several methods of improving the robustness of the algorithm, such as randomization, regularization, using shallow trees, with limited success. Of course, our experiments,

described in Section 5.3, only scratch the surface of what is possible. Robustness deserves more investigation and forms one area of our future work.

Another family of model adaptation methods that we have not studied in this paper is transfer learning, which has been well-studied in the machine learning community (e.g., Caruana, 1997; Marx et al., 2008). We leave it to future work.

To solve the issue of inadequate training data, in addition to model adaptation, researchers have also been exploring the use of implicit user feedback data (extracted from log files) for ranking model training (e.g., Joachims et al., 2005; Radlinski et al., 2008). Although such data is very noisy, it is of a much larger amount and is cheaper to obtain than human-labeled data. It will be interesting to apply the model adaptation methods described in this paper to adapt a ranker which is trained on a large amount of automatically extracted data to a relatively small amount of human-labeled data.

Abstract

This paper addresses the issue of extracting contexts and answers of questions from post discussion of online forums. We propose a novel and unified model by customizing the structural Support Vector Machine method. Our customization has several attractive properties: (1) it gives a comprehensive graphical representation of thread discussion. (2) It designs special inference algorithms instead of general-purpose ones. (3) It can be readily extended to different task preferences by varying loss functions. Experimental results on a real data set show that our methods are both promising and flexible.

1 Introduction

Recently, extracting questions, contexts and answers from post discussions of online forums incurs increasing academic attention (Cong et al., 2008; Ding et al., 2008). The extracted knowledge can be used either to enrich the knowledge base of community question answering (QA) services such as Yahoo! Answers or to augment the knowledge base of chatbot (Huang et al., 2007).

Figure 1 gives an example of a forum thread with questions, contexts and answers annotated. This thread contains *three posts* and *ten sentences*, among which *three questions* are discussed. The three questions are proposed in three sentences, S3, S5 and S6. The *context sentences* S1 and S2 provide contextual information for question sentence S3. Similarly, the *context sentence* S4 provides contextual information for question sentence S5 and S6. There are three question-context-answer triples in this example, $(S3) - (S1, S2) - (S8, S9)$, $(S5) - (S4) - (S10)$ and $(S6) - (S4) - (S10)$. As shown in the example, a forum question usually requires contextual information to complement its expression. For example, the question sentence S3 would be of incomplete meaning without the contexts S1 and S2, since the important keyword *pet friendly* would be lost.

Post1: <context id=1> **S1**: *Hi I am looking for a pet friendly hotel in Hong Kong because all of my family is going there for vacation.* **S2**: *my family has 2 sons and a dog.* </context> <question id=1> **S3**: *Is there any recommended hotel near Sheung Wan or Tsing Sha Tsui?* </question> <context id=2, 3> **S4**: *We also plan to go shopping in Causeway Bay.* </context> <question id=2> **S5**: *What's the traffic situation around those commercial areas?* </question> <question id=3> **S6**: *Is it necessary to take a taxi?* </question> **S7**: *Any information would be appreciated.*
Post2: <answer id=1> **S8**: *The Comfort Lodge near Kowloon Park allows pet as I know, and usually fits well within normal budgets.* **S9**: *It is also conveniently located, nearby the Kowloon railway station and subway.* </answer>
Post3: <answer id=2, 3> **S10**: *It's very crowd in those areas, so I recommend MTR in Causeway Bay because it is cheap to take you around.* </answer>

Figure 1: An example thread with three posts and ten sentences

The problem of extracting questions, contexts, and answers can be solved in two steps: (1) identify questions and then (2) extract contexts and answers for them. Since identifying questions from forum discussions is already well solved in (Cong et al., 2008), in this paper, we are focused on step (2) while assuming questions already identified.

Previously, Ding et al. (2008) employ general-purpose graphical models without any customizations to the specific extraction problem (step 2). In this paper, we improve the existing models in

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 514–523,
Singapore, 6-7 August 2009.

three aspects: *graphical representation*, *inference algorithm* and *loss function*.

Graphical representation. We propose a more comprehensive and unified graphical representation to model the thread for relational learning. Our graphical representation has two advantages over previous work (Ding et al., 2008): *unifying sentence relations* and *incorporating question interactions*.

Three types of relation should be considered for context and answer extraction: (a) relations between successive sentences (e.g., *context* sentence S2 occurs immediately before *question* sentence S3); (b) relations between *context* sentences and *answer* sentences (e.g., *context* S4 presents the phrase *Causeway Bay* linking to *answer* which is absent from *question* S6); and (c) relations between multiple labels for one sentence (e.g., one *question* sentence is unlikely to be the *answer* to another *question* although one sentence can serve as *contexts* for more than one *questions*). Our proposed graphical representation improves the modeling of the three types of sentence relation (Section 2.2).

Certain interactions exist among questions. For example, *question* sentences S5 and S6 interact by sharing *context* sentence S4. Our proposed graphical representation can naturally model the interactions. Previous work (Ding et al., 2008) performs the extraction of contexts and answers in multiple passes of the thread (with each pass corresponding to one question), which cannot address the interactions well. In comparison, our model performs the extraction in one pass of the thread.

Inference algorithm. Inference is usually a time-consuming process for structured prediction. We design special inference algorithms, instead of general-purpose inference algorithms used in previous works (Cong et al., 2008; Ding et al., 2008), by taking advantage of special properties of our task. Specifically, we utilize two special properties of thread structure to reduce the inference (time) cost. First, *context* sentences and *question* sentences usually occur in the same post while *answer* sentences can only occur in the following posts. With this properties, we can greatly reduce *context* (or *answer*) candidate sets of a question, which results in a significant decrease in inference cost (Section 3). Second, *context* candidate set is usually much smaller than the number of sentences in a thread. This property enables our proposal to have an exact and efficient inference (Section 4.1). Moreover, an approximate inference algorithm is also given (Section 4.2).

Loss function. In practice, different application settings usually imply different requirements for system performance. For example, we expect a higher recall for the purpose of archiving questions but a higher precision for the purpose of retrieving questions. A flexible framework should be able to cope with various requirements. We employ structural Support Vector Machine (SVM) model that could naturally incorporate different loss functions (Section 5).

We use a real data set to evaluate our approach to extracting contexts and answers of questions. The experimental results show both the effectiveness and the flexibility of our approach.

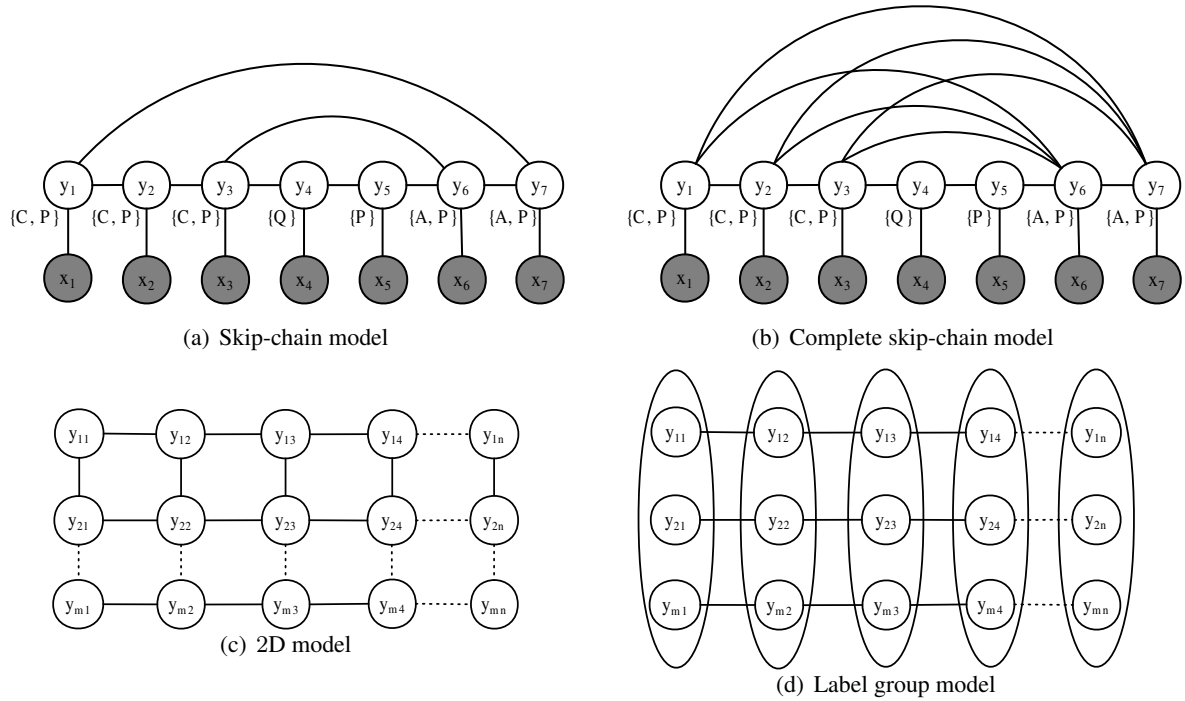
In the next section, we formalize the problem of context and answer extraction and introduce the structural model. In Sections 3, 4 and 5 we give the details of customizing structural model for our task. In Section 6, we evaluate our methods. In Section 7, we discuss the related work. Finally, we conclude this paper in Section 8.

2 Problem Statement

We first introduce our notations in Section 2.1 and then in Section 2.2 introduce how we model the problem of extracting contexts and answers for questions with a novel form of graphical representation. In Section 2.3 we introduce the structured model based on the new representation.

2.1 Notations

Assuming that a given thread contains p posts $\{p_1, \ldots, p_p\}$, which are authored by a set of users $\{u_1, \ldots, u_p\}$. The p posts can be further segmented into n sentences $\mathbf{x} = \{x_1, \ldots, x_n\}$. Among the n sentences, m *question* sentences $\mathbf{q} = \{x_{q_1}, \ldots, x_{q_m}\}$ have been identified. Our task is to identify the *context* sentences and the *answer* sentences for those m question sentences. More formally, we use four types of label $\{C, A, Q, P\}$ to stand for context, answer, question and plain labels. Then, our task is to predict an $m \times n$ label matrix $\mathbf{y} = (y_{ij})_{1 \le i \le m, 1 \le j \le n}$, except m elements $\{y_{1,q_1}, \ldots, y_{m,q_m}\}$ which correspond to (known) *question* labels. The element y_{ij} in label matrix $\mathbf{y}$ represents the role that the jth sentence plays for the ith question. We denote the ith row and jth column of the label matrix $\mathbf{y}$ by $\mathbf{y}_{i\cdot}$ and $\mathbf{y}_{\cdot j}$.



(a) Skip-chain model

(b) Complete skip-chain model

(c) 2D model

(d) Label group model

Figure 2: Structured models

2.2 Graphical Representation

Recently, Ding et al. (2008) use skip-chain and 2D Conditional Random Fields (CRFs) (Lafferty et al., 2001) to perform the relational learning for context and answer extraction. The skip-chain CRFs (Sutton and McCallum, 2004; Galley, 2006) model the long distance dependency between context and answer sentences and the 2D CRFs (Zhu et al., 2005) model the dependency between contiguous questions. The graphical representation of those two models are shown in Figures 2(a) and 2(c), respectively. Those two CRFs are both extensions of the linear chain CRFs for the sake of powerful relational learning. However, directly using the skip-chain and 2D CRFs without any customization has obvious disadvantages: (a) the skip-chain model does not model the *dependency between answer sentence and multiple context sentences*; and (b) the 2D model does not model the *dependency between non-contiguous questions*.

To better model the problem of extracting contexts and answers of questions, we propose two more comprehensive models, *complete skip-chain model* and *label group model* to improve the capability of the two previous models. These two models are shown in Figures 2(b) and 2(d).

In Figures 2(a) and 2(b), each label node is annotated with its allowed labels and the labels C, A, Q and P stand for context, answer, question and plain sentence labels, respectively. Note that the complete skip-chain model *completely* links each two context and answer candidates and the label group model combines the labels of one sentence into one *label group*.

2.3 Structured Model

Following the standard machine learning setup, we denote the input and output spaces by $\mathcal{X}$ and $\mathcal{Y}$, then formulate our task as learning a hypothesis function $h : \mathcal{X} \rightarrow \mathcal{Y}$ to predict a $\mathbf{y}$ when given $\mathbf{x}$. In this setup, $\mathbf{x}$ represents a thread of n sentences and m identified questions. $\mathbf{y}$ represents the $m \times n$ label matrix to be predicted.

Given a set of training examples, $S = \{(\mathbf{x}^{(i)}, \mathbf{y}^{(i)}) \in \mathcal{X} \times \mathcal{Y} : i = 1, \ldots, N\}$, we restrict ourselves to the supervised learning scenario. We focus on hypothesis functions that take the form $h(\mathbf{x}; \mathbf{w}) = \arg\max_{\mathbf{y} \in \mathcal{Y}} \mathcal{F}(\mathbf{x}, \mathbf{y}; \mathbf{w})$ with discriminant function $\mathcal{F} : \mathcal{X} \times \mathcal{Y} \rightarrow \mathcal{R}$ where $\mathcal{F}(\mathbf{x}, \mathbf{y}; \mathbf{w}) = \mathbf{w}^T \Psi(\mathbf{x}, \mathbf{y})$. As will be introduced in Section 4, we employ structural SVMs (Joachims et al., 2009) to find the optimal parameters $\mathbf{w}$. The structural SVMs have several competitive properties as CRFs. First, it follows from the maximum margin strategy, which has been shown with competitive or even better

performance (Tsochantaridis et al., 2005; Nguyen and Guo, 2007). Second, it allows flexible choices of loss functions to users. Moreover, in general, it has theoretically proved convergence in polynomial time (Joachims et al., 2009).

To use structural SVMs in relational learning, one needs to customize three steps according to specific tasks. The three steps are (a) *definition of joint feature mapping* for encoding relations, (b) *algorithm of finding the most violated constraint (inference)* for efficient trainings and (c) *definition of loss function* for flexible uses.

In the following Sections 3, 4 and 5, we describe the customizations of the three steps for our context and answer extraction task, respectively.

3 Encoding Relations

We use a joint feature mapping to model the relations between sentences in a thread. For context and answer extraction, the joint feature mapping can be defined as follows,

$$\Psi(\mathbf{x}, \mathbf{y}) = \begin{bmatrix} \Psi_n(\mathbf{x}, \mathbf{y}) \\ \Psi_h(\mathbf{x}, \mathbf{y}) \\ \Psi_v(\mathbf{x}, \mathbf{y}) \end{bmatrix},$$

where the sub-mappings $\Psi_n(\mathbf{x}, \mathbf{y})$, $\Psi_h(\mathbf{x}, \mathbf{y})$, and $\Psi_v(\mathbf{x}, \mathbf{y})$ encode three types of feature mappings, *node features*, *edge features* and *label group features*. The node features provide the basic information for the output labels. The edge features consist of the sequential edge features and skip-chain edge features for successive label dependencies. The label group features encode the relations within each label group.

Before giving the detail definitions of the sub-mappings, we first introduce *the context and answer candidate sets*, which will be used for the definitions and inferences. Each row of the label matrix $\mathbf{y}$ corresponds to one question. Assuming that the ith row $\mathbf{y}_{i\cdot}$ corresponds to the question with sentence index q_i, we thus have two candidate sets of contexts and answers for this question denoted by $\mathcal{C}$ and $\mathcal{A}$, respectively. We denote the post indices and the author indices for the n sentences as $\mathbf{p} = (p_1, \ldots, p_n)$ and $\mathbf{u} = (u_1, \ldots, u_n)$. Then, we can formally define the two candidate sets for the $\mathbf{y}_{i\cdot}$ as

$$\mathcal{C} = \left\{ c_j \;\middle|\; \underbrace{p_{c_j} = p_{q_i}}_{\text{In Question Post}}, \quad \underbrace{c_j \neq q_i}_{\text{Not Question Sentence}} \right\},$$

$$\mathcal{A} = \left\{ a_j \;\middle|\; \underbrace{p_{a_j} > p_{q_i}}_{\text{After Question Post}}, \quad \underbrace{u_{a_j} \neq u_{q_i}}_{\text{Not by the Same User}} \right\}.$$

In the following, we describe formally about the definitions of the three feature sub-mappings.

The node feature mapping $\Psi_n(\mathbf{x}, \mathbf{y})$ encodes the relations between sentence and label pairs, we define it as follows,

$$\Psi_n(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{m} \sum_{j=1}^{n} \psi_n(x_j, y_{ij}),$$

where $\psi_n(x_j, y_{ij})$ is a feature mapping for a given sentence and a label. It can be formally defined as follows,

$$\psi_n(x_j, y_{ij}) = \Lambda(y_{ij}) \otimes \phi_{q_i}(x_j), \qquad (1)$$

where $\otimes$ denotes a tensor product, $\phi_{q_i}(x_j)$ and $\Lambda(y_{ij})$ denote two vectors. $\phi_{q_i}(x_j)$ contains basic information for output label. $\Lambda(y_{ij})$ is a $0/1$ vector defined as

$$\Lambda(y_{ij}) = [\lambda_C(y_{ij}), \lambda_A(y_{ij}), \lambda_P(y_{ij})]^T,$$

where $\lambda_C(y_{ij})$ equal to one if $y_{ij} = C$, otherwise zero. The $\lambda_A(y_{ij})$ and $\lambda_P(y_{ij})$ are similarly defined. Thus, for example, writing out $\psi_n(x_j, y_{ij})$ for $y_{ij} = C$ one gets,

$$\psi_n(x_j, y_{ij}) = \begin{pmatrix} \phi_{q_i}(x_j) \\ \mathbf{0} \\ \mathbf{0} \end{pmatrix} \begin{matrix} \leftarrow \text{ context} \\ \leftarrow \text{ answer} \\ \leftarrow \text{ plain} \end{matrix}.$$

Note that the node feature mapping does not incorporate the relations between sentences.

The edge feature mapping $\Psi_h(\mathbf{x}, \mathbf{y})$ is used to incorporate two types of relation, the relation between successive sentences and the relation between context and answer sentences. It can be defined as follows,

$$\Psi_h(\mathbf{x}, \mathbf{y}) = \begin{bmatrix} \Psi_{hn}(\mathbf{x}, \mathbf{y}) \\ \Psi_{hc}(\mathbf{x}, \mathbf{y}) \end{bmatrix},$$

where $\Psi_{hn}(\mathbf{x}, \mathbf{y})$ and $\Psi_{hc}(\mathbf{x}, \mathbf{y})$ denote the two types of feature mappings corresponding to sequential edges and skip-chain edges, respectively. Their formal definitions are given as follows,

$$\Psi_{hn}(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{m} \sum_{j=1}^{n-1} \psi_{hn}(x_j, x_{j+1}, y_{ij}, y_{i,j+1}),$$

Descriptions	Dimensions

$$\Psi_{hc}(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{m} \underbrace{\sum_{j \in \mathcal{C}} \sum_{k \in \mathcal{A}}}_{\text{Complete Edges}} \psi_{hc}(x_j, x_k, y_{ij}, y_{ik}),$$

$$\begin{aligned} &\psi_{hn}(x_j, x_{j+1}, y_{ij}, y_{i,j+1}) \\ &= \Lambda(y_{ij}, y_{i,j+1}) \otimes \phi_{hn}(x_j, x_{j+1}, y_{ij}, y_{i,j+1}), \end{aligned}$$

$$\begin{aligned} &\psi_{hc}(x_j, x_k, y_{ij}, y_{ik}) \\ &= \Lambda(y_{ij}, y_{ik}) \otimes \psi_{hc}(x_j, x_k, y_{ij}, y_{ik}) \end{aligned}$$

where $\Lambda(y_{ij}, y_{ik})$ is a 16-dimensional vector. It indicates all 4×4 pairwise transition patterns of four types of labels, the context, answer, question and plain. Note that apart from previous work (Ding et al., 2008) we use *complete skip-chain (context-answer) edges* in $\Psi_{hc}(\mathbf{x}, \mathbf{y})$.

The label group feature mapping $\Psi_v(\mathbf{x}, \mathbf{y})$ is defined as follows,

$$\Psi_v(\mathbf{x}, \mathbf{y}) = \sum_{j=1}^{n} \psi_v(x_j, \mathbf{y}_{\cdot j}),$$

where $\psi_v(x_j, \mathbf{y}_{\cdot j})$ encodes each label group pattern into a vector.

The detail descriptions and vector dimensions of the used features are listed in Table 1.

4 Structural SVMs and Inference

Given a training set $S = \{(\mathbf{x}^{(i)}, \mathbf{y}^{(i)}) \in \mathcal{X} \times \mathcal{Y} : i = 1, \ldots, N\}$, we use the structural SVMs (Taskar et al., 2003; Tsochantaridis et al., 2005; Joachims et al., 2009) formulation, as shown in Optimization Problem 1 (OP1), to learn a weight vector $\mathbf{w}$.

OP 1 *(1-Slack Structural SVM)*

$$\begin{aligned} \min_{\mathbf{w}, \xi \geq 0} \quad & \frac{1}{2}||\mathbf{w}||^2 + \frac{C}{N}\xi \\ \textit{s.t.} \quad & \forall(\bar{\mathbf{y}}^{(1)}, \ldots, \bar{\mathbf{y}}^{(N)}) \in \mathcal{Y}^n, \\ & \frac{1}{N}\mathbf{w}^T \sum_{i=1}^{N} [\Psi(\mathbf{x}^{(i)}, \mathbf{y}^{(i)}) - \Psi(\mathbf{x}^{(i)}, \bar{\mathbf{y}}^{(i)})] \\ & \geq \frac{1}{N} \sum_{i=1}^{N} \Delta(\mathbf{y}^{(i)}, \bar{\mathbf{y}}^{(i)}) - \xi, \end{aligned}$$

where ξ is a slack variable, $\Psi(\mathbf{x}, \mathbf{y})$ is the joint feature mapping and $\Delta(\mathbf{y}, \bar{\mathbf{y}})$ is the loss function that measures the loss caused by the difference between $\mathbf{y}$ and $\bar{\mathbf{y}}$. Though OP1 is already a quadratic optimization problem, directly using off-the-shelf quadratic optimization solver will fail, due to the large number of constraints. Instead, a cutting plane algorithm is used to efficiently solve this problem. For the details of the

5: **end for**
6: $\mathcal{C}_s^* = \arg\max_{\mathcal{C}_s \subseteq \mathcal{C}_i} R(\mathcal{C}_s)$
7: $\bar{\mathbf{y}}_{i.}^* = \bar{\mathbf{y}}_{i.}(\mathcal{C}_s^*)$
8: **end for**
9: **return** $\bar{\mathbf{y}}^*$

structural SVMs, please refer to (Tsochantaridis et al., 2005; Joachims et al., 2009).

The most essential and time-consuming step in structural SVMs is *finding the most violated constraint*, which is equivalent to solve

$$\arg\max_{\mathbf{y} \in \mathcal{Y}} \mathbf{w}^T \Psi(\mathbf{x}^{(i)}, \mathbf{y}) + \Delta(\mathbf{y}^{(i)}, \mathbf{y}). \quad (2)$$

Without the ability to efficiently find the most violated constraint, the cutting plane algorithm is not tractable.

In the next sub-sections, we introduce the algorithms for finding the most violated constraint, also called loss-augmented inference. The algorithms are essential for the success of customizing structural SVMs to our problem.

4.1 Exact Inference

The exact inference algorithm is designed for a simplified model with two sub-mappings Ψ_n and Ψ_h, except Ψ_v.

One naive approach to finding the most violated constraint for the simplified model is to enumerate all the $2^{|\mathcal{C}|+|\mathcal{A}|}$ cases for each row of the label matrix. However, it would be intractable for large candidate sets.

An important property is that the context candidate set is usually much smaller than the whole number of sentences in a thread. This property enables us to design efficient and exact inference algorithm by transforming from the original graph representation in Figure 2 to the graphs in Figure 3. This graph transform merges all the nodes in the context candidate set $\mathcal{C}$ to one node with $2^{|\mathcal{C}|}$ possible labels.

We design an exact inference algorithm in Algorithm 1 based on the graph in Figure 3(c). The algorithm can be summarized in three steps: (1) enumerate all the $2^{|\mathcal{C}|}$ possible labels[1] for the merged node (line 3). (2) For each given label of the merged node, perform the Viterbi algorithm (Rabiner, 1989) on the decomposed graph (line 4) and store the Viterbi algorithm outputs in R and $\hat{\mathbf{y}}_{i.}$. (3) From the $2^{|\mathcal{C}|}$ Viterbi algorithm outputs, select the one with highest score as the output (lines 6 and 7).

The use of the Viterbi algorithm is assured by the fact that there exists certain equivalence between the decomposed graph (Figure 3(c)) and a linear chain. By fixing the the label of the merged node, we could remove the dashed edges in the decomposed graph and regard the rest graph as a linear chain, which results in the Viterbi decoding.

4.2 Approximate Inference

The exact inference cannot handle the complete model with three sub-mappings, Ψ_n, Ψ_h, and Ψ_v, since the label group defeats the graph transform in Figure 3. Thus, we design two approximate algorithms by employing *undergenerating* and *overgenerating* approaches (Finley and Joachims, 2008).

First, we develop an *undergenerating* local greedy search algorithm shown in Algorithm 2. In the algorithm, there are two loops, inner and outer loops. The outer loop terminates when no labels change (steps 3-11). The inner loop enumerates the whole label matrix and greedily determines each label (step 7) by maximizing the Equation (2). Since the whole algorithm terminates only if

[1] Since the merged node is from context candidate set $\mathcal{C}$, enumerating its label is equivalent to enumerating subsets $\mathcal{C}_s$ of the candidate set $\mathcal{C}$

Algorithm 2 Greedy Inference Algorithm

Input: $\mathbf{w}$, $\mathbf{x}$, $\mathbf{y}$
initialize solution: $\bar{\mathbf{y}} \leftarrow \mathbf{y}_0$
repeat
  $\mathbf{y}' \leftarrow \bar{\mathbf{y}}$
  for $i \in \{1, \ldots, m\}$ **do**
    for $j \in \{1, \ldots, n\}$ **do**
      $\bar{y}^*_{ij} \leftarrow \arg\max_{\bar{y}_{ij}} \mathbf{w}^T \Psi(\mathbf{x}, \bar{\mathbf{y}}) + \triangle(\mathbf{y}, \bar{\mathbf{y}})$
      $\bar{y}_{ij} \leftarrow \bar{y}^*_{ij}$
    end for
  end for
until $\bar{\mathbf{y}} = \mathbf{y}'$
$\bar{\mathbf{y}}^* \leftarrow \bar{\mathbf{y}}$
return $\bar{\mathbf{y}}^*$

the label matrix does not change during the last outer loop. This indicates that at least a local optimal solution is obtained.

Second, an *overgenerating* method can be designed by using linear programming relaxation (Finley and Joachims, 2008). To save the space, we skip the details of this algorithm here.

5 Loss Functions

Structural SVMs allow users to customize the loss function $\triangle : \mathcal{Y} \times \mathcal{Y} \rightarrow \mathcal{R}$ according to different system requirements. In this section, we introduce the loss functions used in our work.

Basic loss function. The simplest way to quantify the prediction quality is counting the number of wrongly predicted labels. Formally,

$$\triangle_b(\mathbf{y}, \bar{\mathbf{y}}) = \sum_{i=1}^{m} \sum_{j=1}^{n} I[y_{ij} \neq \bar{y}_{ij}], \qquad (3)$$

where $I[.]$ is an indicative function that equals to one if the condition holds and zero otherwise.

Recall-vs-precision loss function. In practice, we may place different emphasis on recall and precision according to application settings. We could include this preference into the model by defining the following loss function,

$$\begin{aligned} \triangle_p(\mathbf{y}, \bar{\mathbf{y}}) \quad = \quad & \sum_{i=1}^{m} \sum_{j=1}^{n} I[y_{ij} \neq P, \bar{y}_{ij} = P] \cdot c_r \\ & + I[y_{ij} = P, \bar{y}_{ij} \neq P] \cdot c_p. \end{aligned} \qquad (4)$$

This function penalizes the wrong prediction decreasing recall and that decreasing precision with two weights c_r and c_p respectively. Specifically, we denote the loss function with $c_p/c_r = 2$ and that with $c_r/c_p = 2$ by $\triangle^p_p$ and $\triangle^r_p$, respectively.

Various types of loss function can be defined in a similar fashion. To save the space, we skip the definitions of other loss functions and only use the above two types of loss functions to show the flexibility of our approach.

Items in the data set	#items
Thread	515
Post	2,035
Sentence	8,500
question annotation	1,407
context annotation	1,962
answer annotation	4,652
plain annotation	18,198

Table 2: The data statistics

6 Experiments

6.1 Experimental Setup

Corpus. We made use of the same data set as introduced in (Cong et al., 2008; Ding et al., 2008). Specifically, the data set includes about 591 threads from the forum TripAdvisor[2]. Each sentence in the threads is tagged with the labels 'question', 'context', 'answer', or 'plain' by two annotators. We removed 76 threads that have no question sentences or more than 40 sentences and 6 questions. The remaining 515 forum threads form our data set.

Table 2 gives the statistics on the data set. On average, each thread contains 3.95 posts and 2.73 questions, and each question has 1.39 context sentences and 3.31 answer sentences. Note that the number of annotations is much larger than the number of sentences because one sentence can be annotated with multiple labels.

Experimental Details. In all the experiments, we made use of linear models for the sake of computational efficiency. As a preprocessing step, we normalized the value of each feature value into the interval $[0, 1]$ and then followed the heuristic used in SVM-light (Joachims, 1998) to set C to $1/||x||^2$, where $||x||$ is the average length of input samples (in our case, sentences). The tolerance parameter ϵ was set to 0.1 (the value also used in (Cai

[2]TripAdvisor (`http://www.tripadvisor.com/ForumHome`) is one of the most popular travel forums

and Hofmann, 2004)) in all the runs of the experiments.

Evaluation. We calculated the standard precision (P), recall (R) and F_1-score (F_1) for both tasks (context extraction and answer extraction). All the experimental results were obtained through 5-fold cross validation.

6.2 Baseline Methods

We employed binary SVMs (B-SVM), multiclass SVMs (M-SVM), and C4.5 (Quinlan, 1993) as our baseline methods:

B-SVM. We trained two binary SVMs for context extraction (context vs. non-context) and answer extraction (answer vs. non-answer), respectively. We used the feature mapping $\phi_{q_i}(x_j)$ defined in Equation (1) while training the binary SVM models.

M-SVM. We extended the binary SVMs by training multiclass SVMs for three category labels (*context*, *answer*, *plain*).

C4.5. This decision tree algorithm solved the same classification problem as binary SVMs and made use of the same set of features.

Method	$\triangle_b$	P (%)	R (%)	F_1 (%)
Context Extraction				
C4.5	–	74.2	68.7	71.2
B-SVM	–	78.3	72.2	74.9
M-SVM	–	68.0	77.6	72.1
S-SVM	8.86	75.6	71.7	73.4

S-SVM-HCV	**7.98**	65.1	61.2	**63.0**

Table 3: The effectiveness of our approach

6.3 Modeling Sentence Relations and Question Interactions

We demonstrate in Table 3 that our approach can make use of the three types of relation among sentences well to boost the performance.

In Table 3, S-SVM represents the structural SVMs only using the node features $\Psi_n(\mathbf{x}, \mathbf{y})$. The suffixes *H*, *C*, and *V* denote the models using *horizontal sequential edges*, *complete skip-chain edges* and *vertical label groups*, respectively. The suffixes *C** and *V** denote the models using *incomplete skip-chain edges* and *vertical sequential edges* proposed in (Ding et al., 2008), as shown in Figures 2(a) and 2(c). All the structural SVMs were trained using basic loss function Δ_b in Equation (3). From Table 3, we can observe the following advantages of our approaches.

Overall improvement. Our structural approach steadily improves the extraction as more types of relation (corresponding to more types of edge) are included. The best results obtained by using the three types of relation together improve the baseline methods binary SVMs by about 6% and 20% in terms of F_1 values for context extraction and answer extraction, respectively.

The usefulness of relations. The relations encoded by horizontal sequential edges and label groups are useful for both context extraction and answer extraction. The relation encoded by complete skip-chain edges is useful for answer extraction. The complete skip-chain edges not only avoid preprocessing but also boost the performance when compared with the preprocessed skip-chain edges. The label groups improve the vertical sequential edges.

Interactions among questions. The interactions encoded by label groups are especially useful. We conducted significance tests (sign test) on the experimental results. The test result shows that S-SVM-HCV outperforms all the other methods without vertical edges statistically significantly (p-value < 0.01). Our proposed graphical representation in Figure 2(d) eases us to model the complex interactions. In comparison, the 2D model in Figure 2(c) used in previous work (Ding et al., 2008) can only model the interaction between adjacent questions.

6.4 Loss Function Results

We report in Table 4 the comparison between structural SVMs using different loss functions. Note that Δ_p^p prefers precision and Δ_p^r prefers recall. From Table 4, we can observe that the experimental results also exhibit this kind of system

Method	P (%)	R (%)	F_1 (%)
Context Extraction			
S-SVM-HCV-$\triangle_b$	79.7	80.2	79.9
S-SVM-HCV-$\triangle_p^p$	**82.0**	70.3	75.6
S-SVM-HCV-$\triangle_p^r$	75.7	**84.2**	79.7
Answer Extraction			
S-SVM-HCV-$\triangle_b$	65.1	61.2	63.0
S-SVM-HCV-$\triangle_p^p$	**71.8**	52.2	60.2
S-SVM-HCV-$\triangle_p^r$	61.8	**66.1**	63.7

Table 4: The use of different loss functions

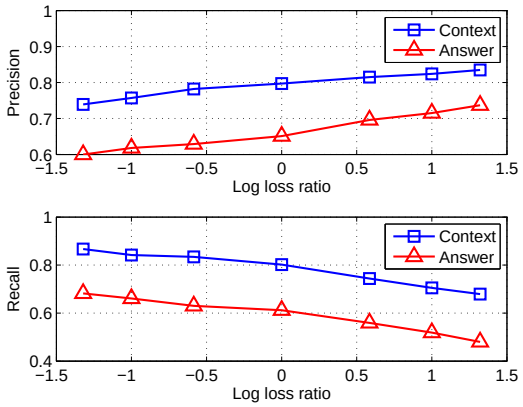

Figure 4: Balancing between precision and recall

preference. Moreover, we further demonstrate the capability of the loss function Δ_p in Figure 4. The curves are achieved by varying the ratio between two parameters c_p/c_r in Equation (4). The curves confirm our intuition: when $\log(c_p/c_r)$ becomes larger, the precisions increase but the recalls decrease and vice versa.

7 Related work

Previous work on extracting questions, answers and contexts is most related with our work. Cong et al. (2008) proposed a supervised approach for question detection and an unsupervised approach for answer detection without considering contexts. Ding et al. (2008) used CRFs to detect contexts and answers of questions from forum threads.

Some researches on summarizing discussion threads and emails are related to our work, too. Zhou and Hovy (2005) segmented internet relay chat, clustered segments into sub-topics, and identified responding segments of the first segment in each sub-topic by assuming the first segment to be focus. In (Nenkova and Bagga, 2003; Wan and McKeown, 2004; Rambow et al., 2004), email summaries were organized by extracting overview sentences as discussion issues. The work (Shrestha and McKeown, 2004) used RIPPER as a classifier to detect interrogative questions and their answers then used the resulting question and answer pairs as summaries. We also note the existing work on extracting knowledge from discussion threads. Huang et al. (2007) used SVMs to extract input-reply pairs from forums for chatbot knowledge. Feng et al. (2006) implemented a discussion-bot which used cosine similarity to match students' query with reply posts from an annotated corpus of archived threaded discussions.

Moreover, extensive researches have been done within the area of question answering (Burger et al., 2006; Jeon et al., 2005; Harabagiu and Hickl, 2006; Cui et al., 2005; Dang et al., 2006). They mainly focused on using sophisticated linguistic analysis to construct answer from a large document collection.

8 Conclusion and Future Work

We have proposed a new form of graphical representation for modeling the problem of extracting contexts and answers of questions from online forums and then customized structural SVM approach to solve it.

The proposed graphical representation is able to naturally express three types of relation among sentences: relation between successive sentences, relation between context sentences and answer sentences, and relation between multiple labels for one sentence. The representation also enables us to address interactions among questions. We also developed the inference algorithms for the structural SVM model by exploiting the special structure of thread discussions.

Experimental results on a real data set show that our approach significantly improves the baseline methods by effectively utilizing various types of relation among sentences.

Our future work includes: (a) to summarize threads and represent the forum threads in question-context-answer triple, which will change the organization of online forums; and (b) to enhance QA services (e.g., Yahoo! Answers) by the contents extracted from online forums.

Abstract

User clicks on a URL in response to a query are extremely useful predictors of the URL's relevance to that query. Exact match click features tend to suffer from severe data sparsity issues in web ranking. Such sparsity is particularly pronounced for new URLs or long queries where each distinct query-url pair will rarely occur. To remedy this, we present a set of straightforward yet informative query-url *n*-gram features that allows for generalization of limited user click data to large amounts of unseen query-url pairs. The method is motivated by techniques leveraged in the NLP community for dealing with unseen words. We find that there are interesting regularities across queries and their preferred destination URLs; for example, queries containing "form" tend to lead to clicks on URLs containing "pdf". We evaluate our set of new query-url features on a web search ranking task and obtain improvements that are statistically significant at a *p*-value < 0.0001 level over a strong baseline with exact match clickthrough features.

1 Introduction

Clickthrough logs record user click behaviors, which are a critical source for improving search relevance (Bilenko and White, 2008; Radlinski et al., 2007; Agichtein and Zheng, 2006; Lu et al. 2006). Previous work (Agichtein et al., 2006) demonstrated that clickthrough features (e.g., IsNextClicked and IsPreviousClicked) can lead to substantial improvements in relevance. Such features summarize query-specific user interactions on a search engine. One commonly used clickthrough feature is generated based on the following observation: if a URL receives a large number of first and last clicks across many user sessions, then it indicates that this URL might be a strongly preferred destination of a query. For example, when a user searches for "yahoo", they tend to only click on the URL www.yahoo.com rather than other alternatives. This results in www.yahoo.com being the first and last clicked URL for the query. We refer to such behavior as being navigational clicks (**NavClicks**). Features that use exact query and URL string matches (e.g., NavClick, IsNextClicked and IsPreviousClicked) are referred to as exact match features (**ExactM**) for the remainder of this paper.

The coverage of ExactM features is sparse, especially for long queries and new URLs. Many long queries are either unique or very low frequency. Hence, the improvements from ExactM features are limited to the more popular queries. In addition, ExactM features tend to be weighted heavily in the ranking of results when they are available. This introduces a bias where the ranking models tend to strongly favor older URLs over new URLs even when the latter otherwise appear to be more relevant.

By inspecting the clickthrough logs, we observed that unseen query-url pairs are often composed of informative previously observed subsequences. Specifically, we saw that query *n*-grams can be correlated with sequences of URL *n*-grams. For example, we find that there are interesting regularities across queries and URLs, such as queries containing "form" tending to lead to clicks on URLs containing "pdf". This strongly motivates the adoption of an approach similar to the Natural Language Processing (**NLP**) technique of using *n*-grams to deal with unseen words. For example, part-of-speech tagging (Brants, 2000) and parsing (Klein and Manning, 2003) both require dealing with unknown words. By using *n*-gram substrings, novel items can be dealt with using any informative substrings they contain that were actually observed in the training data.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 524–533,
Singapore, 6-7 August 2009.

The remainder of the paper is organized as follows. In Section 2, we introduce our overall methodology. Section 2.1 presents a data mining method for building a query-url *n*-gram dictionary, Section 2.2 describes the new ranking features in detail. In section 3, we present our experimental results. Section 4 discusses related work, and Section 5 summarizes the contribution of this work.

2 Methodology

This section describes the detailed methodology used in generating the query-url *n*-gram features. Our features require association scores to be previously calculated, and, hence, we first introduce a data mining approach that is used to build an association dictionary in Section 2.1. Then, we present the procedure used to generate the query-url *n*-gram features that use the dictionary in Section 2.2.

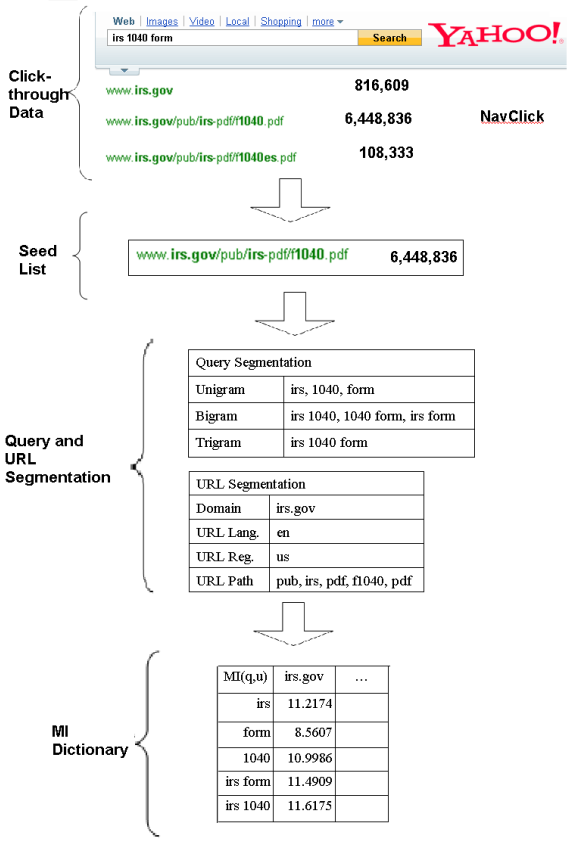

Figure 1: Steps to build a query-url *n*-gram dictionary

2.1 Data Mining on a Query-URL *N*-gram Dictionary

The steps involved in building the dictionary are shown in Figure 1. We first collect seed query-url pairs from clickthrough data based on NavClicks. The queries and URLs from the collected pairs are tokenized and converted into a collection of paired query-url *n*-grams. For each pair, we calculate the mutual information of the query *n*-gram and its corresponding URL *n*-gram. For our experiment, we collect a total of more than 15M seed pairs and 0.5B query-url *n*-gram pairs using six months of query log data. The details are described in the following sections.

2.1.1 Seed List

We identify the seed list based on characteristic user click behavior. Given a query, we select the URL with the most NavClicks as compared to other URLs returned. During data collection, the rank positions of the top 5 URLs were shuffled to avoid the position bias. We aggregate NavClicks for a URL occurring in these positions in order to both obtain more click data and to avoid the position bias issue discussed in Dupret and Piwowarski (2008) and Craswell et al. (2008).

For example, in Figure 1, the numbers of NavClicks for the top three URLs are shown. The URL www.irs.gov/pub/irs-pdf/f1040.pdf receives the largest number of NavClicks, and, therefore, it is used to create the query-url pair:

[irs 1040 form, www.irs.gov/pub/irs-pdf/f1040.pdf]

2.1.2 Query and URL Segmentation

We segment the seed pairs to *n*-gram pairs in order to increase the coverage beyond that of ExactM click features. Within NLP, *n*-grams are typically extracted such that words that are adjacent in the original sequence are also adjacent in the extracted *n*-grams. Furthermore, we attempt to achieve additional generalization by using skip *n*-grams (Lin and Och, 2004). This means we not only extract *n*-grams for adjacent terms but also for sequences that leave out intermediate terms. This is motivated by the observation that the semantics of user queries is often preserved even when some intermediate terms are removed. The details of the segmentation methods are described below.

2.1.2.1 Query Segmentation

Prior to query segmentation, we normalize raw queries by replacing punctuations with spaces. Queries are then segmented into a sequence of

space delimited tokens. From these, we extract all possible query *n*-grams and skip *n*-grams for *n* smaller than or equal to three (i.e., all unigrams, bigrams, and trigrams). For example, given the sequence "irs 1040 form" the adjacent bigrams would be "irs 1040" and "1040 form". With skip *n*-grams we also extract "irs form" as shown in Table 1. We do not use *n*-grams longer than 3 in order to avoid problems with overfitting. We will refer to this segmentation method as **Affix Segmentation**.

Table 1: An Example of Affix Segmentation

N-gram	Affix Segmentation
Unigram	irs, 1040, form
Bigram	irs 1040, 1040 form, irs form
Trigram	irs 1040 form

2.1.2.2 URL Segmentation

As shown in Table 2, after the queries are segmented, URLs are categorized into four groups: domain, URL language, URL region and URL path. In general, a URL is delimited by punctuation characters such as "?", "." "/", and "=".

Table 2: An Example of URL Segmentation

URL Groups	Example
Domain	irs.gov
URL language	en
URL region	us
URL path	pub, irs, pdf, f1040, pdf

The domain group includes one domain token, for example, irs.gov. Although domains could be divided into multiple *n*-grams, we treat them as a single unit, with the exception of encoded language and region information.

The language and region groups are based on the language or region part of the URL *n*-grams such as the suffixes ".en" and ".de". The language and region of a URL *n*-gram are identified by a table look-up method. The table is created based on the information available at en.wikipedia.org/wiki/List_of_ISO_639-1_codes and en.wikipedia.org/wiki/ISO_3166. When there is no clear language or region URL *n*-gram, we use English (en) as the default language and United States (us) as the default region.

2.1.3 Calculation of Mutual Information

After query and URL *n*-grams are extracted, we calculate mutual information (Gale and Church, 1991) to determine the degree of association between the *n*-grams. The definition of query-url *n*-gram mutual information (MI) is given in Equation 1.

$$\mathrm{MI}(q,u) = \log_2 \frac{\mathrm{Freq}(q,u)}{\mathrm{Freq}(q)\,\mathrm{Freq}(u)} \quad (1)$$

Here q corresponds to a query *n*-gram and u corresponds to a URL *n*-gram. Freq (q) is the count of q in the seed list normalized by the total number of q. Freq (u) is the count of u normalized by the total number of u. Freq (q, u) is the count of q and u that co-occurred in a full query-url pair normalized by the total number of q and u. A pair will be assigned to a MI score of zero if the items occur together no more than expected by chance, under the assumption that the two items are statistically independent. When a pair occurs more than is expected by chance, the MI score is positive. On the other hand, if a pair occurs together less than is expected by chance, the mutual information score is negative. In order to increase the confidence of the MI scores, we remove all *n*-grams with less than 3 occurrences in the seed list, and assign a zero MI score for any pairs involving these *n*-grams. No smoothing is applied.

This scoring scheme fits well with the association properties we would like to have for our query-url *n*-gram click features. If a query *n*-gram cues for a certain URL through one of its *n*-grams, the feature will take on a positive value. Similarly, if a query *n*-gram cues against a certain URL, the feature will take on a negative value.

2.1.4 Analysis of Query-URL *N*-gram Association

By examining our dictionary, we observed a number of pairs that are interesting from a relevance ranking perspective. To illustrate, we present four examples of *n*-gram pairs and intuitively explore the nature of the *n*-gram associations in the dictionary.

Table 3: Examples of MI Scores

Query *n*-gram	URL *n*-gram	MI score
"iphone"	apple.com	8.7713
"iphone"	amazon.com	-0.1555
"iphone plan"	att.com	11.5388
"iphone plan"	apple.com	8.9676

First, let's examine the association between query *n*-grams and URL *n*-grams for the queries

"iphone" and "iphone plan". Notice that the query unigram "iphone" is strongly associated with apple.com, but negatively associated with amazon.com. This can be explained by the fact that "iphone" as a product is not only developed by Apple but also strongly associated with the Apple brand. In contrast, while Amazon.com sells iphones, it also sells a large variety of other products, thus is not regarded as a very authoritative source of information about the "iphone". However, by adding additional context, the most preferred URL according to MI can change. The two examples in the bottom of Table 3 illustrate the URL preferences for the query bigram "iphone plan". While apple.com is still a strongly preferred destination, there is a much stronger preference for att.com. This preference follows since apple.com has more product information on the "iphone" while the information provided by att.com will be more targeted at visitors who want to explore what rate plans are available.

Second, Table 4 shows the association between "kimo", ".tw" and ".us". "Kimo" was a Taiwanese start-up acquired by Yahoo!. The mutual information scores accurately reflect the association between the query *n*-gram and region ids.

Table 4: Example of MI Scores

Query *n*-gram	URL *n*-gram	MI score
"kimo"	tw (taiwan)	12.8303
"kimo"	us (united states)	0.7209

Third, Table 5 shows the association between "kanji", and URLs with Language identification of "Japanese", "Chinese" and "English". "Kanji" means "Chinese" in Japanese. Since queries containing "Kanji" are typically from users interested in Japanese sites, the mutual information shows higher correlation with Japanese than with English or Chinese.

Table 5: Example of MI Scores

Query *n*-gram	URL *n*-gram	MI score
"kanji"	ja (japanese)	11.3862
"kanji"	zh (chinese)	6.2567
"kanji"	en (english)	4.2110

Table 6: Example of MI Score

Query *n*-gram	URL *n*-gram	MI score
"form"	pdf	4.9067
"form"	htm	1.0916
"video"	watch	5.7192
"video"	htm	-1.9079

Fourth, Table 6 shows the association between two query *n*-grams, "form" and "video", that at first glance may not actually look very informative for URL path selection. However, notice that the unigram "form" has a strong preference for pdf documents over more standard web pages with an html extension. Similarly, queries that include "video" convey a preference for URLs containing "watch", a characteristic URL *n*-gram for many video sharing websites.

It is reasonable to anticipate that incorporating such associations into a search engine's ranking function should help improve both search quality and user experience. Take the example where, there are two high ranking competing URLs for the query "irs 1040 form". Let's also assume both documents contain the same query relevant keywords, but one is an introduction of the "irs 1040 form" as an htm webpage and the other one is the real filing form given as a pdf document. Since in our dictionary, "form" is more associated with pdf than htm, we predict that most users would prefer the real pdf form directly, so it should be placed first in the list of query results. While click data for the exact query-url pairs confirms this preference, it is reassuring that we could identify it without needing to rely on seeing the specific query string before. As described in detail below, and motivated by this analysis, we designed our query-url click features based on the contents of the *n*-gram MI dictionary.

2.2 Query-URL *N*-gram Features

For our feature set, we explored the use of different query segmentation approaches (concept and affix segmentation) in order to increase the diversity of *n*-grams. In the following section, we use an unseen query "irs 1040 forms" and contrast it with the known query "irs 1040 form" from the last section.

2.2.1 Concept Segmentation Features

Query concept segmentation is a weighted query segmentation approach. Each query is analytically interpreted as being a main concept and a sub concept. We search for the unique segmentation of the query that maximizes its cumulative mutual information score with the URL *n*-grams. Main concepts and sub concepts are *n*-grams from the query that have the strongest association with URL *n*-grams and thus assist in identifying relevant landing URL *n*-grams when the whole query or the whole URL has not been seen.

Algorithm 1: Concept Segmentation

```
for U = domain, URL language, URL region, URL path do
  for j = 0... n-1 do
      M ⇐ W_{0...j}
      S ⇐ W_{j+1...n}
      for k = 0... m do
          curr_mi_M ⇐ arg max_{k=1...m} MI (M, U_k)
          curr_mi_S ⇐ arg max_{k=1...m} MI (S, U_k)
          if curr_mi_M + curr_mi_S > curr_best
          then
              curr_best = curr_mi_M + curr_mi_S
              mi_M ⇐ curr_mi_M
              mi_S ⇐ curr_mi_S
          end if
      end for
      adding mi_M as a feature
      adding mi_S as a feature
  end for
end for
```

Pseudo-code for generating query-url *n*-gram features based on the concept segmentation is given in Algorithm 1. Each query (Q) is composed of a number of words, w_1, w_2, w_3…,w_n. Each URL is segmented and categorized to four groups: domain, URL language, URL region and URL path. Each URL group has *m* number of URL *n*-grams. M is the main concept of Q and S is the sub concept of Q.

One potential drawback of such concept segmentation is data sparsity. When we look for the maximum of cumulative mutual information, we may obtain main concepts with very high mutual information and sub concepts which do not exist in the dictionary. In order to address this problem, we implement a second query segmentation method, affix segmentation, that is discussed in section 2.2.2.

Table 7 shows eight concept segmented features. "Coverage" is the percentage of query-url pairs that have valid feature values. Some of the samples do not have values because no clicks for the pairs were seen in the sample of data used to build the dictionary. When a pair does not have a value, the default value of zero is assigned. This default value is based on the assumption that unless we have evidence otherwise, we assume all query-url *n*-grams are statistically independent and thus provide no preference signal.

Table 7: Eight Features Generated based on Concept Segmentation.

Feature	Query *N*-gram	URL *N*-gram	Coverage (%)
MainDS	M	domain	54.09
SubDS	S	domain	30.46
MainLang	M	lang.	94.41
SubLang	S	lang.	72.40
MainReg	M	reg.	90.34
SubReg	S	reg.	68.19
MainPath	M	path	64.96
SubPath	S	path	58.76

Query-URL Domain Features are defined as the mutual information of a query *n*-gram and the domain level URL. There are two features in this category, one for the query main concept and one for the sub concept. They help to identify the user preferred host given a query.

Table 8: Example of Selecting Query Segmentation

MI(*q*,*u*)	irs.gov	
"irs"		11.2174
"1040"	11.6175	11.5550
"forms"	7.5049	
Cumulative MI	19.1224	22.7724
	Seg. 1	Seg.2

To illustrate the concept segmentation features, let's examine the query, **"**irs 1040 forms" in the context of the domain irs.gov. The query "irs 1040 forms" can be segmented either as "irs 1040" and "forms" or as "irs" and "1040 forms". As shown in Table 8, taking the cumulative maximum, the second segmentation scores higher than the first one. Therefore, the "irs" and "1040 forms" segmentation is preferred. The feature value for the main concept is 11.5550, and the sub concept is then assigned to be 11.2174.

Query-URL Language and Region Features are the mutual information of a query *n*-gram and URL language/region. They are used for providing language and region information.

Query-URL Path Features are the mutual information of a query *n*-gram and a URL path *n*-gram. While there are typically many URL path *n*-grams, only one URL path *n*-gram is selected to be paired with each query *n*-gram. The selected *n*-gram is the one that achieves the highest

cumulative maximum MI score. They are used for providing association between query *n*-grams and url *n*-grams such as "forms" and "pdf".

2.2.2 Affix Segmentation Features

As previously mentioned, affix segmentation addresses sparsity issues associated with concept segmentation. Here, we introduce the features generated based on affix segmentation. Pseudo-code for generating the features is given in Algorithm 2. Two query unigrams (w_0 and w_n) and one bigram (w_0w_n) is used. Each URL is segmented and categorized to four groups: domain, URL language, URL region and URL path. Each URL group has *m* number of URL *n*-grams.

This approach is complementary to the concept segmentation for long queries. The affix *n*-grams are in smaller unit, and therefore, are less sparse. In addition, the skip bigrams allow for generalizations using non-adjacent terms. Table 9 shows the coverage of the twelve affix features.

Algorithm 2: Affix Segmentation

```
for U = domain, URL language, URL region, URL path do
  for q = w0, wn, w0wn do
    for k = 0... m do
      curr_mi_q ⇐ arg max_{k=1...m} MI (q, U_k)
      if curr_mi_q > curr_best then
        curr_best = curr_mi_q
      end if
    end for
    adding curr_mi_q as a feature
  end for
end for
```

Table 9: Twelve Features Generated based on Affix Segmentation

Feature	Query *N*-gram	URL *N*-gram	Coverage (%)
PreDS	w_0	domain	48.09
SufDS	w_n	domain	47.72
PresufDS	w_0w_n	domain	23.57
PreLang	w_0	lang.	55.58
SufLang	w_n	lang.	58.22
PresufLang	w_0w_n	lang.	24.91
PreReg	w_0	reg.	93.82
SufReg	w_n	reg.	93.59
PresufReg	w_0w_n	reg.	69.29
PrePath	w_0	path	98.15
SufPath	w_n	path	97.80
PresufPath	w_0w_n	path	75.81

Query-url domain affix features has three features: MI(w_0, domain), MI(w_n, domain), and MI(w_0w_n, domain). In the example of "irs 1040 forms" and "irs.gov", the features are MI(irs, irs.gov), MI(forms, irs.gov), and MI(irs forms, irs.gov).

Query-url language and region affix features has three features respectively: MI(w_0, language), MI(w_n, language), MI(w_0w_n, language) MI(w_0, region), MI(w_n, region), and MI(w_0w_n, region). In the example of "irs 1040 forms", "en" and "us", the features are MI (irs, en), MI (forms, en), MI (irs forms, en), MI (irs, us), MI (forms, us), and MI (irs forms,us).

Query-url path affix features has three features: MI(w_0, path), MI(w_n, path), and MI(w_0w_n, path). In the example of "irs 1040 forms" and "www.irs.gov/pub/irs-pdf/f1040.pdf", there are four URL path *n*-grams, "pub", "irs", "pdf", and "f1040". The URL path *n*-gram, irs, gets maximum MI score. Therefore, the query-url path affix features are MI (irs, irs), MI (forms, irs), and MI (irs forms, irs).

We demonstrated the procedure to generate 20 query-url *n*-gram features, and in Section 3, we will present their effectiveness in relevance ranking.

3 Experiment

We evaluate the performance of query-url *n*-grams features (8 concept and 12 affix features) on a ranking application and analyze the results from several different perspectives.

3.1 Datasets

For all experiments, our training and test data are query-url pairs annotated with human judgments. In our data, we use five grades to evaluate relevance of a query and URL pair.

The data includes 94K queries for training and 3.4K queries for evaluation, and each query is associated with the top ranked URLs returned from a search engine. Totally, there are 916K query-url pairs for training and 42K pairs for testing. The queries are general and uniformly and randomly sampled with replacement, resulting in more frequent queries also appearing more frequently in our training and test sets.

3.2 Ranking Algorithm

GBRank is a supervised learning algorithm that uses boosted decision trees and incorporates the pair-wise information from the training data (Zheng et al, 2007). It is able to deal with a large amount of training data with hundreds of features. We use an internal C++ implementation of GBRank.

3.3 Evaluation Metric

We use Discounted Cumulative Gain (Järvelin and Kekäläinen, 2002) to evaluate our ranking accuracy. Discounted Cumulative Gain (DCG) has been widely used in evaluating the quality of search engine rankings and is defined as:

$$DCG_k = \sum_{i=1}^{k} \frac{G_i}{\log_2(i+1)} \quad (2)$$

G_i represents the editorial judgment of the i-th document. In this paper, we only report **normalized DCG$_5$**, which is an absolute DCG$_5$ normalized by a baseline, and **relative DCG$_5$ improvement**, which is an improvement normalized by the baseline. Note normalized DCG$_5$ is different than NDCG (Normalized Discounted Cumulative Gain defined in Järvelin and Kekäläinen, 2002). We use Wilcoxon signed test (Wilcoxon, 1945) to evaluate the significance for model comparison.

3.4 Feature Sets

Five feature sets are used in our experiments. Details are listed in Table 10.

Table 10: Five Feature Sets

Tag	Description
Base Feature Set	Core Feature Set and ExactM click features
Q-U *N*-gram Feature Set (I)	Base Feature Set and Q-U *N*-gram features
Core Feature Set	query-based, document-based, query-document based features
NavClick Feature Set	Core Feature Set and NavClick
Q-U *N*-gram Feature Set (II)	Core Feature Set and Q-U *N*-gram features

Base Feature Set is a strong baseline feature set from a state-of-the-art commercial search engine. This set includes NavClick features, and other internal ExactM click features. It is used for evaluating Query-URL *N*-gram Feature Set (I) in order to know whether query-url *n*-gram features can achieve gains when stacked on top of ExactM features.

Core Feature Set is a weaker variant of the baseline system that excludes ExactM click features. This system is used for evaluating NavClick Feature Set and Query-URL *N*-gram Feature Set (II) independently in order to study and contrast the effected queries.

3.5 Experimental Results

We compare the query-URL *N*-gram feature set (I) with the base feature set in Section 3.5.1, and contrast the NavClick features and the query-URL *N*-gram features (II) using the Core Feature Set in Section 3.5.2.

3.5.1 Query-URL *N*-gram Feature Set (I) versus Base Feature Set

As shown in Figure 2, Query-URL *N*-gram Feature Set (I) outperforms Base Feature Set. The additional 20 query-url *n*-gram features achieve statistically significant gains at a p-value < 0.0001 level, suggesting that they are complimentary to ExactM click features. Even though the query-url *n*-gram features are generated from the same data as the ExactM features, the gain is additive and stackable. The DCG$_5$ impact is 0.53% relative improvement when running GBRank using 2500 trees. Every data point is normalized by the DCG$_5$ of the baseline feature set using 2500 trees. This is represented in the graph as the rightmost point of Base Feature Set curve.

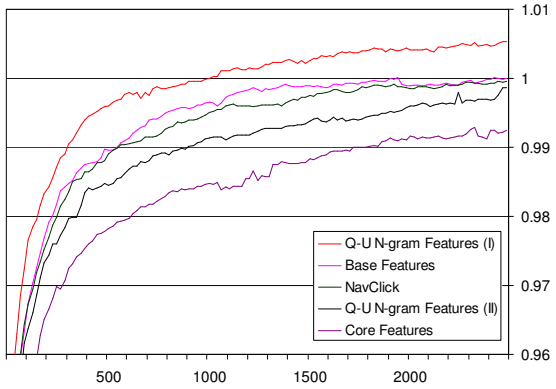

Figure 2: Comparison of the five feature sets on the normalized DCG$_5$ (Y-axis) against number of trees (X-axis).

3.5.2 NavClick and Query-URL *N*-gram Feature Set (II) versus Core Feature Set

We compare NavClick Feature Set and Query-URL *N*-gram Feature Set (II) in the context of Core Feature Set, in order to evaluate the two independently. As shown in Figure 2, both NavClick and Query-URL *N*-gram Feature Set (II) outperform Core Feature Set. It is not surprising that NavClick also outperforms Query-URL *N*-gram Feature Set (II) since the *n*-gram features are backoff of NavClick. However, their gains are competitive suggesting the query-url *n*-gram features are very good relevance indicators. The impact of NavClick and Query-URL *N*-gram Feature Set (II) is 0.72% and 0.62% relative DCG_5 improvement at Tree 2500 respectively.

3.5.3 Feature Importance

Using the GBRank model, features are evaluated and sequentially selected to build the boosted decision trees. The split of each node increases the DCG during training. We evaluate a feature's importance by aggregating the DCG impact of the feature over all trees (Zheng et al., 2007). Here, the feature importance is rescaled so that the feature with largest DCG impact is assigned a normalized score of 1. Figure 3 illustrates the relative influence of each of query-url *n*-gram feature. Of these, *n*-gram features associated with a domain name (i.e., MainDS) rank highest.

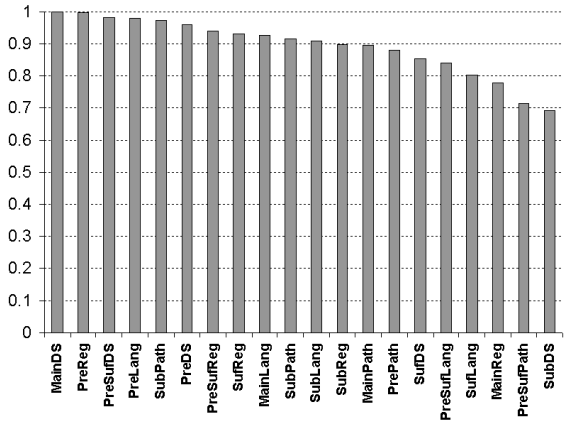

Figure 3: Feature importance of query-url *n*-gram features. The importance (Y axis) is normalized so that the most important feature (MainDS)'s importance is 1.

3.6 Analysis

We access system performance with respect to both query length and frequency using the two click features sets in combination with the Core Feature Set in order to gain insight into the effected queries.

3.6.1 Query Length

As shown in Table 11, NavClick (NavClick Feature Set) best improves relevance for two word queries. In contrast, Query-url *n*-gram features in isolation (Query-URL *N*-gram Feature II) are able to show sizable improvements on longer queries, while slightly degrading performance on short 1-word queries. Using both feature sets together (Query-URL *N*-gram Feature I) results in improvement for queries of all lengths.

These results suggest that the strong signal being provided by NavClick for short queries helps to compensate for any additional noisy introduced by the *n*-gram features, while allowing the *n*-gram features to handle longer queries that are less well covered by NavClick. These longer queries are exactly the type of queries our query-url *n*-gram features were designed to help with.

Table 11: Relative DCG_5 Improvement of NavClick, Query-URL *N*-gram (II), and Query-URL *N*-gram Features (I) vs Core Feature Set

Length	NavClick vs Core (%)	QU *N*-gram (II) vs Core (%)	QU *N*-gram (I) vs Core (%)
1 word	0.03	-0.04	0.62
2 words	1.04	1.06	1.58
3 words	1.00	1.44	2.12
4+ words	0.4	0.68	1.01

3.6.2 Query Frequency

We found that query-url *n*-gram features improve tail queries. Head queries are considered as top two million frequent queries in our traffic and tail queries include anything outside of that range.

Table 12: Relative DCG_5 Improvement of NavClick, Query-URL *N*-gram Features (II) and Query-URL *N*-gram Features (I) vs Core Feature Set

	NavClick vs Core (%)	QU *N*-gram (II) vs Core (%)	QU *N*-gram (I) vs Core (%)
Head	0.91	-0.15	1.11
Tail	0.59	1.11	1.40

As shown in Table 12, query-url *n*-gram features (Query-URL Feature Set II) differ from NavClick (NavClick Feature Set) in that they get

more gain from tail queries. Together, they (Query-URL Feature Set I) improve both head and tail queries.

3.7 Case Study

Below we examine queries from the test set and analyze the effects of Query-URL *N*-gram Feature Set (II) versus Core Feature Set.

3.7.1 Positive Cases

1) Animal shelter in va: this query targets a specific geographic location. Using the baseline feature set, the root url wvanimalshelter.org is incorrectly ranked higher than www.netpets.com/cats/catresc/virginia.htm. Without any additionally ranking information, general URLs (root) tend to be ranked more highly than more specific URLs (path), as the root pages tend to be more popular. However, our new features express a preference between "va" and "virginia", and this correctly flips the ranking order.
2) Myspace profile generator: www. myspacgens.com/handler.php?gen=profile was incorrectly ranked higher than www.profilemods.com/myspace-generators. Our new features convey a high user preference association between "profile generator" and the domain profilemods.com, which helps to correctly swap the order.

3.7.2 Negative Cases

We determined that negative cases where the baseline feature set outperforms the new features are typically one word navigational queries such as "craigslist". However, after we combine the query-url *n*-gram features with NavClick, one word navigational queries are ranked correctly.

4 Related Work

Our work is mainly related to Gao et al. (2009) and Bilenko and White (2008). Gao et al. (2009) addressed the sparsity issue by propagating click information among similar queries in the same cluster. Their idea is based on an observation that similar queries go to similar pages. When two queries have similar clicked URLs, it is likely that they share clicked URLs. In contrast, our idea is to utilize NLP techniques to break down long, infrequent queries into shorter, frequent queries. The two approaches can be mutually beneficial. Bilenko and White (2008) expanded click data with a search engine by using post-search user experience collected from toolbars. Toolbars keep track of users' click behavior both when they are using the search engine directly and beyond. Their relevance features are built based on whole session clicks extracted from the toolbar. In contrast, our *n*-gram features are built on search engine clicks directly. We should be able to expand our method to integrate the post-search clicks with toolbar data.

Other related work can be found in the domain of query rewriting. Our *n*-gram dictionary was originally designed for query rewriting. Query rewriting (Xu and Croft, 1996; Salton and Voorhees, 1984) reformulates a query to its synonyms or related terms automatically. However, the coverage of query rewriting is normally small, because an inappropriate rewrite can cause significant decrease in precision. In contrast, our approach can cover a larger number of queries without decreasing precision, because it does not need to make a binary decision whether a query should be reformulated. The association scores between queries and rewrites are used as ranking features which are trained discriminatively toward search quality.

5 Conclusion

In this paper, we presented a set of straightforward yet informative query-url *n*-gram features. They allow for generalization of limited user click data to large amounts of unseen query-url pairs. Our experiments showed such features gave significant improvement over models without using the features. In addition, we mined an interesting dictionary which contains informative, but not necessarily obvious, query-url synonym pairs such as "form" and "pdf". We are currently extending our work to a variety of exact match features and different sources of clickthrough logs.

Abstract

The ambiguity of person names in the Web has become a new area of interest for NLP researchers. This challenging problem has been formulated as the task of clustering Web search results (returned in response to a person name query) according to the individual they mention. In this paper we compare the coverage, reliability and independence of a number of features that are potential information sources for this clustering task, paying special attention to the role of named entities in the texts to be clustered. Although named entities are used in most approaches, our results show that, independently of the Machine Learning or Clustering algorithm used, named entity recognition and classification per se only make a small contribution to solve the problem.

1 Introduction

Searching the Web for names of people is a highly ambiguous task, because a single name tends to be shared by many people. This ambiguity has recently become an active research topic and, simultaneously, in a relevant application domain for web search services: Zoominfo.com, Spock.com, 123people.com are examples of sites which perform web people search, although with limited disambiguation capabilities.

A study of the query log of the AllTheWeb and Altavista search sites gives an idea of the relevance of the people search task: 11-17% of the queries were composed of a person name with additional terms and 4% were identified as person names (Spink et al., 2004). According to the data available from 1990 U.S. Census Bureau, only 90,000 different names are shared by 100 million people (Artiles et al., 2005). As the amount of information in the WWW grows, more of these people are mentioned in different web pages. Therefore, a query for a common name in the Web will usually produce a list of results where different people are mentioned.

This situation leaves to the user the task of finding the pages relevant to the particular person he is interested in. The user might refine the original query with additional terms, but this risks excluding relevant documents in the process. In some cases, the existence of a predominant person (such as a celebrity or a historical figure) makes it likely to dominate the ranking of search results, complicating the task of finding information about other people sharing her name. The Web People Search task, as defined in the first WePS evaluation campaign (Artiles et al., 2007), consists of grouping search results for a given name according to the different people that share it.

Our goal in this paper is to study which document features can contribute to this task, and in particular to find out which is the role that can be played by named entities (NEs): (i) How reliable is NEs overlap between documents as a source of evidence to cluster pages? (ii) How much recall does it provide? (iii) How unique is this signal? (i.e. is it redundant with other sources of information such as n-gram overlap?); and (iv) How sensitive is this signal to the peculiarities of a given NE recognition system, such as the granularity of its NE classification and the quality of its results?

Our aim is to reach conclusions which are are not tied to a particular choice of Clustering or Machine Learning algorithms. We have taken two decisions in this direction: first, we have focused on the problem of deciding whether two web pages refer to the same individual or not (page coreference task). This is the kind of relatedness measure that most clustering algorithms use, but in this way we can factor out the algorithm and its parameter settings. Second, we have developed a measure, *Maximal Pairwise Accuracy* (PWA) which, given

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 534–542,
Singapore, 6-7 August 2009.

an information source for the problem, estimates an upper bound for the performance of any Machine Learning algorithm using this information. We have used PWA as the basic metric to study the role of different document features in solving the coreference problem, and then we have checked the predictive power of PWA with a Decision Tree algorithm.

The remainder of the paper is organised as follows. First, we examine the previous work in Section 2. Then we describe the our experimental settings (datasets and features we have used) in Section 3 and our empirical study in Section 4. The paper ends with some conclusions in Section 5.

2 Previous work

In this section we will discuss (i) the state of the art in Web People Search in general, focusing on which features are used to solve the problem; and (ii) lessons learnt from the WePS evaluation campaign where most approaches to the problem have been tested and compared.

The disambiguation of person names in Web results is usually compared to two other Natural Language Processing tasks: Word Sense Disambiguation (WSD) (Agirre and Edmonds, 2006) and Cross-document Coreference (CDC) (Bagga and Baldwin, 1998). Most of early research work on person name ambiguity focuses on the CDC problem or uses methods found in the WSD literature. It is only recently that the web name ambiguity has been approached as a separate problem and defined as an NLP task - *Web People Search* - on its own (Artiles et al., 2005; Artiles et al., 2007).

Therefore, it is useful to point out some crucial differences between WSD, CRC and WePS:

- WSD typically concentrates in the disambiguation of common words (nouns, verbs, adjectives) for which a relatively small number of senses exist, compared to the hundreds or thousands of people that can share the same name.
- WSD can rely on dictionaries to define the number of possible senses for a word. In the case of name ambiguity no such dictionary is available, even though in theory there is an exact number of people that can be accounted as sharing the same name.
- The objective of CDC is to reconstruct the coreference chain for every mention of a person. In Web person name disambiguation it suffices to group the documents that contain at least one mention to the same person.

Before the first WePS evaluation campaign in 2007 (Artiles et al., 2007), research on the topic was not based on a consistent task definition, and it lacked a standard manually annotated testbed. In the WePS task, systems were given the top web search results produced by a person name query. The expected output was a clustering of these results, where each cluster should contain all and only those documents referring to the same individual.

2.1 Features for Web People Search

Many different features have been used to represent documents where an ambiguous name is mentioned. The most basic is a **Bag of Words** (BoW) representation of the document text. Within-document coreference resolution has been applied to produce summaries of text surrounding occurrences of the name (Bagga and Baldwin, 1998; Gooi and Allan, 2004). Nevertheless, the full document text is present in most systems, sometimes as the only feature (Sugiyama and Okumura, 2007) and sometimes in combination with others - see for instance (Chen and Martin, 2007; Popescu and Magnini, 2007)-. Other representations use the link structure (Malin, 2005) or generate graph representations of the extracted features (Kalashnikov et al., 2007).

Some researchers (Cucerzan, 2007; Nguyen and Cao, 2008) have explored the use of **Wikipedia information** to improve the disambiguation process. Wikipedia provides candidate entities that are linked to specific mentions in a text. The obvious limitation of this approach is that only celebrities and historical figures can be identified in this way. These approaches are yet to be applied to the specific task of grouping search results.

Biographical features are strongly related to NEs and have also been proposed for this task due to its high precision. Mann (2003) extracted these features using lexical patterns to group pages about the same person. Al-Kamha (2004) used a simpler approach, based on hand coded features (e.g. email, zip codes, addresses, etc). In Wan (2005), biographical information (person name, title, organisation, email address and phone number) improves the clustering results when combined with lexical features (words from the doc-

ument) and NE (person, location, organisation).

The most used feature for the Web People Search task, however, are **NEs**. Ravin (1999) introduced a rule-based approach that tackles both variation and ambiguity analysing the structure of names. In most recent research, NEs (person, location and organisations) are extracted from the text and used as a source of evidence to calculate the similarity between documents -see for instance (Blume, 2005; Chen and Martin, 2007; Popescu and Magnini, 2007; Kalashnikov et al., 2007)-. For instance, Blume (2005) uses NEs coocurring with the ambiguous mentions of a name as a key feature for the disambiguation process. Saggion (2008) compared the performace of NEs versus BoW features. In his experiments a only a representation based on Organisation NEs outperformed the word based approach. Furthermore, this result is highly dependent on the choice of metric weighting (NEs achieve high precision at the cost of a low recall and viceversa for BoW).

In summary, the most common document representations for the problem include BoW and NEs, and in some cases biographical features extracted from the text.

2.2 Named entities in the WePS campaign

Among the 16 teams that submitted results for the first WePS campaign, 10 of them[1] used NEs in their document representation. This makes NEs the second most common type of feature; only the BoW feature was more popular. Other features used by the systems include noun phrases (Chen and Martin, 2007), word n-grams (Popescu and Magnini, 2007), emails and URLs (del Valle-Agudo et al., 2007), etc. In 2009, the second WePS campaign showed similar trends regarding the use of NE features (Artiles et al., 2009).

Due to the complexity of systems, the results of the WePS evaluation do not provide a direct answer regarding the advantages of using NEs over other computationally lighter features such as BoW or word n-grams. But the WePS campaigns did provide a useful, standardised resource to perform the type of studies that were not possible before. In the next Section we describe this dataset and how it has been adapted for our purposes.

3 Experimental settings

3.1 Data

We have used the testbeds from WePS-1 (Artiles et al., 2007)[2] and WePS-2 (Artiles et al., 2009) evaluation campaigns [3].

Each WePS dataset consists of 30 test cases: a random sample of 10 names from the US Census, 10 names from Wikipedia, and 10 names from Programme Committees in the Computer Science domain (ACL and ECDL). Each test case consists of, at most, 100 web pages from the top search results of a web search engine, using a (quoted) person name as query.

For each test case, annotators were asked to organise the web pages in groups where all documents refer to the same person. In cases where a web page refers to more than one person using the same ambiguous name (e.g. a web page with search results from Amazon), the document is assigned to as many groups as necessary. Documents were discarded when they did not contain any useful information about the person being referred.

Both the WePS-1 and WePS-2 testbeds have been used to evaluate clustering systems by WePS task participants, and are now the standard testbed to test Web People Search systems.

3.2 Features

The evaluated features can be grouped in four main groups: token-based, n-grams, phrases and NEs. Wherever possible, we have generated *local* versions of these features that only consider the sentences of the text that mention the ambiguous person name[4]. Token-based features considered include document full text tokens, lemmas (using the OAK analyser, see below), title, snippet (returned in the list of search results) and URL (tokenised using non alphanumeric characters as boundaries) tokens. English stopwords were removed, including Web specific stopwords, as file and domain extensions, etc.

We generated **word n-grams** of length 2 to 5,

[2]The WePS-1 corpus includes data from the Web03 testbed (Mann, 2006) which follows similar annotation guidelines, although the number of document per ambiguous name is more variable.

[3]Both corpora are available from the WePS website http://nlp.uned.es/weps

[4]A very sparse feature might never occur in a sentence with the person name. In that cases there is no *local* version of the feature.

using the sentences found in the document text. Punctuation tokens (commas, dots, etc) were generalised as the same token. N-grams were discarded when they were composed only of stopwords or when they did not contain at least one token formed by alphanumeric characters (e.g. n-grams like "at the" or "# @"). **Noun phrases** (using OAK analyser) were detected in the document and filtered in a similar way.

Named entities were extracted using two different tools: the Stanford NE Recogniser and the OAK System[5].

Stanford NE Recogniser[6] is a high-performance Named Entity Recognition (NER) system based on Machine Learning. It provides a general implementation of linear chain Conditional Random Field sequence models and includes a model trained on data from CoNLL, MUC6, MUC7, and ACE newswire. Three types of entities were extracted: person, location and organisation.

OAK[7] is a rule based English analyser that includes many functionalities (POS tagger, stemmer, chunker, Named Entity (NE) tagger, dependency analyser, parser, etc). It provides a fine grained NE recognition covering 100 different NE types (Sekine, 2008). Given the sparseness of most of these fine-grained NE types, we have merged them in coarser groups: event, facility, location, person, organisation, product, periodx, timex and numex.

We have also used the results of a **baseline NE** recognition for comparison purposes. This method detects sequences of two or more uppercased tokens in the text, and discards those that are found lowercased in the same document or that are composed solely of stopwords.

Other features are: emails, outgoing links found in the web pages and two boolean flags that indicate whether a pair of documents is linked or belongs to the same domain. Because of their low impact in the results these features haven't received an individual analysis, but they are included in the "all features" combination in Figure 7.

[5]From the output of both systems we have discarded person NEs made of only one token (these are often first names that significantly deteriorate the quality of the comparison between documents).

[6]http://nlp.stanford.edu/software/CRF-NER.shtml

[7]http://nlp.cs.nyu.edu/oak . OAK was also used to detect noun phrases and extract lemmas from the text.

4 Experiments and results

4.1 Reformulating WePS as a classification task

As our goal is to study the impact of different features (information sources) in the task, a direct evaluation in terms of clustering has serious disadvantages. Given the output of a clustering system it is not straightforward to assess why a document has been assigned to a particular cluster. There are at least three different factors: the document similarity function, the clustering algorithm and its parameter settings. Features are part of the document similarity function, but its performance in the clustering task depends on the other factors as well. This makes it difficult to perform error analysis in terms of the features used to represent the documents.

Therefore we have decided to transform the clustering problem into a classification problem: deciding whether two documents refer to the same person. Each pair of documents in a name dataset is considered a classification instance. Instances are labelled as coreferent (if they share the same cluster in the gold standard) or non coreferent (if they do not share the same cluster). Then we can evaluate the performance of each feature separately by measuring its ability to rank coreferent pairs higher and non coreferent pairs lower. In the case of feature combinations we can study them by training a classifier or using the maximal pairwise accuracy methods (explained in Section 4.3).

Each instance (pair of documents) is represented by the similarity scores obtained using different features and similarity metrics. We have calculated for each feature three similarity metrics: Dice's coefficient, cosine (using standard tf.idf weighting) and a measure that simply counts the size of the intersection set for a given feature between both documents. After testing these metrics we found that Dice provides the best results across different feature types. Differences between Dice and cosine were consistent, although they were not especially large. A possible explanation is that Dice does not take into account the redundancy of an n-gram or NE in the document, and the cosine distance does. This can be a crucial factor, for instance, in the document retrieval by topic; but it doesn't seem to be the case when dealing with name ambiguity.

The resulting classification testbed consists of 293,914 instances with the distribution shown in

Table 1, where each instance is represented by 69 features.

	true	false	total
WePS1	61,290	122,437	183,727
WePS2	54,641	55,546	110,187
WePS1+WePS2	115,931	177,983	293,914

Table 1: Distribution of classification instances

4.2 Analysis of individual features

There are two main aspects related with the usefulness of a feature for WePS task. The first one is its performance. That is, to what extent the similarity between two documents according to a feature implies that both mention the same person. The second aspect is to what extent a feature is orthogonal or redundant with respect to the standard token based similarity.

4.2.1 Feature performance

According to the transformation of WePS clustering problem into a classification task (described in Section 4.1), we follow the next steps to study the performance of individual features. First, we compute the Dice coefficient similarity over each feature for all document pairs. Then we rank the document pair instances according to these similarities. A good feature should rank positive instances on top. If the number of coreferent pairs in the top n pairs is t_n and the total number of coreferent pairs is t, then $P = \frac{t_n}{n}$ and $R = \frac{t_n}{t}$. We plot the obtained precision/recall curves in Figures 1, 2, 3 and 4.

From the figures we can draw the following conclusions:

First, considering subsets of tokens or lemmatised tokens does not outperform the basic token distance (figure 1 compares token-based features). We see that only local and snippet tokens perform slightly better at low recall values, but do not go beyond recall 0.3.

Second, shallow parsing or n-grams longer than 2 do not seem to be effective, but using bi-grams improves the results in comparison with tokens. Figure 2 compares n-grams of different sizes with noun phrases and tokens. Overall, noun phrases have a poor performance, and bi-grams give the best results up to recall 0.7. Four-grams give slightly better precision but only reach 0.3 recall, and three-grams do not give better precision than bi-grams.

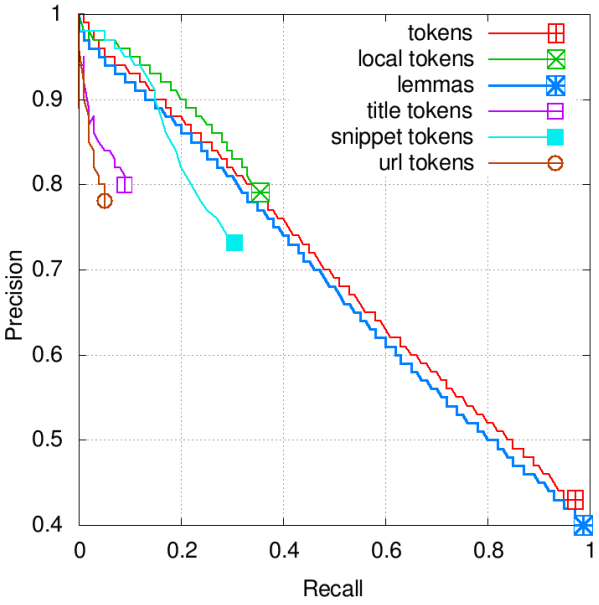

Figure 1: Precision/Recall curve of token-based features

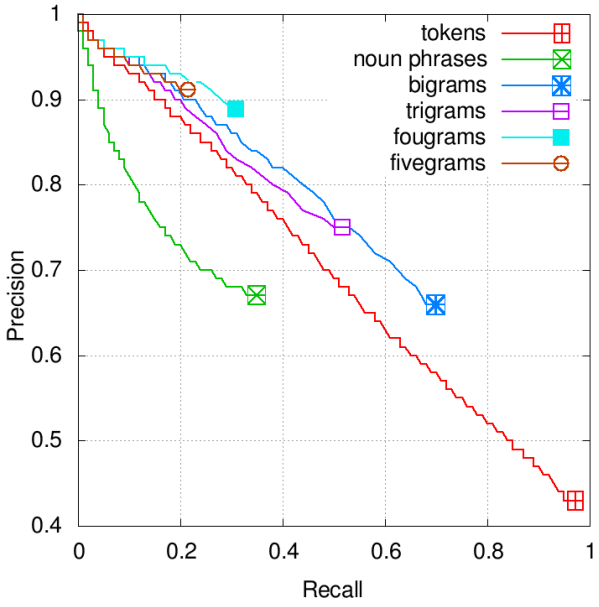

Figure 2: Precision/Recall curve of word n-grams

Third, individual types of NEs do not improve over tokens. Figure 3 and Figure 4 display the results obtained by the Stanford and OAK NER tools respectively. In the best case, Stanford person and organisation named entities obtain results that match the tokens feature, but only at lower levels of recall.

Finally, using different NER systems clearly leads to different results. Surprisingly, the baseline NE system yields better results in a one to one comparison, although it must be noted that this baseline agglomerates different types of en-

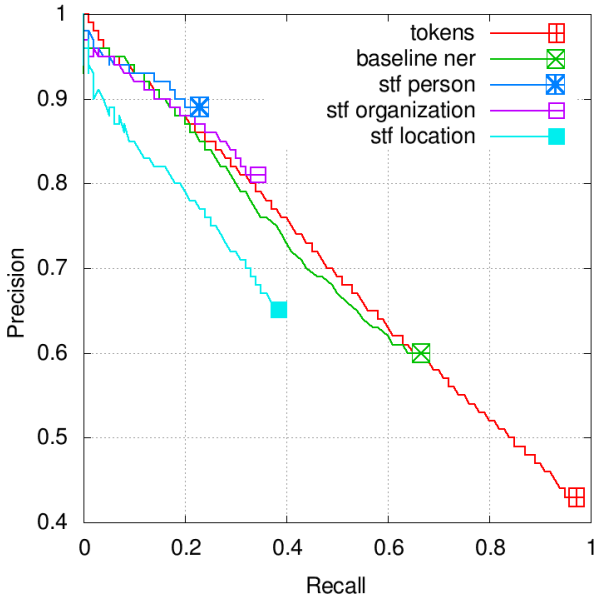

Figure 3: Precision/Recall curve of NEs obtained with the Stanford NER tool

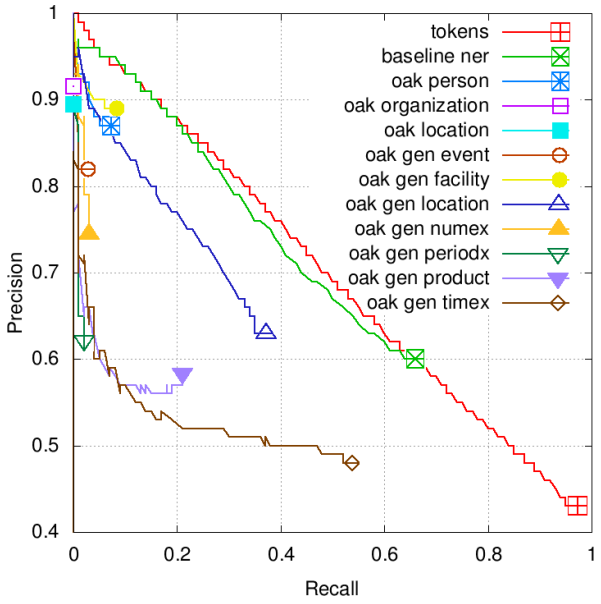

Figure 4: Precision/Recall curve of NEs obtained with the OAK NER tool

tities that are separated in the case of Stanford and OAK, and this has a direct impact on its recall. The OAK results are below the tokens and NE baseline, possibly due to the sparseness of its very fine grained features. In NE types, cases such as person and organisation results are still lower than obtained with Stanford.

4.2.2 Redundancy

In addition to performance, named entities (as well as other features) are potentially useful for the task only if they provide information that complements (i.e. that does not substantially overlap) the basic token based metric. To estimate this redundancy, let us consider all document tuples of size four $< a, b, c, d >$. In 99% of the cases, token similarity is different for $< a, b >$ than for $< c, d >$. We take combinations such that $< a, b >$ are more similar to each other than $< c, d >$ according to tokens. That is:

$$\text{sim}_{\text{token}}(a, b) > \text{sim}_{\text{token}}(c, d)$$

Then for any other feature similarity $sim_x(a, b)$, we will talk about *redundant* samples when $sim_x(a, b) > sim_x(c, d)$, *non redundant* samples when $sim_x(a, b) < sim_x(c, d)$, and *non informative* samples when $sim_x(a, b) = sim_x(c, d)$. If all samples are redundant or non informative, then sim_x does not provide additional information for the classification task.

Figure 5 shows the proportion of redundant, non redundant and non informative samples for several similarity criteria, as compared to token-based similarity. In most cases NE based similarities give little additional information: the baseline NE recogniser, which has the largest independent contribution, gives additional information in less than 20% of cases.

In summary, analysing individual features, the NEs do not outperform BoW in terms of the classification task. In addition, NEs tend to be redundant regarding BoW. However, if we are able to combine optimally the contributions of the different features, the BoW approach could be improved. We address this issue in the next section.

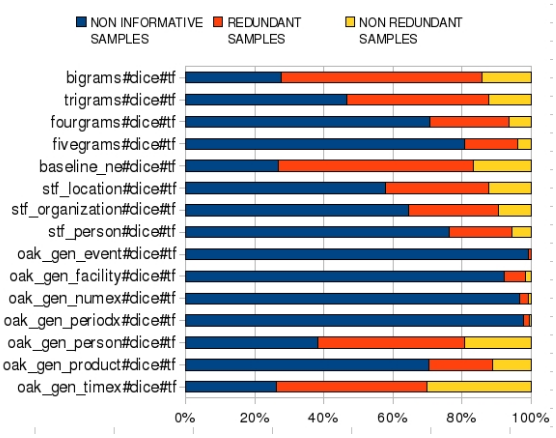

Figure 5: Independence of similarity criteria with respect to the token based feature

4.3 Analysis of feature combinations

Up to now we have analysed the usefulness of individual features for the WePS Task. However, this begs to ask to what extent the NE features can contribute to the task when they are combined together and with token and n-gram based features. First, we use each feature combinations as the input for a Machine Learning algorithm. In particular, we use a Decision Tree algorithm and WePS-1 data for training and WePS-2 data for testing. The Decision Tree algorithm was chosen because we have a small set of features to train (similarity metrics) and some of these features output Boolean values.

Results obtained with this setup, however, can be dependent on the choice of the ML approach. To overcome this problem, in addition to the results of a Decision Tree Machine Learning algorithm, we introduce a *Maximal Pairwise Accuracy* (MPA) measure that provides an upper bound for any machine learning algorithm using a feature combination.

We can estimate the performance of an individual similarity feature x in terms of accuracy. It is considered a correct answer when the similarity $x(a, a')$ between two pages referring to the same person is higher than the similarity $x(b, c)$ between two pages referring to different people. Let us call this estimation *Pairwise Accuracy*. In terms of probability it can be defined as:

$$PWA = \text{Prob}(x(a, a') > x(c, d))$$

PWA is defined over a single feature (similarity metric). When considering more than one similarity measure, the results depend on how measures are weighted. In that case we assume that the best possible weighting is applied. When combining a set of features $X = \{x_1 \dots x_n\}$, a perfect Machine Learning algorithm would learn to always "listen" to the features giving correct information and ignore the features giving erroneous information. In other words, if at least one feature gives correct information, then the perfect algorithm would produce a correct output. This is what we call the *Maximal Pairwise Accuracy* estimation of an upper bound for any ML system using the set of features X:

$$\text{MaxPWA}(X) =$$
$$\text{Prob}(\exists x \in X . x(a, a') > x(c, d))$$

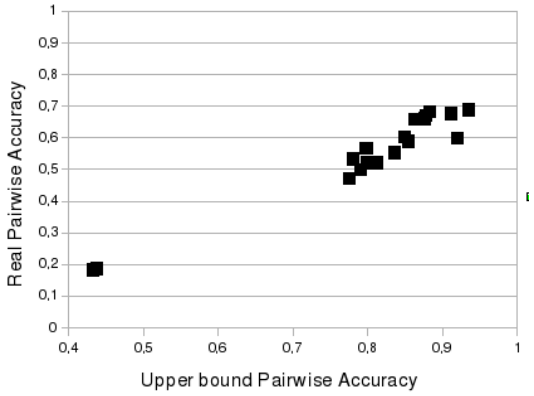

Figure 6: Estimated PWA upper bound versus the real PWA of decision trees trained with feature combinations

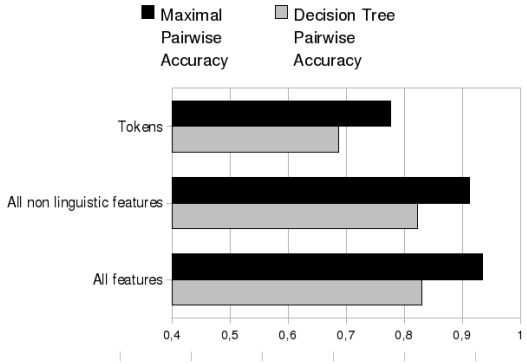

Figure 7: Maximal Pairwise Accuracy vs. results of a Decision Tree

The upper bound (MaxPWA) of feature combinations happens to be highly correlated with the PWA obtained by the Decision Tree algorithm (using its confidence values as a similarity metric). Figure 6 shows this correlation for several features combinations. This is an indication that the Decision Tree is effectively using the information in the feature set.

Figure 7 shows the PWA upper bound estimation and the actual PWA performance of a Decision Tree ML algorithm for three combinations: (i) all features; (ii) non linguistic features, i.e., features which can be extracted without natural language processing machinery: tokens, url, title, snippet, local tokens, n-grams and local n-grams; and (iii) just tokens. The results show that according to both the Decision Tree results and the upper-bound (MaxPWA), adding new features to tokens improves the classification. However, taking non-linguistic features obtains similar results than taking all features. Our conclusion is that NE features are useful for the task, but do not seem to offer a

competitive advantage when compared with non-linguistic features, and are more computationally expensive. Note that we are using NE features in a direct way: our results do not exclude the possibility of effectively exploiting NEs in more sophisticated ways, such as, for instance, exploiting the underlying social network relationships between NEs in the texts.

4.3.1 Results on the clustering task

In order to validate our results, we have tested whether the classifiers learned with our feature sets lead to competitive systems for the full clustering task. In order to do so, we use the output of the classifiers as similarity metrics for a particular clustering algorithm, using WePS-1 to train the classifiers and WePS-2 for testing.

We have used a Hierarchical Agglomerative Clustering algorithm (HAC) with single linkage, using the classifier's confidence value in the negative answer for each instance as a distance metric[8] between document pairs. HAC is the algorithm used by some of the best performing systems in the WePS-2 evaluation. The distance threshold was trained using the WePS-1 data. We report results with the official WePS-2 evaluation metrics: extended B-Cubed Precision and Recall (Amigó et al., 2008).

Two Decision Tree models were evaluated: (i) *ML-ALL* is a model trained using all the available features (which obtains 0.76 accuracy in the classification task) (ii) *ML-NON_LING* was trained with all the features except for OAK and Stanford NEs, noun phrases, lemmas and gazetteer features (which obtains 0.75 accuracy in the classification task). These are the same classifiers considered in Figure 7.

Table 2 shows the results obtained in the clustering task by the two DT models, together with the four top scoring WePS-2 systems and the average values for all WePS-2 systems. We found that a ML based clustering using only non linguistic information slightly outperforms the best participant in WePS-2. Surprisingly, adding linguistic information (NEs, noun phrases, etc.) has a small negative impact on the results (0.81 versus 0.83), although the classifier with linguistic information was a bit better than the non-linguistic one. This seems to be another indication that the use of noun phrases and other linguistic features to improve the task is non-obvious to say the least.

		B-Cubed	
run	F-α $=_{0.5}$	Pre.	Rec.
ML-NON_LING	.83	.91	.77
S-1	.82	.87	.79
ML- ALL	.81	.89	.76
S-2	.81	.85	.80
S-3	.81	.93	.73
S-4	.72	.82	.66
WePS-2 systems aver.	.61	.74	.63

Table 2: Evaluation on the WePS-2 clustering task

5 Conclusions

We have presented an empirical study that tries to determine the potential role of several sources of information to solve the Web People Search clustering problem, with a particular focus on studying the role of named entities in the task.

To abstract the study from the particular choice of a clustering algorithm and a parameter setting, we have reformulated the problem as a coreference classification task: deciding whether two pages refer to the same person or not. We have also proposed the *Maximal Pairwise Accuracy* estimation that establish an upper bound for the results obtained by any Machine Learning algorithm using a particular set of features.

Our results indicate that (i) NEs do not provide a substantial competitive advantage in the clustering process when compared to a rich combination of simpler features that do not require linguistic processing (local, global and snippet tokens, n-grams, etc.); (ii) results are sensitive to the NER system used: when using all NE features for training, the richer number of features provided by OAK seems to have an advantage over the simpler types in Stanford NER and the baseline NER system.

This is not exactly a prescription against the use of NEs for Web People Search, because linguistic knowledge can be useful for other aspects of the problem, such as visualisation of results and description of the persons/clusters obtained: for example, from a user point of view a network of the connections of a person with other persons and organisations (which can only be done with NER) can be part of a person's profile and may help as a summary of the cluster contents. But from the perspective of the clustering problem per se, a direct use of NEs and other linguistic features does not seem to pay off.

[8] The DT classifier output consists of two confidence values, one for the positive and one for the negative answer, that add up to 1.0 .

Abstract

In this paper, we investigate how an accurate question classifier contributes to a question answering system. We first present a Maximum Entropy (ME) based question classifier which makes use of head word features and their WordNet hypernyms. We show that our question classifier can achieve the state of the art performance in the standard UIUC question dataset. We then investigate quantitatively the contribution of this question classifier to a feature driven question answering system. With our accurate question classifier and some standard question answer features, our question answering system performs close to the state of the art using TREC corpus.

1 Introduction

Question answering has drawn significant attention from the last decade (Prager, 2006). It attempts to answer the question posed in natural language by providing the answer phrase rather than the whole documents. An important step in question answering (QA) is to classify the question to the anticipated type of the answer. For example, the question of *Who discovered x-rays* should be classified into the type of human (individual). This information would narrow down the search space to identify the correct answer string. In addition, this information can suggest different strategies to search and verify a candidate answer. In fact, the combination of question classification and the named entity recognition is a key approach in modern question answering systems (Voorhees and Dang, 2005).

The question classification is by no means trivial: Simply using question wh-words can not achieve satisfactory results. The difficulty lies in classifying the *what* and *which* type questions. Considering the example *What is the capital of Yugoslavia*, it is of location (city) type, while *What is the pH scale* is of definition type. As with the previous work of (Li and Roth, 2002; Li and Roth, 2006; Krishnan et al., 2005; Moschitti et al., 2007), we propose a feature driven statistical question classifier (Huang et al., 2008). In particular, we propose head word feature and augment semantic features of such head words using WordNet. In addition, Lesk's word sense disambiguation (WSD) algorithm is adapted and the depth of hypernym feature is optimized. With further augment of other standard features such as unigrams, we can obtain accuracy of 89.0% using ME model for 50 fine classes over UIUC dataset.

In addition to building an accurate question classifier, we investigate the contribution of this question classifier to a feature driven question answering rank model. It is worth noting that, most of the features we used in question answering rank model, depend on the question type information. For instance, if a question is classified as a type of *sport*, we then only care about whether there are sport entities existing in the candidate sentences. It is expected that a fine grained named entity recognizer (NER) should make good use of the accurate question type information. However, due to the lack of a fine grained NER tool at hand, we employ the Stanford NER package (Finkel et al., 2005) which identifies only four types of named entities. Even with such a coarse named entity recognizer, the experiments show that the question classifier plays an important role in determining the performance of a question answering system.

The rest of the paper is organized as following. Section 2 reviews the maximum entropy model which are used in both question classification and question answering ranking. Section 3 presents the features used in question classification. Section 4 presents the question classification

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 543–550,
Singapore, 6-7 August 2009.

accuracy over UIUC question dataset. Section 5 presents the question answer features. Section 6 illustrates the results based on TREC question answer dataset. And Section 7 draws the conclusion.

2 Maximum Entropy Models

Maximum entropy (ME) models (Berger et al., 1996; Manning and Klein, 2003), also known as log-linear and exponential learning models, provide a general purpose machine learning technique for classification and prediction which has been successfully applied to natural language processing including part of speech tagging, named entity recognition etc. Maximum entropy models can integrate features from many heterogeneous information sources for classification. Each feature corresponds to a constraint on the model. Given a training set of (C, D), where C is a set of class labels and D is a set of feature represented data points, the maximal entropy model attempts to maximize the log likelihood

$$\log P(C|D,\lambda) = \sum_{(c,d)\in(C,D)} \log \frac{\exp \sum_i \lambda_i f_i(c,d)}{\sum_{c'} \exp \sum_j \lambda_j f_i(c,d)}, \quad (1)$$

where $f_i(c,d)$ are feature indicator functions. We use ME models for both question classification and question answer ranking. In question answer context, such function, for instance, could be the presence or absence of dictionary entities (as presented in Section 5.2) associated with a particular class type (either *true* or *false*, indicating a sentence can or cannot answer the question). λ_i are the parameters need to be estimated which reflects the importance of $f_i(c,d)$ in prediction.

3 Question Classification Features

Li and Roth (2002) have developed a machine learning approach which uses the SNoW learning architecture. They have compiled the UIUC question classification dataset[1] which consists of 5500 training and 500 test questions.[2] All questions in the dataset have been manually labeled according to the coarse and fine grained categories as shown in Table 1, with coarse classes (in bold) followed by their fine classes.

The UIUC dataset has laid a platform for the follow-up research including (Hacioglu and Ward, 2003; Zhang and Lee, 2003; Li and Roth, 2006; Krishnan et al., 2005; Moschitti et al., 2007). In contrast to Li and Roth (2006)'s approach which makes use of a very rich feature set, we propose to use a compact yet effective feature set. The features are briefly described as following. More detailed information can be found at (Huang et al., 2008).

Table 1: 6 coarse and 50 fine Question types defined in UIUC question dataset.

ABBR	letter	desc	**NUM**
abb	other	manner	code
exp	plant	reason	count
ENTITY	product	**HUMAN**	date
animal	religion	group	distance
body	sport	individual	money
color	substance	title	order
creative	symbol	desc	other
currency	technique	**LOC**	period
dis.med.	term	city	percent
event	vehicle	country	speed
food	word	mountain	temp
instrument	**DESC**	other	size
lang	definition	state	weight

Question wh-word The wh-word feature is the question wh-word in given questions. For example, the wh-word of question *What is the population of China* is *what*.

Head Word *head word* is defined as one *single* word specifying the object that the question seeks. For example the head word of *What is a group of turkeys called*, is *turkeys*. This is different to previous work including (Li and Roth, 2002; Krishnan et al., 2005) which has suggested a contiguous span of words (*a group of turkeys* in this example). The single word definition effectively avoids the noisy information brought by non-head word of the span (*group* in this case). A syntactic parser (Petrov and Klein, 2007) and the Collins rules (Collins, 1999) are modified to extract such head words.

WordNet Hypernym WordNet hypernyms are extracted for the head word of a given question. The classic Lesk algorithm (Lesk, 1986) is used to compute the most probable sense for a head word in the question context, and then the hypernyms are extracted based on that sense. The depth of hypernyms is set to

[1] Available at http://12r.cs.uiuc.edu/∼cogcomp/Data/QA/QC.
[2] Test questions are from TREC 10.

six with trial and error.[3] Hypernyms features capture the general terms of extracted head word. For instance, the head word of question *What is the proper name for a female walrus* is extracted as *walrus* and its direct hypernyms such as *mammal* and *animal* are extracted as informative features to predict the correct question type of ENTY:animal.

Unigram words Bag of words features. Such features provide useful question context information.

Word shape Five word shape features, namely all upper case, all lower case, mixed case, all digits, and other are used to serve as a coarse named entity recognizer.

4 Question Classification Experiments

We train a Maximum Entropy model using the UIUC 5500 training questions and test over the 500 test questions. Tables 2 shows the accuracy of 6 coarse class and 50 fine grained class, with features being fed incrementally. The question classification performance is measured by accuracy, i.e., the proportion of the correctly classified questions among all test questions. The baseline using the wh-head word results in 46.0% and 46.8% respectively for 6 coarse and 50 fine class classification. The incremental use of head word boosts the accuracy significantly to 92.2% and 82.0% for 6 and 50 classes. This reflects the informativeness of such feature. The inclusion of hypernym feature within 6 depths boosts 3.6% for 50 classes, while resulting in slight loss for 6 coarse classes. The further use of unigram feature leads to 2.8% gain in 50 classes. Finally, the use of word shape leads to 0.6% accuracy increase for 50 classes. The best accuracies achieved are 93.6% and 89.0% for 6 and 50 classes respectively.

Table 2: Question classification accuracy using incremental feature sets for 6 and 50 classes over UIUC split.

	6 class	50 class
wh-word	46.0	46.8
+ head word	92.2	82.0
+ hypernym	91.8	85.6
+ unigram	93.0	88.4
+ word shape	93.6	89.0

The individual feature contributions were discussed in greater detail in (Huang et al., 2008). Also, The SVM (rathern than ME model) was employed using the same feature set and the results were very close (93.4% for 6 class and 89.2% for 50 class). Table 3 shows the feature ablation experiment[4] which is missing in that paper. The experiment shows that the proposed head word and its hypernym features play an essential role in building an accurate question classifier.

Table 3: Question classification accuracy by removing one feature at a time for 6 and 50 classes over UIUC split.

	6 class	50 class
overall	93.6	89.0
- wh-word	93.6	89.0
- head word	92.8	88.2
- hypernym	90.8	84.2
- unigram	93.6	86.8
- word shape	93.0	88.4

Our best result feature space only consists of 13'697 binary features and each question has 10 to 30 active features. Compared to the over feature size of 200'000 in Li and Roth (2002), our feature space is much more compact, yet turned out to be more informative as suggested by the experiments. Table 4 shows the summary of the classification accuracy of all question classifiers which were applied to UIUC dataset.[5] Our results are summarized in the last row.

In addition, we have performed the 10 cross validation experiment over the 5500 UIUC training corpus using our best model. The result is 89.05 ± 1.25 and 83.73 ± 1.61 for 6 and 50 classes,[6] which outperforms the best result of 86.1 ± 1.1 for 6 classes as reported in (Moschitti et al., 2007).

5 Question Answer Features

For a pair of a question and a candidate sentence, we extract binary features which include CoNLL named entities presence feature (NE), dictionary

[3] We performed 10 cross validation experiment over training data and tried various depths of 1, 3, 6, 9 and ∞, with ∞ signifies that no depth constraint is imposed.

[4] Remove one feature at a time from the entire feature set.

[5] Note (1) that SNoW accuracy without the related word dictionary was not reported. With the semantically related word dictionary, it achieved 91%. Note (2) that SNoW with a semantically related word dictionary achieved 84.2% but the other algorithms did not use it.

[6] These results are worse than the result over UIUC split; as the UIUC test data includes a larger percentage of easily classified question types.

Table 4: Accuracy of all question classifiers which were applied to UIUC dataset.

Algorithm	6 class	50 class
Li and Roth, SNoW	$-^{(1)}$	$78.8^{(2)}$
Hacioglu et al., SVM+ECOC	–	80.2-82
Zhang & Lee, Linear SVM	87.4	79.2
Zhang & Lee, Tree SVM	90.0	–
Krishnan et al., SVM+CRF	93.4	86.2
Moschitti et al., Kernel	91.8	–
Maximum Entropy Model	93.6	89.0

entities presence feature (DIC), numerical entities presence feature (NUM), question specific feature (SPE), and dependency validity feature (DEP).

5.1 CoNLL named entities presence feature

We use Stanford named entity recognizer (NER) (Finkel et al., 2005) to identify CoNLL style NEs[7] as possible answer strings in a candidate sentence for a given type of question. In particular, if the question is ABBR type, we tag CoNLL LOC, ORG and MISC entities as candidate answers; If the question is HUMAN type, we tag CoNLL PER and ORG entities; And if the question is LOC type, we tag CoNLL LOC and MISC entities. For other types of questions, we assume there is no candidate CoNLL NEs to tag. We create a binary feature **NE** to indicate the presence or absence of tagged CoNLL entities. Further more, we create four binary features **NE-PER**, **NE-LOC**, **NE-ORG**, and **NE-MISC** to indicate the presence of tagged CoNLL PER, LOC, ORG and MISC entities.

5.2 Dictionary entities presence feature

As four types of CoNLL named entities are not enough to cover 50 question types, we include the 101 dictionary files compiled in the Ephyra project (Schlaefer et al., 2007). These dictionary files contain names for specific semantic types. For example, the *actor* dictionary comprises a list of actor names such as *Tom Hanks* and *Kevin Spacey*. For each question, if the head word of such question (see Section 3) matches the name of a dictionary file, then each noun phrase in a candidate sentence is looked up to check its presence in the dictionary. If so, a binary **DIC** feature is created. For example, for the question *What rank did Chester Nimitz reach*, as there is a *military rank* dictionary matches the head word *rank*, then all the noun phrases in a candidate sentence are looked up in the *military rank* dictionary. As a result, a sentence contains word *Admiral* will result in the DIC feature being activated, as such word is present in the *military rank* dictionary.

Note that an implementation tip is to allow the proximity match in the dictionary look up. Consider the question *What film introduced Jar Jar Binks*. As there is a match between the question head word *film* and the dictionary named *film*, each noun phrase in the candidate sentence is checked. However, no dictionary entities have been found from the candidate sentence *Best plays Jar Jar Binks, a floppy-eared, two-legged creature in "Star Wars: Episode I – The Phantom Menace"*, although there is movie entitled *Star Wars Episode I: The Phantom Menace* in the dictionary. Notice that *Star Wars: Episode I – The Phantom Menace* in the sentence and the dictionary entity *Star Wars Episode I: The Phantom Menace* do not have exactly identical spelling. The use of proximity look up which allows edit distance being less than 10% error can resolve this.

5.3 Numerical entities presence feature

There are so far no match for question types of NUM (as shown in Table 1) including NUM:count and NUM:date etc. These types of questions seek the numerical answers such as the amount of money and the duration of period. It is natural to compile regular expression patterns to match such entities. For example, for a NUM:money typed question *What is Rohm and Haas's annual revenue*, we compile NUM:money regular expression pattern which matches the strings of number followed by a currency sign (*$* and *dollars* etc). Such pattern is able to identify *4 billion $* as a candidate answer in the candidate sentence *Rohm and Haas, with 4 billion $ in annual sales...* There are 13 patterns compiled to cover all numerical types. We create a binary feature **NUM** to indicate the presence of possible numerical answers in a sentence.

5.4 Specific features

Specific features are question dependent. For example, for question *When was James Dean born*, any candidate sentence matches the pattern *James Dean (number - number)* is likely to answer such question. We create a binary feature **SPE** to indicate the presence of such match between a ques-

[7] Person (PER), location (LOC), organization (ORG), and miscellaneous (MISC).

tion and a candidate sentence. We list all question and sentence match patterns which are used in our experiments as following:

when born feature 1 The question begins with *when is/was* and follows by a person name and then follows by key word *born*; The candidate sentence contains such person name which follows by the pattern of *(number - number)*.

when born feature 2 The question begins with *when is/was* and follows by a person name and then follows by key word *born*; The candidate sentence contains such person name, a NUM:date entity, and a key word *born*.

where born feature 1 The question begins with *where is/was* and follows by a person name and then follows by key word *born*; The candidate sentence contains such person name, a NER LOC entity, and a key word *born*.

when die feature 1 The question begins with *when did* and follows by a person name and then follows by key word *die*; The candidate sentence contains such person name which follows by the pattern of *(number - number)*.

when die feature 2 The question begins with *when did* and follows by a person name and then follows by key word *die*; The candidate sentence contains such person name, a NUM:date entity, and a key word *died*.

how many feature The question begins with *how many* and follows by a noun; The candidate sentence contains a number and then follows by such noun.

cooccurrent Feature This feature takes two phrase arguments, if the question contains the first phrase and the candidate sentence contains the second, such feature would be activated.

Note that the construction of specific features require the access to aforementioned extracted named entities. For example, the **when born feature 2** pattern needs the information whether a candidate sentence contains a NUM:date entity and **where born feature 1** pattern needs the information whether a candidate sentence contains a NER LOC entity. Note also that the patterns of **when born feature** and **when die feature** have similar structure and thus can be simplified in implementation. **How many feature** can be used to identify the sentence *Amtrak annually serves about 21 million passengers* for question *How many passengers does Amtrak serve annually*. The **cooccurrent feature** is the most general one. An example of cooccurrent feature would take the arguments of *marry* and *husband*, or *marry* and *wife*. Such feature would be activated for question *Whom did Eileen Marie Collins marry* and candidate sentence *... were Collins' husband, Pat Youngs, an airline pilot...* It is worth noting that the two arguments are not necessarily different. For example, they could be both *established*, which makes such feature activated for question *When was the IFC established* and candidate sentence *IFC was established in 1956 as a member of the World Bank Group*. The reason why we use the cooccurrence of the word *established* is due to its main verb role, which may carry more information than other words.

5.5 Dependency validity features

Like (Cui et al., 2004), we extract the dependency path from the question word to the common word (existing in both question and sentence), and the path from candidate answer (such as CoNLL NE and numerical entity) to the common word for each pair of question and candidate sentence using Stanford dependency parser (Klein and Manning, 2003; Marneffe et al., 2006). For example, for question *When did James Dean die* and candidate sentence *In 1955, actor James Dean was killed in a two-car collision near Cholame, Calif.*, we extract the pathes of *When:advmod:nsubj:Dean* and *1955:prep-in:nsubjpass:Dean* for question and sentence respectively, where *advmod* and *nsubj* etc. are grammatical relations. We propose the dependency validity feature (**DEP**) as following. For all paired paths between a question and a candidate sentence, if at least one pair of path in which all pairs of grammatical relations have been seen in the training, then the DEP feature is set to be true, false otherwise. That is, the true validity feature indicates that at least one pair of path between the question and candidate sentence is possible to be a true pair (ie, the candidate noun phrase in the sentence path is the true answer).

6 Question Answer Experiments

Recall that most of the question answer features depend on the question classifier. For instance, the NE feature checks the presence or absence of CoNLL style named entities subject to the classified question type. In this section, we evaluate how the quality of question classifiers affects the question answering performance.

6.1 Experiment setup

We use TREC99-03 factoid questions for training and TREC04 factoid questions for testing. To facilitate the comparison to others work (Cui et al., 2004; Shen and Klakow, 2006), we first retrieve all relevant documents which are compiled by Ken Litkowski[8] to create training and test datasets. We

[8] Available at http://trec.nist.gov/data/qa.html.

then apply key word search for each question and retrieve the top 20 relevant sentences. We create a feature represented data point using each pair of question and candidate sentence and label it either *true* or *false* depending on whether the sentence can answer the given question or not. The labeling is conducted by matching the gold factoid answer pattern against the candidate sentence.

There are two extra steps performed for training set but not for test data. In order to construct a high quality training set, we manually check the correctness of the training data points and remove the false positive ones which cannot support the question although there is a match to gold answer. In addition, in order to keep the training data well balanced, we keep maximum four false data points (question answer pair) for each question but no limit over the true label data points. In doing so, we use 1458 questions to compile 8712 training data points and among them 1752 have true labels. Similarly, we use 202 questions to compile 4008 test data points and among them 617 have true labels.

We use the training data to train a maximum entropy model and use such model to rank test data set. Compared with a classification task (such as the question classifier), the ranking process requires one extra step: For data points which share the same question, the probabilities of being predicted as true label are used to rank the data points. In align with the previous work, performance is evaluated using mean reciprocal rank (MRR), top 1 prediction accuracy (top1) and top 5 prediction accuracy (top5). For the test data set, 157 among the 202 questions have correct answers found in retrieved sentences. This leads to the upper bound of MRR score being 77.8%.

To evaluate how the quality of question classifiers affects the question answering, we have created three question classifiers: QC1, QC2 and QC3. The features which are used to train these question classifiers and their performance are shown in Table 5. Note that QC3 is the best question classifier we obtained in Section 4.

Table 5: Features used to train and the performance of three question classifiers.

Name	features	6 class	50 class
QC1	wh-word	46.0	46.8
QC2	wh-word+ head	92.2	82.0
QC3	All	93.6	89.0

6.2 Experiment results

The first experiment is to evaluate the individual contribution of various features derived using three question classifiers. Table 6 shows the baseline result and results using DIC, NE, NE-4, REG, SPE, and DEP features. The baseline is the key word search without the use of maximum entropy model. As can be seen, the question classifiers do not affect the DIC feature at all, as DIC feature does not depend on question classifiers. Better question classifier boosts considerable gain for NE, NE-4 and REG in their contribution to question answering. For example, the best question classifier QC3 outperforms the worst one (QC1) by 1.5%, 2.0%, and 2.0% MRR scores for NE, NE-4 and REG respectively. However, it is surprising that the MRR and top5 contribution of NE and NE-4 decreases if QC1 is replaced by QC2, although the top1 score results in performance gain slightly. This unexpected results can be partially explained as follows. For some questions, even QC2 produces correct predictions, the errors of NE and NE-4 features may cause over-confident scores for certain candidate sentences. As SPE and DEP are not directly dependent on question classifier, their individual contribution only changes slightly or remains the same for different question classifiers. If the best question classifier is used, the most important features are SPE and REG, which can individually boost the MRR score over 54%, while the others result in less significant gains.

We now incrementally use various features and the results are show in Table 6 as well. As can be seen, the more features and the better question classifier are used, the higher performance the ME model has. The inclusion of REG and SPE results in significant boost for the performance. For example, if the best question classifier QC3 is used, the REG results in 6.9% and 8% gain for MRR and top1 scores respectively. This is due to a large portion of NUM type questions in test dataset. The SPE feature contributes significantly to the performance due to its high precision in answering birth/death time/location questions. NE and NE-4 result in reasonable gains while DEP feature contributes little. However, this does not mean that DEP is not important, as once the model reaches a high MRR score, it becomes hard to improve.

Table 6 clearly shows that the question type classifier plays an essential role in a high perfor-

mance question answer system. Assume all the features are used, the better question classifier significantly boosts the overall performance. For example, the best question classifier QC3 outperforms the worst QC1 by 4.9%, 6.5%, and 2.0% for MRR, top1 and top5 scores respectively. Even compared to a good question classifier QC2, the gain of using QC3 is still 3.4%, 4.0% and 2.0% for MRR, top1 and top5 scores respectively. One can imagine that if a fine grained NER is available (rather than the current four type coarse NER), the potential gain is much significant.

The reason that the question classifier affects the question answering performance is straightforward. As a upstream source, the incorrect classification of question type would confuse the downstream answer search process. For example, for question *What is Rohm and Haas's annual revenue*, our best question classifier is able to classify it into the correct type of NUM:money and thus would put *$ 4 billion* as a candidate answer. However, the inferior question classifiers misclassify it into HUM:ind type and thereby could not return a correct answer. Figure 1 shows the individual MRR scores for the 42 questions (among the 202 test questions) which have different predicted question types using QC3 and QC2. For almost all test questions, the accurate question classifier QC3 achieves higher MRR scores compared to QC2.

Table 7 shows performance of various question answer systems including (Tanev et al., 2004; Wu et al., 2005; Cui et al., 2004; Shen and Klakow, 2006) and this work which were applied to the same training and test datasets. Among all the systems, our model can achieve the best MRR score of 66.3%, which is close to the state of the art of 67.0%. Considering the question answer features used in this paper are quite standard, the boost is mainly due to our accurate question classifier.

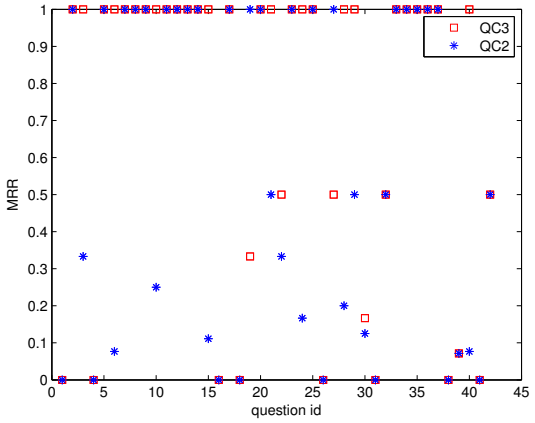

Figure 1: Individual MRR scores for questions which have different predicted question types using QC3 and QC2.

Table 7: Various system performance comparison.

System	MRR	Top1	Top5
Tanev et al. 2004	57.0	49.0	67.0
Cui et al. 2004	60.0	53.0	70.0
Shen and Klakow, 2006	67.0	62.0	74.0
This work	66.3	62.4	73.8

7 Conclusion

In this paper, we have presented a question classifier which makes use of a compact yet efficient feature set. The question classifier outperforms previous question classifiers over the standard UIUC question dataset. We further investigated quantitatively how the quality of question classifier impacts the performance of question answer system. The experiments showed that an accurate question classifier plays an essential role in question answering system. With our accurate question classifier and some standard question answer features, our question answering system performs close to the state of the art.

Abstract

This paper describes an empirical study of high-performance dependency parsers based on a semi-supervised learning approach. We describe an extension of semi-supervised structured conditional models (SS-SCMs) to the dependency parsing problem, whose framework is originally proposed in (Suzuki and Isozaki, 2008). Moreover, we introduce two extensions related to dependency parsing: The first extension is to combine SS-SCMs with another semi-supervised approach, described in (Koo et al., 2008). The second extension is to apply the approach to second-order parsing models, such as those described in (Carreras, 2007), using a two-stage semi-supervised learning approach. We demonstrate the effectiveness of our proposed methods on dependency parsing experiments using two widely used test collections: the Penn Treebank for English, and the Prague Dependency Treebank for Czech. Our best results on test data in the above datasets achieve 93.79% parent-prediction accuracy for English, and 88.05% for Czech.

1 Introduction

Recent work has successfully developed dependency parsing models for many languages using supervised learning algorithms (Buchholz and Marsi, 2006; Nivre et al., 2007). Semi-supervised learning methods, which make use of unlabeled data in addition to labeled examples, have the potential to give improved performance over purely supervised methods for dependency parsing. It is often straightforward to obtain large amounts of unlabeled data, making semi-supervised approaches appealing; previous work on semi-supervised methods for dependency parsing includes (Smith and Eisner, 2007; Koo et al., 2008; Wang et al., 2008).

In particular, Koo et al. (2008) describe a semi-supervised approach that makes use of cluster features induced from unlabeled data, and gives state-of-the-art results on the widely used dependency parsing test collections: the Penn Treebank (PTB) for English and the Prague Dependency Treebank (PDT) for Czech. This is a very simple approach, but provided significant performance improvements comparing with the state-of-the-art supervised dependency parsers such as (McDonald and Pereira, 2006).

This paper introduces an alternative method for semi-supervised learning for dependency parsing. Our approach basically follows a framework proposed in (Suzuki and Isozaki, 2008). We extend it for dependency parsing, which we will refer to as a Semi-supervised Structured Conditional Model (SS-SCM). In this framework, a structured conditional model is constructed by incorporating a series of generative models, whose parameters are estimated from unlabeled data. This paper describes a basic method for learning within this approach, and in addition describes two extensions. The first extension is to combine our method with the cluster-based semi-supervised method of (Koo et al., 2008). The second extension is to apply the approach to second-order parsing models, more specifically the model of (Carreras, 2007), using a two-stage semi-supervised learning approach.

We conduct experiments on dependency parsing of English (on Penn Treebank data) and Czech (on the Prague Dependency Treebank). Our experiments investigate the effectiveness of: 1) the basic SS-SCM for dependency parsing; 2) a combination of the SS-SCM with Koo et al. (2008)'s semi-supervised approach (even in the case we used the same unlabeled data for both methods); 3) the two-stage semi-supervised learning approach that in-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 551–560,
Singapore, 6-7 August 2009.

corporates a second-order parsing model. In addition, we evaluate the SS-SCM for English dependency parsing with large amounts (up to 3.72 billion tokens) of unlabeled data .

2 Semi-supervised Structured Conditional Models for Dependency Parsing

Suzuki et al. (2008) describe a semi-supervised learning method for conditional random fields (CRFs) (Lafferty et al., 2001). In this paper we extend this method to the dependency parsing problem. We will refer to this extended method as *Semi-supervised Structured Conditional Models (SS-SCMs)*. The remainder of this section describes our approach.

2.1 The Basic Model

Throughout this paper we will use $\mathbf{x}$ to denote an input sentence, and $\mathbf{y}$ to denote a labeled dependency structure. Given a sentence $\mathbf{x}$ with n words, a labeled dependency structure $\mathbf{y}$ is a set of n dependencies of the form (h, m, l), where h is the index of the head-word in the dependency, m is the index of the modifier word, and l is the label of the dependency. We use $h = 0$ for the root of the sentence. We assume access to a set of labeled training examples, $\{\mathbf{x}_i, \mathbf{y}_i\}_{i=1}^N$, and in addition a set of unlabeled examples, $\{\mathbf{x}'_i\}_{i=1}^M$.

In conditional log-linear models for dependency parsing (which are closely related to conditional random fields (Lafferty et al., 2001)), a distribution over dependency structures for a sentence $\mathbf{x}$ is defined as follows:

$$p(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \exp\{g(\mathbf{x}, \mathbf{y})\}, \qquad (1)$$

where $Z(\mathbf{x})$ is the partition function, $\mathbf{w}$ is a parameter vector, and

$$g(\mathbf{x}, \mathbf{y}) = \sum_{(h,m,l) \in \mathbf{y}} \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, h, m, l)$$

Here $\mathbf{f}(\mathbf{x}, h, m, l)$ is a feature vector representing the dependency (h, m, l) in the context of the sentence $\mathbf{x}$ (see for example (McDonald et al., 2005a)).

In this paper we extend the definition of $g(\mathbf{x}, \mathbf{y})$ to include features that are induced from unlabeled data. Specifically, we define

$$g(\mathbf{x}, \mathbf{y}) = \sum_{(h,m,l) \in \mathbf{y}} \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, h, m, l) + \sum_{(h,m,l) \in \mathbf{y}} \sum_{j=1}^{k} v_j q_j(\mathbf{x}, h, m, l). \quad (2)$$

In this model $v_1, \ldots, v_k$ are scalar parameters that may be positive or negative; $q_1 \ldots q_k$ are functions (in fact, generative models), that are trained on unlabeled data. The v_j parameters will dictate the relative strengths of the functions $q_1 \ldots q_k$, and will be trained on labeled data.

For convenience, we will use $\mathbf{v}$ to refer to the vector of parameters $v_1 \ldots v_k$, and $\mathbf{q}$ to refer to the set of generative models $q_1 \ldots q_k$. The full model is specified by values for $\mathbf{w}, \mathbf{v}$, and $\mathbf{q}$. We will write $p(\mathbf{y}|\mathbf{x}; \mathbf{w}, \mathbf{v}, \mathbf{q})$ to refer to the conditional distribution under parameter values $\mathbf{w}, \mathbf{v}, \mathbf{q}$.

We will describe a three-step parameter estimation method that: 1) initializes the $\mathbf{q}$ functions (generative models) to be uniform distributions, and estimates parameter values $\mathbf{w}$ and $\mathbf{v}$ from labeled data; 2) induces new functions $q_1 \ldots q_k$ from unlabeled data, based on the distribution defined by the $\mathbf{w}, \mathbf{v}, \mathbf{q}$ values from step (1); 3) re-estimates $\mathbf{w}$ and $\mathbf{v}$ on the labeled examples, keeping the $q_1 \ldots q_k$ from step (2) fixed. The end result is a model that combines supervised training with generative models induced from unlabeled data.

2.2 The Generative Models

We now describe how the generative models $q_1 \ldots q_k$ are defined, and how they are induced from unlabeled data. These models make direct use of the feature-vector definition $\mathbf{f}(\mathbf{x}, \mathbf{y})$ used in the original, fully supervised, dependency parser.

The first step is to partition the d features in $\mathbf{f}(\mathbf{x}, \mathbf{y})$ into k separate feature vectors, $\mathbf{r}_1(\mathbf{x}, \mathbf{y}) \ldots \mathbf{r}_k(\mathbf{x}, \mathbf{y})$ (with the result that $\mathbf{f}$ is the concatenation of the k feature vectors $\mathbf{r}_1 \ldots \mathbf{r}_k$). In our experiments on dependency parsing, we partitioned $\mathbf{f}$ into up to over 140 separate feature vectors corresponding to different feature types. For example, one feature vector $\mathbf{r}_j$ might include only those features corresponding to word bigrams involved in dependencies (i.e., indicator functions tied to the word bigram (x_m, x_h) involved in a dependency $(\mathbf{x}, h, m, l)$).

We then define a generative model that assigns a probability

$$q'_j(\mathbf{x}, h, m, l) = \prod_{a=1}^{d_j} \theta_{j,a}^{r_{j,a}(\mathbf{x},h,m,l)} \qquad (3)$$

to the d_j-dimensional feature vector $\mathbf{r}_j(\mathbf{x}, h, m, l)$. The parameters of this model are $\theta_{j,1} \ldots \theta_{j,d_j}$;

they form a multinomial distribution, with the constraints that $\theta_{j,a} \geq 0$, and $\sum_a \theta_{j,a} = 1$. This model can be viewed as a very simple (naive-Bayes) model that defines a distribution over feature vectors $\mathbf{r}_j \in \mathbb{R}^{d_j}$. The next section describes how the parameters $\theta_{j,a}$ are trained on unlabeled data.

Given parameters $\theta_{j,a}$, we can simply define the functions $q_1 \ldots q_k$ to be log probabilities under the generative model:

$$\begin{aligned} q_j(\mathbf{x}, h, m, l) &= \log q'_j(\mathbf{x}, h, m, l) \\ &= \sum_{a=1}^{d_j} r_{j,a}(\mathbf{x}, h, m, l) \log \theta_{j,a}. \end{aligned}$$

We modify this definition slightly, be introducing scaling factors $c_{j,a} > 0$, and defining

$$q_j(\mathbf{x}, h, m, l) = \sum_{a=1}^{d_j} r_{j,a}(\mathbf{x}, h, m, l) \log \frac{\theta_{j,a}}{c_{j,a}} \quad (4)$$

In our experiments, $c_{j,a}$ is simply a count of the number of times the feature indexed by (j, a) appears in unlabeled data. Thus more frequent features have their contribution down-weighted in the model. We have found this modification to be beneficial.

2.3 Estimating the Parameters of the Generative Models

We now describe the method for estimating the parameters $\theta_{j,a}$ of the generative models. We assume initial parameters $\mathbf{w}, \mathbf{v}, \mathbf{q}$, which define a distribution $p(\mathbf{y}|\mathbf{x}'_i; \mathbf{w}, \mathbf{v}, \mathbf{q})$ over dependency structures for each unlabeled example $\mathbf{x}'_i$. We will re-estimate the generative models $\mathbf{q}$, based on unlabeled examples. The likelihood function on unlabeled data is defined as

$$\sum_{i=1}^{M} \sum_{\mathbf{y}} p(\mathbf{y}|\mathbf{x}'_i; \mathbf{w}, \mathbf{v}, \mathbf{q}) \sum_{(h,m,l) \in \mathbf{y}} \log q'_j(\mathbf{x}'_i, h, m, l), \quad (5)$$

where q'_j is as defined in Eq. 3. This function resembles the Q function used in the EM algorithm, where the hidden labels (in our case, dependency structures), are filled in using the conditional distribution $p(\mathbf{y}|\mathbf{x}'_i; \mathbf{w}, \mathbf{v}, \mathbf{q})$.

It is simple to show that the estimates $\theta_{j,a}$ that maximize the function in Eq. 5 can be defined as follows. First, define a vector of *expected counts* based on $\mathbf{w}, \mathbf{v}, \mathbf{q}$ as

$$\hat{\mathbf{r}}_j = \sum_{i=1}^{M} \sum_{\mathbf{y}} p(\mathbf{y}|\mathbf{x}'_i; \mathbf{w}, \mathbf{v}, \mathbf{q}) \sum_{(h,m,l) \in \mathbf{y}} \mathbf{r}_j(\mathbf{x}'_i, h, m, l).$$

Note that it is straightforward to calculate these expected counts using a variant of the inside-outside algorithm (Baker, 1979) applied to the (Eisner, 1996) dependency-parsing data structures (Paskin, 2001) for projective dependency structures, or the matrix-tree theorem (Koo et al., 2007; Smith and Smith, 2007; McDonald and Satta, 2007) for non-projective dependency structures.

The estimates that maximize Eq. 5 are then

$$\theta_{j,a} = \frac{\hat{r}_{j,a}}{\sum_{a=1}^{d_j} \hat{r}_{j,a}}.$$

In a slight modification, we employ the following estimates in our model, where $\eta > 1$ is a parameter of the model:

$$\theta_{j,a} = \frac{(\eta - 1) + \hat{r}_{j,a}}{d_j \times (\eta - 1) + \sum_{a=1}^{d_j} \hat{r}_{j,a}}. \quad (6)$$

This corresponds to a MAP estimate under a Dirichlet prior over the $\theta_{j,a}$ parameters.

2.4 The Complete Parameter-Estimation Method

This section describes the full parameter estimation method. The input to the algorithm is a set of labeled examples $\{\mathbf{x}_i, \mathbf{y}_i\}_{i=1}^N$, a set of unlabeled examples $\{\mathbf{x}'_i\}_{i=1}^M$, a feature-vector definition $\mathbf{f}(\mathbf{x}, \mathbf{y})$, and a partition of $\mathbf{f}$ into k feature vectors $\mathbf{r}_1 \ldots \mathbf{r}_k$ which underly the generative models. The output from the algorithm is a parameter vector $\mathbf{w}$, a set of generative models $q_1 \ldots q_k$, and parameters $v_1 \ldots v_k$, which define a probabilistic dependency parsing model through Eqs. 1 and 2. The learning algorithm proceeds in three steps:

Step 1: Estimation of a Fully Supervised Model. We choose the initial value $\mathbf{q}^0$ of the generative models to be the uniform distribution, i.e., we set $\theta_{j,a} = 1/d_j$ for all j, a. We then define the regularized log-likelihood function for the labeled examples, with the generative model fixed at $\mathbf{q}^0$, to be:

$$\begin{aligned} L(\mathbf{w}, \mathbf{v}; \mathbf{q}^0) = &\sum_{i=1}^{n} \log p(\mathbf{y}_i|\mathbf{x}_i; \mathbf{w}, \mathbf{v}, \mathbf{q}^0) \\ &- \frac{C}{2} \left(||\mathbf{w}||^2 + ||\mathbf{v}||^2 \right) \end{aligned}$$

This is a conventional regularized log-likelihood function, as commonly used in CRF models. The parameter $C > 0$ dictates the level of regularization in the model. We define the initial parameters $(\mathbf{w}^0, \mathbf{v}^0) = \arg\max_{\mathbf{w},\mathbf{v}} L(\mathbf{w}, \mathbf{v}; \mathbf{q}^0)$. These parameters can be found using conventional methods for estimating the parameters of regularized log-likelihood functions (in our case we use LBFGS (Liu and Nocedal, 1989)). Note that the gradient of the log-likelihood function can be calculated using the inside-outside algorithm applied to projective dependency parse structures, or the matrix-tree theorem applied to non-projective structures.

Step 2: Estimation of the Generative Models. In this step, expected count vectors $\hat{\mathbf{r}}_1 \ldots \hat{\mathbf{r}}_k$ are first calculated, based on the distribution $p(\mathbf{y}|\mathbf{x}; \mathbf{w}^0, \mathbf{v}^0, \mathbf{q}^0)$. Generative model parameters $\theta_{j,a}$ are calculated through the definition in Eq. 6; these estimates define updated generative models q_j^1 for $j = 1 \ldots k$ through Eq. 4. We refer to the new values for the generative models as $\mathbf{q}^1$.

Step 3: Re-estimation of $\mathbf{w}$ and $\mathbf{v}$. In the final step, $\mathbf{w}^1$ and $\mathbf{v}^1$ are estimated as $\arg\max_{\mathbf{w},\mathbf{v}} L(\mathbf{w}, \mathbf{v}; \mathbf{q}^1)$ where $L(\mathbf{w}, \mathbf{v}; \mathbf{q}^1)$ is defined in an analogous way to $L(\mathbf{w}, \mathbf{v}; \mathbf{q}^0)$. Thus $\mathbf{w}$ and $\mathbf{v}$ are re-estimated to optimize log-likelihood of the labeled examples, with the generative models $\mathbf{q}^1$ estimated in step 2.

The final output from the algorithm is the set of parameters $(\mathbf{w}^1, \mathbf{v}^1, \mathbf{q}^1)$. Note that it is possible to iterate the method—steps 2 and 3 can be repeated multiple times (Suzuki and Isozaki, 2008)—but in our experiments we only performed these steps once.

3 Extensions

3.1 Incorporating Cluster-Based Features

Koo et al. (2008) describe a semi-supervised approach that incorporates cluster-based features, and that gives competitive results on dependency parsing benchmarks. The method is a two-stage approach. First, hierarchical word clusters are derived from unlabeled data using the Brown et al. clustering algorithm (Brown et al., 1992). Second, a new feature set is constructed by representing words by bit-strings of various lengths, corresponding to clusters at different levels of the hierarchy. These features are combined with conventional features based on words and part-of-speech tags. The new feature set is then used within a conventional discriminative, supervised approach, such as the averaged perceptron algorithm.

The important point is that their approach uses unlabeled data only for the construction of a new feature set, and never affects to learning algorithms. It is straightforward to incorporate cluster-based features within the SS-SCM approach described in this paper. We simply use the cluster-based feature-vector representation $\mathbf{f}(\mathbf{x}, \mathbf{y})$ introduced by (Koo et al., 2008) as the basis of our approach.

3.2 Second-order Parsing Models

Previous work (McDonald and Pereira, 2006; Carreras, 2007) has shown that second-order parsing models, which include information from "sibling" or "grandparent" relationships between dependencies, can give significant improvements in accuracy over first-order parsing models. In principle it would be straightforward to extend the SS-SCM approach that we have described to second-order parsing models. In practice, however, a bottleneck for the method would be the estimation of the generative models on unlabeled data. This step requires calculation of marginals on unlabeled data. Second-order parsing models generally require more costly inference methods for the calculation of marginals, and this increased cost may be prohibitive when large quantities of unlabeled data are employed.

We instead make use of a simple 'two-stage' approach for extending the SS-SCM approach to the second-order parsing model of (Carreras, 2007). In the first stage, we use a first-order parsing model to estimate generative models $q_1 \ldots q_k$ from unlabeled data. In the second stage, we incorporate these generative models as features within a second-order parsing model. More precisely, in our approach, we first train a first-order parsing model by Step 1 and 2, exactly as described in Section 2.4, to estimate $\mathbf{w}^0$, $\mathbf{v}^0$ and $\mathbf{q}^1$. Then, we substitute Step 3 as a supervised learning such as MIRA with a second-order parsing model (McDonald et al., 2005a), which incorporates $\mathbf{q}^1$ as a real-values features. We refer this two-stage approach to as **two-stage SS-SCM**.

In our experiments we use the 1-best MIRA algorithm (McDonald and Pereira, 2006)[1] as a

[1]We used a slightly modified version of 1-best MIRA, whose difference can be found in the third line in Eq. 7, namely, including $L(\mathbf{y}_i, \mathbf{y})$.

Table 2: Details of the larger unlabeled data set used in English dependency parsing: sentences exceeding 128 tokens in length were excluded for computational reasons.

parameter-estimation method for the second-order parsing model. In particular, we perform the following optimizations on each update $t = 1, ..., T$ for re-estimating $\mathbf{w}$ and $\mathbf{v}$:

$$\begin{aligned} &\min ||\mathbf{w}^{(t+1)} - \mathbf{w}^{(t)}|| + ||\mathbf{v}^{(t+1)} - \mathbf{v}^{(t)}|| \\ &\text{s.t.} \quad S(\mathbf{x}_i, \mathbf{y}_i) - S(\mathbf{x}_i, \hat{\mathbf{y}}) \geq L(\mathbf{y}_i, \hat{\mathbf{y}}) \\ &\hat{\mathbf{y}} = \arg\max_{\mathbf{y}} S(\mathbf{x}_i, \mathbf{y}) + L(\mathbf{y}_i, \mathbf{y}), \end{aligned} \tag{7}$$

where $L(\mathbf{y}_i, \mathbf{y})$ represents the loss between correct output of i'th sample $\mathbf{y}_i$ and $\mathbf{y}$. Then, the scoring function S for each $\mathbf{y}$ can be defined as follows:

$$\begin{aligned} S(\mathbf{x}, \mathbf{y}) = &\mathbf{w} \cdot (\mathbf{f}_1(\mathbf{x}, \mathbf{y}) + \mathbf{f}_2(\mathbf{x}, \mathbf{y})) \\ &+ B \sum_{j=1}^{k} v_j q_j(\mathbf{x}, \mathbf{y}), \end{aligned} \tag{8}$$

where B represents a tunable scaling factor, and $\mathbf{f}_1$ and $\mathbf{f}_2$ represent the feature vectors of first and second-order parsing parts, respectively.

4 Experiments

We now describe experiments investigating the effectiveness of the SS-SCM approach for dependency parsing. The experiments test basic, first-order parsing models, as well as the extensions to cluster-based features and second-order parsing models described in the previous section.

4.1 Data Sets

We conducted experiments on both English and Czech data. We used the Wall Street Journal sections of the Penn Treebank (PTB) III (Marcus et al., 1994) as a source of labeled data for English, and the Prague Dependency Treebank (PDT) 1.0 (Hajič, 1998) for Czech. To facilitate comparisons with previous work, we used exactly the same training, development and test sets as those described in (McDonald et al., 2005a; McDonald et al., 2005b; McDonald and Pereira, 2006; Koo et al., 2008). The English dependency-parsing data sets were constructed using a standard set of head-selection rules (Yamada and Matsumoto, 2003) to convert the phrase structure syntax of the Treebank to dependency tree representations. We split the data into three parts: sections 02-21 for training, section 22 for development and section 23 for test. The Czech data sets were obtained from the predefined training/development/test partition in the PDT. The unlabeled data for English was derived from the Brown Laboratory for Linguistic Information Processing (BLLIP) Corpus (LDC2000T43)[2], giving a total of 1,796,379 sentences and 43,380,315 tokens. The raw text section of the PDT was used for Czech, giving 2,349,224 sentences and 39,336,570 tokens. These data sets are identical to the unlabeled data used in (Koo et al., 2008), and are disjoint from the training, development and test sets. The datasets used in our experiments are summarized in Table 1.

In addition, we will describe experiments that make use of much larger amounts of unlabeled data. Unfortunately, we have no data available other than PDT for Czech, this is done only for English dependency parsing. Table 2 shows the detail of the larger unlabeled data set used in our experiments, where we eliminated sentences that have more than 128 tokens for computational reasons. Note that the total size of the unlabeled data reaches 3.72G (billion) tokens, which is approxi-

[2]We ensured that the sentences used in the PTB were excluded from the unlabeled data, since sentences used in BLLIP corpus are a super-set of the PTB.

mately 4,000 times larger than the size of labeled training data.

4.2 Features

4.2.1 Baseline Features

In general we will assume that the input sentences include both words and part-of-speech (POS) tags. Our baseline features ("baseline") are very similar to those described in (McDonald et al., 2005a; Koo et al., 2008): these features track word and POS bigrams, contextual features surrounding dependencies, distance features, and so on. English POS tags were assigned by MXPOST (Ratnaparkhi, 1996), which was trained on the training data described in Section 4.1. Czech POS tags were obtained by the following two steps: First, we used 'feature-based tagger' included with the PDT[3], and then, we used the method described in (Collins et al., 1999) to convert the assigned rich POS tags into simplified POS tags.

4.2.2 Cluster-based Features

In a second set of experiments, we make use of the feature set used in the semi-supervised approach of (Koo et al., 2008). We will refer to this as the "cluster-based feature set" (CL). The BLLIP (43M tokens) and PDT (39M tokens) unlabeled data sets shown in Table 1 were used to construct the hierarchical clusterings used within the approach. Note that when this feature set is used within the SS-SCM approach, the same set of unlabeled data is used to both induce the clusters, and to estimate the generative models within the SS-SCM model.

4.2.3 Constructing the Generative Models

As described in section 2.2, the generative models in the SS-SCM approach are defined through a partition of the original feature vector $\mathbf{f}(\mathbf{x}, \mathbf{y})$ into k feature vectors $\mathbf{r}_1(\mathbf{x}, \mathbf{y}) \ldots \mathbf{r}_k(\mathbf{x}, \mathbf{y})$. We follow a similar approach to that of (Suzuki and Isozaki, 2008) in partitioning $\mathbf{f}(\mathbf{x}, \mathbf{y})$, where the k different feature vectors correspond to different feature types or feature templates. Note that, in general, we are not necessary to do as above, this is one systematic way of a feature design for this approach.

4.3 Other Experimental Settings

All results presented in our experiments are given in terms of parent-prediction accuracy on *unlabeled* dependency parsing. We ignore the parent-predictions of punctuation tokens for English, while we retain all the punctuation tokens for Czech. These settings match the evaluation setting in previous work such as (McDonald et al., 2005a; Koo et al., 2008).

We used the method proposed by (Carreras, 2007) for our second-order parsing model. Since this method only considers projective dependency structures, we "projectivized" the PDT training data in the same way as (Koo et al., 2008). We used a non-projective model, trained using an application of the matrix-tree theorem (Koo et al., 2007; Smith and Smith, 2007; McDonald and Satta, 2007) for the first-order Czech models, and projective parsers for all other models.

As shown in Section 2, SS-SCMs with 1st-order parsing models have two tunable parameters, C and η, corresponding to the regularization constant, and the Dirichlet prior for the generative models. We selected a fixed value $\eta = 2$, which was found to work well in preliminary experiments.[4] The value of C was chosen to optimize performance on development data. Note that C for supervised SCMs were also tuned on development data. For the two-stage SS-SCM for incorporating second-order parsing model, we have additional one tunable parameter B shown in Eq. 8. This was also chosen by the value that provided the best performance on development data.

In addition to providing results for models trained on the full training sets, we also performed experiments with smaller labeled training sets. These training sets were either created through random sampling or by using a predefined subset of document IDs from the labeled training data.

5 Results and Discussion

Table 3 gives results for the SS-SCM method under various configurations: for first and second-order parsing models, with and without the cluster features of (Koo et al., 2008), and for varying amounts of labeled data. The remainder of this section discusses these results in more detail.

5.1 Effects of the Quantity of Labeled Data

We can see from the results in Table 3 that our semi-supervised approach consistently gives gains

[3] Training, development, and test data in PDT already contains POS tags assigned by the 'feature-based tagger'.

[4] An intuitive meaning of $\eta = 2$ is that this adds one pseudo expected count to every feature when estimating new parameter values.

Table 3: Dependency parsing results for the SS-SCM method with different amounts of labeled training data. Supervised SCM (1od) and Supervised MIRA (2od) are the baseline first and second-order approaches; SS-SCM (1od) and 2-stage SS-SCM(+MIRA) (2od) are the first and second-order approaches described in this paper. "Baseline" refers to models without cluster-based features, "CL" refers to models which make use of cluster-based features.

in performance under various sizes of labeled data. Note that the baseline methods that we have used in these experiments are strong baselines. It is clear that the gains from our method are larger for smaller labeled data sizes, a tendency that was also observed in (Koo et al., 2008).

5.2 Impact of Combining SS-SCM with Cluster Features

One important observation from the results in Table 3 is that SS-SCMs can successfully improve the performance over a baseline method that uses the cluster-based feature set (CL). This is in spite of the fact that the generative models within the SS-SCM approach were trained on the same unlabeled data used to induce the cluster-based features.

5.3 Impact of the Two-stage Approach

Table 3 also shows the effectiveness of the two-stage approach (described in Section 3.2) that integrates the SS-SCM method within a second-order parser. This suggests that the SS-SCM method can be effective in providing features (generative models) used within a separate learning algorithm, providing that this algorithm can make use of real-valued features.

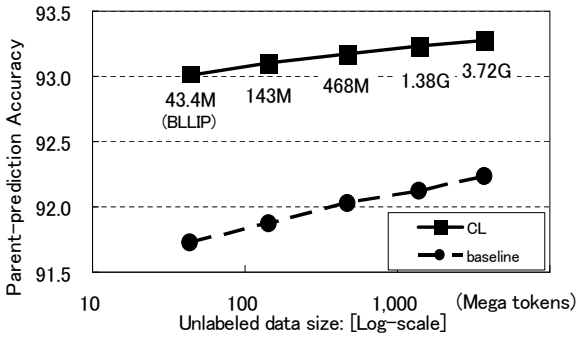

Figure 1: Impact of unlabeled data size for the SS-SCM on development data of English dependency parsing.

5.4 Impact of the Amount of Unlabeled Data

Figure 1 shows the dependency parsing accuracy on English as a function of the amount of unlabeled data used within the SS-SCM approach. (As described in Section 4.1, we have no unlabeled data other than PDT for Czech, hence this section only considers English dependency parsing.) We can see that performance does improve as more unlabeled data is added; this trend is seen both with and without cluster-based features. In addition, Table 4 shows the performance of our proposed method using 3.72 billion tokens of unla-

feature type		baseline	CL
SS-SCM	(1st-order)	92.23	93.23
(gain over Sup. SCM)		(+1.02)	(+0.70)
2-stage SS-SCM(+MIRA)	(2nd-order)	93.68	94.26
(gain over Sup. MIRA)		(+0.66)	(+0.72)

Table 4: Parent-prediction accuracies on development data with 3.72G tokens unlabeled data for English dependency parsing.

beled data. Note, however, that the gain in performance as unlabeled data is added is not as sharp as might be hoped, with a relatively modest difference in performance for 43.4 million tokens vs. 3.72 billion tokens of unlabeled data.

5.5 Computational Efficiency

The main computational challenge in our approach is the estimation of the generative models $\mathbf{q} = \langle q_1 \dots q_k \rangle$ from unlabeled data, particularly when the amount of unlabeled data used is large. In our implementation, on the 43M token BLLIP corpus, using baseline features, it takes about 5 hours to compute the expected counts required to estimate the parameters of the generative models on a single 2.93GHz Xeon processor. It takes roughly 18 days of computation to estimate the generative models from the larger (3.72 billion word) corpus. Fortunately it is simple to parallelize this step; our method takes a few hours on the larger data set when parallelized across around 300 separate processes.

Note that once the generative models have been estimated, decoding with the model, or training the model on labeled data, is relatively inexpensive, essentially taking the same amount of computation as standard dependency-parsing approaches.

5.6 Results on Test Data

Finally, Table 5 displays the final results on test data. There results are obtained using the best setting in terms of the development data performance. Note that the English dependency parsing results shown in the table were achieved using 3.72 billion tokens of unlabeled data. The improvements on test data are similar to those observed on the development data. To determine statistical significance, we tested the difference of parent-prediction error-rates at the sentence level using a paired Wilcoxon signed rank test. All eight comparisons shown in Table 5 are significant with $p < 0.01$.

(a) English dependency parsing: w/ 3.72G token ULD

6 Comparison with Previous Methods

Table 6 shows the performance of a number of state-of-the-art approaches on the English and Czech data sets. For both languages our approach gives the best reported figures on these datasets. Our results yield relative error reductions of roughly 27% (English) and 20% (Czech) over McDonald and Pereira (2006)'s second-order supervised dependency parsers, and roughly 9% (English) and 7% (Czech) over the previous best results provided by Koo et. al. (2008)'s second-order semi-supervised dependency parsers.

Note that there are some similarities between our two-stage semi-supervised learning approach and the semi-supervised learning method introduced by (Blitzer et al., 2006), which is an extension of the method described by (Ando and Zhang,

2005). In particular, both methods use a two-stage approach; They first train generative models or auxiliary problems from unlabeled data, and then, they incorporate these trained models into a supervised learning algorithm as real valued features. Moreover, both methods make direct use of existing feature-vector definitions $\mathbf{f}(\mathbf{x}, \mathbf{y})$ in inducing representations from unlabeled data.

7 Conclusion

This paper has described an extension of the semi-supervised learning approach of (Suzuki and Isozaki, 2008) to the dependency parsing problem. In addition, we have described extensions that incorporate the cluster-based features of Koo et al. (2008), and that allow the use of second-order parsing models. We have described experiments that show that the approach gives significant improvements over state-of-the-art methods for dependency parsing; performance improves when the amount of unlabeled data is increased from 43.8 million tokens to 3.72 billion tokens. The approach should be relatively easily applied to languages other than English or Czech.

We stress that the SS-SCM approach requires relatively little hand-engineering: it makes direct use of the existing feature-vector representation $\mathbf{f}(\mathbf{x}, \mathbf{y})$ used in a discriminative model, and does not require the design of new features. The main choice in the approach is the partitioning of $\mathbf{f}(\mathbf{x}, \mathbf{y})$ into components $\mathbf{r}_1(\mathbf{x}, \mathbf{y}) \ldots \mathbf{r}_k(\mathbf{x}, \mathbf{y})$, which in our experience is straightforward.

Abstract

We present an inexact search algorithm for the problem of predicting a two-layered dependency graph. The algorithm is based on a k-best version of the standard cubic-time search algorithm for projective dependency parsing, which is used as the backbone of a beam search procedure. This allows us to handle the complex non-local feature dependencies occurring in bistratal parsing if we model the interdependency between the two layers.

We apply the algorithm to the syntactic–semantic dependency parsing task of the CoNLL-2008 Shared Task, and we obtain a competitive result equal to the highest published for a system that jointly learns syntactic and semantic structure.

1 Introduction

Numerous linguistic theories assume a multistratal model of linguistic structure, such as a layer of surface syntax, deep syntax, and shallow semantics. Examples include Meaning–Text Theory (Mel'čuk, 1988), Discontinuous Grammar (Buch-Kromann, 2006), Extensible Dependency Grammar (Debusmann et al., 2004), and the Functional Generative Description (Sgall et al., 1986) which forms the theoretical foundation of the Prague Dependency Treebank (Hajič, 1998).

In the statistical NLP community, the most widely used grammatical resource is the Penn Treebank (Marcus et al., 1993). This is a purely syntactic resource, but we can also include this treebank in the category of multistratal resources since the PropBank (Palmer et al., 2005) and NomBank (Meyers et al., 2004) projects have annotated shallow semantic structures on top of it. Dependency-converted versions of the Penn Treebank, PropBank and NomBank were used in the CoNLL-2008 Shared Task (Surdeanu et al., 2008), in which the task of the participants was to produce a bistratal dependency structure consisting of surface syntax and shallow semantics.

Producing a consistent multistratal structure is a conceptually and computationally complex task, and most previous methods have employed a purely pipeline-based decomposition of the task. This includes the majority of work on shallow semantic analysis (Gildea and Jurafsky, 2002, *inter alia*). Nevertheless, since it is obvious that syntax and semantics are highly interdependent, it has repeatedly been suggested that the problems of syntactic and semantic analysis should be carried out *simultaneously* rather than in a pipeline, and that modeling the interdependency between syntax and semantics would improve the quality of all the substructures.

The purpose of the CoNLL-2008 Shared Task was to study the feasibility of a joint analysis of syntax and semantics, and while most participating systems used a pipeline-based approach to the problem, there were a number of contributions that attempted to take the interdependence between syntax and semantics into account. The top-performing system in the task (Johansson and Nugues, 2008) applied a very simple reranking scheme by means of a k-best syntactic output, similar to previous attempts (Gildea and Jurafsky, 2002; Toutanova et al., 2005) to improve semantic role labeling performance by using mul-

tiple parses. The system by Henderson et al. (2008) extended previous stack-based algorithms for dependency parsing by using two separate stacks to build the syntactic and semantic graphs. Lluís and Màrquez (2008) proposed a model that simultaneously predicts syntactic and semantic links, but since its search algorithm could not take the syntactic–semantic interdependencies into account, a pre-parsing step was still needed. In addition, before the CoNLL-2008 shared task there have been a few attempts to jointly learn syntactic and semantic structure; for instance, Merlo and Musillo (2008) appended semantic role labels to the phrase tags in a constituent treebank and applied a conventional constituent parser to predict constituent structure and semantic roles.

In this paper, we propose a new approximate search method for bistratal dependency analysis. The search method is based on a beam search procedure that extends a k-best version of the standard cubic-time search algorithm for projective dependency parsing. This is similar to the search method for constituent parsing used by Huang (2008), who referred to it as *cube pruning*, inspired by an idea from machine translation decoding (Chiang, 2007). The cube pruning approach, which is normally used to solve the $\arg\max$ problem, was also recently extended to summing problems, which is needed in some learning algorithms (Gimpel and Smith, 2009).

We apply the algorithm on the CoNLL-2008 Shared Task data, and obtain the same evaluation score as the best previously published system that simultaneously learns syntactic and semantic structure (Titov et al., 2009).

2 Bistratal Dependency Parsing

In the tradition of dependency representation of sentence structure, starting from Tesnière (1959), the linguistic structure of the sentence is represented as a directed graph of relations between words. In most theories, certain constraints are imposed on this graph; the most common constraint on dependency graphs in syntax, for instance, is that the graph should form a tree (i.e. it should be connected, acyclic, and every node should have at most one incoming edge). This assumption underlies almost all dependency parsing, although there are also a few parsers based on slightly more general problem formulations (Sagae and Tsuji, 2008).

In this paper, we assume a different type of constraint: that the graph can be partitioned into two subgraphs that we will refer to as *strata* or *layers*, where the first of the layers forms a tree. For the second layer, the only assumption we make is that there is at most one link between any two words. However, we believe that for any interesting linguistic structure, the second layer will be highly dependent on the structure of the first layer.

Figure 1 shows an example of a bistratal dependency graph such as in the CoNLL-2008 Shared Task on syntactic and semantic dependency parsing. The figure shows the representation of the sentence *We were expecting prices to fall*. The primary layer represents surface-syntactic relations, shown above the sentence, and the secondary layer consists of predicate–argument links (here, we have two predicates *expecting* and *fall*).

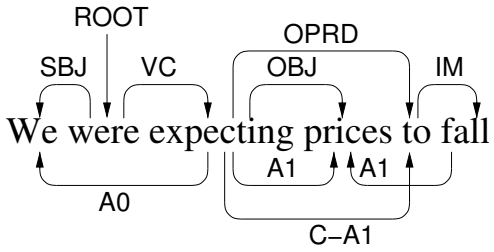

Figure 1: Example of a bistratal dependency graph.

We now give a formal model of the statistical parsing problem of prediction of a bistratal dependency graph. For a given input sentence $\boldsymbol{x}$, the task of our algorithm is to predict a structure $\hat{y}$ consisting of a *primary layer* $\hat{y}_p$ and a *secondary layer* $\hat{y}_s$. In a discriminative modeling framework, we model this prediction problem as the search for the highest-scoring output from the candidate space $\mathcal{Y}$ under a scoring function F:

$$\langle \hat{y}_p, \hat{y}_s \rangle = \arg\max_{\langle y_p, y_s \rangle \in \mathcal{Y}} F(\boldsymbol{x}, y_p, y_s)$$

The learning problem consists of searching in the model space for a scoring function F that minimizes the cost of predictions on unseen examples according to a given *cost function* ρ. In this work, we consider linear scoring functions of the following form:

$$F(\boldsymbol{x}, y_p, y_s) = \boldsymbol{w} \cdot \boldsymbol{\Phi}(\boldsymbol{x}, y_p, y_s)$$

where $\boldsymbol{\Phi}(\boldsymbol{x}, y)$ is a numeric feature representation of the tuple $(\boldsymbol{x}, y_p, y_s)$ and $\boldsymbol{w}$ a high-dimensional vector of feature weights.

Based on the structural assumptions made above, we now decompose the feature representation into three parts:

$$\mathbf{\Phi} = \mathbf{\Phi}_p + \mathbf{\Phi}_i + \mathbf{\Phi}_s$$

Here, $\mathbf{\Phi}_p$ represents the primary layer, assumed to be a tree, $\mathbf{\Phi}_s$ the secondary layer, and finally $\mathbf{\Phi}_i$ is the representation of the interdependency between the layers. For the feature representations of the primary and secondary layers, we employ *edge factorization*, a decomposition widely used in statistical dependency parsing, and assume that all edges can be scored independently:

$$\mathbf{\Phi}_p(\boldsymbol{x}, y_p) = \sum_{f \in y_p} \phi_p(\boldsymbol{x}, f)$$

The representation of the interdependency between the layers assumes that each secondary link is dependent on the primary layer, but independent of other secondary links.

$$\mathbf{\Phi}_i(\boldsymbol{x}, y_p, y_s) = \sum_{f \in y_s} \phi_i(\boldsymbol{x}, f, y_p)$$

The interdependency between layers is the bottleneck for the search algorithm that we will present in Section 3. For semantic role analysis, this involves all features that rely on a syntactic representation, most importantly the PATH feature that represents the grammatical relation between predicate and argument words. For instance, in Figure 1, we can represent the surface-syntactic relation between the tokens *fall* and *prices* as the string IM↑OPRD↑OBJ↓. In this work, all interdependency features will be based on paths in the primary layer.

3 A Bistratal Search Algorithm

This section presents an algorithm to approximately solve the $\arg\max$ problem for prediction of bistratal dependency structures. We present the algorithm in two steps: first, we review a k-best version of the standard search algorithm for projective monostratal dependency parsing, based on the work by Huang and Chiang (2005).[1] In the second step, starting from the k-best monostratal search, we devise a search method for the bistratal problem.

[1]Huang and Chiang (2005) described an even more efficient k-best algorithm based on lazy evaluation, which we will not use here since it is not obviously adaptable to the situation where the search is inexact.

3.1 Review of k-Best Dependency Parsing

The search method commonly used in dependency parsers is a chart-based dynamic programming algorithm that finds the highest-scoring projective dependency tree under an edge-factored scoring function. It runs in cubic time with respect to the sentence length. In a slightly more general formulation, it was first published by Eisner (1996). Starting from McDonald et al. (2005), it has been widely used in recent statistical dependency parsing frameworks.

The algorithm works by creating *open structures*, which consist of a dependency link and the set of links that it spans, and *closed structures*, consisting of the left or right half of a complete subtree. An open structure is created by a procedure LINK that adds a dependency link to connect a right-pointing and a left-pointing closed structure, and a closed structure by a procedure JOIN that joins an open structure with a closed structure. Figure 2 shows schematic illustrations: a LINK operation connects the right-pointing closed structure between s and j with the left-pointing closed structure between $j+1$ and e, and a JOIN operation connects an open structure between s and j with a closed structure between j and e.

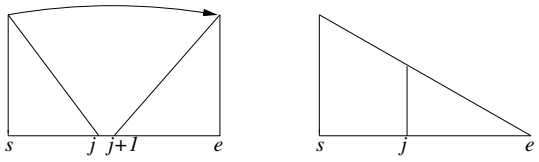

Figure 2: Illustrations of the LINK and JOIN operations.

The search algorithm can easily be extended to find the k best parses, not only the best one. In k-best parsing, we maintain a k-best list in every cell in the dynamic programming table. To create the k-best list of derivations for an open structure between the positions s and e, for instance, there are up to $|L| \cdot (e-s) \cdot k^2$ possible combinations to consider if the set of allowed labels is L. The key observation by Huang and Chiang (2005) is to make use of the fact that the lists are sorted. For every position between s and e, we add the best combination to a priority queue, from which we then repeatedly remove the front item. For every item we remove, we add three successors: an item with a next-best left part, an item with a next-best right part, and finally an item with a next-best edge

label.

The pseudocode of the search algorithm for k-best dependency parsing is given in Algorithms 1 and 2. For brevity, we omitted the code for ADVANCE-LEFT and ADVANCE-RIGHT, which are similar to ADVANCE-EDGE, as well as ADVANCE-LOWER, which resembles ADVANCE-UPPER. The FST function used in the pseudocode returns the first element of a tuple.

The algorithm uses a priority queue with standard operations ENQUEUE, which enqueues an element, and DEQUEUE, which removes the highest-scoring item from the queue. With a standard binary heap implementation of the priority queue, these two operations execute in logarithmic time. To build the queue, we use a constant-time TOSS operation, which appends an item to the queue without enforcing the priority queue constraint, and a HEAPIFY operation that constructs a consistent priority queue in linear time.

3.2 Extension to Bistratal Dependency Parsing

The k-best algorithm forms the core of the inexact bistratal search algorithm. Our method is similar to the forest reranking method by Huang (2008), although there is no forest pruning or reranking involved here. Crucially, we divide the features into *local* features, which can be computed "offline", and *nonlocal* features, which must be computed during search. In our case, the local features are $\mathbf{\Phi}_p$ and $\mathbf{\Phi}_s$, while the nonlocal features are the interdependent features $\mathbf{\Phi}_i$.

Algorithm 3 shows pseudocode for the main part of the bistratal search algorithm, and Algorithm 4 for its support functions. The algorithm works as follows: for every span $\langle s, e \rangle$, the algorithm first uses the LINK procedure from the k-best monostratal search to construct a k-best list of open structures without semantic links. In the next step, secondary links are added in the procedure LINK-SECONDARY. For brevity, we show only the procedures that create open structures; they are very similar to their closed-structure counterparts.

The LINK-SECONDARY procedure starts by creating an initial candidate (FIRST-SEC-OPEN) based on the best open structure for the primary layer. FIRST-SEC-OPEN creates the candidate space for secondary links for a single primary open structure. To reduce search complexity, it makes use of a problem-specific function SCOPE that defines which secondary links are possible from a given token, given a primary-layer context.

An important insight by Huang (2008) is that nonlocal features should be computed as early as possible during search. In our case, we assume that the interdependency features are based on *tree paths* in the primary layer. This means that secondary links between two tokens can be added when there is a complete path in the primary layer between the tokens. When we create an open

      ENQUEUE(q, ADVANCE-UPPER(c))
      ENQUEUE(q, ADVANCE-LOWER(c))
```

Algorithm 2 Support operations for the k-best search.

function CREATE-EDGES(s, e, dir, k)
  $E \leftarrow \emptyset$
  for $l \in$ ALLOWED-LABELS(s, e, dir)
    $score_L \leftarrow \boldsymbol{w} \cdot \phi_p(s, e, dir, l)$
    $edge \leftarrow \langle score_L, s, e, dir, l \rangle$
    APPEND$(E, edge)$
  return the top k edges in E

function CREATE-OPEN(E, l, r, i_e, i_l, i_r)
  $score_L \leftarrow$ FST$(E[i_e])$ + FST$(l[i_l])$ + FST$(r[i_r])$
  return $\langle score_L + score_N, E, l, r, i_e, i_l, i_r \rangle$

function CREATE-CLOSED(u, l, i_u, i_r)
  $score_L \leftarrow$ FST$(u[i_u])$ + FST$(l[i_l])$
  return $\langle score_L + score_N, u, l, i_u, i_l \rangle$

function ADVANCE-EDGE(o)
where $o = (score, E, l, r, i_e, i_l, i_r)$
  if $i_e =$ LENGTH(E)
    return $\emptyset$
  else
    return CREATE-OPEN$(E, l, r, i_e + 1, i_l, i_r)$

function ADVANCE-UPPER(c)
where $c = (u, l, i_u, i_l)$
  if $i_u =$ LENGTH(u)
    return $\emptyset$
  else
    return CREATE-CLOSED$(u, l, i_u + 1, i_l)$

structure by adding a link between two substructures, a complete path is created between the tokens in the substructures. We thus search for possible secondary links only between the two substructures that are joined.

Figure 3 illustrates this process. A primary open structure between s and e has been created by adding a link from the right-pointing closed structure between s and j to the left-pointing closed structure between $j + 1$ and e. We now try to add secondary links between the two substructures. For instance, in the semantic role parsing task described in subsection 3.3, if we know that there is a predicate between s and j, then we look for arguments between $j + 1$ and e, i.e. we apply the SCOPE function to the right substructure.

When computing the scores for secondary links, note that for efficiency only the interdependent part $\boldsymbol{\Phi}_i$ should be computed in CREATE-SECEDGES; the part of the score that does not depend on the primary layer can be computed before entering the search procedure.

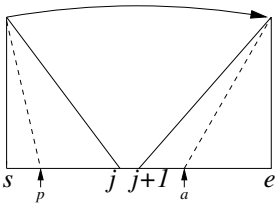

Figure 3: Illustration of the secondary linking process: When two substructures are connected, we can compute the path between a predicate in the left substructure and an argument in the right substructure.

Algorithm 3 Search algorithm for bistratal dependency parsing.

function BISTRATAL-SEARCH(k)
  $n \leftarrow$ length of the sentence
  initialize the table O of open structures
  initialize the table C of closed structures
  using ϕ_s, compute a table $scores_s$ for all
    possible secondary edges $\langle h, d, l \rangle$
  for $m \in [1, \ldots, n]$
    for $s \in [0, \ldots, n - m]$
      LINK$(s, s + m, \rightarrow, k)$
      LINK-SECONDARY$(s, s + m, \rightarrow, k)$
      LINK$(s, s + m, \leftarrow, k)$
      LINK-SECONDARY$(s, s + m, \leftarrow, k)$
      JOIN$(s, s + m, \rightarrow, k)$
      JOIN-SECONDARY$(s, s + m, \rightarrow, k)$
      JOIN$(s, s + m, \leftarrow, k)$
      JOIN-SECONDARY$(s, s + m, \leftarrow, k)$
  return FIRST$(C[0, n, \rightarrow])$

procedure LINK-SECONDARY(s, e, dir, k)
  $q \leftarrow$ empty priority queue
  $o \leftarrow$ FIRST-SEC-OPEN$(O[s, e, dir], 1, k)$
  ENQUEUE(q, o)
  $buf \leftarrow$ empty list
  while $|buf| < k$ and $|q| > 0$
    $o \leftarrow$ DEQUEUE(q)
    if $o \notin buf$
      APPEND(buf, o)
      for $o' \in$ ADVANCE-SEC-OPEN(o, k)
        ENQUEUE(q, o')
  SORT(buf) to $O[s, e, dir]$

3.3 Application on the CoNLL-2008 Shared Task Treebank

We applied the bistratal search method in Algorithm 3 on the data from the CoNLL-2008 Shared Task (Surdeanu et al., 2008). Here, the primary layer is the tree of surface-syntactic relations such as subject and object, and the secondary layer contains the links between the predicate words in the sentence and their respective logical arguments, such as agent and patient. The training corpus consists of sections 02 – 21 of the Penn Treebank, and contains roughly 1 million words.

Algorithm 4 Support operations in bistratal search.

function FIRST-SEC-OPEN(L, i_L, k)
  if $i = \text{LENGTH}(L)$
    return $\emptyset$
  $l \leftarrow$GET-LEFT($L[i_L]$), $r \leftarrow$GET-RIGHT($L[i_L]$)
  for $h \in [\text{START}(l), \ldots, \text{END}(l)]$
    for $d \in \text{SCOPE}(r, h)]$
      $E[h][d] \leftarrow \text{CREATE-SEC-EDGES}(h, d, L[i_L], k)]$
      $I_E[h][d] \leftarrow 1$
  for $h \in [\text{START}(r), \ldots, \text{END}(r)]$
    for $d \in \text{SCOPE}(l, h)]$
      $E[h][d] \leftarrow \text{CREATE-SEC-EDGES}(h, d, L[i_L], k)]$
      $I_E[h][d] \leftarrow 1$
  return CREATE-SEC-OPEN(L, i_L, E, I)

function CREATE-SEC-EDGES(h, d, o, k)
  $E \leftarrow \emptyset$
  for $l \in$ ALLOWED-SEC-LABELS(h, d)
    $score \leftarrow \boldsymbol{w} \cdot \phi_i(h, d, l, o) + scores_s[h, d, l]$
    $edge \leftarrow \langle score, h, d, l \rangle$
    APPEND($E, edge$)
  return the top k edges in E

function CREATE-SEC-OPEN(L, i_L, E, I)
  $score \leftarrow \text{FST}(L[i_L]) + \sum_{h,d} \text{FST}(E[h, d, I_E[h, d]])$
  return $\langle score, L, i_L, E, I_E \rangle$

function ADVANCE-SEC-OPEN(o, k)
where $o = \langle score, L, i_L, E, I_E \rangle$
  $buf \leftarrow \emptyset$
  if $i_L <$ LENGTH(L) and $I_E = [1, \ldots, 1]$
    APPEND(buf, FIRST-SEC-OPEN($L, i_L + 1, k$))
  for h, d
    if $I_E[h, d] <$ LENGTH($E[h, d]$)
      $I'_E \leftarrow \text{COPY}(I_E)$
      $I'_E[h, d] \leftarrow I'_E[h, d] + 1$
      APPEND(buf, CREATE-SEC-OPEN(L, i_L, E, I'_E))
  return buf

To apply the bistratal search algorithm to the problem of syntactic–semantic parsing, a problem-specific implementation of the SCOPE function is needed. In this case, we made two assumptions. First, we assumed that the identities of the predicate words are known a priori[2]. Secondly, we assumed that every argument of a given predicate word is either a direct dependent of the predicate, one of its ancestors, or a direct dependent of one of its ancestors. This assumption is a simple adaptation of the pruning algorithm by Xue and Palmer (2004), and it holds for the vast majority of arguments in the CoNLL-2008 data; in the training set, we measured that this covers 99.04% of the arguments of verbs and 97.55% of the arguments of nouns.

Figure 4 shows an example of how the SCOPE function works in our case. If a predicate is contained in the right substructure, we find two potential arguments: one at the start of the left substructure, and one more by recursively searching the left structure.

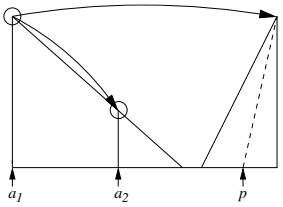

Figure 4: Illustration of the SCOPE function for predicate–argument links. If the right substructure contains a predicate, we can find potential arguments in the left substructure.

While the primary layer is assumed to be projective in Algorithm 3, the syntactic trees in the CoNLL-2008 data have a small number of nonprojective links. We used a pseudo-projective edge label encoding to handle nonprojectivity (Nivre and Nilsson, 2005).

To implement the model, we constructed feature representations $\boldsymbol{\Phi}_p$, $\boldsymbol{\Phi}_s$, and $\boldsymbol{\Phi}_i$. The surface-syntactic representation $\boldsymbol{\Phi}_p$ was a standard first-order edge factorization using the same features as McDonald et al. (2005). The features in $\boldsymbol{\Phi}_s$ and $\boldsymbol{\Phi}_i$ are shown in Table 1 and are standard features in statistical semantic role classification.

$\boldsymbol{\Phi}_s$	$\boldsymbol{\Phi}_i$
Predicate word	Path
Predicate POS	Path + arg. POS
Argument word	Path + pred. POS
Argument POS	Path + arg. word
Pred. + arg. words	Path + pred. word
Predicate word + label	Path + label
Predicate POS + label	Path + arg. POS + label
Argument word + label	Path + pred. POS + label
Argument POS + label	Path + arg. word + label
Pred. + arg. words + label	Path + pred. word + label

Table 1: Feature representation for secondary links.

We trained the discriminative model using the Online Passive–aggressive algorithm (Crammer et al., 2006), which is an efficient online learning method that can be used to train models for learning problems with structured output spaces. A cost function ρ is needed in the learning algorithm; we decomposed it into a pri-

[2]Since our algorithm needs to know the positions of the predicates, we trained a separate classifier using the LIBLINEAR toolkit (Fan et al., 2008) to identify the predicate words. As features for the classifier, we used the words and part-of-speech tags in a ± 3 window around the word under consideration.

mary part ρ_p and a secondary part ρ_s. We computed the primary part as the sum of link errors: $\rho_p(y_p, \hat{y}_p) = \sum_{l \in \hat{y}_p} c_p(l, y_p)$, where

$$c_p(l, y_p) = \begin{cases} 0 & \text{if } l \in y_p \text{ and its label is correct} \\ 0.5 & \text{if } l \in y_p \text{ but its label is incorrect} \\ 1 & \text{if } l \notin y_p \end{cases}$$

In a similar vein, we computed the secondary part ρ_s of the cost function as $\#fp + \#fn + 0.5 \cdot \#fl$, where $\#fp$ is the number of false positive secondary links, $\#fn$ the number of false negative links, and $\#fl$ the number of links with correct endpoints but incorrect label.

The training procedure took roughly 24 hours on an 2.3 GHz AMD Athlon processor. The memory consumption was about 1 GB during training.

4 Experiments

We evaluated the performance of our system on the test set from the CoNLL-2008 shared task, which consists of section 23 of the WSJ part of the Penn Treebank, as well as a small part of the Brown corpus. A beam width k of 4 was used in this experiment. Table 2 shows the results of the evaluation. The table shows the three most important scores computed by the official evaluation script: labeled syntactic dependency accuracy (LAS), labeled semantic dependency F_1-measure (Sem. F1), and the macro-averaged F_1-measure, a weighted combination of the syntactic and semantic scores (M. F1). Our result is competitive; we obtain the same macro F1 as the newly published result by Titov et al. (2009), which is the highest published figure for a joint syntactic–semantic parser so far. Importantly, our system clearly outperforms the system by Lluís and Màrquez (2008), which is the most similar system in problem modeling, but which uses a different search strategy.

System	LAS	Sem. F1	M. F1
This paper	86.6	77.1	81.8
Titov et al. (2009)	87.5	76.1	81.8
H. et al (2008)	87.6	73.1	80.5
L. & M. (2008)	85.8	70.3	78.1

Table 2: Results of published joint syntactic–semantic parsers on the CoNLL-2008 test set.

Since the search procedure is inexact, it is important to quantify roughly how much of a detrimental impact the approximation has on the parsing quality. We studied the influence of the beam width parameter k on the performance of the parser. The results on the development set can be seen in Table 3. As can be seen, a modest increase in performance can be obtained by increasing the beam width, at the cost of increased parsing time.

k	LAS	Sem. F1	M. F1	Time
1	85.14	77.05	81.10	242
2	85.43	77.17	81.30	369
4	85.49	77.20	81.35	625
8	85.58	77.20	81.40	1178

Table 3: Influence of beam width on parsing accuracy.

In addition, to have a rough indication of the impact of search errors on the quality of the parses, we computed the fraction of sentences where the gold-standard parse had a higher score according to the model than the parse returned by the search[3]. Table 4 shows the results of this experiment. This suggests that the search errors, although they clearly have an impact, are not the major source of errors, even with small beam widths.

k	Fraction
1	0.121
2	0.104
4	0.096
8	0.090

Table 4: Fraction of sentences in the development set where the gold-standard parse has a higher score than the parse returned by the search procedure.

To investigate where future optimization efforts should be spent, we used the built-in `hprof` profiling tool of Java to locate the bottlenecks. Once again, we ran the program on the development set with a beam width of 4, and Table 5 shows the three types of operations where the algorithm spent most of its time. It turns out that 74% of the time was spent on the computation and scoring of interdependency features. To make our algorithm truly useful in practice, we thus need to devise a way to speed up or cache these computations.

[3]To be able to compare the scores of the gold-standard and predicted parses, we disabled the automatic classifier for predicate identification and provided the parser with gold-standard predicates in this experiment.

Operation	Fraction
$\boldsymbol{w} \cdot \Phi_i$	0.64
Queue operations	0.15
Computation of Φ_i	0.10

Table 5: The three most significant bottlenecks and their fraction of the total runtime.

5 Discussion

In this paper, we have presented a new approximate search method to solve the problem of jointly predicting the two layers in a bistratal dependency graph. The algorithm shows competitive performance on the treebank used in the CoNLL-2008 Shared Task, a bistratal treebank consisting of a surface-syntactic and a shallow semantic layer. In addition to the syntactic–semantic task that we have described in this paper, we believe that our method can be used in other types of multistratal syntactic frameworks, such as a representation of surface and deep syntax as in Meaning–Text Theory (Mel'čuk, 1988).

The optimization problem that we set out to solve is intractable, but we have shown that reasonable performance can be achieved with an inexact, beam search-based search method. This is not obvious: it has previously been shown that using an inexact search procedure when the learning algorithm assumes that the search is exact may lead to slow convergence or even divergence (Kulesza and Pereira, 2008), but this does not seem to be a problem in our case.

While we used a beam search method as the method of approximation, other methods are certainly possible. An interesting example is the recent system by Smith and Eisner (2008), which used loopy belief propagation in a dependency parser using highly complex features, while still maintaining cubic-time search complexity.

An obvious drawback of our approach compared to traditional pipeline-based semantic role labeling methods is that the speed of the algorithm is highly dependent on the size of the interdependency feature representation $\boldsymbol{\Phi}_i$. Also, extracting these features is fairly complex, and it is of critical importance to implement the feature extraction procedure efficiently since it is one of the bottlenecks of the algorithm. It is plausible that our performance suffers from the absence of other frequently used syntax-based features such as dependent-of-dependent and voice.

It is thus highly dubious that a joint modeling of syntactic and semantic structure is worth the additional implementational effort. So far, no system using tightly integrated syntactic and semantic processing has been competitive with the best systems, which have been either completely pipeline-based (Che et al., 2008; Ciaramita et al., 2008) or employed only a loose syntactic–semantic coupling (Johansson and Nugues, 2008). It has been conjectured that modeling the semantics of the sentence would also help in syntactic disambiguation; however, it is likely that this is already implicitly taken into account by the lexical features present in virtually all modern parsers.

In addition, a problem that our beam search method has in common with the constituent parsing method by Huang (2008) is that highly non-local features must be computed late. In our case, this means that if there is a long distance between a predicate and an argument, the secondary link between them will be unlikely to influence the final search result.

Abstract

This paper presents a simple and effective approach to improve dependency parsing by using subtrees from auto-parsed data. First, we use a baseline parser to parse large-scale unannotated data. Then we extract subtrees from dependency parse trees in the auto-parsed data. Finally, we construct new subtree-based features for parsing algorithms. To demonstrate the effectiveness of our proposed approach, we present the experimental results on the English Penn Treebank and the Chinese Penn Treebank. These results show that our approach significantly outperforms baseline systems. And, it achieves the best accuracy for the Chinese data and an accuracy which is competitive with the best known systems for the English data.

1 Introduction

Dependency parsing, which attempts to build dependency links between words in a sentence, has experienced a surge of interest in recent times, owing to its usefulness in such applications as machine translation (Nakazawa et al., 2006) and question answering (Cui et al., 2005). To obtain dependency parsers with high accuracy, supervised techniques require a large amount of hand-annotated data. While hand-annotated data are very expensive, large-scale unannotated data can be obtained easily. Therefore, the use of large-scale unannotated data in training is an attractive idea to improve dependency parsing performance.

In this paper, we present an approach that extracts subtrees from dependency trees in auto-parsed data to improve dependency parsing. The auto-parsed data are generated from large-scale unannotated data by using a baseline parser. Then, from dependency trees in the data, we extract different types of subtrees. Finally, we represent subtree-based features on training data to train dependency parsers.

The use of auto-parsed data is not new. However, unlike most of the previous studies (Sagae and Tsujii, 2007; Steedman et al., 2003) that improved the performance by using entire trees from auto-parsed data, we exploit partial information (i.e., subtrees) in auto-parsed data. In their approaches, they used entire auto-parsed trees as newly labeled data to train the parsing models, while we use subtree-based features and employ the original gold-standard data to train the models. The use of subtrees instead of complete trees can be justified by the fact that the accuracy of partial dependencies is much higher than that of entire dependency trees. Previous studies (McDonald and Pereira, 2006; Yamada and Matsumoto, 2003; Zhang and Clark, 2008) show that the accuracies of complete trees are about 40% for English and about 35% for Chinese, while the accuracies of relations between two words are much higher: about 90% for English and about 85% for Chinese. From these observations, we may conjecture that it is possible to conduct a more effective selection by using subtrees as the unit of information.

The use of word pairs in auto-parsed data was tried in van Noord (2007) and Chen et al. (2008). However, the information on word pairs is limited. To provide richer information, we consider more words besides word pairs. Specifically, we use subtrees containing two or three words extracted from dependency trees in the auto-parsed data. To demonstrate the effectiveness of our proposed approach, we present experimental results on En-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 570–579,
Singapore, 6-7 August 2009.

glish and Chinese data. We show that this simple approach greatly improves the accuracy and that the use of richer structures (i.e, word triples) indeed gives additional improvement. We also demonstrate that our approach and other improvement techniques (Koo et al., 2008; Nivre and McDonald, 2008) are complementary and that we can achieve very high accuracies when we combine our method with other improvement techniques. Specifically, we achieve the best accuracy for the Chinese data.

The rest of this paper is as follows: Section 2 introduces the background of dependency parsing. Section 3 proposes an approach for extracting subtrees and represents the subtree-based features for dependency parsers. Section 4 explains the experimental results and Section 5 discusses related work. Finally, in section 6 we draw conclusions.

2 Dependency parsing

Dependency parsing assigns head-dependent relations between the words in a sentence. A simple example is shown in Figure 1, where an arc between two words indicates a dependency relation between them. For example, the arc between "ate" and "fish" indicates that "ate" is the head of "fish" and "fish" is the dependent. The arc between "ROOT" and "ate" indicates that "ate" is the ROOT of the sentence.

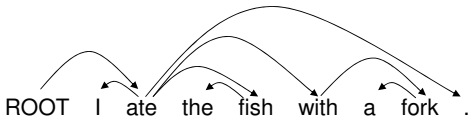

Figure 1: Example for dependency structure

2.1 Parsing approach

For dependency parsing, there are two main types of parsing models (Nivre and McDonald, 2008): graph-based model and transition-based model, which achieved state-of-the-art accuracy for a wide range of languages as shown in recent CoNLL shared tasks (Buchholz et al., 2006; Nivre et al., 2007). Our subtree-based features can be applied in both of the two parsing models.

In this paper, as the base parsing system, we employ the graph-based MST parsing model proposed by McDonald et al. (2005) and McDonald and Pereira (2006), which uses the idea of Maximum Spanning Trees of a graph and large margin structured learning algorithms. The details of parsing model were presented in McDonald et al. (2005) and McDonald and Pereira (2006).

2.2 Baseline Parser

In the MST parsing model, there are two well-used modes: the first-order and the second-order. The first-order model uses first-order features that are defined over single graph edges and the second-order model adds second-order features that are defined on adjacent edges.

For the parsing of unannotated data, we use the first-order MST parsing model, because we need to parse a large number of sentences and the parser must be fast. We call this parser the Baseline Parser.

3 Our approach

In this section, we describe our approach of extracting subtrees from unannotated data. First, we preprocess unannotated data using the Baseline Parser and obtain auto-parsed data. Subsequently, we extract the subtrees from dependency trees in the auto-parsed data. Finally, we generate subtree-based features for the parsing models.

3.1 Subtrees extraction

To ease explanation, we transform the dependency structure into a more tree-like structure as shown in Figure 2, the sentence is the same as the one in Figure 1.

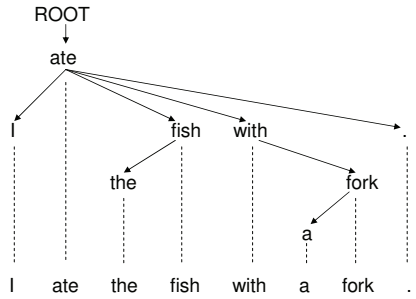

Figure 2: Example for dependency structure in tree-format

Our task is to extract subtrees from dependency trees. If a subtree contains two nodes, we call it a bigram-subtree. If a subtree contains three nodes, we call it a trigram-subtree.

3.2 List of subtrees

We extract subtrees from dependency trees and store them in list L_{st}. First, we extract bigram-subtrees that contain two words. If two words have

a dependency relation in a tree, we add these two words as a subtree into list L_{st}. Similarly, we can extract trigram-subtrees. Note that the dependency direction and the order of the words in the original sentence are important in the extraction. To enable this, the subtrees are encoded in the string format that is expressed as $st = w : wid : hid(-w : wid : hid)+$[1], where w refers to a word in the subtree, wid refers to the ID (starting from 1) of a word in the subtree (words are ordered according to the positions of the original sentence)[2] , and hid refers to an ID of the head of the word (hid=0 means that this word is the root of a subtree). For example, "ate" and "fish" have a right dependency arc in the sentence shown in Figure 2. So the subtree is encoded as "ate:1:0-fish:2:1". Figure 3 shows all the subtrees extracted from the sentence in Figure 2, where the subtrees in (a) are bigram-subtrees and the ones in (b) are trigram-subtrees.

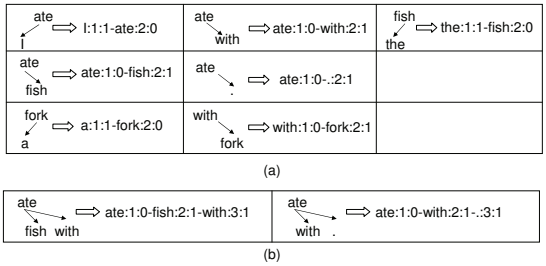

Figure 3: Examples of subtrees

Note that we only used the trigram-subtrees containing a head, its dependent $d1$, and $d1$'s leftmost right sibling[3]. We could not consider the case where two children are on different sides[4] of the head (for instance, "I" and "fish" for "ate" in Figure 2). We also do not use the child-parent-grandparent type (grandparent-type in short) trigram-subtrees. These are due to the limitations of the parsing algorithm of (McDonald and Pereira, 2006), which does not allow the features defined on those types of trigram-subtrees.

We extract the subtrees from the auto-parsed data, then merge the same subtrees into one entry, and count their frequency. We eliminate all subtrees that occur only once in the data.

[1] + refers to matching the preceding element one or more times and is the same as a regular expression in Perl.

[2] So, wid is in fact redundant but we include it for ease of understanding.

[3] Note that the order of the siblings is based on the order of the words in the original sentence.

[4] Here, "side" means the position of a word relative to the head in the original sentence.

3.3 Subtree-based features

We represent new features based on the extracted subtrees and call them subtree-based features. The features based on bigram-subtrees correspond to the first-order features in the MST parsing model and those based on trigram-subtrees features correspond to the second-order features.

We first group the extracted subtrees into different sets based on their frequencies. After experiments with many different threshold settings on development data sets, we chose the following way. We group the subtrees into three sets corresponding to three levels of frequency: "high-frequency (HF)", "middle-frequency (MF)", and "low-frequency (LF)". HF, MF, and LF are used as set IDs for the three sets. The following are the settings: if a subtree is one of the TOP-10% most frequent subtrees, it is in set HF; else if a subtree is one of the TOP-20% subtrees, it is in set MF; else it is in set LF. Note that we compute these levels within a set of subtrees with the same number of nodes. We store the set ID for every subtree in L_{st}. For example, if subtree "ate:1:0-with:2:1" is among the TOP-10%, its set ID is HF.

3.3.1 First-order subtree-based features

The first-order features are based on bigram-subtrees that are related to word pairs. We generate new features for a head h and a dependent d in the parsing process. Figure 4-(a)[5] shows the words and their surrounding words, where h_{-1} refers to the word to the left of the head in the sentence, h_{+1} refers to the word to the right of the head, d_{-1} refers to the word to the left of the dependent, and d_{+1} refers to the word to the right of the dependent. Temporary bigram-subtrees are formed by word pairs that are linked by dashed-lines in the figure. Then we retrieve these subtrees in L_{st} to get their set IDs (if a subtree is not included in L_{st}, its set ID is ZERO. That is, we have four sets: HF, MF, LF, and ZERO.).

Then we generate first-order subtree-based features, consisting of indicator functions for set IDs of the retrieved bigram-subtrees. When generating subtree-based features, each dashed line in Figure 4-(a) triggers a different feature.

To demonstrate how to generate first-order subtree-based features, we use an example that is as follows. Suppose that we are going to parse the sentence "He ate the cake with a fork." as shown

[5] Please note that d could be before h.

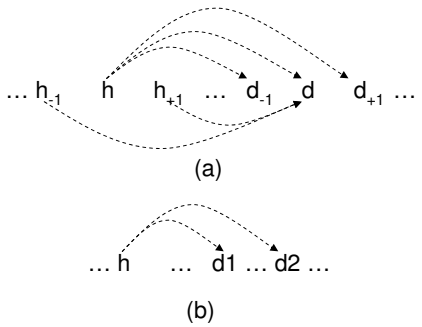

Figure 4: Word pairs and triple for feature representation

in Figure 5, where h is "ate" and d is "with". We can generate the features for the pairs linked by dashed-lines, such as $h - d$, $h - d_{+1}$ and so on. Then we have the temporary bigram-subtrees "ate:1:0-with:2:1" for $h - d$ and "ate:1:0-a:2:1" for $h - d_{+1}$, and so on. If we can find subtree "ate:1:0-with:2:1" for $h - d$ from L_{st} with set ID HF, we generate the feature "H-D:HF", and if we find subtree "ate:1:0-a:2:1" for $h - d_{+1}$ with set ID ZERO, we generate the feature "H-D+1:ZERO". The other three features are also generated similarly.

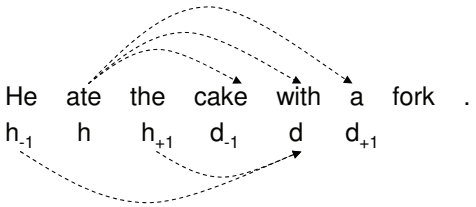

Figure 5: First-order subtree-based features

3.3.2 Second-order subtree-based features

The second-order features are based on trigram-subtrees that are related to triples of words. We generate features for a triple of a head h, its dependent $d1$, and $d1$'s right-leftmost sibling $d2$. The triple is shown in Figure 4-(b). A temporary trigram-subtree is formed by the word forms of h, $d1$, and $d2$. Then we retrieve the subtree in L_{st} to get its set ID. In addition, we consider the triples of "h-NULL"[6], $d1$, and $d2$, which means that we only check the words of sibling nodes without checking the head word.

Then, we generate second-order subtree-based features, consisting of indicator functions for set IDs of the retrieved trigram-subtrees.

[6]h-NULL is a dummy token

We also generate combined features involving the set IDs and part-of-speech tags of heads, and the set IDs and word forms of heads. Specifically, for any feature related to word form, we remove this feature if the word is not one of the Top-N most frequent words in the training data. We used N=1000 for the experiments in this paper. This method can reduce the size of the feature sets.

In this paper, we only used bigram-subtrees and the limited form of trigram-subtrees, though in theory we can use k-gram-subtrees, which are limited in the same way as our trigram subtrees, in (k-1)th-order MST parsing models mentioned in McDonald and Pereira (2006) or use grandparent-type trigram-subtrees in parsing models of Carreras (2007). Although the higher-order MST parsing models will be slow with exact inference, requiring O(n^k) time (McDonald and Pereira, 2006), it might be possible to use higher-order k-gram subtrees with approximated parsing model in the future. Of course, our method can also be easily extended to the labeled dependency case.

4 Experiments

In order to evaluate the effectiveness of the subtree-based features, we conducted experiments on English data and Chinese Data.

For English, we used the Penn Treebank (Marcus et al., 1993) in our experiments and the tool "Penn2Malt"[7] to convert the data into dependency structures using a standard set of head rules (Yamada and Matsumoto, 2003). To match previous work (McDonald et al., 2005; McDonald and Pereira, 2006; Koo et al., 2008), we split the data into a training set (sections 2-21), a development set (Section 22), and a test set (section 23). Following the work of Koo et al. (2008), we used the MXPOST (Ratnaparkhi, 1996) tagger trained on training data to provide part-of-speech tags for the development and the test set, and we used 10-way jackknifing to generate tags for the training set. For the unannotated data, we used the BLLIP corpus (Charniak et al., 2000) that contains about 43 million words of WSJ text.[8] We used the MXPOST tagger trained on training data to assign part-of-speech tags and used the Basic Parser to process the sentences of the BLLIP corpus.

For Chinese, we used the Chinese Treebank

[7]http://w3.msi.vxu.se/~nivre/research/Penn2Malt.html

[8]We ensured that the text used for extracting subtrees did not include the sentences of the Penn Treebank.

(CTB) version 4.0[9] in the experiments. We also used the "Penn2Malt" tool to convert the data and created a data split: files 1-270 and files 400-931 for training, files 271-300 for testing, and files 301-325 for development. We used gold standard segmentation and part-of-speech tags in the CTB. The data partition and part-of-speech settings were chosen to match previous work (Chen et al., 2008; Yu et al., 2008). For the unannotated data, we used the PFR corpus[10], which has approximately 15 million words whose segmentation and POS tags are given. We used its original segmentation though there are differences in segmentation policy between CTB and this corpus. As for POS tags, we discarded the original POS tags and assigned CTB style POS tags using a TNT-based tagger (Brants, 2000) trained on the training data. We used the Basic Parser to process all the sentences of the PFR corpus.

We measured the parser quality by the unlabeled attachment score (UAS), i.e., the percentage of tokens (excluding all punctuation tokens) with the correct HEAD. And we also evaluated on complete dependency analysis.

4.1 Experimental Results

In our experiments, we used MSTParser, a freely available implementation[11] of the first- and second-order MST parsing models. For baseline systems, we used the first- and second-order basic features, which were the same as the features used by McDonald and Pereira (2006), and we used the default settings of MSTParser throughout the paper: iters=10; training-k=1; decode-type=proj. We implemented our systems based on the MSTParser by incorporating the subtree-based features.

4.1.1 Main results of English data

	English	
	UAS	Complete
Ord1	90.95	37.45
Ord1s	91.76(+0.81)	40.68
Ord2	91.71	42.88
Ord2s	92.51(+0.80)	46.19
Ord2b	92.28(+0.57)	45.44
Ord2t	92.06(+0.35)	42.96

Table 1: Dependency parsing results for English

[9]http://www.cis.upenn.edu/~chinese/.

[10]http://www.icl.pku.edu.

[11]http://mstparser.sourceforge.net

The results are shown in Table 1, where Ord1/Ord2 refers to a first-/second-order MSTParser with basic features, Ord1s/Ord2s refers to a first-/second-order MSTParser with basic+subtree-based features, and the improvements by the subtree-based features over the basic features are shown in parentheses. Note that we use both the bigram- and trigram- subtrees in Ord2s. The parsers using the subtree-based features consistently outperformed those using the basic features. For the first-order parser, we found that there is an absolute improvement of 0.81 points (UAS) by adding subtree-based features. For the second-order parser, we got an absolute improvement of 0.8 points (UAS) by including subtree-based features. The improvements of parsing with subtree-based features were significant in McNemar's Test ($p < 10^{-6}$).

We also checked the sole effect of bigram- and trigram-subtrees. The results are also shown in Table 1, where Ord2b/Ord2t refers to a second-order MSTParser with bigram-/trigram-subtrees only. The results showed that trigram-subtrees can provide further improvement, although the effect of the bigram-subtrees seemed larger.

4.1.2 Comparative results of English data

Table 2 shows the performance of the systems that were compared, where Y&M2003 refers to the parser of Yamada and Matsumoto (2003), CO2006 refers to the parser of Corston-Oliver et al. (2006), Hall2006 refers to the parser of Hall et al. (2006), Wang2007 refers to the parser of Wang et al. (2007), Z&C 2008 refers to the combination graph-based and transition-based system of Zhang and Clark (2008), KOO08-dep1c/KOO08-dep2c refers to a graph-based system with first-/second-order cluster-based features by Koo et al. (2008), and Carreras2008 refers to the paper of Carreras et al. (2008). The results showed that Ord2s performed better than the first five systems. The second-order system of Koo et al. (2008) performed better than our systems. The reason may be that the MSTParser only uses sibling interactions for second-order, while Koo et al. (2008) uses both sibling and grandparent interactions, and uses cluster-based features. Carreras et al. (2008) reported a very high accuracy using information of constituent structure of the TAG grammar formalism. In our systems, we did not use such knowledge.

Our subtree-based features could be combined

with the techniques presented in other work, such as the cluster-based features in Koo et al. (2008), the integrating methods of Zhang and Clark (2008), and Nivre and McDonald (2008), and the parsing methods of Carreras et al. (2008).

Table 2: Dependency parsing results for English, for our parsers and previous work

To demonstrate that our approach and other work are complementary, we thus implemented a system using all the techniques we had at hand that used subtree- and cluster-based features and applied the integrating method of Nivre and McDonald (2008). We used the word clustering tool[12], which was used by Koo et al. (2008), to produce word clusters on the BLLIP corpus. The cluster-based features were the same as the features used by Koo et al. (2008). For the integrating method, we used the transition MaxEnt-based parser of Zhao and Kit (2008) because it was faster than the MaltParser. The results are shown in the bottom part of Table 2, where Ord1c/Ord2c refers to a first-/second-order MSTParser with cluster-based features, Ord1i/Ordli refers to a first-/second-order MSTParser with integrating-based features, Ord1sc/Ord2sc refers to a first-/second-order MSTParser with subtree-based+cluster-based features, and Ord1sci/Ord2sci refers to a first-/second-order MSTParser with subtree-based+cluster-based+integrating-based features. Ord1c/Ord2c was worse than KOO08-dep1c/-dep2c, but Ord1sci outperformed KOO08-dep1c and Ord2sci performed similarly to KOO08-dep2c by using all of the techniques we had. These results indicated that subtree-based features can provide different information and work well with other techniques.

4.1.3 Main results of Chinese data

The results are shown in Table 3 where abbreviations are the same as in Table 1. As in the English experiments, parsers with the subtree-based features outperformed parsers with the basic features, and second-order parsers outperformed first-order parsers. For the first-order parser, the subtree-based features provided 1.3 absolute points improvement. For the second-order parser, the subtree-based features achieved an absolute improvement of 1.25 points. The improvements of parsing with subtree-based features were significant in McNemar's Test ($p < 10^{-5}$).

Table 3: Dependency parsing results for Chinese.

4.1.4 Comparative results of Chinese data

Table 4 shows the comparative results, where Wang2007 refers to the parser of Wang et al. (2007), Chen2008 refers to the parser of Chen et al. (2008), and Yu2008 refers to the parser of Yu et al. (2008) that is the best reported results for this data set. And "all words" refers to all the sentences in test set and "$\leq$ 40 words"[13] refers to the sentences with the length up to 40. The table shows that our parsers outperformed previous systems.

We also implemented integrating systems for Chinese data as well. When we applied the cluster-based features, the performance dropped a little. The reason may be that we are using gold-POS tags for Chinese data[14]. Thus we did not

[13]Wang et al. (2007) and Chen et al. (2008) reported the scores on these sentences.

[14]We tried to use the cluster-based features for Chinese with the same setting of POS tags as English data, then the cluster-based features did provide improvement.

use cluster-based features for the integrating systems. The results are shown in Table 4, where Ord1si/Ord2si refers to the first-order/second-order system with subtree-based+intergrating-based features. We found that the integrating systems provided better results. Overall, we have achieved a high accuracy, which is the best known result for this dataset.

Zhang and Clark (2008) and Duan et al. (2007) reported results on a different data split of Penn Chinese Treebank. We also ran our systems (Ord2s) on their data and provided UAS 86.70 (for non-root words)/77.39 (for root words), better than their results: 86.21/76.26 in Zhang and Clark (2008) and 84.36/73.70 in Duan et al. (2007).

4.1.5 Effect of different sizes of unannotated data

Here, we consider the improvement relative to the sizes of the unannotated data. Figure 6 shows the results of first-order parsers with different numbers of words in the unannotated data. Please note that the size of full English unannotated data is 43M and the size of full Chinese unannotated data is 15M. From the figure, we found that the parser obtained more benefits as we added more unannotated data.

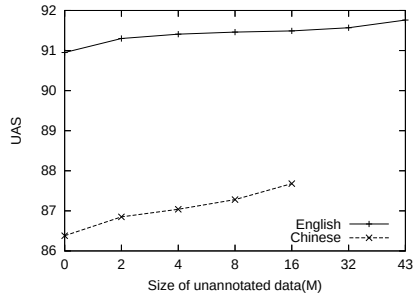

Figure 6: Results with different sizes of large-scale unannotated data.

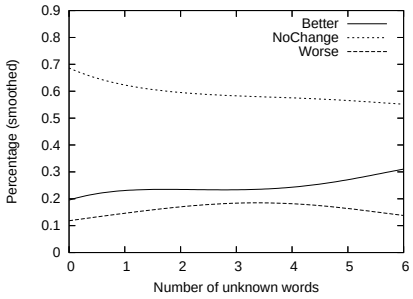

Figure 7: Improvement relative to unknown words for English

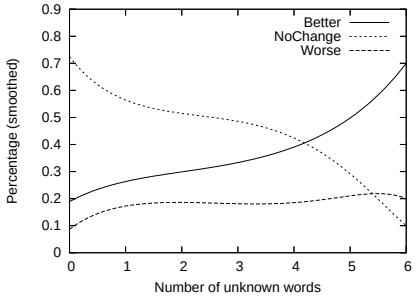

Figure 8: Improvement relative to unknown words for Chinese

4.2 Additional Analysis

In this section, we investigated the results on sentence level from different views. For Figures 7-12, we classified each sentence into one of three classes: "Better" for those where the proposed parsers provided better results relative to the parsers with basic features, "Worse" for those where the proposed parsers provided worse results relative to the basic parsers, and "NoChange" for those where the accuracies remained the same.

4.2.1 Unknown words

Here, we consider the unknown word[15] problem, which is an important issue for parsing. We calculated the number of unknown words in one sentence, and listed the changes of the sentences with unknown words. Here, we compared the Ord1 system and the Ord1s system.

Figures 7 and 8 show the results, where the x axis refers to the number of unknown words in one sentence and the y axis shows the percentages of the three classes. For example, for the sentences having three unknown words in the Chinese data, 31.58% improved, 23.68% worsened, and 44.74% were unchanged. We did not show the results of

[15] An unknown word is a word that is not included in the training data.

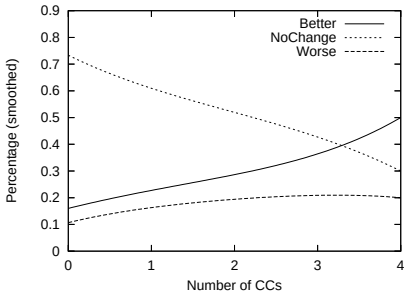

Figure 9: Improvement relative to number of conjunctions for English

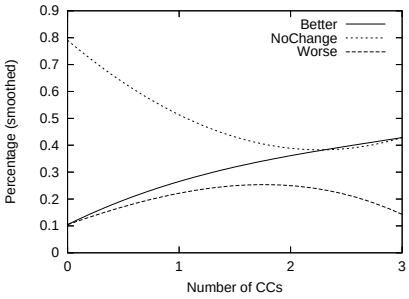

Figure 10: Improvement relative to number of conjunctions for Chinese

the sentences with more than six unknown words because their numbers were very small. The Better and Worse curves showed that our approach always provided better results. The results indicated that the improvements apparently became larger when the sentences had more unknown words for the Chinese data. And for the English data, the graph also showed the similar trend, although the improvements for the sentences have three and four unknown words were slightly less than the others.

4.2.2 Coordinating conjunctions

We analyzed our new parsers' behavior for coordinating conjunction structures, which is a very difficult problem for parsing (Kawahara and Kurohashi, 2008). Here, we compared the Ord2 system with the Ord2s system.

Figures 9 and 10 show how the subtree-based features affect accuracy as a function of the number of conjunctions, where the x axis refers to the number of conjunctions in one sentence and the y axis shows the percentages of the three classes. The figures indicated that the subtree-based features improved the coordinating conjunction problem. In the trigram-subtree list, many subtrees are related to coordinating conjunctions, such as "utilities:1:3 and:2:3 businesses:3:0" and "pull:1:0 and:2:1 protect:3:1". These subtrees can provide additional information for parsing models.

4.2.3 PP attachment

We analyzed our new parsers' behavior for preposition-phrase attachment, which is also a difficult task for parsing (Ratnaparkhi et al., 1994). We compared the Ord2 system with the Ord2s system. Figures 11 and 12 show how the subtree-based features affect accuracy as a function of the number of prepositions, where the x axis refers to the number of prepositions in one sentence and the y axis shows the percentages of the three classes. The figures indicated that the subtree-based features improved preposition-phrase attachment.

5 Related work

Our approach is to incorporate unannotated data into parsing models for dependency parsing. Several previous studies relevant to our approach have been conducted.

Chen et al. (2008) previously proposed an approach that used the information on short dependency relations for Chinese dependency parsing. They only used the word pairs within two word distances for a transition-based parsing algorithm. The approach in this paper differs in that we use richer information on trigram-subtrees besides bigram-subtrees that contain word pairs. And our work is focused on graph-based parsing models as opposed to transition-based models. Yu et al. (2008) constructed case structures from auto-parsed data and utilized them in parsing. Compared with their method, our method is much simpler but has great effects.

Koo et al. (2008) used the Brown algorithm to produce word clusters on large-scale unannotated data and represented new features based on the clusters for parsing models. The cluster-based features provided very impressive results. In addition, they used the parsing model by Carreras (2007) that applied second-order features on both sibling and grandparent interactions. Note that our approach and their approach are complementary in that we can use both subtree- and cluster-based features for parsing models. The experimental results showed that we achieved better accuracy for first-order models when we used both of these two types of features.

Sagae and Tsujii (2007) presented an co-training approach for dependency parsing adap-

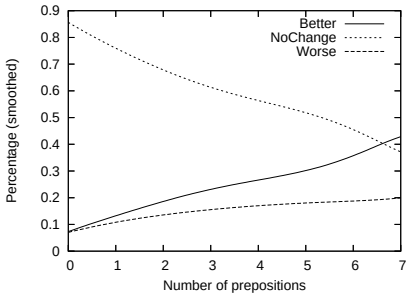

Figure 11: Improvement relative to number of prepositions for English

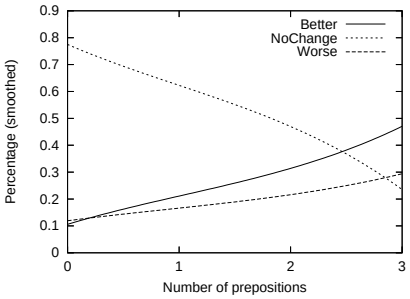

Figure 12: Improvement relative to number of prepositions for Chinese

tation. They used two parsers to parse the sentences in unannotated data and selected only identical results produced by the two parsers. Then, they retrained a parser on newly parsed sentences and the original labeled data. Our approach represents subtree-based features on the original gold-standard data to retrain parsers. McClosky et al. (2006) presented a self-training approach for phrase structure parsing and the approach was shown to be effective in practice. However, their approach depends on a high-quality reranker, while we simply augment the features of an existing parser. Moreover, we could use the output of our systems for co-training/self-training techniques.

6 Conclusions

We present a simple and effective approach to improve dependency parsing using subtrees from auto-parsed data. In our method, first we use a baseline parser to parse large-scale unannotated data, and then we extract subtrees from dependency parsing trees in the auto-parsed data. Finally, we construct new subtree-based features for parsing models. The results show that our approach significantly outperforms baseline systems. We also show that our approach and other techniques are complementary, and then achieve the best reported accuracy for the Chinese data and an accuracy that is competitive with the best known systems for the English data.

Topic-wise, Sentiment-wise, or Otherwise? Identifying the Hidden Dimension for Unsupervised Text Classification

Sajib Dasgupta and **Vincent Ng**
Human Language Technology Research Institute
University of Texas at Dallas
Richardson, TX 75083-0688
{sajib,vince}@hlt.utdallas.edu

Abstract

While traditional work on text clustering has largely focused on grouping documents by topic, it is conceivable that a user may want to cluster documents along other dimensions, such as the author's mood, gender, age, or sentiment. Without knowing the user's intention, a clustering algorithm will only group documents along the most prominent dimension, which may not be the one the user desires. To address this problem, we propose a novel way of incorporating user feedback into a clustering algorithm, which allows a user to easily specify the dimension along which she wants the data points to be clustered via inspecting only a small number of words. This distinguishes our method from existing ones, which typically require a large amount of effort on the part of humans in the form of document annotation or interactive construction of the feature space. We demonstrate the viability of our method on several challenging sentiment datasets.

1 Introduction

Text clustering is one of the most important applications in Natural Language Processing (NLP). A common approach to this problem consists of (1) computing the similarity between each pair of documents, each of which is typically represented as a bag of words; and (2) using an unsupervised clustering algorithm to partition the documents. The majority of existing work on text clustering has focused on *topic-based* clustering, where high accuracies can be achieved even for datasets with a large number of classes (e.g., 20 Newsgroups).

On the other hand, there has been relatively little work on *sentiment-based* clustering and the related task of *unsupervised polarity classification*, where the goal is to cluster (or classify) a set of documents (e.g., reviews) according to the polarity (e.g., "thumbs up" or "thumbs down") expressed by the author in an unsupervised manner. Despite the large amount of recent work on sentiment analysis and opinion mining, much of it has focused on *supervised* methods (e.g., Pang et al. (2002), Kim and Hovy (2004), Mullen and Collier (2004)). One weakness of these existing supervised polarity classification systems is that they are typically *domain-* and *language-specific*. Hence, when given a new domain or language, one needs to go through the expensive process of collecting a large amount of annotated data in order to train a high-performance polarity classifier. Some recent attempts have been made to leverage existing sentiment corpora or lexica to automatically create annotated resources for new domains or languages. However, such methods require the existence of either a parallel corpus/machine translation engine for projecting/translating annotations/lexica from a resource-rich language to the target language (Banea et al., 2008; Wan, 2008), or a domain that is "similar" enough to the target domain (Blitzer et al., 2007). When the target domain or language fails to meet this requirement, sentiment-based clustering or unsupervised polarity classification become appealing alternatives. Unfortunately, to our knowledge, these tasks are largely under-investigated in the NLP community. Turney's (2002) work is perhaps one of the most notable examples of unsupervised polarity classification. However, while his system learns the semantic orientation of the phrases in a review in an unsupervised manner, this information is used to predict the polarity of a review heuristically.

Despite its practical significance, sentiment-based clustering is a challenging task. To illustrate its difficulty, consider the task of clustering a set of movie reviews. Since each review may contain a description of the plot and the author's

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 580–589,
Singapore, 6-7 August 2009.

sentiment, a clustering algorithm may cluster reviews along either the *plot* dimension or the *sentiment* dimension; and without knowing the user's intention, they will be clustered along the most *prominent* dimension. Assuming the usual bag-of-words representation, the most prominent dimension will more likely be *plot*, as it is not uncommon for a review to be devoted almost exclusively to the plot, with the author briefly expressing her sentiment only at the end of the review. Even if the reviews contain mostly subjective material, the most prominent dimension may still not be *sentiment*, due to the fact that many reviews are *sentimentally ambiguous*. Specifically, a reviewer may have negative opinions on the actors but at the same time talk enthusiastically about how much she enjoyed the plot. The presence of both positive and negative sentiment-bearing words in these reviews renders the sentiment dimension *hidden* (i.e., less prominent) as far as clustering is concerned. Therefore, there is no guarantee that the clustering algorithm will automatically produce a sentiment-based clustering of the reviews.

Hence, it is important for a user to provide feedback on the clustering process to ensure that the reviews are clustered along the *sentiment* dimension, possibly in an interactive manner. One way to do this would be to ask the user to annotate a small number of reviews with polarity information, possibly through an active learning procedure to minimize human intervention (Dredze and Crammer, 2008). Another way would be to have the user explicitly identify the relevant features (in our case, the sentiment-bearing words) at the beginning of the clustering process (Liu et al., 2004), or incrementally construct the set of relevant features in an interactive fashion (Bekkerman et al., 2007; Raghavan and Allan, 2007; Roth and Small, 2009). In addition, the user may supply constraints on which pairs of documents must or must not appear in the same cluster (Wagstaff et al., 2001), or simply tell the algorithm whether two clusters should be *merged* or *split* during the clustering process (Balcan and Blum, 2008). It is worth noting that many of these feedback mechanisms were developed by machine learning researchers for general clustering tasks and not for sentiment-based clustering.

Our goal in this paper is to propose a novel mechanism allowing a user to cluster a set of documents along the desired dimension, which may be a hidden dimension, with *very limited* user feedback. In comparison to the aforementioned feedback mechanisms, ours is arguably much simpler: we only require that the user *select* a dimension by examining a small number of features for each dimension, as opposed to having the user *generate* the feature space in an interactive manner or *identify* clusters that need to be merged or split. In particular, identifying clusters for merging or splitting in Balcan and Blum's algorithm may not be as easy as it appears: for each MERGE or SPLIT decision the user makes, she has to sample a large number of documents from the cluster(s), read through the documents, and base her decision on the extent to which the documents are (dis)similar to each other. Perhaps more importantly, our human experiments involving five users indicate that all of them can easily identify the sentiment dimension based on the features, thus providing suggestive evidence that our method is viable.

In sum, our contributions in this paper are threefold. First, we propose a novel feedback mechanism for clustering allowing a user to easily specify the dimension along which she wants data points to be clustered and apply the mechanism to the challenging, yet under-investigated problem of sentiment-based clustering. Second, spectral learning, which is the core of our method, has not been applied extensively to NLP problems, and we hope that our work can increase the awareness of this powerful machine learning technique in the NLP community. Finally, we demonstrate the viability of our method not only by evaluating its performance on sentiment datasets, but also via a set of human experiments, which is typically absent in papers that involve algorithms for incorporating user feedback.

The rest of the paper is organized as follows. Section 2 presents the basics of spectral clustering, which will facilitate the discussion of our feedback mechanism in Section 3. We describe our human experiments and evaluation results on several sentiment datasets in Section 4, and present our conclusions in Section 5.

2 Spectral Clustering

When given a clustering task, an important question to ask is: which clustering algorithm should we use? A popular choice is k-means. Nevertheless, it is well-known that k-means has the major drawback of not being able to separate data points

that are not linearly separable in the given feature space (e.g., see Dhillon et al. (2004) and Cai et al. (2005)). Spectral clustering algorithms were developed in response to this problem with k-means. The central idea behind spectral clustering is to (1) construct a low-dimensional space from the original (typically high-dimensional) space while retaining as much information about the original space as possible, and (2) cluster the data points in this low-dimensional space. The rest of this section provides the details of spectral clustering.

2.1 Algorithm

Although there are several well-known spectral clustering algorithms in the literature (e.g., Weiss (1999), Shi and Malik (2000), Kannan et al. (2004)), we adopt the one proposed by Ng et al. (2002), as it is arguably the most widely-used. The algorithm takes as input a similarity matrix S created by applying a user-defined similarity function to each pair of data points. Below are the main steps of the algorithm:

1. Create the diagonal matrix D whose (i,i)-th entry is the sum of the i-th row of S, and then construct the Laplacian matrix $L = D^{-1/2}SD^{-1/2}$.
2. Find the eigenvalues and eigenvectors of L.
3. Create a new matrix from the m eigenvectors that correspond to the m largest eigenvalues.[1]
4. Each data point is now rank-reduced to a point in the m-dimensional space. Normalize each point to unit length (while retaining the sign of each value).
5. Cluster the resulting data points using k-means.

In essence, each dimension in the reduced space is defined by exactly one eigenvector. The reason why eigenvectors with large eigenvalues are used is that they capture the largest variance in the data. As a result, each of them can be thought of as revealing an important dimension of the data.

2.2 Clustering with Eigenvectors

As Ng et al. (2002) point out, "different authors still disagree on which eigenvectors to use, and how to derive clusters from them". There are two common methods for deriving clusters using the eigenvectors. These methods will serve as our baselines in our evaluation.

[1]For brevity, we will refer to the eigenvector with the n-th largest eigenvalue simply as the n-th eigenvector.

Method 1: Using the second eigenvector only
The first method is to use only the second eigenvector, $\mathbf{e}_2$, to partition the points. Besides revealing one of the most important dimensions of the data, this eigenvector induces an intuitively ideal partition of the data — the partition induced by the minimum normalized cut of the similarity graph[2], where the nodes are the data points and the edge weights are the pairwise similarity values of the points (Shi and Malik, 2000). Clustering in a one-dimensional space is trivial: since we have a linearization of the points, all we need to do is to determine a threshold for partitioning the points. However, we follow Ng et al. (2002) and cluster using 2-means in this one-dimensional space.

Method 2: Using m eigenvectors
Recall from Section 2.1 that after eigen-decomposing the Laplacian matrix, each data point is represented by m co-ordinates. In the second method, we simply use 2-means to cluster the data points in this m-dimensional space, effectively exploiting all of the m eigenvectors.

3 Our Approach

As mentioned before, sentiment-based clustering is challenging, in part due to the fact that the reviews can be clustered along more than one dimension. In this section, we propose and incorporate a user feedback mechanism into a spectral clustering algorithm, which makes it easy for a user to specify the dimension along which she wants to cluster the data points.

Recall that our method first applies spectral clustering to reveal the most important dimensions of the data, and then lets the user select the desired dimension. To motivate the importance of user feedback, it helps to understand why the two baseline clustering algorithms described in Section 2.2, which are also based on spectral methods but do not rely on user feedback, may not always yield a sentiment-based clustering. To begin with, consider the first method, where only the second eigenvector is used to induce the partition. Recall that the second eigenvector reveals the most prominent dimension of the data. Hence, if sentiment is not the most prominent dimension (which can happen if the non-sentiment-bearing

[2]Using the normalized cut (as opposed to the usual cut) ensures that the size of the two clusters are relatively balanced, avoiding trivial cuts where one cluster is empty and the other is full. See Shi and Malik (2000) for details.

words outnumber the sentiment-bearing words in the bag-of-words representation of a review), then the resulting clustering of the reviews may not be sentiment-oriented. A similar line of reasoning can be used to explain why the second baseline clustering algorithm, which clusters based on all of the eigenvectors in the low-dimensional space, may not always work well. Since each eigenvector corresponds to a different dimension (and, in particular, some of them correspond to non-sentiment dimensions), using all of them to represent a review may hamper the accurate computation of the similarity of two reviews as far as clustering along the sentiment dimension is concerned. In the rest of this section, we discuss the major steps of our user-feedback mechanism in detail.

Step 1: Identify the important dimensions
To identify the important dimensions of the given reviews, we take the top eigenvectors computed from the eigen-decomposition of the Laplacian matrix, which is in turn formed from the input similarity matrix. We compute the similarity between two reviews by taking the dot product of their feature vectors (see Section 4.1 for details on feature vector generation). Following Ng et al., we set the diagonal entries of the similarity matrix to 0.

Step 2: Identify the relevant features
Given the eigen-decomposition from Step 1, we first obtain the second through the fifth eigenvectors[3], which as mentioned above, correspond to the most important dimensions of the data. Then, we ask the user to select one of the four dimensions defined by these eigenvectors according to their relevance to sentiment. One way to do this is to (1) induce one partition of the reviews from each of the four eigenvectors, using a procedure identical to Method 1 in Section 2.2, and (2) have the user inspect the four partitions and decide which corresponds most closely to a sentiment-based clustering. The main drawback associated with this kind of user feedback is that the user may have to read a large number of reviews in order to make a decision. Hence, to reduce human effort, we employ an alternative procedure: we (1) identify the most informative features for characterizing each partition, and (2) have the user inspect just the features rather than the reviews.

While traditional feature selection techniques such as log-likelihood ratio and information gain can be applied to identify these informative features (see Yang and Pedersen (1997) for an overview), we employ a more sophisticated feature-ranking method that we call *maximum margin feature ranking* (MMFR). Recall that a maximum margin classifier (e.g., a support vector machine) separates data points from two classes while maximizing the margin of separation. Specifically, a maximum margin hyperplane is defined by $\mathbf{w} \cdot \mathbf{x} - b = 0$, where $\mathbf{x}$ is a feature vector representing an arbitrary data point, and $\mathbf{w}$ (a weight vector) and b (a scalar) are parameters that are learned by solving the following constrained optimization problem:

$$\arg\min \ \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_i \xi_i$$

subject to

$$c_i(\mathbf{w} \cdot \mathbf{x}_i - b) \geq 1 - \xi_i, \quad 1 \leq i \leq n,$$

where $c_i \in \{+1, -1\}$ is the class of the i-th training point $\mathbf{x}_i$, ξ_i is the degree of misclassification of $\mathbf{x}_i$, and C is a regularization parameter that balances training error and model complexity.

We use $\mathbf{w}$ to identify the most informative features for a partition. Note that a feature with a large positive weight is strongly indicative of the positive class, whereas a feature with a large negative weight is strongly indicative of the negative class. In other words, the most informative features are those with large absolute weight values. We exploit this observation and identify the most informative features for a partition by (1) training an SVM classifier[4] on the partition, where data points in the same cluster belong to the same class; (2) sorting the features according to the SVM-learned feature weights; and (3) generating two ranked lists of informative features using the top and bottom 100 features, respectively.

Given the ranked lists generated for each of the four partitions, the user will select one of the partitions/dimensions as most relevant to sentiment by inspecting as many features in the ranked lists as needed. After picking the most relevant dimension, the user will label one of the two feature lists associated with this dimension as POSITIVE and the other as NEGATIVE. Since each feature list represents one of the clusters, the cluster associated with the positive list is labeled POSITIVE and

[3]The first eigenvector is not used because it is a constant vector, meaning that it cannot be used to partition the data.

[4]All the SVM classifiers in this paper are trained using the SVM^{light} package (Joachims, 1999), with the learning parameters set to their default values.

the cluster associated with the negative list is labeled NEGATIVE.

In comparison to existing user feedback mechanisms for assisting a clustering algorithm, ours requires comparatively little human intervention: we only require that the user select a dimension by examining a small number of features, as opposed to having the user construct the feature space or identify clusters that need to be merged or split as is required with other methods.

Step 3: Identify the unambiguous reviews
There is a caveat, however. As mentioned in the introduction, many reviews contain both positive and negative sentiment-bearing words. These ambiguous reviews are more likely to be clustered incorrectly than their unambiguous counterparts. Now, since the ranked lists of features are derived from the partition, the presence of these ambiguous reviews can adversely affect the identification of informative features using MMFR. As a result, we remove the ambiguous reviews before deriving informative features from a partition.

We employ a simple method for identifying unambiguous reviews. In the computation of eigenvalues, each data point factors out the orthogonal projections of each of the other data points with which they have an affinity. Ambiguous data points receive the orthogonal projections from both the positive and negative data points, and hence they have near zero values in the pivot eigenvectors. We exploit this important information. The basic idea is that the data points with near zero values in the eigenvectors are more ambiguous than those with large absolute values. As a result, we posit 250 reviews from each cluster whose corresponding values in the eigenvector are farthest away from zero as unambiguous, and induce the ranked list of features only from the resulting 500 unambiguous reviews.[5]

Step 4: Cluster along the selected dimension
Finally, we employ the 2-means algorithm to cluster all the reviews along the dimension (i.e., the eigenvector) selected by the user, regardless of whether a review is ambiguous or not.

[5]Note that 500 is a somewhat arbitrary choice. Underlying this choice is our assumption that a fraction of the reviews is unambiguous. As we will see in the evaluation section, these 500 reviews can be classified with a high accuracy; consequently, the features induced from the resulting clusters are also of high quality. Additional experiments reveal that the list of top-ranking features does not change significantly when induced from a smaller number of unambiguous reviews.

4 Evaluation

4.1 Experimental Setup

Datasets. We use five sentiment classification datasets, including the widely-used movie review dataset [MOV] (Pang et al., 2002) as well as four datasets containing reviews of four different types of products from Amazon [books (BOO), DVDs (DVD), electronics (ELE), and kitchen appliances (KIT)] (Blitzer et al., 2007). Each dataset has 2000 labeled reviews (1000 positives and 1000 negatives). To illustrate the difference between topic-based clustering and sentiment-based clustering, we will also show topic-based clustering results on POL, a dataset created by taking all the documents from two sections of 20 Newsgroups, namely, `sci.crypt` and `talks.politics`.

To preprocess a document, we first tokenize and downcase it, and then represent it as a vector of unigrams, using frequency as presence. In addition, we remove from the vector punctuation, numbers, words of length one, and words that occur in only a single review. Following the common practice in the information retrieval community, we also exclude words with high document frequency, many of which are stopwords or domain-specific general-purpose words (e.g., "movies" in the movie domain). A preliminary examination of our evaluation datasets reveals that these words typically comprise 1–2% of a vocabulary. The decision of exactly how many terms to remove from each dataset is subjective: a large corpus typically requires more removals than a small corpus. To be consistent, we simply sort the vocabulary by document frequency and remove the top 1.5%.

Evaluation metrics. We employ two evaluation metrics. First, we report results in terms of the accuracy achieved on the 2000 labeled reviews for each dataset. Second, following Kamvar et al. (2003), we evaluate the clusters produced by our approach against the gold-standard clusters using the Adjusted Rand Index (ARI). ARI ranges from –1 to 1; better clusterings have higher ARI values.

4.2 Baseline Systems

Clustering using the second eigenvector only. As our first baseline, we adopt Shi and Malik's approach and cluster the reviews using only the second eigenvector, $\mathbf{e}_2$, as described in Section 2.2. Results on POL and the five sentiment datasets are

System Variation	Accuracy						Adjusted Rand Index					
	POL	MOV	KIT	BOO	DVD	ELE	POL	MOV	KIT	BOO	DVD	ELE
Baseline: 2nd eigenvector	93.7	70.9	69.7	58.9	55.3	50.8	0.76	0.17	0.15	0.03	0.01	0.01
Baseline: m eigenvectors	95.9	59.3	63.2	60.1	62.5	63.8	0.84	0.03	0.07	0.04	0.06	0.08
Our approach	93.7	70.9	69.7	69.5	70.8	65.8	0.76	0.17	0.15	0.15	0.17	0.10

Table 1: Results in terms of accuracy and Adjusted Rand Index for the six datasets.

shown in row 1 of Table 1.[6] As we can see, this baseline achieves an accuracy of 90% on POL, but a much lower accuracy (of 50–70%) on the sentiment datasets. The same performance trend can be observed with ARI. These results provide support for the claim that sentiment-based clustering is more difficult than topic-based clustering.

In addition, it is worth noting that the baseline achieves much lower accuracies and ARI values on BOO, DVD, and ELE than on the remaining two sentiment datasets. Since $\mathbf{e}_2$ captures the most prominent dimension, these results suggest that sentiment dimension is not the most prominent dimension in these three datasets. In fact, this is intuitively plausible. For instance, in the book domain, positive book reviews typically contain a short description of the content, with the reviewer only briefly expressing her sentiment somewhere in the review. Similarly for the electronics domain: electronic product reviews are typically aspect-oriented, with the reviewer talking about the pros and cons of each aspect of the product (e.g., battery, durability). Since the reviews are likely to contain both positive and negative sentiment-bearing words, the sentiment-based clustering is unlikely to be captured by $\mathbf{e}_2$.

Clustering using top five eigenvectors. As our second baseline, we represent each data point using the top five eigenvectors (i.e., $\mathbf{e}_1$ through $\mathbf{e}_5$), and cluster them using 2-means in this 5-dimensional space, as described in Section 2.2. Hence, this can be thought of as an "ensemble" approach, where the clustering decision is collectively made by the five eigenvectors.

Results are shown in row 2 of Table 1. In comparison to the first baseline, we see improvements in accuracy and ARI for the three datasets on which the first baseline performs poorly (i.e., BOO, DVD, and ELE), with the most drastic improvement observed on ELE. On the other hand, performance on the remaining two sentiment datasets deteriorates. These results can be attributed to the fact that for BOO, DVD, and ELE, $\mathbf{e}_2$ does not capture the sentiment dimension, but since some other eigenvector in the ensemble does, we see improvements. On the other hand, $\mathbf{e}_2$ has already captured the sentiment dimension in MOV and KIT; as a result, employing additional dimensions, which may not be sentiment-related, may only introduce noise into the computation of the similarities between the reviews.

[6] Owing to the randomness in the choice of seeds for 2-means, these and all other experimental results involving 2-means are averaged over ten independent runs.

4.3 Our Approach

Human experiments. Unlike the two baselines, our approach requires users to specify which of the four dimensions (defined by the second through fifth eigenvectors) are most closely related to sentiment by inspecting a set of features derived from the unambiguous reviews for each dimension using MMFR. To better understand how easy it is for a human to select the desired dimension given the features, we performed the experiment independently with five humans (all of whom are computer science graduate students not affiliated with this research) and computed the agreement rate.

More specifically, for each dataset, we showed each human judge the top 100 features for each cluster according to MMFR (see Tables 4–6 for a snippet). In addition, we informed them of the intended dimension: for example, for POL, the judge was told that the intended clustering is Politics vs. Science. Also, if she determined that more than one dimension was relevant to the intended clustering, she was instructed to rank these dimensions in terms of their degree of relevance, where the most relevant one would appear first in the list.

The dimensions (expressed in terms of the IDs of the eigenvectors) selected by each of the five judges for each dataset are shown in Table 2. The agreement rate (shown in the last row of the table) was computed based on only the highest-ranked dimension selected by each judge. As we can see, perfect agreement is achieved for four of the five sentiment datasets, and for the remaining two datasets, near-perfect agreement is achieved.

Judge	POL	MOV	KIT	BOO	DVD	ELE
1	2,3,4	2	2	4	3	3
2	2,4	2	2	4	3	3
3	4	2,4	4	4	3	3
4	2,3	2	2	4	3	3,4
5	2	2	2	4	3	3
Agr	80%	100%	80%	100%	100%	100%

Table 2: Human agreement rate.

	POL	MOV	KIT	BOO	DVD	ELE
Acc	99.8	87.0	87.6	86.2	87.4	77.6

Table 3: Accuracies on unambiguous documents.

These results together with the fact that it took 5–6 minutes to identify the relevant dimension, indicate that asking a human to determine the intended dimension based on solely the "informative" features is a viable task.

Clustering results. Next, we cluster all 2000 documents for each dataset using the dimension selected by the majority of the human judges. The clustering results are shown in row 3 of Table 1. In comparison to the better baseline for each dataset, we see that our approach performs substantially better on BOO, DVD and ELE, at almost the same level on MOV and KIT, but slightly worse on POL. Note that the improvements observed for BOO, DVD and ELE can be attributed to the failure of $\mathbf{e}_2$ to capture the sentiment dimension. Perhaps most importantly, by exploiting human feedback, our approach has achieved more stable performance across the datasets than the baselines, with accuracies ranging from 65.8% to 93.7% and ARI ranging from 0.10 to 0.76.

Role of unambiguous documents. Recall that the features with the largest MMFR were computed from the unambiguous documents only. To get an intuitive understanding of the role of unambiguous documents in our approach, we show in Table 3 the accuracy when the unambiguous documents in each dataset were clustered using the eigenvector selected by the majority of the judges. As we can see, the accuracy of each dataset is higher than the corresponding accuracy shown in row 3 of Table 1. In fact, an accuracy of more than 85% was achieved on all but one dataset. This suggests that our method of identifying unambiguous documents is useful.

Note that it is crucial to be able to achieve a high accuracy on the unambiguous documents: if clustering accuracy is low, the features induced from the clusters may not be an accurate representation of the corresponding dimension, and the human judge may have a difficult time identifying the intended dimension. In fact, some human judges reported difficulty in identifying the correct dimension for the ELE dataset, and this can be attributed in part to the low accuracy achieved on the unambiguous documents.

Features as summary. Recall that the method we proposed represents each dimension with a small number of features and asks a user to select the desired dimension by inspecting the corresponding feature lists. In other words, each feature list serves as a "summary" of its corresponding dimension, and inspecting the features induced for each dimension can give us insights into the different dimensions of a dataset. Hence, if a user is not sure how she wants the data points to be clustered (due to lack of knowledge of the data, for instance), our automatically induced features may serve as an overview of the different dimensions of the data. To better understand whether these features can indeed provide a user with additional useful information about a dataset, we show in Tables 4–6 the top ten features induced for each cluster and each dimension for the six datasets. As an example, consider the MOV dataset. Inspecting the induced features, we can determine that it has a sentiment dimension ($\mathbf{e}_2$), as well as a humor vs. thriller dimension ($\mathbf{e}_4$). In other words, if we cluster along $\mathbf{e}_2$, we get a sentiment-based clustering; and if we cluster along $\mathbf{e}_4$, we obtain a genre-based (humor vs. thriller) clustering.

User feedback vs. labeled data. Recall that our two baselines are unsupervised, whereas our approach can be characterized as semi-supervised, as it relies on user feedback to select the intended dimension. Hence, it should not be surprising to see that the average clustering performance of our approach is better than that of the baselines.

To do a fairer comparison, we conduct another experiment in which we compare our approach against a semi-supervised sentiment classification system, which uses transductive SVM as the underlying semi-supervised learner. More specifically, the goal of this experiment is to determine how many labeled documents are needed in order for the transductive learner to achieve the same level of performance as our approach. To answer this question, we first give the transductive learner access to the 2000 documents for each dataset as

unlabeled data. Next, we randomly sample 50 unlabeled documents and assign them the true label. We then re-train the classifier and compute its accuracy on the 2000 documents. We keep adding more labeled data (50 in each iteration) until it reaches the accuracy achieved by our system. Results of this experiment are shown in Table 7. Owing in the randomness involved in the selection of unlabeled documents, these results are averaged over ten independent runs. As we can see, our

user feedback is equivalent to the effort of hand-annotating 275 documents per dataset on average.

Multiple relevant dimensions. As seen from Table 2, some human judges selected more than one dimension for some datasets (e.g., 2,3,4 for POL; 2,4 for MOV; and 3,4 for ELE). However, we never took into account these "extra" dimensions in our previous experiments. To better understand whether these extra dimensions can help improve accuracy and ARI, we conduct another experiment in which we apply 2-means to cluster the documents in a space that is defined by all of the selected dimensions. The final accuracy turns out to be 95.9%, 70.9%, and 67.5% for POL, MOV, and ELE respectively, which is considerably better than using only the optimal dimension and suggests that the extra dimensions contain useful information.

5 Conclusions

Unsupervised clustering algorithms typically group objects along the most prominent dimension, in part owing to their objective of simultaneously maximizing inter-cluster similarity and intra-cluster dissimilarity. Hence, if the user's intended clustering dimension is not the most prominent dimension, these unsupervised clustering algorithms will fail miserably. To address this problem, we proposed to integrate a novel user feedback mechanism into a spectral clustering algorithm, which allows us to mine the intended, possibly hidden, dimension of the data and produce the desired clustering. This mechanism differs from competing methods in that it requires very limited feedback: to select the intended dimension, the user only needs to inspect a small number of features. We demonstrated its viability via a set of human and automatic experiments with unsupervised sentiment classification, obtaining promising results.

In future work, we plan to explore several extensions to our proposed method. First, we plan to use our user-feedback method in combination with existing methods (e.g., Bekkerman et al. (2007)) for improving its performance. For instance, instead of having the user construct a relevant feature space from scratch, she can simply extend the set of informative features identified for the user-selected dimension. Second, since none of the steps in our method is specifically designed for sentiment classification, we plan to apply it to other non-topic-based text classification tasks.

Adapting a Polarity Lexicon using Integer Linear Programming for Domain-Specific Sentiment Classification

Abstract

Polarity lexicons have been a valuable resource for sentiment analysis and opinion mining. There are a number of such lexical resources available, but it is often suboptimal to use them as is, because general purpose lexical resources do not reflect domain-specific lexical usage. In this paper, we propose a novel method based on integer linear programming that can adapt an existing lexicon into a new one to reflect the characteristics of the data more directly. In particular, our method collectively considers the relations among words and opinion expressions to derive the most likely polarity of each lexical item (*positive, neutral, negative*, or *negator*) for the given domain. Experimental results show that our lexicon adaptation technique improves the performance of fine-grained polarity classification.

1 Introduction

Polarity lexicons have been a valuable resource for sentiment analysis and opinion mining. In particular, they have been an essential ingredient for fine-grained sentiment analysis (e.g., Kim and Hovy (2004), Kennedy and Inkpen (2005), Wilson et al. (2005)). Even though the polarity lexicon plays an important role (Section 3.1), it has received relatively less attention in previous research. In most cases, polarity lexicon construction is discussed only briefly as a preprocessing step for a sentiment analysis task (e.g., Hu and Liu (2004), Moilanen and Pulman (2007)), but the effect of different alternative polarity lexicons is not explicitly investigated. Conversely, research efforts that focus on constructing a general purpose polarity lexicon (e.g., Takamura et al. (2005), Andreevskaia and Bergler (2006), Esuli and Sebastiani (2006), Rao and Ravichandran (2009)) generally evaluate the lexicon in isolation from any potentially relevant NLP task, and it is unclear how the new lexicon might affect end-to-end performance of a concrete NLP application.

It might even be unrealistic to expect that there can be a general-purpose lexical resource that can be effective across *all* relevant NLP applications, as general-purpose lexicons will not reflect domain-specific lexical usage. Indeed, Blitzer et al. (2007) note that the polarity of a particular word can carry opposite sentiment depending on the domain (e.g., Andreevskaia and Bergler (2008)).

In this paper, we propose a novel method based on integer linear programming to adapt an existing polarity lexicon into a new one to reflect the characteristics of the data more directly. In particular, our method considers the relations among words and opinion expressions collectively to derive the most likely polarity of each word for the given domain.

Figure 1 depicts the key insight of our approach using a bipartite graph. On the left hand side, each node represents a word, and on the right hand side, each node represents an opinion expression. There is an edge between a word w_i and an opinion expression e_j, if the word w_i appears in the expression e_j. We assume the possible polarity of each expression is one of the following three values: {*positive, neutral, negative*}, while the possible polarity of each word is one of: {*positive*, *neutral*, *negative* or *negator*}. Strictly speaking, *negator* is not a value for polarity, but we include them in our lexicon, because *valence shifters* or *negators* have been shown to play an important role for sentiment analysis (e.g., Polanyi and Zaenen (2004), Moilanen and Pulman (2007), Choi and Cardie (2008)).

Typically, the ultimate goal of the sentiment analysis task is to determine the expression-level (or sentiment/ document-level) polarities, rather

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 590–598,
Singapore, 6-7 August 2009.

than the correct word-level polarities with respect to the domain. Therefore, word-level polarities can be considered as latent information. In this paper, we show how we can improve the word-level polarities of a general-purpose polarity lexicon by utilizing the expression-level polarities, and in return, how the adapted word-level polarities can improve the expression-level polarities.

In Figure 1, there are two types of relations we could exploit when adapting a general-purpose polarity lexicon into a domain-specific one. The first are word-to-word relations within each expression. That is, if we are not sure about the polarity of a certain word, we can still make a guess based on the polarities of other words within the same expression and knowledge of the polarity of the expression. The second type of relations are word-to-expression relations: e.g., some words appear in expressions that take on a variety of polarities, while other words are associated with expressions of one polarity class or another.

In relation to previous research, analyzing word-to-word (intra-expression) relations is most related to techniques that determine expression-level polarity *in context* (e.g., Wilson et al. (2005)), while exploring word-to-expression (inter-expression) relations has connections to techniques that employ more of a global-view of corpus statistics (e.g., Kanayama and Nasukawa (2006)).[1]

While most previous research exploits only one or the other type of relation, we propose a unified method that can exploit both types of semantic relation, while adapting a general purpose polarity lexicon into a domain specific one. We formulate our lexicon adaptation task using integer linear programming (ILP), which has been shown to be very effective when solving problems with complex constraints (e.g., Roth and Yih (2004), Denis and Baldridge (2007)). And the word-to-word and word-to-expression relations discussed above can be encoded as soft and hard constraints in ILP. Unfortunately, one class of constraint that we would like to encode (see Section 2) will require an exponentially many number of constraints when grounded into an actual ILP problem. We therefore propose an approximation scheme to make the problem more practically solvable.

We evaluate the effect of the adapted lexicon in the context of a concrete NLP task: expression-level polarity classification. Experimental results show that our lexicon adaptation technique improves the accuracy of two competitive expression-level polarity classifiers from 64.2% - 70.4% to 67.0% - 71.2%..

[1] In case of document-level polarity classification, word-to-expression relations correspond to word-to-document relations.

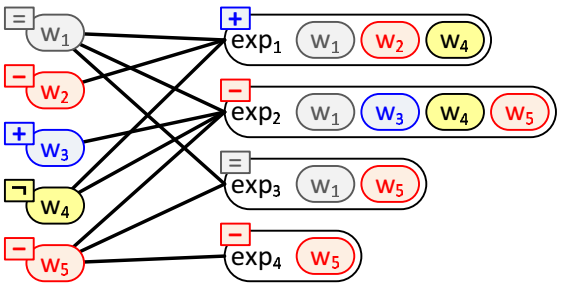

Figure 1: The relations among words and expressions. + indicates positive, - indicates negative, = indicates neutral, and ¬ indicates a negator.

2 An Integer Linear Programming Approach

In this section, we describe how we formulate the lexicon adaptation task using integer linear programming. Before we begin, we assume that we have a general-purpose polarity lexicon $\mathcal{L}$, and a polarity classification algorithm $f(e_l, \mathcal{L})$, that can determine the polarity of the opinion expression e_l based on the words in e_l and the initial lexicon $\mathcal{L}$. The polarity classification algorithm $f(\cdot)$ can be either a heuristic-based one, or a machine-learning based one – we consider it as a black box for now.

Constraints for word-level polarities: For each word x_i, we define four binary variables: $x_i^+, x_i^=, x_i^-, x_i^\neg$ to represent positive, neutral, negative polarity, and negators respectively. If $x_i^\delta = 1$ for some $\delta \in \{+, =, -, \neg\}$, then the word x_i has the polarity δ. The following inequality constraint states that at least one polarity value must be chosen for each word.

$$x_i^+ + x_i^= + x_i^- + x_i^\neg >= 1 \qquad (1)$$

If we allow only one polarity per word, then the above inequality constraint should be modified as an equality constraint. Although most words tend to associate with a single polarity, some can take on more than one polarity. In order to capture this observation, we introduce an auxiliary binary variable α_i for each word x_i. Then the next inequality

constraint states that at most two polarities can be chosen for each word.

$$x_i^+ + x_i^= + x_i^- + x_i^\neg <= 1 + \alpha_i \quad (2)$$

Next we introduce the initial part of our objective function.

$$\text{maximize} \sum_i \Big(w_i^+ x_i^+ + w_i^= x_i^= + w_i^- x_i^- + w_i^\neg x_i^\neg - w_\alpha \alpha_i \Big) + \cdots \quad (3)$$

For the auxiliary variable α_i, we apply a constant weight w_α to discourage ILP from choosing more than one polarity for each word. We can allow more than two polarities for each word, by adding extra auxiliary variables and weights. For each variable x_i^δ, we define its weight w_i^δ, which indicates how likely it is that word x_i carries the polarity δ. We define the value of w_i^δ using two different types of information as follows:

$$w_i^\delta := {}^{\mathcal{L}}w_i^\delta + {}^{\mathcal{C}}w_i^\delta$$

where ${}^{\mathcal{L}}w_i^\delta$ is the degree of polarity δ for word x_i determined by the general-purpose polarity lexicon $\mathcal{L}$, and ${}^{\mathcal{C}}w_i^\delta$ is the degree of polarity δ determined by the corpus statistics as follows:[2]

$${}^{\mathcal{C}}w_i^\delta := \frac{\#\text{ of } x_i \text{ in expressions with polarity } \delta}{\#\text{ of } x_i \text{ in the corpus } \mathcal{C}}$$

Note that the occurrence of word x_i in an expression e_j with a polarity δ does not necessarily mean that the polarity of x_i should also be δ, as the interpretation of the polarity of an expression is more than just a linear sum of the word-level polarities (e.g., Moilanen and Pulman (2007)). Nonetheless, not all expressions require a complicated inference procedure to determine their polarity. Therefore, ${}^{\mathcal{C}}w_i^\delta$ still provides useful information about the likely polarity of each word based on the corpus statistics.

From the perspective of Chomskyan linguistics, the weights ${}^{\mathcal{L}}w_i^\delta$ based on the prior polarity from the lexicon can be considered as having a "competence" component , while ${}^{\mathcal{C}}w_i^\delta$ derived from the corpus counts can be considered as a "performance" component (Noam Chomsky (1965)).

[2]If a word x_i is in an expression that is not an opinion, then we count it as an occurrence with neutral polarity.

Constraints for content-word negators: Next we describe a constraint that exploits knowledge of the typical distribution of *content-word negators* in natural language. Content-word negators are words that are not function words, but act semantically as negators (Choi and Cardie, 2008).[3] Although it is possible to artificially construct a very convoluted sentence with lots of negations, it is unlikely for multiple layers of negations to appear very often in natural language (Pickett et al. (1996)). Therefore, we allow at most one content-word negator for each expression e_l. Because we do not restrict the number of function-word negators, our constraint still gives room for multiple layers of negations.

$$\sum_{i \in \mu(e_l)} x_i^\neg <= 1 \quad (4)$$

In the above constraint, $\mu(e_l)$ indicates the set of indices of content words appearing in e_l. For instance, if $i \in \mu(e_l)$, then x_i appears in e_l. This constraint can be polished further to accommodate longer expressions where multiple content-word negators are more likely to appear, by adding a separate constraint with a sliding window.

Constraints for expression-level polarities: Before we begin, we introduce $\pi(e_l)$ that will be used often in the remaining section. For each expression e_l, we define $\pi(e_l)$ to be the set of content words appearing in e_l, together with the most likely polarity proposed by a general-purpose polarity lexicon $\mathcal{L}$. For instance, if $x_i^+ \in \pi(e_l)$, then the polarity of word x_i is $+$ according to $\mathcal{L}$.

Next we encode constraints that consider expression-level polarities. If the polarity classification algorithm $f(e_l, \mathcal{L})$ makes an incorrect prediction for e_l using the original lexicon $\mathcal{L}$, then we need to encourage ILP to fix the error by suggesting different word-level polarities. We capture this idea by the following constraint:

$$\sum_{x_i^\delta \in \pi(e_l)} x_i^\delta <= |\pi(e_l)| - 1 + \beta_l \quad (5)$$

The auxiliary binary variable β_l is introduced for each e_l so that the assignment $\pi(e_l)$ does not have to be changed if paying for the cost w_β in the objective function. (See equation (10).) That is, suppose the ILP solver assigns '1' to all variables

[3]Examples of content-word negators are *destroy*, *eliminate*, *prevent* etc.

in $\phi(e_l)$, (which corresponds to keeping the original lexicon as it is for all words in the given expression e_l), then the auxiliary variable β_l must be also set as '1' in order to satisfy the constraint (5). Because β_l is associated with a negative weight in the objective function, doing so will act against maximizing the objective function. This way, we discourage the ILP solver to preserve the original lexicon as it is.

To verify the constraint (5) further, suppose that the ILP solver assigns '1' for all variables in $\phi(e_l)$ except for one variable. (Notice that doing so corresponds to proposing a new polarity for one of the words in the given expression e_l.) Then the constraint (5) will hold regardless of whether the ILP solver assigns '0' or '1' to β_l. Because β_l is associated with a negative weight in the objective function, the ILP solver will then assign '0' to β_l to maximize the objective function. In other words, we encourage the ILP solver to modify the original lexicon for the given expression e_l.

We use this type of *soft* constraint in order to cope with the following two noise factors: first, it is possible that some annotations are noisy. Second, $f(e_l, \mathcal{L})$ is not perfect, and might not be able to make a correct prediction even with the correct word-level polarities.

Next we encode a constraint that is the opposite of the previous one. That is, if the polarity classification algorithm $f(e_l, \mathcal{L})$ makes a correct prediction on e_l using the original lexicon $\mathcal{L}$, then we encourage ILP to keep the original word-level polarities for words in e_l.

$$\sum_{x_i^\delta \in \pi(e_l)} x_i^\delta \ >= \ |\pi(e_l)| - |\pi(e_l)|\beta_l \qquad (6)$$

Interpretation of constraint (6) with the auxiliary binary variable β_l is similar to that of constraint (5) elaborated above.

Notice that in equation (5), we encouraged ILP to fix the current lexicon $\mathcal{L}$ for words in e_l, but we have not specified the consequence of a modified lexicon ($\mathcal{L}'$) in terms of expression-level polarity classification $f(e_l, \mathcal{L}')$. Certain changes to $\mathcal{L}$ might not fix the prediction error for e_l, and those might even cause extra incorrect predictions for other expressions. Then it would seem that we need to replicate constraints (5) & (6) for all permutations of word-level polarities. However, doing so would incur exponentially many number of constraints ($4^{|e_l|}$) for each expression.[4]

To make the problem more practically solvable, we only consider changes to the lexicon that are within edit-one distance with respect to $\pi(e_l)$. More formally, let us define $\pi'(e_l)$ to be the set of content words appearing in e_l, together with the most likely polarity proposed by a modified polarity lexicon $\mathcal{L}'$. Then we need to consider all $\pi'(e_l)$ such that $|\pi'(e_l) \cap \pi(e_l)| = |\pi(e_l)| - 1$. There are $(4-1)|e_l|$ number of different $\pi'(e_l)$, and we index them as $\pi'_k(e_l)$. We then add following constraints similarly as equation (5) & (6):

$$\sum_{x_i^\delta \in \pi'_k(e_l)} x_i^\delta \ <= \ |\pi'_k(e_l)| - 1 + \beta_{(l,k)} \qquad (7)$$

if the polarity classification algorithm $f(\cdot)$ makes an incorrect prediction based on $\pi'_k(e_l)$. And,

$$\sum_{x_i^\delta \in \pi'_k(e_l)} x_i^\delta \ >= \ |\pi'_k(e_l)| - |\pi'_k(e_l)|\beta_{(l,k)} \qquad (8)$$

if the polarity classification algorithm $f(\cdot)$ makes a correct prediction based on $\pi'_k(e_l)$. Remember that none of the constraints (5) - (8) enforces assignment $\pi(e_l)$ or $\pi'_k(e_l)$ as a hard constraint. In order to enforce at least one of them to be chosen, we add the following constraint:

$$\sum_{x_i^\delta \in \pi(e_l)} x_i^\delta \ >= \ |\pi(e_l)| - 1 \qquad (9)$$

This constraint ensures that the modified lexicon $\mathcal{L}'$ is not drastically different from $\mathcal{L}$. Assuming that the initial lexicon $\mathcal{L}$ is a reasonably good one, constraining the search space for $\mathcal{L}'$ will regulate that $\mathcal{L}'$ does not turn into a degenerative one that overfits to the current corpus $\mathcal{C}$.

Objective function: Finally, we introduce our full objective function.

[4]For certain simple polarity classification algorithm $f(e_l, \mathcal{L})$, it is possible to write polynomially many number of constraints. However our approach intends to be more general by treating $f(e_l, \mathcal{L})$ as a black box, so that algorithms that do not factor nicely can also be considered as an option.

$$\begin{aligned}\text{maximize} \sum_i \Big(& w_i^+ x_i^+ + w_i^= x_i^= \\ + & w_i^- x_i^- + w_i^\neg x_i^\neg \\ - & w_\alpha \alpha_i \Big) \\ -\sum_l & w_\beta \rho_l \beta_l \\ -\sum_{l,k} & w_\beta \rho_{(l,k)} \beta_{(l,k)} \end{aligned} \quad (10)$$

We have already described the first part of the objective function (equation (3)), thus we only describe the last two terms here. w_β is defined similarly as w_α; it is a constant weight that applies for any auxiliary binary variable β_l and $\beta_{(l,k)}$.

We further define ρ_l and $\rho_{(l,k)}$ as secondary weights, or *amplifiers* to adjust the constant weight w_β. To enlighten the motivation behind the amplifiers ρ_l and $\rho_{(l,k)}$, we bring out the following observations:

1. Among the incorrect predictions for expression-level polarity classification, some are more incorrect than the other. For instance, classifying positive class to negative class is more wrong than classifying positive class to neutral class. Therefore, the cost of not fixing very incorrect predictions should be higher than the cost of not fixing less incorrect predictions. (See [R2] and [R3] in Table 1.)

2. If the current assignment $\pi(e_l)$ for expression e_l yields a correct prediction using the classifier $y(e_l, \mathcal{L})$, then there is not much point in changing $\mathcal{L}$ to $\mathcal{L}'$, even if $y(e_l, \mathcal{L}')$ also yields a correct prediction. In this case, we would like to assign slightly higher confidence in the original lexicon $\mathcal{L}$ then the new one $\mathcal{L}'$. (See [R1] in Table 1.)

3. Likewise, if the current assignment $\pi(e_l)$ for expression e_l yields an incorrect prediction using the classifier $y(e_l, \mathcal{L})$, then there is not much point in changing $\mathcal{L}$ to $\mathcal{L}'$, if $y(e_l, \mathcal{L}')$ also yields an equally incorrect prediction. Again we assign slightly higher confidence in the original lexicon $\mathcal{L}$ than the new one $\mathcal{L}'$ in such cases. (Compare each row in [R2] with a corresponding row in [R3] in Table 1.)

[R1]	If $\pi(e_l)$ correct	ρ_l	$\leftarrow 1.5$
	If $\pi'_k(e_l)$ correct	$\rho_{(l,k)}$	$\leftarrow 1.0$
[R2]	If $\pi(e_l)$ very incorrect	ρ_l	$\leftarrow 1.0$
	If $\pi(e_l)$ less incorrect	ρ_l	$\leftarrow 0.5$
[R3]	If $\pi'_k(e_l)$ very incorrect	$\rho_{(l,k)}$	$\leftarrow 1.5$
	If $\pi'_k(e_l)$ less incorrect	$\rho_{(l,k)}$	$\leftarrow 1.0$

Table 1: The value of amplifiers ρ_l and $\rho_{(l,k)}$.

To summarize, for correct predictions, the degree of ρ determines the degree of cost of (undesirably) altering the current lexicon for e_l. For incorrect predictions, the degree of ρ determines the degree of cost of not fixing the current lexicon for e_l.

3 Experiments

In the experiment section, we seek for answers for the following questions:

Q1 What is the effect of a polarity lexicon on the expression-level polarity classification task? In particular, is it useful when using a machine learning technique that might be able to learn the necessary polarity information just based on the words in the training data, without consulting a dictionary? (Section 3.1)

Q2 What is the effect of an adapted polarity lexicon on the expression-level polarity classification task? (Section 3.2)

Notice that we include the *neutral* polarity in the polarity classification. It makes our task much harder (e.g., Wilson et al. (2009)) than those that assume inputs are guaranteed to be either strongly positive or negative (e.g., Pang et al. (2002), Choi and Cardie (2008)). But in practice, one cannot expect that a given input is strongly polar, as automatically extracted opinions are bound to be noisy. Furthermore, Wiebe et al. (2005) discuss that some opinion expressions do carry a neutral polarity.

We experiment with the Multi-Perspective Question Answering (MPQA) corpus (Wiebe et al., 2005) for evaluation. It contains 535 newswire documents annotated with phrase-level subjectivity information. We evaluate on all opinion expressions that are known to have high level of inter-annotator agreement. That is, we include opinions with intensity marked as 'medium' or

higher, and exclude those with annotation confidence marked as 'uncertain'. To focus our study on the direct influence of the polarity lexicon upon the sentiment classification task, we assume the boundaries of the expressions are given. However, our approach can be readily used in tandem with a system that extracts opinion expressions (e.g., Kim and Hovy (2005), Breck et al. (2007)). Performance is reported using 10-fold cross-validation on 400 documents, and a separate 135 documents were used as a development set. For the general-purpose polarity lexicon, we expand the polarity lexicon of Wilson et al. (2005) with General Inquirer dictionary as suggested by Choi and Cardie (2008).

We report the performance in two measures: *accuracy* for 3-way classification, and *average error distance*. The reason why we consider *average error distance* is because classifying a positive class into a negative class is worse than classifying a positive class into a neutral one. We define the error distance between 'neutral' class and any other class as 1, while the error distance between 'positive' class and 'negative' class as 2. If a predicted polarity is correct, then the error distance is 0. We compute the error distance of each prediction and take the average over all predictions in the test data.

3.1 Experiment-I: Effect of a Polarity Lexicon

To verify the effect of a polarity lexicon on the expression-level polarity classification task, we experiment with simple classification-based machine learning technique. We use the Mallet (McCallum, 2002) implementation of Conditional Random Fields (CRFs) (Lafferty et al., 2001).[5] To highlight the influence of a polarity lexicon, we compare the performance of CRFs with and without features derived from polarity lexicons.

Features: We encode basic features as words and lemmas for all content words in the given expression. The performance of CRFs using only the basic features are given in the first row of the Table 2. Next we encode features derived from polarity lexicons as follows.

- The output of Vote & Flip algorithm. (Section 3.2 & Figure 2.)

[5]We use the CRF implementation of Mallet (McCallum, 2002) with Markov-order 0, which is equivalent to Maximum Entropy models (Berger et al. (1996)).

	Accuracy	Avg. Error Distance
Without Lexicon	63.9	0.440
With Lexicon	70.4	0.334

Table 2: Effect of a polarity lexicon on expression-level classification using CRFs

- Number of positive, neutral, negative, and negators in the given expression.
- Number of positive (or negative) words in conjunction with number of negators.
- (boolean) Whether the number of positive words dominates negative ones.
- (boolean) Whether the number of negative words dominates positive ones.
- (boolean) None of the above two cases
- Each of the above three boolean values in conjunction with the number of negators.

Results: Table 2 shows the performance of CRFs with and without features that consult the general-purpose lexicon. As expected, CRFs can perform reasonably well (accuracy = 63.9%) even without consulting the dictionary, by learning directly from the data. However, having the polarity lexicon boosts the performance significantly (accuracy = 70.4%), demonstrating that lexical resources are very helpful for fine-grained sentiment analysis. The difference in performance is statistically significant by paired t-test for both accuracy ($p < 0.01$) and average error distance ($p < 0.01$).

3.2 Experiment-II: Adapting a Polarity Lexicon

In this section, we assess the quality of the adapted lexicon in the context of an expression-level polarity classification task. In order to perform the lexicon adaptation via ILP, we need an expression-level polarity classification algorithm $f(e_l, \mathcal{L})$ as described in Section 2. According to Choi and Cardie (2008), voting algorithms that recognize content-word negators achieve a competitive performance, so we will use a variant of it for simplicity. Because none of the algorithms proposed by Choi and Cardie (2008) is designed to handle the neutral polarity, we invent our own version as shown in Figure 2.

For each expression e_i,
  $nPositive \leftarrow$ # of positive words in e_i
  $nNeutral \leftarrow$ # of neutral words in e_i
  $nNegative \leftarrow$ # of negative words in e_i
  $nNegator \leftarrow$ # of negating words in e_i

  if ($nNegator$ % 2 = 0)
    then $fFlipPolarity \leftarrow false$
  else
    then $fFlipPolarity \leftarrow true$

  if ($nPositive > nNegative$) & $\neg$ $fFlipPolarity$
    then Polarity(e_i) $\leftarrow$ $positive$
else if ($nPositive > nNegative$) & $fFlipPolarity$
    then Polarity(e_i) $\leftarrow$ $negative$
else if ($nPositive < nNegative$) & $\neg$ $fFlipPolarity$
    then Polarity(e_i) $\leftarrow$ $negative$
else if ($nPositive < nNegative$) & $fFlipPolarity$
    then Polarity(e_i) $\leftarrow$ $neutral$
else if $nNeutral > 0$
    then Polarity(e_i) $\leftarrow$ $neutral$
else
    then Polarity(e_i) $\leftarrow$ $default\_polarity$ (the most prominent polarity in the corpus)

Figure 2: Vote & Flip Algorithm

It might look a bit complex at first glance, but the intuition is simple. The variable $fFlipPolarity$ determines whether we need to flip the overall majority polarity based on the number of negators in the given expression. If the positive (or negative) polarity words dominate the given expression, and if there is no need to flip the majority polarity, then we take the positive (or negative) polarity as the overall polarity. If the positive (or negative) polarity words dominate the given expression, and if we need to flip the majority polarity, then we take the negative (or neutral) polarity as the overall polarity.

Notice that the result of flipping the negative polarity is *neutral*, not *positive*. In our pilot study, we found that this strategy works better than flipping the negative polarity to positive.[6] Finally, if the number of positive words and the negative words tie, and there is any neutral word, then we assign the neutral polarity. In this case, we don't worry if there is a negator, because flipping a neutral polarity would still result in a neutral polarity. If none of above condition is met, than we default to the most prominent polarity of the data, which is the negative polarity in the MPQA corpus. We name this simple algorithm as Vote & Flip algorithm. The performance is shown in the first row in Table 2.

Next we describe the implementation part of the ILP. For 10 fold-cross validation, we formulate the ILP problem using the training data (360 documents), and then test the effect of the adapted lexicon on the remaining 40 documents. We include only those content words that appeared more than 3 times in the training data. From the pilot test using the development set, we picked the value of w_β as 0.1. We found that having the auxiliary variables α_l which allow more than one polarity per word does not necessarily help with the performance, so we omitted them. We suspect it is because the polarity classifiers we experimented with is not highly capable of disambiguating different lexical usages and select the right polarity for a given context. We use CPLEX integer programming solver to solve our ILP problems. On a machine with 4GHz CPU, it took several minutes to solve each ILP problem.

In order to assess the effect of the adapted lexicon using CRFs, we need to first train the CRFs model. Using the same training set used for the lexicon adaptation would be suboptimal, because the features generated from the adapted lexicon will be unrealistically good in that particular data. Therefore, we prepared a separate training data for CRFs using 135 documents from the development set.

Results: Table 3 shows the comparison of the original lexicon and the adapted lexicon in terms of polarity classification performance using the Vote & Flip algorithm. The adapted lexicon improves the accuracy as well as reducing the average error distance. The difference in performance is statistically significant by paired t-test for both accuracy ($p < 0.01$) and average error distance ($p < 0.01$).

Table 4 shows the comparison of the original lexicon and the adapted lexicon using CRFs. The improvement is not as substantial as that of Vote & Flip algorithm but the difference in performance is also statistically significant for both accuracy ($p = 0.03$) and average error distance ($p = 0.04$).

[6]This finding is not surprising. For instance, if we consider the polarity of *"She did not get hurt much from the accident."*, it can be viewed as neutral; although it is good that one did not hurt much, it is still bad that there was an accident. Hence it gives a mixed feeling, which corresponds to the neutral polarity.

	Accuracy	Avg. Error Distance
Original Lexicon	64.2	0.395
Adapted Lexicon	67.0	0.365

Table 3: Effect of an adapted polarity lexicon on expression-level classification using the Vote & Flip Algorithm

4 Related Work

There are a number of previous work that focus on building polarity lexicons (e.g., Takamura et al. (2005), Kaji and Kitsuregawa (2007), Rao and Ravichandran (2009)). But most of them evaluated their lexicon in isolation from any potentially relevant NLP task, and it is unclear how the new lexicon might affect end-to-end performance of a concrete NLP application. Our work differs in that we try to draw a bridge between general purpose lexical resources and a domain-specific NLP application.

Kim and Hovy (2005) and Banea et al. (2008) present bootstrapping methods to construct a subjectivity lexicon and measure the effect of the new lexicon for sentence-level subjectivity classification. However, their lexicons only tell whether a word is a subjective one, but not the polarity of the sentiment. Furthermore, the construction of lexicon is still an isolated step from the classification task. Our work on the other hand allows the classification task to directly influence the construction of lexicon, enabling the lexicon to be adapted for a concrete NLP application and for a specific domain.

Wilson et al. (2005) pioneered the expression-level polarity classification task using the MPQA corpus. The experimental results are not directly comparable to ours, because Wilson et al. (2005) limit the evaluation only for the words that appeared in their polarity lexicon. Choi and Cardie (2008) also focus on the expression-level polarity classification, but their evaluation setting is not as practical as ours in that they assume the inputs are guaranteed to be either strongly positive or negative.

5 Conclusion

In this paper, we present a novel lexicon adaptation technique based on integer linear programming to reflect the characteristics of the domain more directly. In particular, our method collectively considers the relations among words and opinion expressions to derive the most likely polarity of each lexical item for the given domain. We evaluate the effect of our lexicon adaptation technique in the context of a concrete NLP application: expression-level polarity classification. The positive results from our experiments encourage further research for lexical resource adaptation techniques.

Abstract

Sentiment analysis often relies on a semantic orientation lexicon of positive and negative words. A number of approaches have been proposed for creating such lexicons, but they tend to be computationally expensive, and usually rely on significant manual annotation and large corpora. Most of these methods use WordNet. In contrast, we propose a simple approach to generate a high-coverage semantic orientation lexicon, which includes both individual words and multi-word expressions, using only a Roget-like thesaurus and a handful of affixes. Further, the lexicon has properties that support the Polyanna Hypothesis. Using the General Inquirer as gold standard, we show that our lexicon has 14 percentage points more correct entries than the leading WordNet-based high-coverage lexicon (SentiWordNet). In an extrinsic evaluation, we obtain significantly higher performance in determining phrase polarity using our thesaurus-based lexicon than with any other. Additionally, we explore the use of visualization techniques to gain insight into the our algorithm beyond the evaluations mentioned above.

1 Introduction

Sentiment analysis involves determining the opinions and private states (beliefs, emotions, speculations, and so on) of the speaker (Wiebe, 1994). It has received significant attention in recent years due to increasing online opinion content and applications in tasks such as automatic product recommendation systems (Tatemura, 2000; Terveen et al., 1997), question answering (Somasundaran et al., 2007; Lita et al., 2005), and summarizing multiple view points (Seki et al., 2004) and opinions (Mohammad et al., 2008a).

A crucial sub-problem is to determine whether positive or negative sentiment is expressed. Automatic methods for this often make use of lexicons of words tagged with positive and negative semantic orientation (Turney, 2002; Wilson et al., 2005; Pang and Lee, 2008). A word is said to have a positive **semantic orientation (SO)** (or **polarity**) if it is often used to convey favorable sentiment or evaluation of the topic under discussion. Some example words that have positive semantic orientation are *excellent, happy, honest*, and so on. Similarly, a word is said to have negative semantic orientation if it is often used to convey unfavorable sentiment or evaluation of the target. Examples include *poor, sad,* and *dishonest*.

Certain semantic orientation lexicons have been manually compiled for English—the most notable being the **General Inquirer (GI)** (Stone et al., 1966).[1] However, the GI lexicon has orientation labels for only about 3,600 entries. The **Pittsburgh subjectivity lexicon (PSL)** (Wilson et al., 2005), which draws from the General Inquirer and other sources, also has semantic orientation labels, but only for about 8,000 words.

Automatic approaches to creating a semantic orientation lexicon and, more generally, approaches for word-level sentiment annotation can be grouped into two kinds: (1) those that rely on manually created lexical resources—most of which use WordNet (Strapparava and Valitutti, 2004; Hu and Liu, 2004; Kamps et al., 2004; Takamura et al., 2005; Esuli and Sebastiani, 2006; An-

Singapore, 6-7 August 2009.

dreevskaia and Bergler, 2006; Kanayama and Nasukawa, 2006); and (2) those that rely on text corpora (Hatzivassiloglou and McKeown, 1997; Turney and Littman, 2003; Yu and Hatzivassiloglou, 2003; Grefenstette et al., 2004). Many of these lexicons, such as **SentiWordNet (SWN)** (Esuli and Sebastiani, 2006) were created using supervised classifiers and significant manual annotation, whereas others such as the **Turney and Littman lexicon (TLL)** (2003) were created from very large corpora (more than 100 billion words).

In contrast, we propose a computationally inexpensive method to compile a high-coverage semantic orientation lexicon without the use of any text corpora or manually annotated semantic orientation labels. Both of these resources may be used, if available, to further improve results. The lexicon has about twenty times the number of entries in the GI lexicon, and it includes entries for both individual words and common multi-word expressions. The method makes use of a Roget-like thesaurus and a handful of antonym-generating affix patterns. Whereas thesauri have long been used to estimate semantic distance (Jarmasz and Szpakowicz, 2003; Mohammad and Hirst, 2006), the closest thesaurus-based work on sentiment analysis is by Aman and Szpakowicz (2007) on detecting emotions such as happiness, sadness, and anger. We evaluated our thesaurus-based algorithm both intrinsically and extrinsically and show that the semantic orientation lexicon it generates has significantly more correct entries than the state-of-the-art high-coverage lexicon SentiWordNet, and that it has a significantly higher coverage than the General Inquirer and Turney–Littman lexicons.

In Section 2 we examine related work. Section 3 presents our algorithm for creating semantic orientation lexicons. We describe intrinsic and extrinsic evaluation experiments in Section 4, followed by a discussion of the results in Section 5. Additionally, in Section 6 we show preliminary visualizations of how our algorithm forms chains of positive and negative thesaurus categories. Good visualizations are not only effective in presenting information to the user, but also help us better understand our algorithm. Section 7 has our conclusions.

2 Related Work

Pang and Lee (2008) provide an excellent survey of the literature on sentiment analysis. Here we briefly describe the work closest to ours.

Hatzivassiloglou and McKeown (1997) proposed a supervised algorithm to determine the semantic orientation of adjectives. They first generate a graph that has adjectives as nodes. An edge between two nodes indicates either that the two adjectives have the same or opposite semantic orientation. A clustering algorithm partitions the graph into two subgraphs such that the nodes in a subgraph have the same semantic orientation. The subgraph with adjectives that occur more often in text is marked positive and the other negative. They used a 21 million word corpus and evaluated their algorithm on a labeled set of 1336 adjectives (657 positive and 679 negative). Our approach does not require manually annotated semantic orientation entries to train on and is much simpler.

Esuli and Sebastiani (2006) used a supervised algorithm to attach semantic orientation scores to WordNet glosses. They train a set of ternary classifiers using different training data and learning methods. The set of semantic orientation scores of all WordNet synsets is released by the name SentiWordNet.[2] An evaluation of SentiWordNet by comparing orientation scores of about 1,000 WordNet glosses to scores assigned by human annotators is presented in Esuli (2008). Our approach uses a Roget-like thesaurus, and it does not use any supervised classifiers.

Turney and Littman (2003) proposed a minimally supervised algorithm to calculate the semantic orientation of a word by determining if its tendency to co-occur with a small set of positive words is greater than its tendency to co-occur with a small set of negative words. They show that their approach performs better when it has a large amount of text at its disposal. They use text from 350 million web-pages (more than 100 billion words). Our approach does not make use of any text corpora, although co-occurrence statistics could be used to further improve the lexicon. Furthermore, our lexicon has entries for commonly used multi-word expressions as well.

Mohammad et al. (2008b) developed a method to determine the degree of antonymy (contrast) between two words using the *Macquarie The-*

[2] http://sentiwordnet.isti.cnr.it/

saurus (Bernard, 1986), co-occurrence statistics, and a small set of antonym-generating affix patterns such as X–*dis*X. Often, one member of a pair of contrasting terms is positive and one member is negative. In this paper, we describe how a subset of those affix patterns can be used in combination with a thesaurus and the edicts of marking theory to create a large lexicon of words and phrases marked with their semantic orientation.

3 Generating the Semantic Orientation Lexicon

Our algorithm to generate a semantic orientation lexicon has two steps: (1) identify a seed set of positive and negative words; (2) use a Roget-like thesaurus to mark the words synonymous with the positive seeds "positive" and words synonymous with the negative seeds "negative". The two steps are described in the subsections below. Our implementation of the algorithm used the *Macquarie Thesaurus* (Bernard, 1986). It has about 100,000 unique words and phrases.

3.1 Seed words

3.1.1 Automatically identifying seed words

It is known from marking theory that overtly marked words, such as *dishonest, unhappy,* and *impure*, tend to have negative semantic orientation, whereas their unmarked counterparts, *honest, happy,* and *pure*, tend to have positive semantic orientation (Lehrer, 1974; Battistella, 1990). Exceptions such as *biased–unbiased* and *partial–impartial* do exist, and in some contexts even a predominantly negative marked word may be positive. For example *irreverent* is negative in most contexts, but positive in the sentence below:

> *Millions of fans follow Moulder's irreverent quest for truth.*

However, as we will show through experiments, the exceptions are far outnumbered by those that abide by the predictions of marking theory.

We used a set of 11 antonym-generating affix patterns to generate overtly marked words and their unmarked counterparts (Table 1). Similar antonyms-generating affix patterns exist for many languages (Lyons, 1977). The 11 chosen affix patterns generated 2,692 pairs of marked and unmarked valid English words that are listed in the *Macquarie Thesaurus*. The marked words

Affix pattern		**# word**	
w_1	w_2	**pairs**	**example word pair**
X	*dis*X	382	*honest–dishonest*
X	*im*X	196	*possible–impossible*
X	*in*X	691	*consistent–inconsistent*
X	*mal*X	28	*adroit–maladroit*
X	*mis*X	146	*fortune–misfortune*
X	*non*X	73	*sense–nonsense*
X	*un*X	844	*happy–unhappy*
X	X*less*	208	*gut–gutless*
*l*X	*ill*X	25	*legal–illegal*
*r*X	*ir*X	48	*responsible–irresponsible*
X*less*	X*ful*	51	*harmless–harmful*
Total		2692	

Table 1: Eleven affix patterns used to generate the seed set of marked and unmarked words. Here 'X' stands for any sequence of letters common to both words w_1 and w_2.

are deemed negative and the unmarked ones positive, and these form our seed set of positive and negative words. We will refer to this set of orientation-marked words as the **affix seeds lexicon (ASL)**. Note that some words may have multiple marked counterparts, for example, *trust–trustless* and *trust–mistrust*. Thus, ASL has more negative words (2,652) than positive ones (2,379). Also, the X*less*–X*ful* pattern generates word pairs that are both overtly marked; words generated from X*less* are deemed negative and words generated from X*ful* are deemed positive.

It should be noted that the affix patterns used here are a subset of those used in Mohammad et al. (2008b) to generate antonym pairs. The affix patterns ignored are those that are not expected to generate pairs of words with opposite semantic orientation. For instance, the pattern *imX-exX* generates word pairs such as *import–export* and *implicit–explicit* that are antonymous, but do not have opposite semantic orientations.

3.1.2 Using manually annotated seed words

Since manual semantic orientation labels exist for some English words (the GI lexicon), we investigated their usefulness in further improving the coverage and correctness of the entries in our lexicon. We used the GI words as seeds in the same way as the words generated from the affix patterns were used (Section 3.1.1).

3.2 Generalizing from the seeds

A published thesaurus such as the *Roget's* or *Macquarie* has about 1,000 categories, each consisting of on average 120 words and commonly used

SO lexicon	Mode of creation	Resources used	# entries	# positives	# negatives
ASL	automatic	11 affix rules	5,031	2,379 (47.3%)	2,652 (52.7%)
GI	manual	human SO annotation	3,605	1,617 (44.9%)	1,988 (55.1%)
GI-subset	manual	human SO annotation	2,761	1,262 (45.7%)	1,499 (54.3%)
MSOL(ASL)	automatic	thesaurus, 11 affix rules	51,157	34,152 (66.8%)	17,005 (33.2%)
MSOL(GI)	automatic	GI, thesaurus	69,971	25,995 (37.2%)	43,976 (62.8%)
MSOL(ASL and GI)	automatic	GI, thesaurus, 11 affix rules	76,400	30,458 (39.9%)	45,942 (60.1%)
PSL	mostly manual	GI, other sources	6,450	2,298 (35.6%)	4,485 (64.4%)
SWN	automatic	human SO annotation, WordNet, ternary classifiers	56,200	47,806 (85.1%)	8,394 (14.9%)
TLL	automatic	100 billion word corpus, minimal human SO annotation	3,596	1,625 (45.2%)	1,971 (54.8%)

Table 2: Key details of semantic orientation (SO) lexicons. ASL = affix seeds lexicon, GI = General Inquirer, MSOL = Macquarie semantic orientation lexicon, PSL = Pitt subjectivity lexicon, SWN = SentiWordNet, TLL = Turney–Littman lexicon.

multi-word expressions. Terms within a category tend to be closely related, and they are further grouped into sets of near-synonymous words and phrases called **paragraphs**. There are about 10,000 paragraphs in most Roget-like thesauri.

Every thesaurus paragraph is examined to determine if it has a seed word (by looking up the seed lexicon described in Section 3.1). If a thesaurus paragraph has more positive seed words than negative seed words, then all the words (and multi-word expressions) in that paragraph are marked as positive. Otherwise, all its words are marked negative.

Note that this method assigns semantic orientation labels to word–**thesaurus paragraph** pairs. Thesaurus paragraphs can be thought of as word senses. A word with multiple meanings is listed in multiple thesaurus paragraphs, and so will be assigned semantic orientation labels for each of these paragraphs. Thus, the method assigns a semantic orientation to a word–sense combination similar to the SentiWordNet approach and differing from the General Inquirer and Turney–Littman lexicons.

However, in most natural language tasks, the intended sense of the target word is not explicitly marked. So we generate a word-based lexicon by asking the different senses of a word to vote. If a word is listed in multiple thesaurus paragraphs, then the semantic orientation label most common to them is chosen as the word's label. We will refer to this set of word–**semantic orientation** pairs as the **Macquarie Semantic Orientation Lexicon (MSOL)**. A set created from only the affix seeds will be called **MSOL(ASL)**, a set created from only the GI seeds will be called **MSOL(GI)**, and the set created using both affix seeds and GI seeds will be called **MSOL(ASL and GI)**.[3] We generated a similar word-based lexicon for SentiWordNet (SWN) by choosing the semantic orientation label most common to the synsets pertaining to a target word.

Table 2 summarizes the details of all the lexicons. MSOL(ASL and GI) has a much larger percentage of negatives than MSOL(ASL) because GI has a much larger percentage of negative words. These negative seeds generate many more negative entries in MSOL(ASL and GI). Of the 51,157 entries in MSOL(ASL), 47,514 are single-word entries and 3,643 are entries for multi-word expressions. Of the 69,971 entries in MSOL(GI), 45,197 are single-word entries and 24,774 are entries for common multi-word expressions. Of the 76,400 entries in MSOL(ASL and GI), 51,208 are single-word entries and 25,192 are entries for common multi-word expressions. In our evaluation, we used only the single-word entries to maintain a level playing field with other lexicons.

4 Evaluation

We evaluated the semantic orientation lexicons both intrinsically (by comparing their entries to the General Inquirer) and extrinsically (by using them in a phrase polarity annotation task).

4.1 Intrinsic: Comparison with GI

Similar to how Turney and Littman (2003) evaluated their lexicon (TLL), we determine if the semantic orientation labels in the automatically generated lexicons match the semantic orientation la-

[3] MSOL is publicly available at: www.umiacs.umd.edu/~saif/WebPages/ResearchInterests.html.

Lexicon	All	Positives	Negatives
MSOL(ASL)	74.3	84.2	65.9
SWN	60.1	86.5	37.9
TLL	**83.3**	83.8	82.8

Table 3: The percentage of GI-subset entries (all, only the positives, only the negatives) that match those of the automatically generated lexicons.

bels of words in GI. GI, MSOL(ASL), SWN, and TLL all have 2,761 words in common. We will call the corresponding 2,761 GI entries the **GI-subset**.

Table 3 shows the percentage of GI-subset entries that match those of the three automatically-generated lexicons (MSOL(ASL), SWN, and TLL). (The differences in percentages shown in the table are all statistically significant—$p < 0.001$.) We do not show results for MSOL(GI), MSOL(ASL and GI), and the Pittsburgh subjectivity lexicon (PSL) because these lexicons were created using GI entries. TLL most closely matches the GI-subset, and MSOL matches the GI-subset more closely than SWN with the GI-subset. However, the goal of this work is to produce a high-coverage semantic orientation lexicon and so we additionally evaluate the lexicons on the extrinsic task described below.

4.2 Extrinsic: Identifying phrase polarity

The MPQA corpus contains news articles manually annotated for opinions and private states.[4] Notably, it also has polarity annotations (positive/negative) at the phrase-level. We conducted an extrinsic evaluation of the manually-generated and automatically-generated lexicons by using them to determine the polarity of phrases in the MPQA version 1.1 collection of positive and negative phrases (1,726 positive and 4,485 negative).

We used a simple algorithm to determine the polarity of a phrase: (1) If any of the words in the target phrase is listed in the lexicon as having negative semantic orientation, then the phrase is marked negative. (2) If none of the words in the phrase is negative and if there is at least one positive word in the phrase, then it is marked positive. (3) In all other instances, the classifier refrains from assigning a tag. Indeed better accuracies in phrase semantic orientation annotation can be obtained by using supervised classifiers and more sophisticated context features (Choi and Cardie, 2008). However, our goal here is only to use this task as a testbed for evaluating different semantic orientation lexicons, and so we use the method described above to avoid other factors from influencing the results.

Table 4 shows the performance of the algorithm when using different lexicons. The performance when using lexicons that additionally make use of GI entries—MSOL(GI), MSOL(ASL and GI), PSL, and a combined GI-SWN lexicon—is shown lower down in the table. GI–SWN has entries from both GI and SWN. (For entries with opposing labels, the GI label was chosen since GI entries were created manually.) Observe that the best F-scores are obtained when using MSOL (in both categories—individual lexicons and combinations with GI). The values are significantly better than those attained by others ($p < 0.001$).

5 Discussion

The extrinsic evaluation shows that our thesaurus- and affix-based lexicon is significantly more accurate than SentiWordNet. Moreover, it has a much larger coverage than the GI and Pitt lexicons. Observe also that the affix seeds set, by itself, attains only a modest precision and a low recall. This is expected because it is generated by largely automatic means. However, the significantly higher MSOL performance suggests that the generalization step (described in Section 3.2) helps improve both precision and recall. Precision is improved because multiple seed words vote to decide the semantic orientation of a thesaurus paragraph. Recall improves simply because non-seed words in a paragraph are assigned the semantic orientation that is most prevalent among the seeds in the paragraph.

5.1 Support for the Polyanna Hypothesis

Boucher and Osgood's (1969) Polyanna Hypothesis states that people have a preference for using positive words and expressions as opposed to using negative words and expressions. Studies have shown that indeed speakers across languages use positive words much more frequently than negative words (Kelly, 2000). The distribution of positive and negative words in MSOL(ASL) further supports the Polyanna Hypothesis as it shows that even if we start with an equal number of positive and negative seed words, the expansion of the positive set through the thesaurus is much more pro-

nounced than the expansion of the negative set. (About 66.8% of MSOL(ASL) words are positive, whereas only 33.2% are negative.) This suggests that there are many more near-synonyms of positive words than near-synonyms of negative ones, and so there are many more forms for expressing positive sentiments than forms for expressing negative sentiment.

5.2 Limitations

Some of the errors in MSOL were due to non-antonymous instantiations of the affix patterns. For example, *immigrate* is not antonymous to *migrate*. Other errors occur because occasionally the words in the same thesaurus paragraph have differing semantic orientations. For example, one paragraph has the words *slender* and *slim* (which, many will agree, are positive) as well as the words *wiry* and *lanky* (which many will deem negative). Both these kinds of errors can be mitigated using a complementary source of information, such as co-occurrence with other known positive and negative words (the Turney–Littman method).

5.3 Future work

Theoretically, a much larger Turney–Littman lexicon can be created even though it may be computationally intensive when working with 100 billion words. However, MSOL and TLL are created from different sources of information—MSOL from overtly marked words and a thesaurus, and TLL from co-occurrence information. Therefore, a combination of the two approaches is expected to produce an even more accurate semantic orientation lexicon, even with a modest-sized corpus at its disposal. This is especially attractive for low resource languages. We are also developing methods to leverage the information in an English thesaurus to create semantic orientation lexicons for a low-resource language through the use of a bilingual lexicon and a translation disambiguation algorithm.

6 Visualizing the semantic orientation of thesaurus categories

In recent years, there have been substantial developments in the field of information visualization, and it is becoming increasingly clear that good visualizations can not only convey information quickly, but are also an important tool for gaining insight into an algorithm, detecting systematic errors, and understanding the task. In this section, we present some preliminary visualizations that are helping us understand our approach beyond the evaluations described above.

As discussed in Section 3.1.1, the affix seeds set connects the thesaurus words with opposite semantic orientation. Usually these pairs of words occur in different thesaurus categories, but this is not necessary. We can think of these connections as relationships of contrast in meaning and semantic orientation, not just between the two words but also between the two categories. To better aid our understanding of the automatically determined category relationships we visualized this network using the Fruchterman-Reingold force-directed graph layout algorithm (Fruchterman and Reingold, 1991) and the NodeXL network analysis tool (Smith et al., 2009) [5].

Our dataset consists of 812 categories from the *Macquarie Thesaurus* and 27,155 antonym edges between them. There can be an edge from a cat-

[5] Available from http://www.codeplex.com/NodeXL

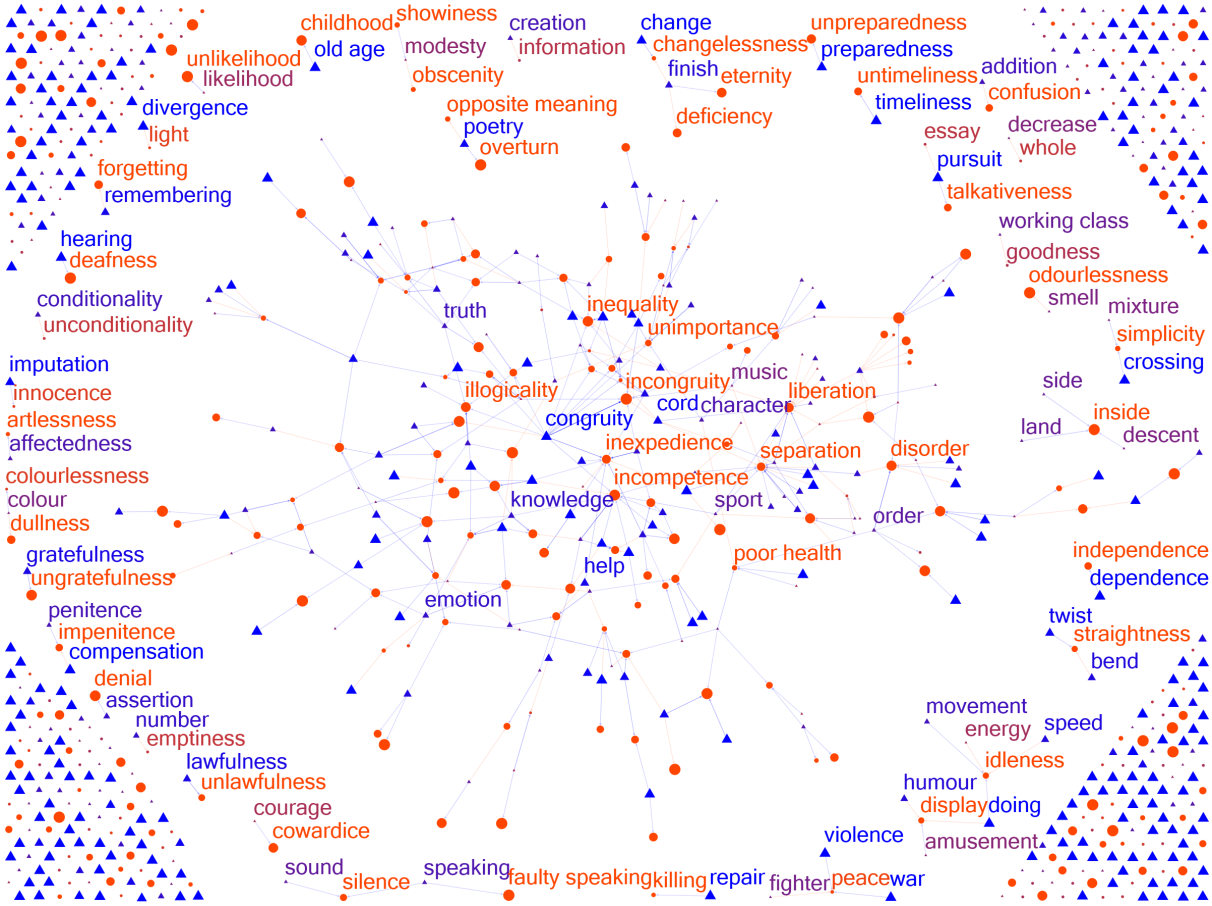

Figure 1: After removing edges with low weight we can see the structure the network backbone. Isolate category pairs are drawn in a ring around the main connected component and singletons are staggered in the corners. Each node is colored by its semantic orientation (red for negative, blue for positive) and edges are colored by their weight, from red to blue. Node shape also codes semantic orientation, with triangles positive and circles negative. Size codes the magnitude the semantic orientation, with the largest nodes representing the extremes. Node labels are shown for nodes in isolates and those in the top 20 for betweenness centrality.

egory to itself called a self-edge, indicating that a word and its antonym (with opposite semantic orientation) both exist in the same category. There can be multiple edges between two categories indicating that one or more words in one category have one or more antonyms in the other category. These multiple edges between category pairs were merged together resulting in 14,597 weighted meta-edges. For example, if there are n edges between a category pair they were replaced by a single meta-edge of weight n.

The network is too dense and interconnected for force-directed placement to generate a useful publication-size drawing of the entire network. By removing edges that had a weight less than 6, we can visualize a smaller and more understandable 540 edge network of the core categories and any new isolates created. Additionally, we show only edges between categories with opposite semantic orientations (Figure 1). Observe that there are three groups of nodes: those in the core connected component, the small isolates in the ring surrounding it, and the connectionless singletons arranged in the corners.

Each node c (thesaurus category) is colored on a red to blue continuous scale according to its semantic orientation SO, which is computed purely from its graph structure (in-degree ID and out-degree OD):

$$SO(c) = \frac{OD(c) - ID(c)}{OD(c) + ID(c)} \quad (1)$$

Blue nodes represent categories with many positive words; we will call them **positive cate-**

gories (p). Red nodes are categories with many negative words; we will call them **negative categories (n)**. Shades of purple in between are categories that have words with both positive and negative semantic orientation (**mixed categories**). Similarly, edges are colored according to their weight from red (small weight) to blue (large weight). We also use shape coding for semantic orientation, with triangles being positive and circles negative, and the size of the node depicts the magnitude of the semantic orientation. For example, the pair HEARING(p)–DEAFNESS(n) in the top left of Figure 1 represent the two size extremes: HEARING has a semantic orientation of 1 and DEAFNESS has a score of -1. The mixed categories with near 0 semantic orientation such as LIKELIHOOD with a score of .07 are the smallest.

Nodes are labeled by the thesaurus-provided head words—a word or phrase that best represents the coarse meaning of the category. For readability, we have restricted the labels to nodes in the isolates and the top 20 nodes in the core connected component that have the highest **betweenness centrality**, which means they occur on more shortest paths between other nodes in the network (i.e., they are the bridges or gatekeepers).

From the ring of isolates we can see how many antonymous categories, and their semantic orientations, are correctly recognized. For example, ASSERTION(p)–DENIAL(n), HEARING(p)–DEAFNESS(n), GRATEFULNESS(p)–UNGRATEFULNESS(n), and so on. Some codings may seem less intuitive, such as those in the core, but much of this is the effect of abstracting away the low weight edges, which may have more clearly identified the relationships.

An alternative approach to removing edges with low weight is to filter categories in the network based on graph-theoretic metrics like betweenness centrality, **closeness centrality**, and **eigenvector centrality**. We discussed betweenness centrality before. The closeness centrality of a node is the average distance along the shortest path between that node and all other nodes reachable from it. Eigenvector centrality is another measure of node importance, assigning node score based on the idea that connections to high-scoring nodes are more important than those to low-scoring ones. We removed nodes with less than 0.1 betweenness centrality, less than 0.04 eigenvector centrality, and above 2.1 closeness centrality, leaving the key 56 nodes. They have 497 edges between them, of which we show only those between categories with opposite semantic orientations (Figure 2). Node and edge color, size, and shape coding is as before.

Observe that most of these categories have a strongly evaluative nature. Also, as our algorithm makes connections using overt negative markers, it makes sense that the central categories in our network have negative orientation (negative categories have many words with overt markings). It is interesting, though, how some positive and mixed categories reside in the core too. Further inspection revealed that these categories have a large number of words within them. For example, it may be less intuitive as to why the category of MUSIC is listed in the core, but this is because it has about 1,200 words in it (on average, each category has about 120 words), and because many of these words, such as *harmonious(p), melodious(n),* and *lament(n)* are evaluative in nature.

7 Conclusion

We created a high-coverage semantic orientation lexicon using only affix rules and a Roget-like thesaurus. The method does not require terms with manually annotated semantic orientation labels, though we show that if available they can be used to further improve both the correctness of its entries and its coverage. The lexicon has about twenty times as many entries as in the General Inquirer and the Turney–Littman lexicons, and includes entries for both individual words and common multi-word expressions. Experiments show that it has significantly more correct entries than SentiWordNet. The approach is complementary to that of Turney and Littman (2003) and a combination of this approach with co-occurrence statistics (even if drawn from a modest sized corpus) is expected to yield an even better lexicon.

Visualization of the thesaurus categories as per the semantic orientations assigned to them by our algorithm reveals that affix patterns produce a strongly connected graph and that indeed there are many long chains of positive and negative categories. Furthermore, the key categories of this graph (the ones with high centrality and closeness) are strongly evaluative in nature, and most of them tend to have negative semantic orientation.

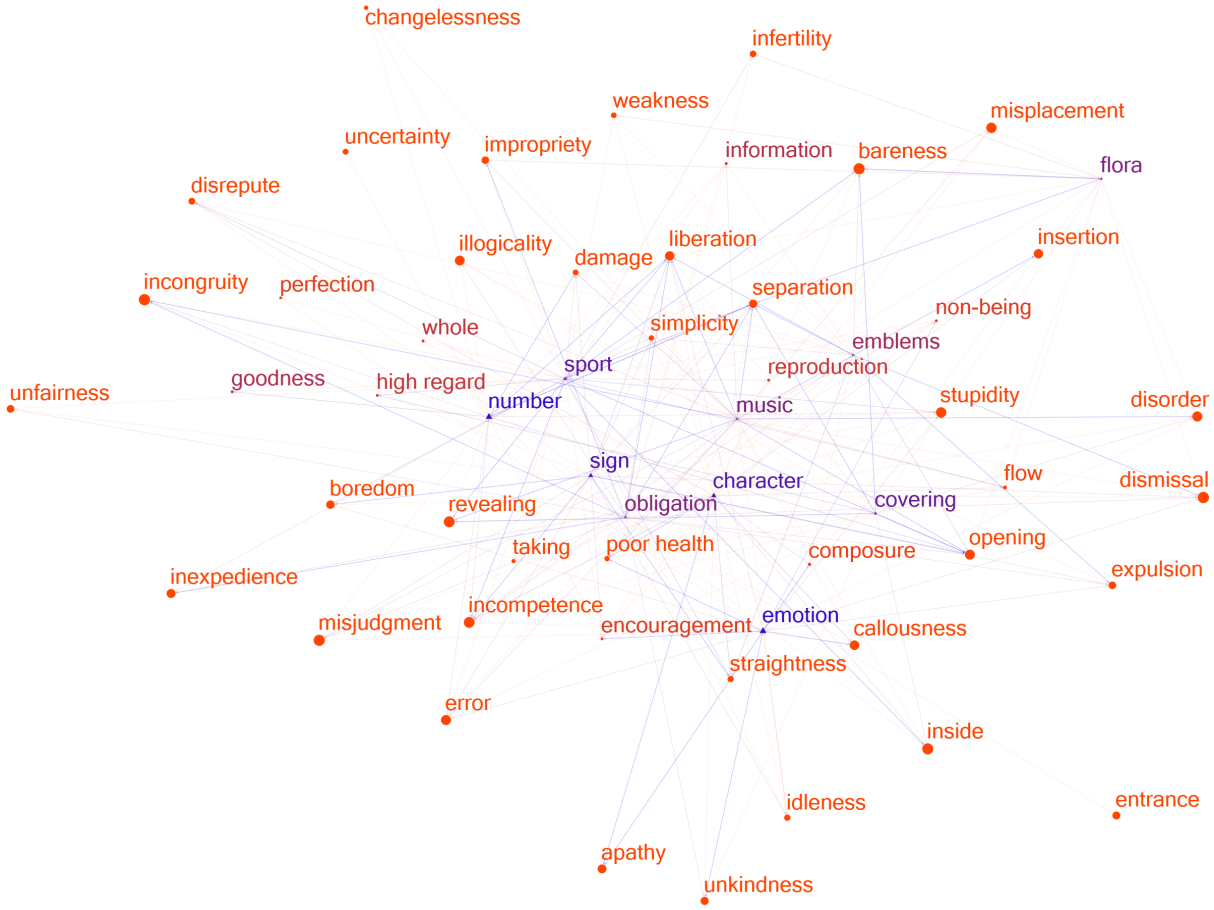

Figure 2: After filtering out nodes based on graph-theoretic metrics, the core of the network becomes visible. The visualization is colored as in Figure 1, and we can see how the core is dominated by categories with negative semantic orientation (red). Shape, size, and color coding is as before.

Matching Reviews to Objects using a Language Model

Abstract

We develop a general method to match unstructured text reviews to a structured list of objects. For this, we propose a language model for generating reviews that incorporates a description of objects and a generic review language model. This mixture model gives us a principled method to find, given a review, the object most likely to be the topic of the review. Extensive experiments and analysis on reviews from Yelp show that our language model-based method vastly outperforms traditional tf-idf-based methods.

1 Introduction

Consider a user searching for reviews of "Casablanca Moroccan Restaurant." The search engine would like to obtain as many reviews of this restaurant as possible, both to offer a high-quality result set for even obscure restaurants, and to enable advanced applications such as aggregation/summarization/categorization of reviews and recommendation of alternate restaurants. To solve this problem, it faces two high-level challenges: first, identify the restaurant review pages on the Web; and second, given a review, identify the restaurant that is being reviewed. There has been previous work addressing the first challenge (Section 2). We focus in this paper on the second.

The Web is replete with restaurant reviews available on top restaurant verticals such as Yelp and CitySearch, as well as newspaper articles, newsgroup discussions, blog posts, small local review aggregators and so forth. Ideally, the search engine would like to obtain reviews from all possible sources. While identifying the subject matter of a given review on the large sites may be amenable to structured extraction through wrapper induction or related techniques, it is typically not cost-effective to apply such techniques to smaller "tail" sites, and purely unstructured sources require alternate approaches altogether. In this paper, we explore the setting of matching reviews to objects using only their textual content. Note that matching reviews to objects is a pervasive problem beyond the restaurant domain. Shopping verticals like to aggregate camera reviews, entertainment verticals wish to collect movie reviews, and so on. We use restaurant reviews as a running example, but the techniques are general.

More specifically, the problem we consider in this paper is the following. Given a list of structured objects (restaurants/cameras/movies) and a text review, identify the object from the list that is the topic of the review. Our focus on textual content allows us to expand the universe of sources from which we can extract reviews to include sources that are purely textual, such as forum posts, blog posts, newsgroup postings, and the like. In fact, even among collections of "structured" sources like review aggregators, there are no highly accurate unsupervised techniques to match a known review page to an object. Structured (e.g., HTML) cues provide valuable leverage in attacking this problem, but the types of textual cues we focus on are also a key part of the puzzle; in such a context, our techniques can still contribute to the overall matching problem.

It is important to contrast our problem against two settings of related flavor — *entity matching*, whose goal is to find the correspondence between two structured objects and *information retrieval (IR)*, whose goal is to match unstructured short text (query) against unstructured text (document).

Our problem is considerably harder than entity matching for the following reasons. In matching two structured objects there is often a natural correspondence between their attributes, whereas no such correspondence exists between an object and

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 609–618,
Singapore, 6-7 August 2009.

its review. For instance, while trying to match a review to a restaurant object, it is unclear if a specific portion of the review refers to the name of the restaurant, or to its location, or is a statement not concerning specifics of the restaurant. Moreover, even if we wish to use entity matching, we must first recognize the entities from a review. There are two methods to do this, namely, wrapper induction and information extraction. Wrapper induction methods have serious limitations: they are applicable only to highly-structured websites and involve human labeling effort that is expensive and error-prone and entails constant maintenance to keep wrappers up-to-date. Information extraction methods (Cardie, 1997; Sarawagi, 2008), on the other hand, often have limited accuracy.

Our problem is also not amenable to classical IR methods such as tf-idf. For example, suppose we want to find the relevant restaurant for a given review. The standard tf-idf will treat the review as the query, the set of restaurant as documents and compute the tf-idf scores. Now consider a restaurant called "Food."[1] Since the term "food" is rare as a restaurant name, it will get a very high idf score and hence will likely be the top match for all reviews containing the word "food." In fact, unlike in traditional IR, a "query" (i.e., review) is long and a "document" (i.e., restaurant) is short — this demands adapting established IR concepts such as inverse document frequency and document length normalization to our setting. If we take the opposite view by considering reviews as documents and restaurants as queries, we still deviate from the IR setting, since now we need to rank and find the best "query" for a given "document." In Section 3.4, we illustrate the shortcomings of both these approaches.

In fact, the nature of the object database we consider provides several unique opportunities over traditional IR. First the "document", i.e., the object to be matched, has more semantics, since each document is associated with one or more semantic attribute, such as the name/location of the restaurant. Second, the "query", i.e., the text we are matching is known to be a review of the object, and hence is rendered in a language that is "review-like" — this can be modeled by a generative process that produces reviews from objects. Third, the set of objects we are interested in is given a priori, and we only seek to match reviews with one of these objects; this makes our problem more tractable than open-ended entity recognition.

Our contributions. We propose a general method to match reviews to objects. To this end, we postulate a language model for generating reviews. The intuition behind our model is simple and natural: when a review is written about an object, each word in the review is drawn either from a description of the object or from a generic review language that is independent of the object. This mixture model leads to a method to find, given a review, the object most likely to be the topic of the review.

Our method is light-weight and scalable and can be viewed as obviating the need for highly-expensive information extraction. Since the method is text-based and does not rely on any HTML structural clues, it is especially applicable to reviews present in blogs and the so-called tail web sites — web sites for which it is not feasible to maintain wrappers to automatically extract the object of a review.

We then report results on over 11K restaurant reviews from Yelp. The experiments and our extensive analysis show that our language model-based method significantly outperforms traditional tf-idf based methods, which fail to take full advantage of the properties that are specific to our setting.

2 Related work

Opinion topic identification is the work closest to ours. In a recent paper, Stoyanov and Cardie (2008) approach this problem by treating it as an exercise in topic coreference resolution. Though they have to deal with topic ambiguities and a lack of explicit topic mentions as in our case, their notion of a topic is not driven by a structured listing. There has been some work on fine-grained opinion extraction from reviews (Kobayashi et al., 2004; Yi et al., 2003; Popescu and Etzioni, 2005; Hu and Liu, 2004); see (Pang and Lee, 2008) for a comprehensive survey. Most of this body of work focused on identifying product features of the object under review, rather than identifying the product itself. Note that while a dictionary of products is often more readily available than a dictionary of product features, identifying objects of reviews is non-trivial even with the help of the former. Indeed, it has been reported that lexicon-

[1] 1569 Lexington Ave., New York, NY 10029. (212) 348-0200.

lookup methods have limited success on general non-product review texts (Stoyanov and Cardie, 2008). In general, this line of work is more rooted in the information extraction literature, where text spans covering the object (or features of the object) were extracted as the first step; in contrast, we do not have an explicit extraction phase. Since the (very extensive) list of candidate objects are given as input, our task is to rank all matching objects, and in this sense is closer in nature to information retrieval tasks. There has been some work on detecting reviews in large-scale collections (Ng et al., 2006; Barbosa et al., 2009); this is a logical step that precedes the review matching step, the topic of our paper.

Language modeling is becoming a powerful paradigm in the realm of information retrieval applications (Ponte and Croft, 1998; Hiemstra, 1998; Song and Croft, 1999; Lafferty and Zhai, 2003; Zhai, 2008). The basic theme behind language modeling is to first postulate a model for each document and for a given query select the document that is most likely to have generated the query; smoothing is an important means to manage data sparsity in language models (Zhai and Lafferty, 2004). As noted earlier, language models developed for IR are unsuitable for our setting. Furthermore, there are opportunities, such as the presence of structure in our data, which we use in this work (Section 3.2). In fact, in a subsequent paper, we show how a language model specific to each attribute can further improve the accuracy of review matching (Dalvi et al., 2009).

Entity matching is a well-studied topic in databases. There are several approaches to entity matching: non-relational approaches, which consider pairwise attribute similarities between entities (Newcombe et al., 1959; Fellegi and Sunter, 1969), relational approaches, which exploit the relationships that exist between entities (Ananthakrishna et al., 2002; Kalashnikov et al., 2005), and collective approaches, which exploit the relationship between various matching decisions, (Bhattacharya and Getoor, 2007; McCallum and Wellner, 2004). The EROCS system (Chakaravarthy et al., 2006), which uses information extraction and entity matching, is closest in spirit to our problem; they, however, employ tf-idf to match, which we show to be significantly sub-optimal in our setting.

3 Model and method

In this section we present the problem formulation, the basic generative model for reviews, a method based on this model to associate an object with a review, and the techniques to estimate the parameters of this model.

Problem formulation. Let $\mathcal{E}$ denote a set of objects. Each object $e \in \mathcal{E}$ has a set of attributes and let $\text{text}(e)$ denote the union of the textual content of all its attributes. Suppose we have a collection of reviews $\mathcal{R}$, where each review is written (mainly) about one of the objects in the listing $\mathcal{E}$. The problem now is to correctly associate each $r \in \mathcal{R}$ with exactly one of $e \in \mathcal{E}$.

We model each review as a bag of words. Therefore, notation such as "$w \in r$" for a word w and a review r makes sense. For a review r and an object e, let $r_e = r \cap \text{text}(e)$.

As a running example, we use $\mathcal{E}$ to denote the set of all restaurants and $\mathcal{R}$ to denote the set of all restaurant reviews.

3.1 A generative model for reviews

We first state the intuition behind our generative model: when a review r is written about an object e, some words in r (e.g., the name and the address of the restaurant) are drawn from $\text{text}(e)$ to refer to the object under discussion, while some other words are drawn from a *generic review language* independent of e.

Formally, let $\alpha \in (0, 1)$ be a parameter. Let $P_e(\cdot)$ denote a distribution whose support is $\text{text}(e)$; this corresponds to the distribution of words specific to the object e, taken from the description $\text{text}(e)$. We use $P_e(w)$ to denote the probability the word w is chosen according to this distribution. Let $P(\cdot)$ be an object-independent distribution whose support is the review language, i.e., all the words that can be used to write a review; we use $P(w)$ to denote the probability the word w is chosen according to this distribution. Now, for a given object e, a review r is generated as follows. Each word in r is generated independently: with probability α, a word w is chosen with probability $P_e(w)$ and with probability $1 - \alpha$, a word w is chosen with probability $P(w)$. Thus, the review generation process is a multinomial, where the underlying process is a mixture of object-specific language and a generic review language.

Given a review r and an object e, by our independence assumption,

$$\begin{aligned}\Pr[r \mid e] &= Z(r) \prod_{w \in r} \Pr[w \mid e] \\ &= Z(r) \prod_{w \in r} ((1-\alpha)P(w) + \alpha P_e(w)), \quad (1)\end{aligned}$$

where $Z(r)$ is a normalizing term that only depends on the length of r and the counts of the words in it. Recalling $r_e = r \cap \text{text}(e)$, we note that $P_e(w)$ assigns zero probability to $w \notin r_e$. From (1), we get

$$\begin{aligned}\Pr[r \mid e] &= Z(r) \prod_{w \in r \setminus r_e} (1-\alpha)P(w) \cdot \\ &\quad \prod_{w \in r_e} ((1-\alpha)P(w) + \alpha P_e(w)) \\ &= Z(r) \prod_{w \in r} (1-\alpha)P(w) \cdot \\ &\quad \prod_{w \in r_e} \left(1 + \frac{\alpha}{1-\alpha} \frac{P_e(w)}{P(w)}\right). \quad (2)\end{aligned}$$

Note that Eq. (2) appears similar to the formula obtained in the language model approach for IR (Hiemstra and Kraaij, 1998); the interpretation of terms, however, is very different. For instance, $P(w)$ in our case is computed over the "query" corpus whereas the analogous term (collection frequency) in (Hiemstra and Kraaij, 1998) is computed over the "document" corpus. As the "Food" restaurant example in Section 1 suggests, using the "document" frequency is undesirable. The use of "query" corpus frequency arises naturally from our generative story and also guides us to a different way to estimate $P(w)$; see Section 3.3.

3.2 Matching a review to an object

Given the above review language model (RLM), we now state how to match a given review to an object. According to our model, the most likely object e^* to have generated a review r is given by

$$e^* = \arg\max_e \Pr[e \mid r] = \arg\max_e \frac{\Pr[e]}{\Pr[r]} \cdot \Pr[r \mid e].$$

In the absence of any information, we assume a uniform distribution for $\Pr[e]$. (Additional information about objects, such as their rating/popularity, can be used to model $\Pr[e]$ more accurately.) From this, we get

$$e^* = \arg\max_e \Pr[r \mid e],$$

or equivalently,

$$e^* = \arg\max_e \log \Pr[r \mid e].$$

Since $Z(r) \prod_{w \in r}((1-\alpha)P(w))$ is independent of e, using (2), we have

$$e^* = \arg\max_e \sum_{w \in r_e} \log \left(1 + \frac{\alpha}{1-\alpha} \frac{P_e(w)}{P(w)}\right). \quad (3)$$

3.3 Estimating the parameters

We now describe how to estimate the parameters of the model, namely, $P(\cdot)$, $P_e(\cdot)$, and α.

Recall that $P(\cdot)$ is the distribution of generic review language. Ideally, for each review r, if we know the component $r^{(e)}$ that came from the distribution $P_e(\cdot)$ and the component $r^{(g)}$ that came from $P(\cdot)$, then we can collect the $r^{(g)}$ components of all the reviews in $\mathcal{R}$, denoted as $\mathcal{R}^{(g)}$, and estimate $P(\cdot)$ by the fraction of occurrences of w in $\mathcal{R}^{(g)}$. More specifically, let $c(w, \mathcal{R}^{(g)})$ denote the number of times w occurs in $\mathcal{R}^{(g)}$. With add-one smoothing, we estimate

$$P(w) = \frac{c(w, \mathcal{R}^{(g)}) + 1}{\sum_{w'} c(w', \mathcal{R}^{(g)}) + |V|},$$

where $|V|$ is the vocabulary size.

In reality, we only have access to r and not to the components $r^{(e)}$ and $r^{(g)}$. If we have an aligned review corpus $\mathcal{R}'$, where for each review r, we know the true object e that generated it, we can closely approximate $r^{(e)}$ with r_e.[2] Let no-obj($\mathcal{R}'$) be the set of processed reviews where for each review-object pair (r, e), words in $\text{text}(e)$ are removed from r. By treating no-obj($\mathcal{R}'$) as an approximation of $\mathcal{R}^{(g)}$, we can compute $P(w)$ in the aforementioned manner. If we only have access to a review collection $\mathcal{R}'$ with no object alignment, there are other ways to effectively approximate $\mathcal{R}^{(g)}$; see Section 5.3 for more details.

Unlike $P(\cdot)$, we cannot learn an individual language model $P_e(\cdot)$ for each e, since we cannot expect to have training examples of reviews for each possible object e in the dataset. Thus, we need a simpler way to model $P_e(w)$. The most naive way would be to assume a uniform distribution, i.e., $P_e(w) = 1/|\text{text}(e)|$. However, each word

[2] There can be exceptions to this, e.g., review of a restaurant called "Tasty Bites" might use the word "tasty" from the review language, but not to refer to the restaurant. Nonetheless, we believe these will be rare exceptions and will not have significant effect in the estimation of $P(\cdot)$.

in $\text{text}(e)$ may not be generated with equal probability. In our running example, consider the case when $\text{text}(e)$ contains the full name of the restaurant, i.e., "Casablanca Moroccan Restaurant." A review for this restaurant is more likely to choose the word "Casablanca" than any other word to refer to this restaurant since this is arguably more informative than "Moroccan" or "Restaurant." This can be captured by using the frequency f_w of the word w in $\mathcal{R}$ or in $\{\text{text}(e) \mid e \in \mathcal{E}\}$. For a suitable function $g(w)$ that is inversely growing as f_w (say, $g(w) = \log(1/f_w)$), we let

$$P_e(w) = \frac{g(w)}{\sum_{w' \in \text{text}(e)} g(w')}.$$

Alternatively, it is possible to construct models where $P_e(w)$ is more directly estimated from the data; in fact, one can also use suitable translation models to estimate $P_e(w)$ for w that may not even occur in $\text{text}(e)$ — this will help in cases where reviews use an abbreviation such as "Casa" or "CMR" to refer to our running example. Such models require either fine-grained labeled examples or, as we show in (Dalvi et al., 2009), more sophisticated estimation techniques.

It is tempting to assume that common words such as "Restaurant" may not contribute towards matching a review to an object and hence one can conveniently set $P_e(w) = 0$ for such words w. (Such a list of words can easily be compiled using a domain-specific stopword list.) This may hurt — in our example, the presence of the word "Restaurant" in a review might help to disambiguate the object of reference, if the listing were also to contain a "Casablanca Moroccan Cafe".

3.4 Properties of the model

Eq. (3) indicates that our method (denoted as RLM) gives less importance to common words with high $P(w)$. This corresponds to the intuition behind the standard tf-idf scheme. Why, then, do we expect RLM to be more effective? Here, we discuss the salient features of our method, contrasting it with tf-idf in particular.

First, we take a closer look at different ways to apply tf-idf techniques to our setting. Since the task is to find the most relevant object given a review, a naive way to apply the standard tf-idf (denoted TFIDF) will treat each review to be the query and each object to be a document and score documents using the standard tf-idf scoring. This, however, leads to severe problems since this computes the inverse document scores over the object corpus — recall the "Food" example in Section 1.

A more reasonable way to apply tf-idf is to instead treat objects as queries and reviews as documents for computing tf-idf scores (denoted TFIDF$^+$). For a word w, let $Q(w) = \frac{\text{df}(w)}{N}$, where N is the number of reviews in the corpus and $\text{df}(w)$ is the number of reviews containing w. Given a review r and an object e, the score of the object is given by $\sum_{w \in r_e} \log(1/Q(w))$, and we want to pick the object with the maximum score. As we will discuss later, document-length normalization (i.e., normalizing by object description length so that a restaurant with a long name does not get an unfair disadvantage) is still non-trivial here.

As noted earlier, Eq. (3), used by RLM for matching reviews with objects, has a striking resemblance to the TFIDF$^+$ scoring function. Both have the form

$$e^* = \arg\max_e \sum_{w \in r_e} \log f(w),$$

where for RLM,

$$f(w) = f_R(w) = 1 + \frac{\alpha}{1-\alpha}\frac{P_e(w)}{P(w)},$$

and for TFIDF$^+$,

$$f(w) = f_B(w) = \frac{1}{Q(w)}.$$

In both cases, $f(w)$ is monotonically decreasing in the frequency of w in the corpus. However, there are several differences between the two cases. We highlight some of them here, with the aim of illustrating the power of our review language model (RLM).

Object length normalization. First note that the $P_e(w)$ term in $f_R(w)$ acts as an object length normalizing term, i.e., it adds up to one for each e and weighs down $P(w)$ for objects with long $\text{text}(e)$. This also has the effect of penalizing reviews that are missing critical words in the object description. In contrast, $f_B(w)$ is unnormalized with respect to the object length. The standard document normalization techniques in IR do not apply well to our setting since our "documents" (i.e., object descriptions) are short. E.g., if the object description contains only one token, the standard cosine-normalization technique (Salton et al.,

1975) will yield a normalized score of 1 *irrespective* of the token. Thus for a review containing the words "Food" and "Casablanca", the standard normalization will yield the same score for a restaurant named "Food" and a restaurant named "Casablanca", ignoring the fact that "Food" is much more likely to be an object-independent term. Note that this only becomes a problem when the entire "document" is part of the match, which rarely happens in an IR setting where the documents are typically much longer than the queries. Indeed, in our experiments, we observe lower performance when we apply cosine-normalization to the tf-idf scores. On the other hand, in $f_R(w)$, the $P(w)$ term can still distinguish the two aforementioned objects even when $P_e(w)$ are equal.

Dampening. With $\alpha < 1$, $f_R(w)$ is effectively a dampened version of $\frac{P_e(w)}{P(w)}$. In other words, differences between very frequent words and very infrequent words are somewhat smoothed out. Indeed, if we modify TFIDF$^+$ by introducing a similar dampening factor into $f_B(w)$, we observe improvement in its performance (Section 5.4).

Removing mentions of an object. Another difference is that in RLM, $P(w)$ is estimated on reviews with object mentions removed, since the model indicate that $P(w)$ accounts for object-independent review language. In contrast, TFIDF$^+$ computes $Q(w)$ on full reviews. We illustrate the difference on the following example. Consider a review that reads "...Maggiano's has great Fondue." If "Maggiano's" and "Fondue" both occur the same number of times in the corpus, then they get the same idf (i.e., $Q(w)$) score. In RLM, however, "Maggiano's" will get much smaller probability in the generic review distribution $P(\cdot)$ than "Fondue", since "Maggiano's" almost always occurs in reviews as restaurant name mentions, thus is removed from the estimation of its $P(\cdot)$ probability. On the other hand, the word "Fondue" is more likely to retain higher probability in $P(\cdot)$ since it tends to appear as dish names. As a result, our model will assign higher weight to "Maggiano's Restaurant" than "Fondue Restaurant". As we can see, RLM evaluates the ability of a word to identify the review object rather than rely on the absolute rarity of the word, which is done by tf-idf.

Using term counts. One last difference is that $f_R(w)$ uses term counts of words rather than the standard document counts used by $f_B(w)$. Our evaluation suggests that at least in practice, this does not have a big impact on the overall accuracy.

In the experiments we show that these factors together account for the performance difference between RLM and tf-idf. Our model gives a principled way to introduce these factors, however.

4 Data

In this section we describe the dataset constructed for the task of matching restaurant reviews to the corresponding restaurant objects. Our goal is to obtain a large collection of reviews on which to estimate the generic language model, with a significant portion of them aligned with the objects for which the reviews were written; this portion will serve as the gold-standard test set.

To this end, we obtained a set of reviews from the Yelp website, `yelp.com`. This website contains a collection of reviews about various businesses and for each business, has a webpage containing the business information and a list of reviews. We crawled all restaurant pages from Yelp. For each restaurant, we extracted its name and city location from the business information section via HTML cues, and a list of no more than 40 reviews. We obtained the textual content of 299,762 reviews, each aligned with one of a set of 12,408 unique restaurants hosted on Yelp. Note that while our technique is not targeted for head sites like Yelp (where wrapper induction might be a more accurate approach), this provides a large-scale dataset, conveniently labeled with object information, and simulates the tail-site scenario where we rely heavily on the textual content of reviews to identify objects.

Many of the reviews in Yelp do not contain any identifying information. In fact, some of them are as short as "Great place. Awesome food!!". We processed the dataset to retain only reviews that mention the name of the restaurant, even if partially, and, when the restaurant name is a common word, also the city of the restaurant. Each of the remaining reviews is expected to have enough information for a human to identify the restaurant corresponding to the review.

To further increase the difficulty of the matching task, we obtained a much more extensive list of restaurant objects in the Yahoo! Local database, which contains 681,320 restaurants. Our task is to match a given Yelp review, using only its free-form textual content, with its corresponding

restaurant in the Yahoo! Local database. We then proceeded to generate the gold standard that contains the correct restaurant in the Yahoo! Local database for each review. We employed geocoding to match addresses across the two databases along with approximate name matches. Note that in the final dataset, only half of the restaurants have the exact same name listed in both Yelp and Yahoo! Local; this limits the success of naive dictionary-based methods.

The final aligned dataset contained 24,910 Yelp reviews ($\mathcal{R}$), covering 6,010 restaurants. We set aside half of the reviews ($\mathcal{R}'$) to estimate the models and the other half ($\mathcal{R}_{\text{test}}$) to evaluate our technique. We also set aside 1,000 reviews as development set, on which we conducted initial experiments. The total size of the test corpus, $\mathcal{R}_{\text{test}}$ was 11,217. The splitting of $\mathcal{R}$ into $\mathcal{R}'$, $\mathcal{R}_{\text{test}}$, and the development set was done in such a way that there are no overlapping restaurants between them. Also, the reviews that were filtered out because of lack of identifying information were added back to $\mathcal{R}'$ for learning the review language model, expanding $\mathcal{R}'$ to a total of 205,447 reviews.

5 Evaluation

In this section we evaluate our proposed review-language based matching algorithm RLM.

5.1 Experimental considerations

Baseline system. We use the TFIDF and TFIDF$^+$ algorithms described in Section 3.4 as baseline algorithms. Since we are comparing objects that can have varying lengths, we tried the standard cosine-normalization techniques for document length normalization. For reasons described in Section 3.4, however, the normalization significantly lowered the accuracy. All the numbers reported here are using tf-idf scores without normalization.

Efficiency. For both RLM and the baseline algorithms, it is impractical to compute the similarity of a review with each object in the database. Since all objects that do not intersect with the review have a zero score, we built an inverted index to retrieve all objects containing a given word. Even a simple inverted index can be very inefficient since for each review, words such as "Restaurant" or "Cafe" retrieve a substantial fraction of the whole database. Hence, we further optimized the index by looking at the document frequencies of the words and considering word bigrams in object descriptions. The index only retrieves objects that have a non-trivial overlap with the review; e.g., an overlap of "Casablanca" is considered non-trivial while an overlap of "Restaurant" is considered trivial. Once these candidates are retrieved, our scoring function takes into account all overlapping tokens.

For the YELP dataset, the index returns an average of 200 restaurants for each review. This points to the general difficulty of review matching over a large corpus of objects, since a simple dictionary-based named-entity recognition will hit at least 200 objects for many reviews.

Experiment settings. For RLM, we conducted initial experiments and performed parameter estimation on the development data. The experimental settings we used for RLM are as follows: we set $g(w) = \log(1/f_w)$ for P_e, where f_w is estimated on the review collection. $P(w)$ is estimated on all reviews in R', where for each review, all tokens of its corresponding $\text{text}(e)$, if present, are removed, in order to approximate the *generic* review language independent of e, as required by our generative model. We estimate α to be 0.002, tuned on the development set; in our experiments, we observe that the performance is not very sensitive to α.

5.2 Main results

In this section we present the main comparisons between RLM and the baseline in details.

Performance measure. Our task resembles a standard IR task in that our algorithm ranks candidate objects for a given review by their "aboutness" level. Unlike a standard IR task, however, we are not interested in retrieving multiple "relevant" objects, as each review in our dataset has only one single correct match from $\mathcal{E}$. A review match is correct if the top-1 prediction (i.e., e^*) is accurate. In what follows, we report the average accuracy for various experimental settings. Note that we can take the average accuracy over all reviews (reported as micro-average), regardless of which restaurants they are about; or we can first compute the average for reviews about the same restaurant, and report the average over all restaurants (macro-average). When not specified, we report the micro-average.

Main comparisons. Table 1(a) summarizes the main comparison. Our proposed algorithm RLM

Method	Micro-avg.	Macro-avg.
RLM	0.647	0.576
TFIDF$^+$	0.518	0.481
TFIDF	0.314	0.317

(a) Main comparison.

Method	Micro-avg.	Macro-avg.
RLM-UNIFORM	0.634	0.562
RLM-UNCUT	0.627	0.546
RLM-DECAP	0.640	0.573

(b) RLM variants.

Method	Micro-avg.	Macro-avg.
TFIDF$^+$-N	0.586	0.523
TFIDF$^+$-D	0.593	0.533
TFIDF$^+$-O	0.522	0.488
TFIDF$^+$-ND	0.628	0.549
TFIDF$^+$-NDO	0.647	0.576

(c) TFIDF$^+$ variants.

Table 1: Average accuracy of the top-1 prediction for various techniques. Micro-average computed over 11,217 reviews in $\mathcal{R}_{\text{test}}$; macro-average computed over 2,810 unique restaurants in $\mathcal{R}_{\text{test}}$.

clearly outperforms the TFIDF$^+$ baseline measured by either micro- or macro-average accuracy. The standard TFIDF, as predicted, performs the worst.

Some reviews can be particularly difficult to match, which can be reflected in a low matching score. Nonetheless, we predict the most likely object. Suppose we impose a threshold and return the most likely object only when its score is above threshold, we can then compute precision and recall at different thresholds. Figure 1 presents the precision–recall curve (using micro-average) for both RLM and TFIDF$^+$. Again, RLM clearly outperforms TFIDF$^+$ across the board.

We then generalize the definition of accuracy into accuracy@k: a review is considered as correctly matched if one of the top-k objects returned is the correct match. We plot accuracy@k as a function of k. While the gap between RLM and TFIDF$^+$ is smaller as k increases, RLM clearly outperforms TFIDF$^+$ for all $k \in \{1, \ldots, 10\}$.

One final comparison is accuracy@1 as a function of the review length. Given our current setting, longer reviews might be more difficult to match since they may include more proper nouns such as dish names and related restaurants, and

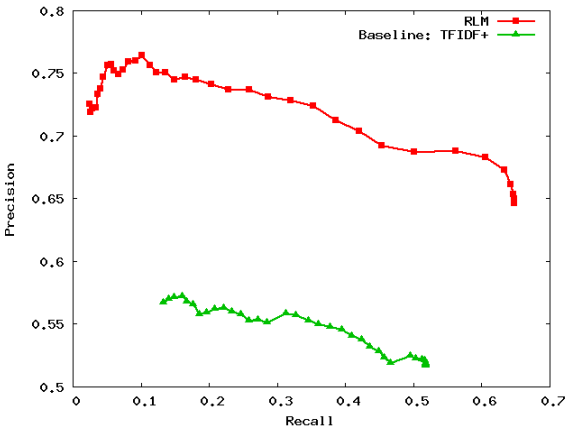

Figure 1: Precision–recall curve (of top one prediction): RLM vs. TFIDF$^+$ baseline.

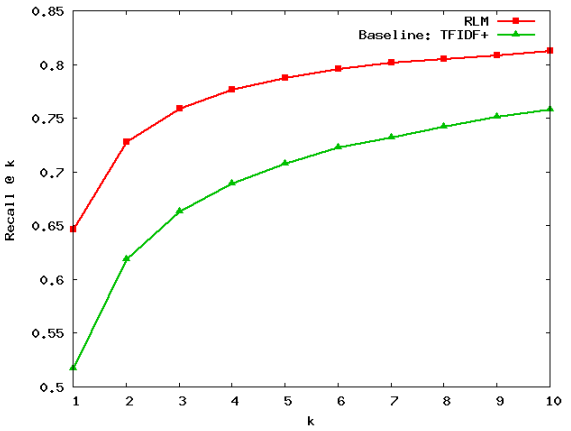

Figure 2: Accuracy@k (percentage of reviews whose correct match is returned in one of its top-k predictions): RLM vs. TFIDF$^+$ baseline.

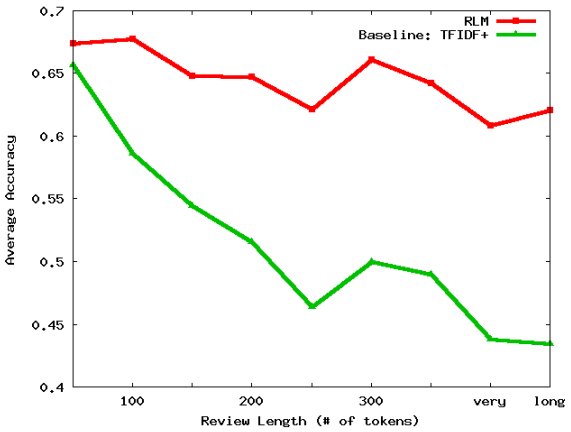

Figure 3: Average accuracy of the top-1 prediction for reviews with different length (on test set): RLM vs. TFIDF$^+$ baseline.

yield a longer list of highly competitive candidate objects. Interestingly, the gap between RLM and TFIDF$^+$ is much smaller for shorter reviews. As reviews get longer, the performance of RLM is relatively stable, whereas the performance of TFIDF$^+$ drops down significantly.

5.3 Experimental choices for RLM

We now examine the experimental choices we made for different components of RLM by defining the following variations of RLM.

RLM-UNIFORM: rather than setting $g(w) = \log(1/f_w)$ for P_e, we use the uniform distribution $P_e(w) = 1/|\text{text}(e)|$. From the third line of Table 1 (b), there is a slight accuracy drop of $\sim 1.3\%$.

RLM-UNCUT: suppose we only have access to a review corpus with no alignment to $\text{text}(e)$, and thus have to approximate $P(w)$ by estimating it on the set of original "un-cut" reviews, how much does that affect our performance? As indicated in the fourth row of Table 1 (b), this reduces accuracy by about 2% on our test data.

RLM-DECAP: as an alternative way to deal with lack of aligned data, we consider a variation of the above algorithm by removing all the capitalized words from un-annotated reviews. Clearly, this can result in both "over-cutting" and "under-cutting" of true restaurant name mentions. However, as indicated in the fourth row of Table 1 (b), this is very close to the best accuracy achieved. Thus, an effective model can be learned even without aligned data.

5.4 Revisiting TFIDF$^+$: what's amiss?

In this section we revisit the main differences between our model and the TFIDF$^+$ outlined in Section 3.4, and investigate their empirical importance by introducing these features into TFIDF$^+$ and examine their effectiveness in that framework.

Object length normalization. We consider a modified TFIDF$^+$ measure $f_M(w) = P_e(w)/Q(w)$, which we call TFIDF$^+$-N (normalized). As shown in Table 1 (c), this change alone can increase the average accuracy by nearly 7%.

Dampening. We consider a modified TFIDF$^+$ measure $f_M(w) = 1 + \beta \cdot \frac{N}{\text{df}(w)}$, which we call TFIDF$^+$-D. Table 1 (c) reports the performance of using this measure, with $\beta = 0.1$ (set on development data). Again, this measure alone can induce over 7% increase in accuracy. Indeed, combining normalization and dampening, (i.e., $f_M(w) = 1 + \beta \cdot P_e(w) \cdot \frac{N}{\text{df}(w)}$), denoted as TFIDF$^+$-ND, we get comparable performance to RLM-UNCUT.

Removing mentions of objects. Again, we can incorporate this in a heuristic way in TFIDF$^+$, which we denote by TFIDF$^+$-O. Interestingly, while using the original $f_B(w)$ function with $\text{df}(w)$ computed on the object-removed review collection does not yield a big improvement, this does bring the performance of the fully modified TFIDF$^+$ to the same level of the standard RLM (see line marked TFIDF$^+$-NDO.)

Using term counts. Our investigation suggests that at least in practice, using $Q(w)$ vs. $P(w)$ is not a critical decision, as a fully modified TFIDF$^+$ can achieve the same performance using $\text{df}(w)$ to quantify frequency of the word. Our experiments on this dataset show that each of the other modeling decisions incorporated in RLM is important.

6 Conclusions

We proposed a generative model for reviews where reviews are generated from the mixture of a distribution involving object terms and a generic review language model. The model provides us a principled way to match reviews to objects. Our evaluation on a real-world dataset shows that our techniques vastly outperforms standard tf-idf based techniques.

Abstract

Mitchell et al. (2008) demonstrated that corpus-extracted models of semantic knowledge can predict neural activation patterns recorded using fMRI. This could be a very powerful technique for evaluating conceptual models extracted from corpora; however, fMRI is expensive and imposes strong constraints on data collection. Following on experiments that demonstrated that EEG activation patterns encode enough information to discriminate broad conceptual categories, we show that corpus-based semantic representations can predict EEG activation patterns with significant accuracy, and we evaluate the relative performance of different corpus-models on this task.

1 Introduction

Models of semantic relatedness induced from corpus data have proven effective in a number of empirical tasks (Sahlgren, 2006) and there is increasing interest in whether distributional information extracted from corpora correlates with aspects of speakers' semantic knowledge: see Lund and Burgess (1996), Landauer and Dumais (1997), Almuhareb (2006), Padó and Lapata (2007), Schulte im Walde (2008), among many others. For this purpose, corpus models have been tested on datasets that are based on semantic judgements (metalinguistic or meta-cognitive intuitions about synonymy, semantic distance, category-membership) or behavioural experiments (semantic priming, property generation, free association). While all these data are valuable, they are indirect reflections of semantic knowledge, and when the predictions they make diverge from those of corpora, interpretation is problematic: is the corpus model missing essential aspects of semantics, or are non-semantic factors biasing the data elicited from informants?

Reading semantic processes and representations directly from the brain would be an ideal way to get around these limitations. Until recently, analysis of linguistic quantities using neural data collected with EEG (measurement at the scalp of voltages induced by neuronal firing) or fMRI (measurement of changes of oxygen concentrations in the brain tied to cognitive processes) had neither the advantages of corpora (scale) nor of informants (finer grained judgements).

However, some clear patterns of differential activity have been found for broad semantic classes. Viewing images of natural (typically animals and plants) and non-natural (typically artefacts like tools or vehicles) objects elicits different loci of activity in fMRI (Martin and Chao, 2001) and EEG (Kiefer, 2001), that persist across participants. Differences have also been found in response to auditorily or visually presented words of different lexical classes, such as abstract/concrete, and verb/noun (Pulvermüller, 2002). But interpretation of such group results remains somewhat difficult, as they may be consistent with more than one distinction: the natural/artefactual division just mentioned, may rather be between living/non-living entities, dynamic/static entities, or be based on embodied experience (e.g. manipulable or not).

More recently, however, machine learning and other numerical techniques have been successfully applied to extract semantic information from neural data in a more discriminative fashion, down to the level of individual concepts. The work presented here builds on two strands of previous work: Murphy et al. (2008) use EEG data to perform semantic categorisation on single stimuli; and Mitchell et al. (2008) introduce an fMRI-based method that detects word level distinctions by learning associations between features of neural activity and semantic features derived from a

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 619–627,
Singapore, 6-7 August 2009.

corpus. We combine these innovations by introducing a method that extracts featural representations from the EEG signal, and uses corpus-based models to predict word level distinctions in patterns of EEG activity. The proposed method achieves a performance level significantly above chance (also when distinguishing between concepts from the same semantic category, e.g., *dog* and *cat*), and approaching that achieved with fMRI.

The paper proceeds as follows. The next section describes a simple behavioural experiment where Italian-speaking participants had to name photographic images of mammals and tools while their EEG activity was being recorded, and continues to detail how the rich and multidimensional signals collected were reduced to a small set of optimally informative features using a new method. Section 3 describes a series of corpus-based semantic models derived from both a raw-text web corpus, and from various parsings of a conventional corpus. In Section 4 we describe the training of a series of linear models, that each learn the associations between a set of corpus semantic features and an individual EEG activity feature. By combining these models it is possible to predict the EEG activity pattern for a single unseen word, and compare this to the observed pattern for the corresponding concept. Results (Section 5) show that these predictions succeed at a level significantly above chance, both for coarser distinctions between words in different superordinate categories (e.g., differentiating between *drill* and *gorilla*), and, at least for the model based on the larger web corpus, for those within the same category (e.g., *drill* vs *spanner*, *koala* vs *gorilla*).

2 Neural Activation Data

2.1 Data collection

EEG data was gathered from native speakers of Italian during a simple behavioural experiment at the CIMeC/DiSCoF laboratories at Trento University. Seven participants (five male and two female; age range 25-33; all with college education) performed a silent naming task. Each of them was presented[1] on screen with a series of contrast-normalised greyscale photographs of tools (garden and work tools) and land mammals (excluding emotionally valent domesticated animals and predators), for which they had to think of the most appropriate name (see figure 1). They were not explicitly asked to group the entities into superordinate categories, or to concentrate on their semantic properties, but completing the task involved resolving each picture to its corresponding concept. Images remained on screen until a keyboard response was received from the participant to indicate a suitable label had been found, and presentations were interleaved with three second rest periods. Thirty stimuli in each of the two classes were each presented six times, in random order, to give a total of 360 image presentations in the session. Response rates were over 95%, and a post-session questionnaire determined that participants agreed on image labels in approximately 90% of cases. English terms for the concepts used are listed below.

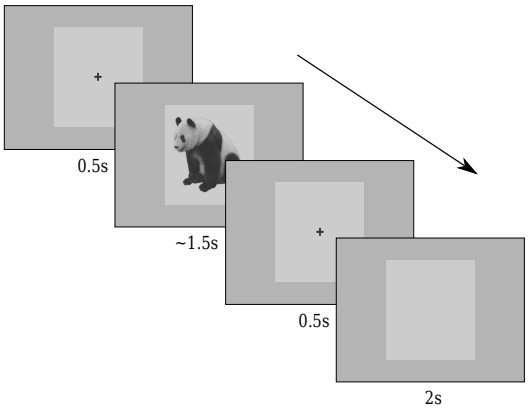

Figure 1: Presentation of image stimuli

Mammals anteater, armadillo, badger, beaver, bison, boar, camel, chamois, chimpanzee, deer, elephant, fox, giraffe, gorilla, hare, hedgehog, hippopotamus, ibex, kangaroo, koala, llama, mole, monkey, mouse, otter, panda, rhinoceros, skunk, squirrel, zebra

Tools Allen key, axe, chainsaw, craft knife, crowbar, file, garden fork, garden trowel, hacksaw, hammer, mallet, nail, paint brush, paint roller, pen knife, pick axe, plaster trowel, pliers, plunger, pneumatic drill, power drill, rake, saw, scissors, scraper, screw, screwdriver, sickle, spanner, tape measure

The EEG signals were recorded at 500Hz from 64 scalp locations based on the 10-20 standard

[1] Using the E-Prime software package: `http://www.pstnet.com/e-prime/`.

montage.[2] The EEG recording computer and stimulus presentation computer were synchronised by means of parallel port transmitted triggers. After the experiment, pre-processing of the recorded signals was carried out using the EEGLAB package (Delorme and Makeig, 2003): signals were band-pass filtered at 1-50Hz to remove slow drifts and high-frequency noise, and then down-sampled to 120Hz. An ICA decomposition was subsequently applied (Makeig et al., 1996), and signal components due to eye-movements were manually identified and removed.

As a preliminary test to verify that the recorded signals included category specific patterns, we applied a discriminative classification technique based on source-separation, similar to that described in Murphy et al. (2008). This found that the categories of mammals and tools could be distinguished with an accuracy ranging from 57% to 80% (mean of 72% over the seven participants).

2.2 Feature extraction

The features extracted are metrics of signal power at a particular scalp location, in a particular frequency band, and at a particular time latency relative to the presentation of each image stimulus. Termed Event Related Synchronisation (ERS) or Event Related Spectral Perturbation (ERSP), such frequency-specific changes in signal amplitude are known to correlate with a wide range of cognitive functions (Pfurtscheller and Lopes da Silva, 1999), and have specifically been shown to be sensitive to category distinctions during the processing of linguistic and visual stimuli (Murphy et al., 2008; Gilbert et al., 2009).

Feature extraction and selection is performed individually on a per-participant basis. As a first step all signal channels are z-score normalised to control for varying conductivity at each electrode site, and a Laplacian sharpening is applied to counteract the spatial blurring of signals caused by the skull, and so minimise redundancy of information between channels.

For each stimulus presentation, 14,400 signal power features are extracted: 64 electrode channels by 15 frequency bands (of width 3.3Hz, between 1 and 50Hz) by 15 time intervals (of length 67ms, in the first second after image presentation). A z-score normalisation is carried out across all stimulus presentations to equalise variance across frequencies and times: to control both for the low-pass filtering action of the skull, and for the reduced synchronicity of activity at increasing latencies. For each stimulus a mean is then taken over each of six presentations to arrive at a more reliable power estimate for each feature.[3]

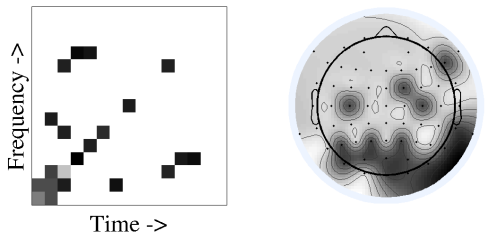

Figure 2: Mean rank of selected features in the time/frequency space (left panel) and on the scalp (right panel) for participant E

The feature ranking method used in Mitchell et al. (2008) evaluates the extent to which the relationship among stimuli is stable across across presentations, using a correlational measure,[4] but preliminary analyses with this selection method on EEG features proved disappointing. Here, two additional ranking criteria are used: each feature is evaluated for its noisiness (the amount of power variation seen across presentations of the same stimulus), and for its distinctiveness (the amount of variation in power estimates across different stimuli). A combination of these three strategies is used to rank the features by their informativeness, and the top 50 features are then selected for each participant.[5]

A qualitative evaluation of the feature selection strategy can be carried out by examining the distribution of features selected. Figure 2 shows the distribution of selected features over the time/frequency spectrum (left panel), and over the scalp (right panel - viewed from above, with the nose pointing upwards). The distribution seen is

[2]Using a Brain Vision BrainAmp system: `http://www.brainproducts.com/`.

[3]Stimulus power features are isolated by band-pass filtering for the required frequencies, cropping following the relevant time interval relative to each image presentation, and then taking the variance of the resulting signal, which is proportional to power.

[4]See the associated supplementary materials of Mitchell et al. (2008) for details: `http://www.sciencemag.org/cgi/content/full/320/5880/1191/DC1`.

[5]Several combinations of these parameters (selection thresholds of 5, 20, 50, 100, 200 features; ranking criteria in isolation and in combination) were investigated - the one chosen gave highest overall performance with the web-derived corpus model: 50 features, combined ranking criteria.

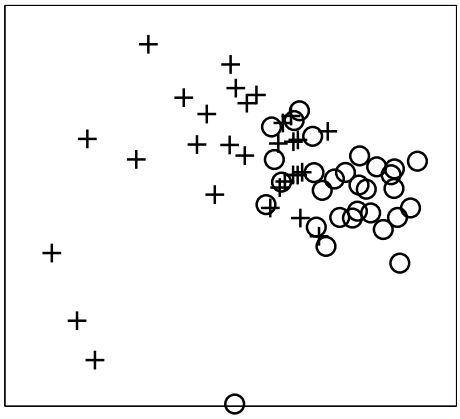

Figure 3: First two components of principal components analysis of selected features for participant E (crosses: mammals; circles: tools)

plausible in reference to previous work: lower frequencies (Pfurtscheller and Lopes da Silva, 1999), latencies principally in the first few hundred milliseconds (Kiefer, 2001), and activity in the visual centres at the rear of the head, as well as parietal areas (Pulvermüller, 2005). A principal components analysis can also be performed on the selected features to see if they reflect any plausible semantic space. As figure 3 shows, the feature selection stage has captured quite faithfully the mammal/tool distinction in a totally unsupervised fashion.

3 Corpus-based semantic models

Data from linguistics (Pustejovsky, 1995; Fillmore, 1982) and neuroscience (Barsalou, 1999; Barsalou, 2003; Pulvermüller, 2005) underline how certain verbs, by emphasising typical ways in which we interact with entities and how they behave, are pivotal in the representation of concrete nominal concepts. Following these traditions, Mitchell et al. (2008) use 25 manually picked verbs as their corpus-based features.

Here that approach is replicated by translating these verbs into Italian. Mitchell et al. (2008) selected verbs that denote our interaction with objects and living things, such as *smell* and *ride*. While the translations are not completely faithful (because frequent verbs of this sort tend to span different sets of senses in the two languages), the aim was to respect the same principle when building the Italian list. The full list, with our back translations into English, is presented in Table 1. We refer to this set as the "Mitchell" verbs.

alzare "raise"	annusare "smell/sniff"
aprire "open"	ascoltare "listen"
assaggiare "taste"	avvicinare "near"
cavalcare "ride"	correre "run/flow"
dire "say/tell"	entrare "enter"
guidare "drive"	indossare "wear"
maneggiare "handle"	mangiare "eat"
muovere "move"	pulire "clean"
puzzare "stink"	riempire "fill"
rompere "break"	sentire "feel/hear"
sfregare "rub"	spingere "push"
temere "fear"	toccare "touch"
vedere "see"	

Table 1: The "Mitchell" verbs, with English translations

As in Mitchell et al. (2008), in order to find a corpus large enough to provide reliable co-occurrence statistics for our target concepts and the 25 verbs, we resorted to the Web, queried using the Yahoo! API.[6] In particular, we represent each concept by a vector that records how many times it co-occurred with each target verb within a span of 5 words left and right, according to Yahoo! counts. We refer to this corpus-based model as the *yahoo-mitchell* model below.

While manual verb picking has proved effective for Mitchell and colleagues (and for us, as we will see in a moment), ultimately what we are interested in is discovering the most distinctive features of each conceptual category. We are therefore interested in more systematic approaches to inducing corpus-based concept descriptions, and in which of these approaches works best for this task. The alternative models we consider were not extracted from the Web, but from an existing corpus, so that we could rely on pre-existing linguistic annotation (POS tagging, lemmatization, dependency paths), and perform more flexible, annotation-aware queries to collect co-occurrence statistics.

More specifically, we used the *la Repubblica/SSLMIT* corpus[7], that contains about 400 million tokens of newspaper text. From this, we extracted four models where nominal concepts are represented in terms of patterns of co-occurrence with verbs (we collected statistics for the top 20,000 most common nouns in the corpus, including the concepts used as stimuli in the silent nam-

[6] http://developer.yahoo.com/search/
[7] http:://sslmit.unibo.it/repubblica/

ing experiment, and the top 5,000 verbs). We first re-implemented a "classic" window-based word space model (Sahlgren, 2006), referred to below as *repubblica-window*, where each noun lemma is represented by its co-occurrence with verb lemmas within the maximum span of a sentence, with no more than one other intervening noun. The *repubblica-position* model is similar, but it also records the position of the verb with respect to the noun (so that *X-usare* "X-use" and *usare-X* "use-X" count as different features), analogously to the seminal HAL model (Lund and Burgess, 1996). It has been shown that models that take the syntactic relation between a target word and a collocate feature into account can outperform "flat" models in some tasks (Padó and Lapata, 2007). The next two models are based on the dependency parse of the *la Repubblica* corpus documented by Lenci (2009). We only counted as collocates those verbs that were linked to nouns by a direct path (such as subject and object) or via preposition-mediated paths (e.g., *tagliare* ***con*** *forbici* "to cut **with** scissors"), and where the paths were among the top 30 most frequent in the corpus. In the *repubblica-depfilter* model, we record co-occurrence with verbs that are linked to the nouns by one of the top 30 paths, but we do not preserve the paths themselves in the features. This is analogous to the model proposed by Padó and Lapata (2007). In the *repubblica-deppath* model, we preserve the paths as part of the features (so that *subj-uccidere* "subj-kill" and *obj-uccidere* count as different features), analogously to Lin (1998), Curran and Moens (2002) and others. For all models, following standard practice in computational linguistics (Evert, 2005), we transform raw co-occurrence counts into log-likelihood ratios.

Following the evaluation paradigm of Mitchell et al. (2008), linear models trained on corpus-based features are used to predict the pattern of EEG activity for unseen concepts. This only works if we have a very limited number of features (or else we would have more parameters to estimate than data-points to estimate them). The Repubblica-based models have thousands of features (one per verb collocate, or verb+path collocate). We adopt two strategies to select a reduced number of features. In the *topfeat* versions, we first pick the 50 features that have the highest association with each of the target concepts. We then count in how many of these concept-specific top lists a feature occurs, and we pick the 25 features that occur in the largest number of them. The intuition is that this should give us a good trade-off between how characteristic the features are (we only use features that are highly associated with some of our concepts), and their generalization capabilities (we pick features that are associated with multiple concepts). Randomly selected examples of the features extracted in this way for the various Repubblica models are reported in Table 2.

repubblica-window	*repubblica-position*
abbattere "demolish"	X-ferire "X-wound"
afferrare "seize"	X-usare "X-use"
impugnare "grasp"	dipingere-X "paint-X"
tagliare "cut"	munire-X "supply-X"
trovare "find"	tagliare-X "cut-X"
repubblica-depfilter	*repubblica-deppath*
abbattere "demolish"	con+tagliare "with+cut"
correre "run"	obj+abbattere "obj+demolish"
parlare "speak"	obj+uccidere "obj+kill"
saltare "jump"	intr-subj+vivere "intr-subj+live"
tagliare "cut"	tr-subj+aprire "tr-subj+open"

Table 2: Examples of top features from the *la Repubblica* models

Alternatively, instead of feature *selection* we perform feature *reduction* by means of a Singular Value Decomposition (SVD) of the noun-by-verb matrix. We apply the SVD to matrices that include the top 20,000 most frequent nouns in the corpus (including our target concepts) since the quality of the resulting reduced model should improve if we can exploit richer patterns of correlations among the columns – verbs – across rows – nouns (Landauer and Dumais, 1997; Schütze, 1997). In the *svd* versions of our models, we pick as features the top 25 left singular vectors, weighted by the corresponding singular values. These features do not have a straightforward interpretation, but they tend to group verb meanings that belong to broad semantic domains. For example, among the original verbs that are most strongly correlated with one of the top singular vectors of *repubblica-window* we find *giocare* "play", *vincere* "win" and *perdere* "lose". Another singular vector is associated with *ammontare* "amount", *costare* "cost", *pagare* "pay", etc. One of the top singular vectors of *repubblica-deppath* is strongly correlated with *in+scendere* "descend into", *in+mettere* "put into", *in+entrare* "enter into", though not all singular vectors are so clearly characterized by the verbs they correlate with.

None of the *la Repubblica* models had full coverage of our concept stimulus set (see the second column of Table 3 below), because our extraction method missed some multi-word units, and feature selection led to losing some more items due to data sparseness (e.g., some target words had no collocates connected by the dependency paths we selected). The experiments reported in the next section used all the target concepts available in each model, but a replication using the 50 concepts that were common to all models obtained results that are comparable. For a direct comparison between Yahoo! and *la Repubblica* derived features, we tried collecting statistics for the Mitchell verbs from Repubblica as well, but the resulting model was extremely sparse, and we do not report its performance here.

Finally, it is important to note that any representation yielded by a corpus semantic model does not characterise a concept directly, but is rather an aggregate of the various senses and usages of the noun chosen to represent it. This obvious limitation will persist until comprehensive, robust and computationally efficient word-sense disambiguation techniques become available. However these models are designed to extract semantic (as opposed to syntactic or phonological) properties of words, and as noted in the introduction, have been demonstrated to correlate with behavioural effects of conceptual processing.

4 Predicting EEG patterns using corpus-based models

In Section 2.2 above we showed how we extracted features summarizing the spatial, temporal and frequency distribution of the EEG signal collected while participants were processing each of the target concepts. In Section 3, we described various ways to obtain a compact representation of the same concepts in terms of corpus-derived features. We will now discuss the method we employed to verify whether the corpus-derived features can be used to predict the EEG patterns – that is whether semantics can be used to predict neural activity. Our hope is that a good corpus-based model will provide a decomposition of concepts into meaningful properties, corresponding to coherent subpatterns of activation in the brain, and thus capture generalizations across concepts. For example, if a concept is particularly visually evocative (e.g., *zebra*), we might expect it to be strongly associated with the verb *see*, while also causing particular activation of the vision centres of the brain. Similarly, concepts with strong associations with a particular sound (e.g., *cuckoo*) might be semantically associated with *hear* while also disproportionately activating auditory areas of the brain. It should thus be possible to learn a model of corpus-to-EEG-pattern correspondences on training data, and use it to predict the EEG activation patterns of unseen concepts.

We follow the paradigm proposed by Mitchell et al. (2008) for fMRI data. For each participant and selected EEG feature, we train a model where the level of activation of the latter in response to different concepts is approximated by a linear combination of the corpus features:

$$\vec{f} = \mathbf{C}\vec{\beta} + \vec{\epsilon}$$

where $\vec{f}$ is the vector of activations of a specific EEG feature for different concepts, the matrix $\mathbf{C}$ contains the values of the corpus features for the same concepts (row-normalised to z-scores), $\vec{\beta}$ is the weight we must learn for each corpus feature, and $\vec{\epsilon}$ is a vector of error terms. We use the method of least squared errors to learn the weights that maximize the fit of the model. We can then predict the activation of an EEG feature in response to a new concept that was not in the training data by a $\vec{\beta}$-weighted sum of the values of each corpus feature for the new concept. In some cases collinearity in the corpus data (regular linear relationships among the corpus-feature columns) prevented the estimation procedure from finding a solution. In such cases (due to the small number of data, relative to the number of unknowns), the least informative corpus-features (those that correlated on average most highly with other features) were iteratively removed until a solution was reached. All models were trained with between 23 and 25 corpus features.

Again following Mitchell and colleagues, we adopt a leave-2-out paradigm in which a linear model for each EEG feature is trained in turn on all concepts minus 2. For each of the 2 left out concepts, we predict the EEG activation pattern using the trained linear model and their corpus features, as just described. We then try to correctly match the predicted and observed activations, by measuring the Euclidean distance between the model-generated EEG activity (a vector of estimated power levels for the n EEG fea-

tures selected) and the corresponding EEG activity recorded in the experiment (other distance metrics gave similar results to the ones reported here). Given the 2 left-out concepts *a* and *b*, we compute 2 *matched* distances (i.e., distance between predicted and observed pattern for *a*, and the same for *b*) and 2 *mismatched* distances (predicted *a* and observed *b*; predicted *b* and observed *a*). If the average of the matched distances is lower than the average of the mismatched distances, we consider the prediction successful – otherwise we count is as a failed prediction. At chance levels, expected matching accuracy is 50%.

5 Results

Table 3 shows the comparative results for all the corpus models introduced in Section 3. The third column (*all*) shows the overall accuracy in correctly matching predicted to observed EEG activity patterns, and so successfully distinguishing word meanings. The significance of the figures is indicated with the conventional annotation (calculated using a one-way two-sided t-test across the individual participant accuracy figures against an expected population mean of 50%).[8] The second column shows the coverage of each model of the 60 mammal and tool concepts used, which ranged from full (for the *yahoo-mitchell* model) to 51 concepts (for the *depfilter-topfeat* model). The corresponding number of matching comparisons over which accuracy was calculated ranged from 1770 down to 1225.

As suggested by previous work (Murphy et al., 2008), and illustrated by figure 3, coarse distinctions between words in different superordinate categories (e.g., *hammer* vs *armadillo*; *giraffe* vs *nail*) may be easier to detect than those among concepts within the same category (e.g., *hammer* vs *nail*; *giraffe* vs *armadillo*). The fourth and fifth columns give these accuracies, and while between-category discriminations do prove more reliable, they indicate that, for the top rated model at least, finer within-category distinctions are also being captured. Figures from the top two performing models are given for individual participants in tables 4 and 5.

[8]On average, the difference seen between matched and mismatched pairs was small, at about 3% of the distance between observed and predicted representations, and was marginally bigger for correct than for incorrect predictions ($p < 0.01$).

6 Discussion

Our results show that corpus-extracted conceptual models can be used to distinguish between the EEG activation levels associated with conceptual categories to a degree that is significantly above chance. Though category specific patterns are detectable in the EEG signal alone (as illustrated by the PCA analysis in figure 3), on that basis we cannot be sure that semantics is being detected. Some other property of the stimuli that co-varies with the semantic classes of interest could be responsible, such as visual complexity, conceptual familiarity, lexical frequency, or phonological form. Only by cross-training with individual corpus features and showing that these hold a predictive relationship to neural activity have we been able to establish that EEG patterns encode semantics.

Present evidence indicates that fMRI may provide richer data for training such models than EEG (Mitchell and colleagues obtain an average accuracy of 77%, and 65% for the within category setting). However, fMRI has several clear disadvantages as a tool for language researchers. First of all, the fine spatial resolution it provides (down to 2-3mm), while of great interest to neuroscientists, is not in itself linguistically informative. Its coarse temporal resolution (of the order of several seconds), makes it ill-suited to analysing on-line linguistic processes. EEG on the other hand, despite its low spatial resolution (several centimetres), gives millisecond-level temporal resolution,

model	*coverage*	*all*	*within cat*	*between cat*
yahoo-mitchell	100	58.3** (5.7)	53.6* (3.7)	63.0** (8.9)

Table 3: Comparison across corpus models, with percentage concept coverage, mean cross-subject percentage prediction accuracy and standard deviation; $*p < 0.05$, $**p < 0.01$

enabling the separate analysis of sequential cognitive processes and states (e.g., auditory processing, word comprehension, semantic representation). fMRI is also prohibitively expensive for most researchers (ca. 300 euros per hour at cost price), compared to EEG (ca. 30 euros per hour). Finally, there is no prospect of fMRI being miniaturised, while wearable EEG systems are already becoming commercially available, making experimentation in more ecological settings a possibility (e.g., playing with a child, meeting at a desk, walking around). In short, while EEG can be used to carry out systematic investigations of categorical distinctions, doing so with fMRI would be prohibitively expensive.

Present results indicate that distinctions between categories are easier than distinctions between category elements; and that selecting the conceptual features by hand gives better results than discovering them automatically. Both of these results however may be due to limitations of the current method. One limitation is that we have been using the same set of features for all concepts, which is likely to blur the distinctions between members of a category more than those between categories. A second limitation of our present methodology is that it is constrained to use very small numbers of semantic features, which limits its applicability. For example it is hard to conceive of a small set of verbs, or other parts-of-speech, whose co-occurrence patterns could successfully characterise the full range of meaning found in the human lexicon. Even the more economical corpus-extracted conceptual models tend to run in the hundreds of features (Almuhareb, 2006). We are currently working on variations in the method that will address these shortcomings.

The web-based model with manually picked features outperformed all *la Repubblica*-based models. However, the results attained with *repubblica-window-svd* are encouraging, especially considering that we are reporting results for an EEG feature configuration optimised for the web data (see footnote 5), and that *la Repubblica* is several orders of magnitude smaller than the web. That data sparseness might be the main issue with *la Repubblica* models is suggested by the fact that *repubblica-window-svd* is the least sparse of them, since it does not filter data by position or dependency path, and compresses information from many verbs via SVD. In future research, we plan to extract richer models from larger corpora. And as the discriminative accuracy of cross-training techniques improves, further insights into the relative validity of corpus representations will be attainable. One research aim is to see if individual corpus semantic properties are encoded neurally, so providing strong evidence for a particular model. These techniques may also prove more objective and reliable in evaluating representations of abstract concepts, for which it is more difficult to collect reliable judgements from informants.

A Comparison of Windowless and Window-Based Computational Association Measures as Predictors of Syntagmatic Human Associations

Abstract

Distance-based (windowless) word association measures have only very recently appeared in the NLP literature and their performance compared to existing windowed or frequency-based measures is largely unknown. We conduct a large-scale empirical comparison of a variety of distance-based and frequency-based measures for the reproduction of syntagmatic human assocation norms. Overall, our results show an improvement in the predictive power of windowless over windowed measures. This provides support to some of the previously published theoretical advantages and makes windowless approaches a promising avenue to explore further. This study also serves as a first comparison of windowed methods across numerous human association datasets. During this comparison we also introduce some novel variations of window-based measures which perform as well as or better in the human association norm task than established measures.

1 Introduction

Automatic discovery of semantically associated words has attracted a large amount of attention in the last decades and a host of computational association measures have been proposed to deal with this task (see Section 2). These measures traditionally rely on the co-ocurrence frequency of two words in a corpus to estimate a relatedness score. There has been a recent emergence of distance-based language modelling techiques in NLP (Savicki and Hlavacova, 2002; Terra and Clarke, 2004) in which the number of tokens separating words is the essential quantity. While some of this work has considered distance-based alternatives to conventional association measures (Hardcastle, 2005; Washtell, 2009), there has been no principled empirical evaluation of these measures as predictors of human association. We remedy this by conducting a thorough comparison of a wide variety of frequency-based and distance-based measures as predictors of human association scores as elicited in several different *free word association tasks*.

In this work we focus on first-order association measures as predictors of *syntagmatic* associations. This is in contrast to second and higher-order measures which are better predictors of paradigmatic associations, or word *similarity*. The distinction between syntagmatic and paradigmatic relationship types is neither exact nor mutually exclusive, and many paradigmatic relationships can be observed syntagmatically in the text. Roughly in keeping with (Rapp, 2002), we hereby regard *paradigmatic* assocations as those based largely on word similarity (i.e. including those typically classed as synonyms, antonyms, hypernyms, hyponyms etc), whereas *syntagmatic* associations are all those words which strongly invoke one another yet which cannot readily be said to be similar. Typically these will have an identifiable semantic or grammatical relationship (meronym/holonym: *stem – flower*, verb/object: *eat – food* etc), or may have harder-to-classify topical or idiomatic relationships (*family – Christmas*, *rock – roll*).

We will show in Section 3.2 that syntagmatic relations by themselves constitute a substantial 25-40% of the strongest human responses to cue words. Although the automatic detection of these assocations in text has received less attention than that of paradigmatic associations, they are nonetheless important in applications such as the resolution of bridging anaphora (Vieira and Poesio, 2000).[1] Furthermore, first-order associations

[1] where for example resolving *my house – the windows* to *the windows of my house* can be aided by the knowledge that windows are often (syntagmatically) associated with houses.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 628–637,
Singapore, 6-7 August 2009.

are often the basis of higher-order vector word-space models used for predicting paradigmatic relationships: i.e. through the observation of words which share similar sets of syntagmatic associations. Therefore improvements made at the level we are concerned with may reasonably be expected to carry through to applications which hinge on the identification of paradigmatic relationships.

After a discussion of previous work in Section 2, we formulate the exact association measures and parameter settings which we compare in Section 3, where we also introduce the corpora and human association sets used. Then, by using evaluations similar to those described in (Baroni et al., 2008) and by Rapp (2002), we show that the best distance-based measures correlate better overall with human association scores than do the best window based configurations (see Section 4), and that they also serve as better predictors of the strongest human associations (see Section 5).

2 Related Work

Measures based on co-ocurrence frequency. The standard way of estimating the syntagmatic association of word pairs in a corpus is to examine the frequency of their co-occurence, and then usually to compare this to some expected frequency. There are a host of measures which exist for this purpose. After raw co-occurrence frequency, the simplest and most prevalent in the literature is Pointwise Mutual Information, famously used by Church (1989) (as the *association ratio*). This is defined as the log of the ratio of the observed co-occurrence frequency to the frequency expected under independence. More sophisticated and statistically-informed measures include t-Score, z-Score, Chi-Squared and Log-Likelihood (see Evert (2005) for a thorough review).

All of these measures have in common that they require co-occurrence frequency to be specified, and therefore require some definition of a region within which to count co-occurrences. This region might be the entirety of a document at one extreme, or a bigram at the other. A versatile and hugely popular generalised approach is therefore to consider a "'window"' of w words, where w can be varied to suit the application. Unsurprisingly, it has been found that this is a parameter which can have a significant impact upon performance (Yarowsky and Florian, 2002; Lamjiri et al., 2004; Wang, 2005). While choosing an optimum window size for an application is often subject to trial and error, there are some generally recognized trade-offs between small versus large windows, such as the impact of data-sparseness, and the nature of the associations retrieved (Church and Hanks, 1989; Church and Hanks, 1991; Rapp, 2002)

Measures based on distance between words in the text. The idea of using distance as an alternative to frequency for modelling language has been touched upon in recent literature (Savicki and Hlavacova, 2002; Terra and Clarke, 2004; Hardcastle, 2005). Washtell (2009) showed that it is possible to build distance-based analogues of existing syntagmatic association measures, by using the notions of mean and expected distance rather than of frequency. These measures have certain theoretical qualities - notably scale-independence and relative resilience to data-sparseness - which might be expected to provide gains in tasks such as the reproduction of human association norms from corpus data. The specific measure introduced by Washtell, called Co-Dispersion, is based upon an established biogeographic dispersion measure (Clark and Evans, 1954). We provide a thorough empirical investigation of Co-Dispersion and some of its derivatives herein.

Measures based on syntactic relations. Several researchers (Lin, 1998; Curran, 2003; Pado and Lapata, 2007) have used word space models based on grammatical relationships for detecting and quantifying (mostly paradigmatic) word associations. In this paper, we will not use syntactic relation measures for two main reasons. Firstly these depend on the availability of parsers, which is not a given for many languages. Secondly, this may not be the most pertinent approach for predicting human free associations, in which certain observed relationsips can be hard to express in terms of syntactic relationships.

3 Methodology

Similar to (Rapp, 2002; Baroni et al., 2008, among others), we use comparison to human assocation datasets as a test bed for the scores produced by computational association measures. An alternative might be to validate scores against those derived from a structured resource such as WordNet.

Table 1: Human association datasets

Name	Origin	Cues	Respondents
Kent	Kent & Rosanoff (1910)	100	$\sim$ 1000
Minnesota	Russell & Jenkins (1954)	100	$\sim$ 1000
EAT	Kiss et al (1973)	8400	100
Florida	Nelson et al (1980)	5019	$\sim$ 140

However, relatedness measures for WordNet are many and varied and are themselves the subject of evaluation (Pedersen et al., 2004). Although human association datasets have their own peculiarities, they do at least provide some kind of definite Gold Standard. Yet another alternative might be to incorporate our computational association scores into an application (such as anaphora resolution), and measure the performance of that, but noise from other submodules would complicate evaluation. We leave such extensions to possible future work.

We use evaluations similar to those used before (Rapp, 2002; Pado and Lapata, 2007; Baroni et al., 2008, among others). However, whereas most existing studies use only one dataset, or hand-selected parts thereof, we aim to evaluate measures across four different human datasets. In this way we hope to get as unbiased a picture as possible.

3.1 Association data

The datasets used are listed in Table 1. While the exact experimental conditions may differ, the datasets used were all elicited using the same basic methodology: by presenting individual words (*cues*) to a number of healthy human subjects and asking in each case for the word that is most immediately or strongly evoked. An association score can then be derived for each cue/response pair in a dataset by dividing the number of participants providing a given response by the number who were presented with the cue word. In Table 1, *respondents* refers to the number of people from whom a response was solicited for each cue word in a study (this is not to be confused with the number of unique responses).

Of these four datasets, one (Kent & Rosanoff) appears not to have been previously used in any peer-reviewed study of corpus-derived lexical association. It is worth noting that some of these datasets are quite dated, which might affect correlations with corpus-derived scores, as culture and contemporary language have a fundamental impact upon the associations humans form (White and Abrams, 2004).

3.2 Frequency of Syntagmatic Associations

To verify that strong human associations do include a large number of syntagmatic associations, we manually annotated all pairs consisting of a cue and its strongest human response in the `Minnesota` and `Kent` datasets as expressing either a syntagmatic or a paradigmatic relationship. The overall set to be annotated consisted of 200 pairs.

Annotators were given short (half-page) guidelines on syntagmatic and paradigmatic assocations, stating that very similar items (including hyponyms/hypernyms) as well as antonyms were to be judged as paradigmatic whereas words that do not fulfil this criterion are to be judged as syntagmatic. The two annotators were the authors of this paper (one native and one near-native speaker). After independent annotation, agreement was measured at a percentage agreement of 91/93% and a kappa of 0.80/0.82 for `Minnesota` and `Kent`, respectively. Therefore, the distinction can be made with high reliability.

Overall, 27/39% of the human responses were syntagmatic in the Kent/Minnesota datasets, showing that syntagmatic relations make up a large proportion of even the strongest human associations.

3.3 Corpora

We use two randomized subsets of the British National Corpus (BNC), a representative 100 million word corpus of British English (Burnard, 1995): one 10 million word sample, and a 1 million word sample. A vocabulary of approximately 33,000 word types was used. The selected words included approximately 24,000 word types comprising all cue and target words from the multiple sets of human association norms to be used in this study. To these were added a top-cut of the most frequent words in the BNC, until the total of 33,000 word types was reached. The resultant set included ap-

proximately the 24,000 most common word types in the BNC, with the remaining 9000 words types therefore comprising relatively uncommon words taken from the human associative responses.

The words included in the vocabulary accounted for over 94.5% of tokens in the corpus. Although statistics for the remaining word types in the BNC were not gathered, their corresponding tokens were left in the corpus so that these could be properly accounted for when calculating distances and window spans.

In order to maximize matching between word types in the corpus and association norms, all words in both were normalized by converting to lower-case and removing hyphens and periods. Words consisting entirely of numerals, or numerals and punctuation, and all "phrasal" associative responses (those containing spaces) were discarded. The 33,000 word count was satisfied after making these normalizations.

In order to maximize the variety of the language in the samples, the subsets were built from approximately the first 2000 words only of each randomly selected document from the BNC (a similar strategy to that used in constructing the 1 million word Brown Corpus). Both a 10 million word and a 1 million word sample were constructed in this fashion, allowing us to also examine the effects of varying corpus size and content.

3.4 Association measures used

3.4.1 Frequency-based measures

In the following, x is the cue word and y a (possible) response word. Therefore $p(x)$ is the probability of observing x, and $p(\bar{x})$ refers to the probability of not observing x.

Pointwise Mutual Information (hereonin PMI) was introduced in Section 2. For ranking word pairs, we can neglect the usual logarithm.

$$PMI = \frac{p(x,y)}{p(x)p(y)}$$

PMI is infamous for its tendency to attribute very high association scores to pairs involving low frequency words, as the denominator is small in such cases, even though the *evidence* for association in such cases is also small. This can result in some unlikely associations. There exist a number of alternative measures which factor in the amount of evidence to give an estimate of the *significance of association*. One popular and statistically appealing such measure is Log-Likelihood (LL) (Dunning, 1993). LL works on a similar principle to PMI but considers the ratio of the observed to expected co-occurrence frequencies for *all contingencies* (i.e. including those where the words do not co-occur). LL, as it most frequently appears in the literature, is not actually a measure of positive association: it also responds to significant *negative* association. Therefore LL is arguably not suited to the task in hand. Krenn & Evert (2001) experiment with one-tailed variants of LL and Chi-Squared measures, although they do not define these variants. Here, we construct a one-tailed variant of LL by simply reversing the signs of the terms which respond to negative association.

$$\begin{aligned} LL_{1tail} &= p(x,y)\log\frac{p(x,y)}{p(x)p(y)} - p(x,\bar{y})\log\frac{p(x,\bar{y})}{p(x)p(\bar{y})} \\ &- p(\bar{x},y)\log\frac{p(\bar{x},y)}{p(\bar{x})p(y)} + p(\bar{x},\bar{y})\log\frac{p(\bar{x},\bar{y})}{p(\bar{x})p(\bar{y})} \end{aligned}$$

LL does not have a clear analogue amongst the distance-based measures (introduced in Section 3.4.2), whereas PMI for instance does. We therefore construct variants of PMI and other measures which take the *amount of evidence* into account in a way which can be directly reproduced in the distance domain. For this we borrow from Sackett (2001) who asserts that, all other things being equal, statistical significance is proportional to the square root of the sample size. There are a number of ways one might quantify sample size. We take a consistent approach across the various distance-based and frequency-based measures: we assume sample size to be equivalent to the lesser of the frequencies of the two words as this represents the total number of words available for pairing, with fewer observed pairs therefore being considered to constitute negative evidence.

$$PMI_{sig} = \sqrt{\min(p(x),p(y))}\frac{p(x,y)}{p(x)p(y)}$$

All of the above measures are symmetric. Human associative responses however are not (Michelbacher et al., 2007): a person's tendency to give the response *because* to the cue *why* does not necessarily reflect their tendency to give the response *why* to the cue *because*.[2] A simple asymmetric association measure is conditional probability (CP)

[2]This notion of assymmetry is not to be confused with

- the probability of observing the response, given that the cue has already occurred.

$$CP = p(y|x) = \frac{p(x,y)}{p(x)}$$

CP suffers from the fact that it does not account at all for the general frequency of the response word. It therefore tends to favour very frequent words, such as function words. An obvious solution would be to divide CP by the frequency of the response word, however this merely results in PMI which is symmetric. By multiplying CP with PMI (and taking the root, to simplify) we obtain a measure which is asymmetric yet does not overtly favour frequent response words.[3] We refer to this herein as Semi-Conditional Information (SCI).

$$SCI = \frac{p(x,y)}{p(x)\sqrt{p(y)}}$$

We also explore variants of both CP and SCI with the additional significance correction presented for PMI_{sig}. These can be easily inferred from the formulae above.

3.4.2 Distance-based Measures

Co-Dispersion (herein CD), introduced by Washtell (2009), is defined as the ratio of the mean observed distance to the expected distance, where the expected distance is derived from the frequency of the more frequent word type. Distance refers to the number of tokens separating an occurrence of one word and the *nearest* occurrence of another word. Pairs spanning an intervening occurrence of *either* word type or a document boundary are not considered. Note that here we specify only the generalised mean M, as we wish to keep the specific choice of mean as a parameter to be explored,

$$CD = \frac{1/\max(p(x),p(y))}{M(dist_{xy1} \ldots dist_{xyn})}$$

where $dist_{xyi}$ is i^{th} observed distance between some occurrence of word type x and its nearest preceding or following occurrence of word type y, and n is the total number of such distances observed (being at most equal to the frequency of the rarer word).

In cases where many occurrences of the less frequent word were not able to be paired, raw CD gives midleading results. This is because unpairable words themselves provide useful negative evidence which CD ignores. A more appropriate measure can be formed in which the mean distance is calculated using the frequency of the less frequent word, regardless of whether this many distances were actually observed. This gives us Neutrally-Weighted Co-Dispersion (NWCD). Note that for convenience, we keep the standard definition of the mean and introduce a correction factor instead.

$$NWCD = \frac{n}{\min(p(x),p(y))} \frac{1/\max(p(x),p(y))}{M(dist_{xy1} \ldots dist_{xyn})}$$

An asymmetric association measure can be formed in a similar manner. Instead of calculating the mean using the frequency of the less frequent word as described above, we explicitly use the frequency of the cue word (which in some cases may actually *exceed* the number of distances observed). This gives us Cue-Weighted Co-Dispersion (CWCD).

$$CWCD = \frac{n}{p(x)} \frac{1/\max(p(x),p(y))}{M(dist_{xy1} \ldots dist_{xyn})} \quad (1)$$

In addition to these measures, we also explore significance-corrected forms NWCD_{sig} and CWCD_{sig}, by introducing the same sample size term employed by PMI_{sig}, CP_{sig} and SCI_{sig}. Again, these can readily be inferred from the existing formulae in the above two sections.

3.5 Co-occurrence Parameters

For frequency-based co-occurrence statistics, the principle parameter is the window size. We will use five window sizes separated by a constant scaling factor, chosen so as to span those most commonly encountered in the literature, with some extension towards the upper end. We use w to represent this parameter, with $w = 2$ implying a window size of +/-2. The parameter values explored

that of *direction* in the text. While the two may correlate, one can find ample counter-examples: *jerky* triggers *beef* more strongly than *beef* triggers *jerky*.

[3] Note that Wettler & Rapp (1993) introduced a more general asymmetric measure for predicting human associations, by employing an exponent parameter to $p(y)$. Our formulisation is equivalent to their measure with an exponent of 0.5, whereas they found an exponent of 0.66 to be most effective in their empirical study. Exponents of 0 and 1 result in CP and PMI respectively.

are $w = 2$, $w = 10$, $w = 50$, $w = 250$ and $w = 1250$. We examine such large window sizes so as to give a fairer comparison with the distance approach which is not bounded by a window, and in acknowledgement of the fact that the entire document as context has been used with some success in other application areas (most notably information retrieval).

For distance-based statistics, the principle parameter is the function via which the various observed distances between tokens are reduced to a single mean value. In this investigation we will explore five means. These are the power means with exponents (which herein we refer to as m) ranging from -2 to +2. These give us the quadratic mean or RMS ($m = 2$), the arithmetic mean ($m = 1$), the geometric mean ($m = 0$), the harmonic mean ($m = -1$), and the inverse quadratic mean ($m = -2$).

4 Task I: Correlations on word pairs

One of the ESSLLI Workshop shared tasks (Baroni et al., 2008) required the evaluation of correlation between a small, manually selected subset of human cue-response scores from the `EAT` dataset and automatic scores for the same word pairs. Here, tather than focusing on word pairs which meet certain grammatical and frequency criteria we test on all pairs. For the `EAT` and `Florida` datasets, this amounts to many tens of thousands of cue-response pairs. Although this makes the task of correlation harder, it means we can attribute a great deal of statistical significance to the results and make our observations as general as possible.

4.1 Evaluation Measures, Upper Bounds and Baselines

For evaluating agreement between corpus-derived associations and human associations, we use Spearman's Rank correlation. This is appropriate because we are primarily interested in the relative ranking of word pair associations (in order to predict particularly strong responses, for example). Although some studies have used Pearson's correlation, the various association measures explored here are not linear within each another and it would be inappropriate to evaluate them under the assumption of a linear relationship with the human norms.

Two of the human datasets, `Kent` and `Minnesota`, though collected independently, are based on the same set of 100 cue words established by Kent (1910). Therefore by performing a rank correlation of these two datasets with one another, (each of which was produced by pooling the responses of some 1000 people) we can get a useful upper-bound for correlations: if a computer-based system were to exceed this upper-bound in correlations with either dataset, then we would need to suspect it of over-fitting.

As a baseline, we use the corpus frequency of the response word. The simple assumption is that the more frequent a word is, the more likely it is to appear as a human response independent of the cue given. This is also the simplest formulation which does not assign equal scores to the various possible responses, and which is therefore capable of producing a rank-list of predictions.

4.2 Task I Results

Figure 1 shows the Spearman's rank correlation co-efficients across all paramaterisations of all association measures (frequency-based on the left, and distance-based on the right), with each human dataset, for the 10 million word corpus. Emboldened are the best performing windowed and windowless configurations for each dataset. The difference of these figures over the baseline is highly significant ($p < 0.0001$ in most cases). The panels to the right show summary statistics for these figures, and for the 1 million word corpus (for which full figures are not included owing to space limitations). These statistics include the performance of the baseline, where relevant the estimated upper-bound (see Section 4.1), and the difference in performance of the distance-based method over the window-based. The accuracy and error figures are based on the co-efficients of determination (r^2) and are expressed both as a relative improvement in accuracy (how much closer (r^2) is to 1 under the distance-based approach) and reduction in error (how much further r^2 is from zero). Also the significance of the difference in the r values is given.

4.3 Discussion

The two-way Spearman's rank correlations between the `Kent` and `Minesota` datasets suggested an upper bound of $r = 0.4$. In theory, a large proportion of this agreement is accounted for by paradigmatic associations which we are not likely to fully reproduce with these first-order measures. By this standard, the general levels of

Figure 1: Correlations for window-based and windowless measures on a 10 million word corpus

correlation seen here (for these datasets $r = 0.235$ and $r = 0.239$ respectively) seem very reasonable.

What is immediately clear from Figure 1 is that, for the range of parameters tested here, we see a relatively small but statistically significant improvement across four of the five datasets when adopting the distance-based approach.

The correlations are unsurprisingly lower across the board for the much smaller 1 million word corpus. Here, the best distance-based measure statistically significantly outperforms the best window-based one (with a significance level of $p < 0.0001$) on one out of four datasets, while the differences are not great enough to be considered statistically significant on the other three datasets. There is therefore some evidence that the benefits observed with the larger corpus hold in the presence of limited data, which is in support of the general theory that distance-based methods capture more information from the corpus at the co-occurrence level (Washtell, 2009). It remains clear, however, that no method is presently a substitute for using a larger corpus.

In terms of optimum configurations, we find that for the frequency-based approach with the larger corpus, a window size of around +/-10 to +/-50 words more or less consistently produces the best results, irrespective of association the measure. Interestingly on the small corpus the tendency appears to be towards a somewhat larger window size than with the larger corpus. This may be related to the larger windows' increased resilience to data-sparseness. Somewhat surprisingly, we also see that our assymmetric association measures SCI and SCI_{sig} perform the best overall amongst the windowed measures, largely irrespective of the window or corpus, size.

In the large corpus, the best distance-based measure is the asymmetric $CWCD$, with the significance corrected measure $CWCD_{sig}$ showing greater strength in the small corpus: perhaps, again, for its improved reliability in the presence of very low-frequency data. The optimum mean for the distance-based parameterisations is somewhere around $m = -1$ (the harmonic) to $m = 0$ (the geometric). We find this unsurprising as the typical distribution of inter-word distances in a corpus is heavily skewed towards the smaller distances - indeed even a random corpus exhibits this characteristic with the distances following a geometric distribution.

5 Task II: Agreement with strongest human associations

The correlation evalation presented considers all word pairs present in the human datasets. However, human association norms tend to contain a very long tail of *hapax legomena* - responses which were given by only one individual. Such responses are extremely difficult for corpus-based

association measures to predict, and given that there is so little consensus amongst human respondents over these items, it is probably not particularly useful to do so. Rather, it might be most useful to predict common or majority human responses.

5.1 Evaluation measure and Upper Bound

For the strongest human response to each cue in the human datasets, its rank was calculated amongst all $33,000$ possible responses to that cue, according to each association measure and parameterisation. Where there were tied scores for various responses, a median rank was assigned. As a rough upper bound, we would be impressed by a computer system which was able to predict the most popular human response as often as a randomly selected individual in the human experiments happened to chose the most popular response.

5.2 Task II Results

Figure 2 illustrates the range of computational association scores attributed to only the strongest human responses. The position of the strongest human response to each cue word, within the computationally-ranked lists of all possible responses, is plotted on the y-axis. For each association measure the points are ordered from best to worst along the x-axis. In the ideal case therefore, the most popular human response for every cue word would appear at rank 1 amongst the computer-generated responses, resulting in a horizonal line at y=1. Generally speaking therefore, the smaller the area above a line the better the performance of a measure.

Three summary statistics can be derived from Figure 2:

1) The number of most popular human responses that are correctly predicted by a measure is indicated by the x-position at which its line departs from y=1. This can be seen to be around 11% for CWCD$_{sig}$ and is zero for the two best PMI parameterizations, with other illustrated measures performing intermediately.

2) The width of the flat horizontal tails at the opposite corner of the figure indicate the proportion of the cue words for which a measure was unable to differentiate the strongest human response from the large contingent of zero association scores resulting from unobservable co-occurrences. This tail is non-existent for CWCD$_{sig}$, but afflicts some 25% and 62% of cue words under the two best PMI parameterizations, again with other illustrated measures performing intermediately.

3) The median rank of the most popular human response for each measure can be read of on the y-axis at the horizontal mid-point (indicated by a feint vertical line).

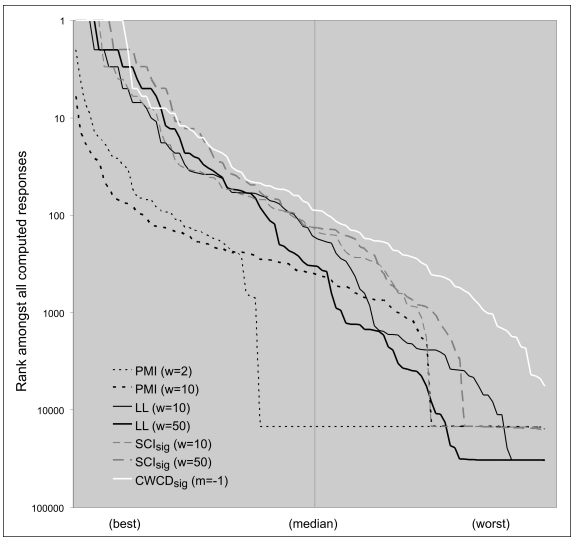

Figure 2: Agreement of computational measures with strongest human responses

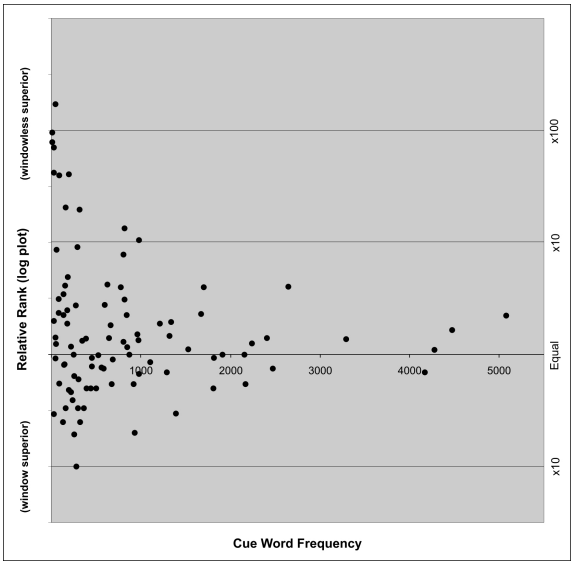

Figure 3: Relative agreement of computational measures with strongest human responses

The results shown are for the Kent dataset, and are highly typical. Included in the figure are the three frequency-based configurations with the highest median rank: SCI$_{sig}$ at window sizes $w = 10$ and $w = 50$, and standard LL at $w = 10$. Three

other frequency-based configurations are included for contrast. Also included is the single windowless configuration with the highest median rank - in this case CWCD$_{sig}$ using the harmonic mean. Several other windowless configurations (notably CWCD and the nearby means) and had very similar profiles.

Figure 3 shows the magnitude of the difference in the ranking of each of the same 100 strong human cue/response pairs, between the best windowless versus best windowed method. Points above the axis represent those cue/response pairs which the windowless method ranked more highly, and vice-versa. The points have been ordered on the x-axis according the the cue word frequency.

5.3 Discussion

Noteworthy, studying Figure 2, is the great sensitivity of the frequency-based measures to the window size parameter. There exists a cut-off point, linked to window size, beyond which the frequency-based measures are unable to make any differentiation between the desired human response and a large portion of the $33,000$ candidate responses. This is almost certainly due to a lack of evidence in the presence of very low frequency words. Log-Likelihood performs somewhat better in this respect, as it takes negative information into account.

Although the distance-based approach follows the same general trend as the other measures, it is nonetheless able to generate a distinct non-zero association score for *every* strong human response and overall it aptly ranks them more highly. A larger number these responses are actually ranked first (i.e. successfully predicted) by the distance-based approach. In fact this number is comparable to, and sometimes exceeds, the upper-bound of 10% implied by taking the average proportion of human respondents who give the most popular response to a given cue.

Whilst Figure 2 showed that overall the windowless method fairs better, on a per-cue basis (Figure 3) things are a little more interesting: For a little over a third of cue-words the windowed method actually appears to perform somewhat better. For the majority however, the windowless approach performs *considerably better* (note that the y-axis scale is logarithmic). It can also be seen that the difference between the methods is most pronounced for low frequency cue words, with responses to some cues exhibiting a relative ranking of around one-hundred times lower for the windowed method. This further supports the theory that the windowless methods are better able to exploit sparse data.

6 Conclusions and Future work

This paper presented the first empirical comparison of window-based and the relatively recently introduced windowless association measures, using their ability to reproduce human association scores as a testbed. We show that the best windowless measures are always at least as good as the best window-based measures, both when it comes to overall correlation with human association scores and predicting the strongest human response. In addition, for several human association sets, they perform significantly better. Although not all parameter settings and corpus sizes could be explored, we conclude that it is worthwhile investigating windowless association measures further. As a side-benefit, we have also introduced new variants of existing frequency-based association measures and shown them to perform as well as or better than their existing counterparts. Although these measures were semi-principled in their construction, a deeper understanding of why they work so well is needed. This may in turn lead to the construction of superior windowless measures.

In our own future work, we are especially interested in using higher-order windowless association measures for retrieving paradigmatic relations as well as exploring their use in various NLP applications.

Improving Verb Clustering with Automatically Acquired Selectional Preferences

Abstract

In previous research in automatic verb classification, syntactic features have proved the most useful features, although manual classifications rely heavily on semantic features. We show, in contrast with previous work, that considerable additional improvement can be obtained by using semantic features in automatic classification: verb selectional preferences acquired from corpus data using a fully unsupervised method. We report these promising results using a new framework for verb clustering which incorporates a recent subcategorization acquisition system, rich syntactic-semantic feature sets, and a variation of spectral clustering which performs particularly well in high dimensional feature space.

1 Introduction

Verb classifications have attracted a great deal of interest in natural language processing (NLP). They have proved useful for various important NLP tasks and applications, including e.g. parsing, word sense disambiguation, semantic role labeling, information extraction, question-answering, and machine translation (Swier and Stevenson, 2004; Dang, 2004; Shi and Mihalcea, 2005; Zapirain et al., 2008).

Verb classes are useful because they offer a powerful tool for generalization and abstraction which can be beneficial when faced e.g. with the problem of data sparsity. Particularly useful can be classes which capture generalizations over a range of (cross-)linguistic properties, such as the ones proposed by Levin (1993). Being defined in terms of similar meaning and (morpho-)syntactic behaviour of words, Levin style classes generally incorporate a wider range of properties than e.g. classes defined solely on semantic grounds (Miller, 1995).

In recent years, a variety of approaches have been proposed for automatic induction of verb classes from corpus data (Schulte im Walde, 2006; Joanis et al., 2008; Sun et al., 2008; Li and Brew, 2008; Korhonen et al., 2008; Ó Séaghdha and Copestake, 2008; Vlachos et al., 2009). This work opens up the opportunity of learning and tuning classifications tailored to the application and domain in question. Although manual classification may always yields higher accuracy, automatic verb classification is cost-effective and gathers statistical information as a side-effect of the acquisition process which is difficult for humans to gather but can be highly useful for NLP applications.

To date, both supervised and unsupervised machine learning (ML) methods have been proposed for verb classification and used to classify a variety of features extracted from raw, tagged and/or parsed corpus data. The best performing features on cross-domain verb classification have been syntactic in nature (e.g. syntactic slots, subcategorization frames (SCFs)). Disappointingly, semantic features have not yielded significant additional improvement, although they play a key role in manual and theoretical work on verb classification and could thus be expected to offer a considerable contribution to classification performance.

Since the accuracy of automatic verb classification shows room for improvement, we further investigate the potential of semantic features – verb selectional preferences (SPs) – for the task. We introduce a novel approach to verb clustering which involves the use of (i) a recent subcategorization frame (SCF) acquisition system (Preiss et al., 2007) which produces rich lexical, SCF and syntactic data, (ii) novel syntactic-semantic feature sets extracted from this data which incorporate a variety of linguistic information, including SPs, and (iii) a new variation of spectral cluster-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 638–647,
Singapore, 6-7 August 2009.

ing based on the MNCut algorithm (Meila and Shi, 2001) which is well-suited for dealing with the resulting, high dimensional feature space.

Using this approach, we show on two well-established test sets that automatically acquired SPs can be highly useful for verb clustering. They yield high performance when used in combination with syntactic features. We obtain our promising results using a fully unsupervised approach to SP acquisition which differs from previous approaches in that it does not exploit WordNet (Miller, 1995) or other lexical resources. It is based on clustering argument head data in the grammatical relations associated with verbs.

We describe our features in section 2 and the clustering methods in section 3. Experimental evaluation and results are reported in sections 4 and 5, respectively. Section 6 provides discussion and describes related work, and section 7 concludes.

2 Features

Our target classification is the taxonomy of Levin (1993) where verbs taking similar diathesis alternations are assumed to share meaning components and are organized into semantically coherent classes. The main feature of this classification is a diathesis alternation which manifests at the level of syntax in alternating sets of SCF (e.g. in the causative/inchoative alternation an NP frame alternates with an intransitive frame: *Tony broke the window* ↔ *The window broke*).

Since automatic detection of diathesis alternations is very challenging (McCarthy, 2001), most work on automatic classification has exploited the fact that similar alternations tend to result in similar SCFs. The research reported so far[1] has used mainly syntactic features for classification, ranging from shallow syntactic slots (e.g. NPs preceding or following the verb) to SCFs. Some researchers have discovered that supplementing basic syntactic features with information about adjuncts, co-occurrences, tense, and/or voice of the verb have resulted in better performance.

However, additional information about semantic SPs of verbs has not yielded considerable improvement on verb classification although SPs can be strong indicators of diathesis alternations (McCarthy, 2001) and although fairly precise semantic descriptions, including information about verb selectional restrictions, can be assigned to the majority of Levin classes, as demonstrated by VerbNet (Kipper-Schuler, 2005).

SP acquisition from undisambiguated corpus data is arguably challenging (Brockmann and Lapata, 2003; Erk, 2007; Bergsma et al., 2008). It is especially challenging in the context of verb classification where SP models are needed for specific syntactic slots for which the data may be sparse, and the resulting feature vectors integrating both syntactic and semantic features may be high dimensional. However, we wanted to investigate whether better results could be obtained if the features were optimised for richness, the feature extraction for accuracy, and a clustering method capable of dealing with the resulting high dimensional feature space was employed.

2.1 Feature extraction

We adopted a recent SCF acquisition system which has proved more accurate than previous comparable systems[2] but which has not been employed for verb clustering before: the system of Preiss et al. (2007). This system tags, lemmatizes and parses corpus data using the current version of the RASP (Robust Accurate Statistical Parsing) toolkit (Briscoe et al., 2006), and on the basis of resulting grammatical relations (GRs) assigns each occurrence of a verb to one of 168 verbal SCFs classes[3].

The system provides a filter which can be used to remove adjuncts from the resulting lexicon. We do not employ this filter since adjuncts have proved informative for verb classification (Sun et al., 2008; Joanis et al., 2008). However, we do frequency-based thresholding to minimise the noise (e.g. erroneous scfs) and sparse data in verb classification and to ensure that only features supported by several verbs are used in classification: we only consider SCFs and GRs which have frequency larger than 40 with 5 or more verbs[4].

The system produces a rich lexicon which includes raw and processed input sentences and provides a variety of material for verb clustering, including e.g. (statistical) information related to the part-of-speech (POS) tags, GRs, SCFs, argument heads, and adjuncts of verbs. Using this material, we constructed a wide range of feature sets

[1] See section 6 for discussion on previous work.

[2] See Preiss et al. (2007) for the details of evaluation.

[3] We used an implementation of the SCF classifier provided by Paula Buttery.

[4] These and other threshold values mentioned in this paper were determined empirically on corpus data.

for experimentation, both shallow and deep syntactic and semantic features. As described below, some of the feature types have been employed in previous works and some are novel.

2.2 Feature sets

The first feature set F1 includes information about the lexical context (co-occurrences) of verbs which has proved useful for supervised verb classification (Li and Brew, 2008):

F1: Co-occurrence (CO): We adopt the best method of Li and Brew (2008) where collocations are extracted from the four words immediately preceding and following a lemmatized verb. Stop words are removed prior to extraction, and the 600 most frequent resulting COs are kept.

F2-F3 provide information about lexical preferences of verbs in argument head positions of specific GRs associated with the verb:

F2: Prepositional preference (PP): the type and frequency of prepositions in the indirect object relation.

F3: Lexical preference (LP): the type and frequency of nouns and prepositions in the subject, object, and indirect object relation.

All the other feature sets include information about SCFs which have been widely employed in verb classification, e.g. (Schulte im Walde, 2006; Sun et al., 2008; Li and Brew, 2008; Korhonen et al., 2008). F4-F7 include basic SCF information and/or refine it with additional information which has proved useful in previous works:

F4: SCFs and relative frequencies with verbs. SCFs abstract over particles and prepositions.

F5: F4 with COs (F1). The SCF and CO feature vectors are concatenated.

F6: F4 with the tense of the verb. The frequency of verbal POS tags is calculated specific to each SCF.

F7: F4 with PPs (F2). This feature parameterizes SCFs for prepositions.

F8: Basic SCF feature corresponding to F4 but extracted from the VALEX lexicon (Korhonen et al., 2006)[5].

The following 9 feature sets are novel. They build on F7, refining it further. F9-F11 refine F7 with information about LPs:

F9: F7 with F3 (subject only)

F10: F7 with F3 (object only)

F11: F7 with F3 (subject, object, indirect object)

F12-17 refine F7 with SPs. We adopt a fully unsupervised approach to SP acquisition. We acquire the SPs by

1. taking the GR relations (subject, object, indirect object) associated with verbs,

2. extracting all the argument heads in these relations which occur with frequency > 20 with more than 3 verbs, and

3. clustering the resulting N most frequent argument heads into M classes using the spectral clustering method described in the following section.

We tried the N settings $\{200, 500\}$ and the M settings $\{10, 20, 30, 80\}$. The best settings $N = 200, M = 20$ and $N = 500, M = 30$ are reported in this paper. We enforce the features to be shared by all the potential members of a verb class. The expected class size is approximately N/K, and we allow for 10% outliers (the features occurring less than $(N/K) \times 0.9$ verbs are thus removed).

The resulting SPs are combined with SCFs in a similar fashion as LPs are combined with SCFs in F9-F11:

F12-F14: as F9-F11 but SPs (20 clusters from 200 argument heads) are used instead of LPs

F15-F17: as F9-F11 but SPs (30 clusters from 500 argument heads) are used instead of LPs

[5]This feature was included to enable comparing the contribution of the recent SCF system to that of an older, comparable system which was used for constructing the VALEX lexicon.

3 Clustering methods

We use two clustering methods: (i) pairwise clustering (PC) which obtained the best performance in comparison with several other methods in recent work on biomedical verb clustering (Korhonen et al., 2008), and (ii) a method which is new to the task (and to the best of our knowledge, to NLP): a variation of spectral clustering which exploits the MNCut algorithm (Meila and Shi, 2001) (SPEC). Spectral clustering has been shown to be effective for high dimensional and non-convex data in NLP (Chen et al., 2006) and it has been applied to German verb clustering by Brew and Schulte im Walde (2002). However, previous work has used Ng et al. (2002)'s algorithm, while we adopt the MNCut algorithm. The latter has shown a wider applicability (von Luxburg, 2007; Verma and Meila, 2003) and it can be justified from the random walk view, which has a clear probabilistic interpretation.

Clustering groups a given set of items (verbs in our experiment) $V = \{v_n\}_{n=1}^{N}$ into a disjoint partition of K classes $I = \{I_k\}_{k=1}^{K}$. Both our algorithms take a similarity matrix as input. We construct this from the skew divergence (Lee, 2001). The skew divergence between two feature vectors v and v' is $d_{skew}(v, v') = D(v'||a \cdot v + (1-a) \cdot v')$ where D is the KL-divergence. v is smoothed with v'. The level of smoothing is controlled by a whose value is set to a value close to 1 (e.g. 0.9999). We symmetrize the skew divergence as follows: $d(v, v')_{sskew} = \frac{1}{2}(d_{skew}(v, v') + d_{skew}(v', v))$.

SPEC is typically used with the Radial Basis Function (RBF) kernel. We adopt a new kernel similar to the symmetrized KL divergence kernel (Moreno et al., 2004) which avoids the need for scale parameter estimation.

$$w(v, v') = \exp(-d_{sskew}(v, v'))$$

The similarity matrix W is constructed where $W_{ij} = w(v_i, v_j)$.

Pairwise clustering

PC (Puzicha et al., 2000) is a method where a cost criterion guides the search for a suitable partition. This criterion is realized through a cost function of the similarity matrix W and partition I:

$$H = -\sum n_j \cdot \text{Avgsim}_j,$$
$$\text{Avgsim}_j = \frac{\sum_{\{a,b \in A_j\}} w(a,b)}{n_j \cdot (n_j - 1)}$$

where n_j is the size of the j_{th} cluster and Avgsim_j is the average similarity between cluster members.

Spectral clustering

In SPEC, the similarities W_{ij} are viewed as the weight on the edges ij of a graph G over V. The similarity matrix W is thus the adjacency matrix for G. The degree of a vertex i is $d_i = \sum_{j=1}^{N} w_{ij}$. A cut between two partitions A and A' is defined to be $\text{Cut}(A, A') = \sum_{m \in A, n \in A'} W_{mn}$.

In MNCut algorithm, the similarity matrix W is transformed to a stochastic matrix P.

$$P = D^{-1}W \quad (1)$$

The degree matrix D is a diagonal matrix where $D_{ii} = d_i$.

It was shown by Meila and Shi (2001) that if P has the K leading eigenvectors that are piecewise constant[6] with respect to a partition I^* and their eigenvalues are not zero, then I^* minimizes the multiway normalized cut(MNCut):

$$\text{MNCut}(I) = K - \sum_{k=1}^{K} \frac{\text{Cut}(I_k, I_k)}{\text{Cut}(I_k, I)}$$

P_{mn} can be interpreted as the transition probability between vertices m, n. The criterion can thus be expressed as $\text{MNCut}(I) = \sum_{k=1}^{K}(1 - P(I_k \rightarrow I_k|I_k))$ (Meila, 2001), which is the sum of transition probabilities across different clusters. The criterion finds the partition where the random walks are most likely to happen within the same cluster.

In practice, the K leading eigenvectors of P is not piecewise constant. But we can extract the partition by finding the approximately equal elements in the eigenvectors using a clustering algorithm like K-means.

The numerator of MNCut is similar to the cost function of PC. The main differences between the two algorithms are: 1) MNCut takes into account of the cross cluster similarity, while PC does not. 2) PC optimizes the cost function using deterministic annealing, whereas SPEC uses eigensystem decomposition.

The spectral clustering algorithm is based on the Multicut algorithm (Meila and Shi, 2001).

[6] The eigenvector v is piecewise constant with respect to I if $v(i) = v(j) \forall i, j \in I_k$ and $k \in 1, 2...K$

Input: Dataset S, Number of clusters K

1. Compute similarity matrix W and Degree matrix D
2. Construct stochastic matrix P using equation 1
3. Compute the eigenvalues and eigenvectors $\{\lambda_n, x_n\}_{n=1}^{N}$ of P, where $\lambda_n \geq \lambda_{n+1}$, form a matrix $X = [x_2, \ldots, x_k]$ by stacking the eigenvectors in columns.
4. Form a matrix Y from X by normalizing the row sums to have norm 1: $Y_{ij} = X_{ij}/(\sum_j X_{ij}^2)^{\frac{1}{2}}$
5. Consider the row of Y to be the transformed feature vectors for each verb and cluster them into clusters $C_1 \ldots C_k$ using K-means clustering algorithm.

Output: Clusters $C_1 \ldots C_k$

4 Experimental evaluation

4.1 Test sets

We employed two test sets which have been used to evaluate previous work on English verb classification:

T1 The test set of Joanis et al. (2008) provides a classification of 835 verbs into 15 (some coarse, some fine-grained) Levin classes. 11 tests are provided for 2-14 way classifications. We employ the 14 way classification because this corresponds the closest to our target (Levin's fine-grained) classification[7]. We select 586 verbs according to Joanis et al.'s selection criteria, resulting in 10-120 verbs per class. We restrict the class imbalance to 1:1.5.[8]. This yields 205 verbs (10-15 verbs per class) which is similar to the sub-set of T1 employed by Stevenson and Joanis (2003).

T2 The test set of Sun et al. (2008) classifies 204 verbs to 17 fine-grained Levin classes, so that each class has 12 member verbs.

Table 1 shows the classes in T1 and T2.

4.2 Data processing

For each verb in T1 and T2, we extracted all the occurrences (up to 10,000) from the raw corpus data gathered originally for constructing the VALEX lexicon (Korhonen et al., 2006). The data was gathered from five corpora, including e.g. the British National Corpus (Leech, 1992) and the North American News Text Corpus (Graff, 1995). The average frequency of verbs in T1 was 1448 and T2 2166, showing that T1 is a more sparse data set.

The data was first processed using the feature extraction module. Table 2 shows (i) the total number of features in each feature set and (ii) the average per verb in the resulting lexicons for T1 and T2.

We normalized the feature vectors by the sum of the feature values before applying the clustering techniques. Since both clustering algorithms have

[7]However, the correspondence is not perfect with half of the classes including two or more Levin's fine-grained classes.

[8]Otherwise, in the case of a large class imbalance the evaluation measure would be dominated by the classes with large population.

an element of randomness, we run them multiple times. The step 5 of SPEC (K-means) was run for 50 times. The result that minimizes the distortion (the distances to cluster centroid) is reported. PC was run 20 times, and the results are averaged.

4.3 Evaluation measures

To facilitate meaningful comparisons, we employ the same measures for evaluation as previously employed e.g. by Korhonen et al. (2008); Ó Séaghdha and Copestake (2008).

The first measure is modified purity (mPUR) – a global measure which evaluates the mean precision of clusters. Each cluster is associated with its prevalent class. The number of verbs in a cluster K that take this class is denoted by $n_{prevalent}$(K). Verbs that do not take it are considered as errors. Clusters where $n_{prevalent}$(K) = 1 are disregarded as not to introduce a bias towards singletons:

$$\text{mPUR} = \frac{\sum_{n_{prevalent(k_i)>2}} n_{prevalent(k_i)}}{\text{number of verbs}}$$

The second measure is weighted class accuracy (ACC): the proportion of members of dominant clusters DOM-CLUST$_i$ within all classes c_i.

$$\text{ACC} = \frac{\sum_{i=1}^{C} \text{verbs in DOM-CLUST}_i}{\text{number of verbs}}$$

mPUR and ACC can be seen as a measure of precision(P) and recall(R) respectively. We calculate F measure as the harmonic mean of P and R:

$$\text{F} = \frac{2 \cdot \text{mPUR} \cdot \text{ACC}}{\text{mPUR} + \text{ACC}}$$

The random baseline(BL) is calculated as follows:

$$\text{BL} = 1/\text{number of classes}$$

5 Results

5.1 Quantitative evaluation

Table 3 includes the F-measure results for all the feature sets when the two methods (PC and SPEC) are used to cluster verbs in the test sets T1 and T2, respectively. A number of tendencies can be observed in the results. Firstly, the results for T2 are clearly better than those for T1. Including a higher number of verbs lower in frequency from classes of variable granularity, T1 is probably a more challenging test set than T2. T2 is controlled for the number and frequency of verbs to facilitate cross-class comparisons. While this may contribute to better results, T2 is a more accurate test set for us in the sense that it offers a better correspondence with our target (fine-grained Levin) classes.

Table 3: Results on testsets T1 and T2

Secondly, the difference between the two clustering methods is clear: the new SPEC outperforms PC on both test sets and across all the feature sets. The performance of the two methods is still fairly similar with the more basic, less sparse feature sets (F1-F2, F4, F6-7) but when the more sophisticated feature sets are used (F3, F5, F9-F17) SPEC performs considerably better. This demonstrates that it is clearly a better suited method for high dimensional feature sets.

Comparing the feature sets, the simple co-occurrence based F1 performs clearly better than the random baseline. F2 and F3 which exploit lexical data in the argument head positions of GRs prove significantly better than F1. F3 yields surprisingly good results on T2: it is the second best feature set on this test set. Also on T1, F3 performs better than the SCF-based feature sets F4-F7. This demonstrates the usefulness of lexical data when obtained from argument positions in relevant GRs.

Our basic SCF feature set F4 performs considerably better than the comparable feature set F8 obtained from the VALEX lexicon. The difference is 19.50 in F-measure. As both lexicons were extracted from the same corpus data, the improvement can be attributed to improved parser and SCF acquisition performance (Preiss et al., 2007).

F5-F7 refine the basic SCF feature set F4 further. F5 which combines a SCF with CO information proved the best feature set in the supervised verb classification experiment of Li and Brew (2008). In our experiment, F5 produces substantially lower result than CO and SCF alone (i.e.

F1 and F4). However, our corpus is smaller (Li and Brew used the large Gigaword corpus), our SCFs are different, and our approach is unsupervised, making meaningful comparisons difficult.

F6 combines F4 with information about verb tense. This was not helpful: F6 produces worse results than F4. F7, on the other hand, yields better results than F4 on both test sets. This demonstrates what the previous research has shown: SCF perform better when parameterized for prepositions.

Looking at our novel feature sets F9-F17, F9-F11 combine the most accurate SCF feature set F4 with the LP-based features F2-F3. Although the feature space gets more sparse, all the feature sets outperform F2-F3 on T1. On T2, F3 performs exceptionally well, and thus yields a better result than F9-F11, but F9-F11 nevertheless perform clearly better than the best SCF-based feature set F4 alone. The differences among F9, F10 and F11 are small on T2, but on T1 F9 yields the best performance. It could be that F9 works the best for the more sparse T1 because it suffers the least from data sparsity (it uses LPs only for the subject relation).

F12-F17 replace the LPs in F9-F11 by semantic SPs. When only 20 clusters are used as SP models and acquired from the smaller sample of (200) argument heads (F12-F14), SPs do not perform better than LPs on T2. A small improvement can be observed on T1, especially with F12 which uses only the subject data (yielding the best F measure on T1: 57.75%). However, when 30 more fine-grained clusters are acquired from a bigger sample of (500) argument heads (F15-F17), lower results can be seen on T1. On T2, on the other hand, F15 yields dramatic improvement and we get the best performance for this test set: 80.35% F-measure.

The fact that no improvement is observed when using F16 and F17 on T2 could be explained by the fact that SPs are stronger for the subject position which also suffers less from the sparse data problem than e.g. i. object position. The fact that no improvement is observed on T1 is likely to be due to the fact that verbs have strong SPs only at the finer-grained level of Levin classification. Recall that in T1, as many as half of the classes are coarser-grained.

5.2 Qualitative evaluation

The best performing feature sets on both T1 and T2 were thus our new SP-based feature sets. We conducted qualitative analysis of the best 30 SP clusters in the T2 data created using SPEC to find out whether these clusters were really semantic in nature, i.e. captured semantically meaningful preferences. As no gold standard specific to our verb classification task was available, we did manual cluster analysis using VerbNet (VN) as aid. In VN, Levin classes are assigned with semantic descriptions: the arguments of SCFs involved in diathesis alternations are labeled with thematic roles some of which are labeled with selectional restrictions.

Human	mother, wife, parent, girl, child
Role	patient, student, user, worker, teacher
Body-part	neck, shoulder, back, knee, corner
Authority	committee, police, court, council, board
Organization	society, firm, union, bank, institution
Money	cash, currency, pound, dollar, fund
Amount	proportion, value, size, speed, degree
Time	minute, moment, night, hour, year
Path	street, track, road, stair, route
Building	office, shop, hotel, hospital, house
Region	site, field, area, land, island
Technology	system, model, facility, engine, machine
Task	operation, test, study, analysis, duty
Arrangement	agreement, policy, term, rule, procedure
Matter	aspect, subject, issue, question, case
Problem	difficulty, challenge, loss, pressure, fear
Idea	argument, concept, idea, theory, belief
Power	control, lead, influence, confidence, ability
Form	colour, style, pattern, shape, design
Item	letter, book, goods, flower, card

Table 4: Cluster analysis: 20 clusters, their SP labels, and prototypical member nouns

From the 30 thematic role types in VN, as many as 20 are associated with the 17 Levin classes in T2. The most frequent role in T2 is agent, followed by theme, location, patient, recipient, and source. From the 36 possible selectional restriction types, 7 appear in T2; the most frequent ones being +animate and +organization, followed by +concrete, +location, and +communication.

As SP clusters capture selectional *preferences* rather than *restrictions*, we examined manually whether the 30 clusters (i) capture semantically meaningful classes, and whether they (ii) are plausible given the VN semantic descriptions/restrictions for the classes in T2.

The analysis revealed that all the 30 clusters had a predominant, semantically motivated SP supported by the majority of the member nouns. Although many clusters could be further divided into more specific SPs (and despite the fact that some nouns were clearly misclassified), we were able to assign each cluster a descriptive label characterizing the predominant SP. Table 4 shows 15 sam-

ple clusters, the SP labels assigned to them, and a number of example nouns in these clusters.

When comparing each SP cluster against the VN semantic descriptions/restrictions for T2, we found that each predominant SP was plausible. Also, the SPs frequent in our data were also frequent among the 17 classes according to VN. For example, the many SP clusters labeled as arrangements, issues, ideas and other abstract concepts were also frequent in T2, e.g. among COMMUNICATION (37), CHARACTERISE (29.2), AMALGAMATE (22.2) and other classes.

This analysis showed that the SP models which performed well in verb clustering were semantically meaningful for our task. An independent evaluation using one of the standard datasets available for SP acquisition research (Brockmann and Lapata, 2003) is of course needed to determine how well the acquisition method performs in comparison with other existing methods.

Finally, we evaluated the quality of the verb clusters created using the SP-based features. We found that some of the errors were similar to those seen on T2 when using syntactic features: errors due to polysemy and syntactic idiosyncracy. However, a new error type clearly due to the SP-based feature was detected. A small number of classes got confused because of strong similar SPs in the subject (agent) position. For example, some PEER (30.3) verbs (e.g. *look, peer*) were found in the same cluster with SAY (37.7) verbs (e.g. *shout, yell*) – an error which purely syntactic features do not produce. Such errors were not numerous and could be addressed by developing more balanced SP models across different GRs.

6 Discussion and related work

Although features incorporating semantic information about verb SPs make theoretical sense they have not proved equally promising in previous experiments which have compared them against syntactic features in verb classification. Joanis et al. (2008) incorporated an 'animacy' feature (a kind of a 'SP') which was determined by classifying e.g. pronouns and proper names in data to this single SP class. A small improvement was obtained when this feature was used in conjunction with syntactic features in supervised classification.

Joanis (2002) and Schulte im Walde (2006) experimented with more conventional SPs with syntactic features in English and German verb classification, respectively. They employing top level WordNet (Miller, 1995) and Germanet (Kunze and Lemnitzer, 2002) classes as SP models. Joanis (2002) obtained no improvement over syntactic features, whereas Schulte im Walde (2006) obtained insignificant improvement.

		Method	Result

	Ó Séaghdha et al. 2008	supervised	67.3
	SPEC	unsupervised	80.35

Table 5: Previous verb classification results

Korhonen et al. (2008) combined SPs with SCFs when clustering biomedical verbs. The SPs were acquired automatically from syntactic slots of SCFs (not from GRs as in our experiment) using PC clustering. A small improvement was obtained using LPs extracted from the same syntactic slots, but the SP clusters offered no improvement. Recently, Schulte im Walde et al. (2008) proposed an interesting SP acquisition method which involves combining EM training and the MDL principle for an verb classification incorporating SPs. However, no comparison against purely syntactic features is provided.

In our experiment, we obtained a considerable improvement over syntactic features, despite using a fully unsupervised approach to both verb clustering and SP acquisition. In addition to the rich, syntactic-semantic feature sets, our good results can be attributed to the clustering technique capable of dealing with them. The potential of spectral clustering for the task was recognised earlier by Brew and Schulte im Walde (2002). Although a different version of the algorithm was employed and applied to German (rather than to English), and although no SP features were used, these earlier experiments did demonstrate the ability of the method to perform well in high dimensional feature space.

To get an idea of how our performance compares with that of related approaches, we examined recent works on verb classification (supervised and unsupervised) which were evaluated on same test sets using comparable evaluation measures. These works are summarized in table 5. ACC and F-measure are shown for T1 and T2, respectively.

On T1, the best performing supervised method reported so far is that of Li and Brew (2008). Li and Brew used Bayesian Multinomial Regression for classification. A range of feature sets integrating COs, SCFs and/or LPs were evaluated. The combination of COs and SCFs gave the best result, shown in the table. Joanis et al. (2008) report the second best supervised result on T1, using Support Vector Machines for classification and features derived from linguistic analysis: syntactic slots, slot overlaps, tense, voice, aspect, and animacy of NPs. Stevenson and Joanis (2003) report a semi- and unsupervised experiment on T1. A feature set similar to that of Joanis et al. (2008) was employed (features were selected in a semi-supervised fashion) and hierarchical clustering was used.

Our unsupervised method SPEC performs substantially better than the unsupervised method of Stevenson et al. and nearly as well as the supervised approach of Joanis et al. (2008) (note, however, that the different experiments involved different sub-sets of T1 so are not entirely comparable).

On T2, the best performing supervised method so far is that of Ó Séaghdha and Copestake (2008) which employs a distributional kernel method to classify SCF features parameterized for prepositions in the automatically acquired VALEX lexicon. Using exactly the same data and feature set, Sun et al. (2008) obtain a slightly lower result when using a supervised method (Gaussian) and a notably lower result when using an unsupervised method (PC clustering). Our method performs considerably better and also outperforms the supervised method of Ó Séaghdha and Copestake (2008).

7 Conclusion and Future Work

We introduced a new approach to verb clustering which involves the use of (i) rich lexical, SCF and GR data produced by a recent SCF system, (ii) novel syntactic-semantic feature sets which combine a variety of linguistic information, and (iii) a new variation of spectral clustering which is particularly suited for dealing with the resulting, high dimensional feature space. Using this approach, we showed on two well-established test sets that automatically acquired SPs can be highly useful for verb clustering. This result contrasts with most previous works but is in line with theoretical work on verb classification which relies not only on syntactic but also on semantic features (Levin, 1993).

In addition to the ideas mentioned earlier, our future plans include looking into optimal ways of acquiring SPs for verb classification. Considerable research has been done on SP acquisition most of which has involved collecting argument headwords from data and generalizing to WordNet classes. Brockmann and Lapata (2003) have showed that WordNet-based approaches do not always outperform simple frequency-based models, and a number of techniques have been recently proposed which may offer ideas for refining our current unsupervised approach (Erk, 2007; Bergsma et al., 2008). The number and type (and combination) of GRs for which SPs can be reliably acquired, especially when the data is sparse, requires also further investigation.

In addition, we plan to investigate other potentially useful features for verb classification (e.g. named entities and preposition classes) and explore semi-automatic ML technology and active learning for guiding the classification. Finally, we plan to conduct a bigger experiment with a larger number of verbs, and conduct evaluation in the context of practical application tasks.

Acknowledgments

Our work was funded by the Dorothy Hodgkin Postgraduate Award, the Royal Society University Research Fellowship, and the EPSRC grant EP/F030061/1, UK. We would like to thank Paula Buttery for letting us use her implementation of the SCF classifier and Yuval Krymolowski for the support he provided for feature extraction.

Abstract

Most existing information retrieval (IR) systems do not take much advantage of natural language processing (NLP) techniques due to the complexity and limited observed effectiveness of applying NLP to IR. In this paper, we demonstrate that substantial gains can be obtained over a strong baseline using NLP techniques, if properly handled. We propose a framework for deriving semantic text matching features from named entities identified in Web queries; we then utilize these features in a supervised machine-learned ranking approach, applying a set of emerging machine learning techniques. Our approach is especially useful for queries that contain multiple types of concepts. Comparing to a major commercial Web search engine, we observe a substantial 4% DCG5 gain over the affected queries.

1 Introduction

Most existing IR models score documents primarily based on various term statistics. In traditional models—from classic probabilistic models (Croft and Harper, 1979; Fuhr, 1992), through vector space models (Salton et al., 1975; Narita and Ogawa, 2000), to well studied statistical language models (Ponte and Croft, 2000; Lafferty and Zhai, 2001)—these term statistics have been captured directly in the ranking formula. More recently, *learning to rank* approaches to IR (Friedman, 2002) have become prominent; in these frameworks, that aim at learning a ranking function from data, term statistics are often modeled as *term matching features* in a machine learning process.

Traditional text matching features are mainly based on frequencies of n-grams of the user's query in a variety of document sections, such as the document title, body text, anchor text, and so on. Global information such as frequency of term or term group in the corpus may also be used, as well as its combination with local statistics – producing relative scores such as $tf \cdot idf$ or BM25 scores (Robertson et al., 1995). Matching may be restricted to certain window sizes to enforce proximity, or may be more lenient, allowing unordered sequences and nonconsecutive sequences for a higher recall.

Even before machine learning was applied to IR, NLP techniques such as Named Entity Recognition (NER), Part-of-Speech (POS) tagging, and parsing have been applied to both query modeling and document indexing (Smeaton and van Rijsbergen, 1988; Narita and Ogawa, 2000; Sparck-Jones, 1999). For example, statistical concept language models generalize classic n-gram models to concept n-gram model by enforcing query term proximity within each concept (Srikanth and Srihari, 2003). However, researchers have often reported limited gains or even decreased performance when applying NLP to IR (Voorhees, 1999).

Typically, concepts detected through NLP techniques either in the query or in documents are used as proximity constraints for text matching (Sparck-Jones, 1999), ignoring the actual concept type. The machine learned approach to document ranking provides us with an opportunity to revisit the manner in which NLP information is used for ranking. Using knowledge gained from NLP application as features rather than heuristically allows us much greater flexibility in the amount and variability of information used – e.g., incorporating knowledge about the actual entity types. This has several benefits: first, entity types appearing in queries are an indicator of the user's intent. A query consisting of a business *category* and a location (e.g., *hotels Palo Alto*) appears to be

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 648–657,
Singapore, 6-7 August 2009.

informational, and perhaps is best answered with a page containing a list of hotels in Palo Alto. Queries containing a business *name* and a location (e.g., *Fuki Sushi Palo Alto*) are more navigational in nature – for many users, the intent is finding the home page of a specific business. Similarly, entity types appearing in documents are an indicator of the document type. For example, if "Palo Alto" appears ten times in document's body text, it is more likely to be a local listing page than a home page. For the query *hotels Palo Alto*, a local listing page may be a good page, while for the query *Fuki Sushi Palo Alto* a listing page is not a good page.

In addition, knowledge of the particular entities in queries allows us to incorporate external knowledge about these entities, such as entity-specific stopwords ("inc." as in *Yahoo Inc.* or "services" as in *kaiser medical service*), and so on.

Finally, even when using named entities only for deriving proximity-related features, we can benefit from applying different levels of proximity for different entities. For example, for entities like cities (e.g., "River Side"), the proximity requirement is fairly strict: we should not allow extra words between the original terms, and preserve their order. For other entities the proximity constraint can be relaxed—for example, for person names, due to the middle name convention: *Hillary Clinton* vs. *Hillary R. Clinton*.

In this paper, we propose a systematic approach to modeling semantic features, incorporating concept types extracted from query analysis. Vertical attributes, such as city-state relationships, metropolitan definition, or idf scores from a domain specific corpus, are extracted for each concept type from vertical database. The vertical attributes, together with the concept attributes, are used to compose a set of semantic features for machine learning based IR models. A few machine learning techniques are discussed to further improve relevance for subclass of difficult queries such as queries containing multiple types of concepts. Figure 1 shows an overview of our approach; after discussing related work in Section 2, we spend Sections 3 to 5 of the paper describing the components of our system. We then evaluate the effectiveness of our approach both using general queries and with a set of "difficult" queries; our results show that the techniques are robust, and particularly effective for this type of queries. We conclude in Section 7.

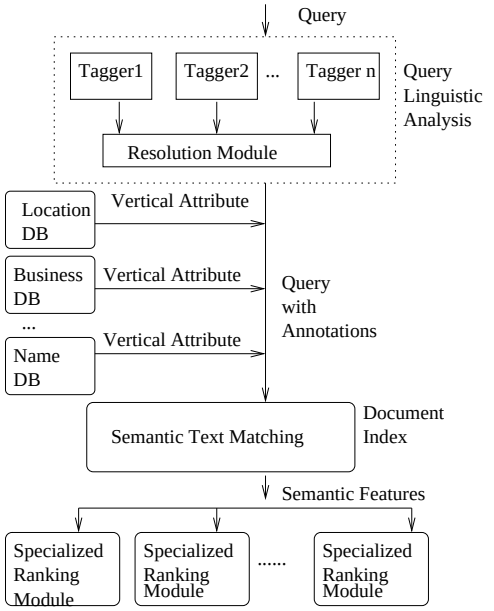

Figure 1: Ranking with Semantic Features

2 Related Work

There is substantial body of work involving usage of NLP techniques to improve information retrieval (Brants, 2003; Strzalkowski et al., 1996). Allan and Ragahavan (Allan and Raghavan, 2002) use Part-of-Speech tagging to reduce ambiguity of difficult queries by converting short queries to questions. In other POS-tags work, Arampatzis *et al.* (Arampatzis et al., 1990) observed an improvement when using nouns only for retrieval. Croft et al. (Croft et al., 1991) and Tong et al. (Buckley et al., 1993; Tong et al., 1996) explored phrases and structured queries and found phrases are effective in improving retrieval performance. Voorhees (Voohees, 1993) uses word sense disambiguation to improve retrieval performance. One IR domain that consistently benefits from usage of various NLP techniques is question answering, where queries are formed in natural language format; e.g., (Peng et al., 2005).

In general, however, researchers often observe limited gains or even degraded performance when applying NLP to IR (Voorhees, 1999). Having said this, most past studies use small datasets and a modest baseline; it is unclear whether a similar conclusion would be reached when using a state-of-art system such as a commercial web search engine as a baseline, and a full-web corpus – as we do in this paper. This leads to another difference between this work and existing work involving named entity recognition for retrieval. Most

previous research on usage of named entities in IR combines entity detection in documents and queries (Prager et al., 2000). Entity detection in document has a high indexing cost that is often overlooked, but cannot be ignored in the case of commercial search engines. For this reason, we restrict NLP processing to queries only – although we believe that document-side NLP processing will provide additional useful information.

3 Query Analysis

We begin by briefly describing our approach to named entity recognition in web queries, which serves as the basis for deriving the semantic text matching features.

Named entity recognition (NER) is the task of identifying and classifying entities, such as person names or locations, in text. The majority of state-of-the-art NER methods utilize a statistical approach, attempting to learn a mapping between a sequence of observations (words) and a sequence of tags (entity types). In these methods, the sequential nature of the data is often central to the model, as named entities tend to appear in particular context in text. For example, for most types of text, in the two sequences *met with X* and *buy the Y*, the likelihood of X being a person name is substantially higher than the corresponding likelihood of Y. Indeed, many named entity taggers perform well when applied to grammatical text with sufficient contexts, such as newswire text (Sang and Meulder, 2003).

Web queries, however, tend to be short, with most queries consisting of 1–3 words, and lack context – posing a particular challenge for identifying named entities in them. Existing work on NER in web queries focuses on tailoring a solution for a particular entity type and its usage in web search (Wang et al., 2005; Shen et al., 2008); in contrast, we aim at identifying a large range of possible entities in web queries, and using a generic solution for all of them.

In web queries, different entity types may benefit from different detection techniques. For example, an entity type with a large variability among instances as well as existence of external resources like product name calls for an approach that can make use of many features, such as a conditional random field; for entity types that are more structured like person names, a grammar-based approach can be more effective (Shen et al., 2008). To this end, we utilize multiple approaches for entity detection and combine them into a single, coherent "interpretation" of the query.

Given a query, we use several entity recognizers in parallel, one for each of the common entity types found in web queries. The modeling types may differ between the recognizers: some are Markovian models, while others are just dictionary lookups; the accuracy of each recognizer is also different. We then have a machine-learned disambiguation module that combines output from different taggers, ranking the tagging sequences. The details of scoring is out of the scope of this paper, and we omit it for simplicity.

4 Semantic Text Matching Features

Our proposed semantic features operate at the semantic type level rather than at the term level: instead of matching a term (or set of terms) in documents, we match their semantic type. Given the query *San Francisco colleges* and the annotation $[San\ Francisco]_{CityName}\ [colleges]_{BusinessCategory}$, the semantic text matching features would describe how relevant a document section is for a entity of type $CityName$, for $BusinessCategory$, and for their combination.

Concretely, we exploit a set of features that attempts to capture proximity, general relevance, and vertical relevance for each type of semantic tag and for each section of the document. We now review these feature by their broad types.

4.1 Semantic Proximity Features

Proximity features—features that capture the degree to which search terms appear close to each other in a document—are among the most important feature sets in ranking functions. Traditional proximity features are typically designed for all query terms (Metzler and Croft, 2005) and may suffer from wrong segmentations of the query. For example, for the query *New York city bus charter*, a traditional proximity feature may treat "city bus" similarly to "York city." But given detailed information about the entities in the query in their types, we can enforce proximity for "New York city" and "bus charter" more accurately. Different types of entities usually have different proximity characteristics in relevant documents. Strongly-bound entities such as city names typically have very high proximity in relevant documents, while entities such as business names may have much

lower proximity: a search for *Kaiser medical office*, for example, may be well-served with documents referring to *Kaiser Permanente medical office*, and as we mentioned before, person names matches may also benefit from lenient proximity enforcement. This is naturally addressed by treating each entity type differently.

We propose a set of semantic proximity features that associate each semantic tag type with generic proximity measures. We also consider tagging confidence together with term group proximity; we discuss these two approaches next.

4.1.1 Semantic Minimum Coverage (SMC)

Minimum Coverage (MC) is a popular span based proximity distance measure, which is defined as the length of the shortest document segment that cover the query term at least once in a document (Tao and Zhai, 2007). We extend this measure to Semantic Minimum Coverage (SMC) for each semantic type t in document section s and define it as

$$\text{SMC}_{t,s} = \frac{1}{|\{k|T_k = t\}|} \sum_{i \in \{k|T_k=t\}} w_i \text{MC}_{i,s},$$

where w_i is a weight for tagged term group i, $\text{MC}_{i,s}$ is the the minimum coverage of term group i in document section s, $\{k|T_k = t\}$ denotes the set of all concepts having type t, and $|\{k|T_k = t\}|$ is the size of the set. The definition of the weight w is flexible. We list a few candidate weighting schemes in this paper: uniform weights (w^u), weights based on idf scores (w^{idf}) and "strength"-based weight (w^s), which we define as follows:

$$w^u = 1;$$
$$w^{\text{idf}} = \frac{c}{f_q}$$

where c is a constant and f_q is the frequency of the term group in a large query log;

$$w^s = \min_l \text{MI}_l$$

where MI_l is the point-wise mutual information of the l-th consecutive pair within the semantic tag. We can also combine strength and idf scores such that the weight reflects both relative importance and constraints in proximity. In this paper, we use

$$w^{si} = w^s w^{\text{idf}}.$$

In Section 6, we use all four weighting schemes mentioned above in the semantic feature set.

4.1.2 Semantic Moving Average BM25 (SMABM25)

BM25, a commonly-used bag-of-words relevance estimation method (Robertson et al., 1995), is defined (when applied to document sections) as

$$\text{BM25} = \sum_j \text{idf}_j \frac{f_{j,s}(c_1+1)}{f_{i,s} + c_1(1 - c_2 + c_2 \frac{l_s}{\bar{l_s}})}$$

where $f_{j,s}$ is the frequency of term j in section s, l_s is the length of section s, $\bar{l_s}$ is the average length of document section s, c_1, c_2, c_3 are constants and the idf score of term j is defined as

$$\text{idf}_j = \log \frac{c_4 - d_j + c_5}{d_j + c_5},$$

where d_j is the number of sections in all collections that contains term j and c_4, c_5 are constants.

To characterize proximity, we could use a fixed length sliding window and calculate the average BM25. We further associate each sliding average BM25 with each type of semantic term groups. This results in a Semantic Moving Average BM25 (SMABM25) of type t, which we define as follows:

$$\frac{1}{|\{k|T_k = t\}|} \sum_{i \in \{k|T_k=t\}} (1/M) \sum_m BM25_m$$

where m is a fixed length sliding window m and M is the total number of sliding windows (that depends on the length of the section window size).

4.2 Semantic Vertical Relevance Features

Vertical databases contain a large amount of structured domain knowledge typically discarded by traditional web relevance features. Having access to the semantic types in queries, we can tap into that knowledge to improve accuracy. For example, term frequencies in different corpora can assist in determining relevance given an entity type. As we mentioned in Section 1, we observe that term frequency in a database of business names provides an indication of the business brand, the key part of the business name phrase. While both "yahoo" and "inc" are very common terms on the web, in a database of businesses only "inc" is common enough to be considered a stopword in the context of business names.

We propose a Vertical Moving Average BM25 (VMABM25) as a feature aiming at quantifying the vertical knowledge for web search. The basic idea here is to replace the idf score idf_j of

SMABM25 with an idf score calculated from a vertical database for type t, namely idf_j^t:

$$\frac{1}{|\{k|T_k = t\}|} \sum_{i \in \{k|T_k=t\}} (1/M) \sum_m \text{BM25}_{m,t}$$

where

$$\text{BM25}_{m,t} = \sum_j \text{idf}_j^t \frac{f_{j,s}(c1+1)}{f_{i,s} + c_1(1 - c_2 + c_2 \frac{l_s}{l_s})}$$

where the idf_j^t is associated with the semantic type t and calculated from the corpus associated with that type.

VMABM25 links vertical knowledge, proximity, and page relevance together; we show later that it is one of most salient features among all semantic features.

4.3 Generalized Semantic Features

Finally, we develop a generalized feature based on the previous features by removing tags. Semantic features are often sparse, as many queries contain one entity or no entities at all; generalized features increase their coverage by combining the basic semantic features. An entity without tag is essentially a segment.

A segment feature x_i for query i does not have entity type and can be expressed as

$$x_i = \frac{1}{K_i} \sum_{k=1}^{K_i} x_{T(k)}$$

where K_i is the number of segments in the query and $T(k)$ is the semantic type associated with kth concept.

Although these features are less informative than type-specific features, one advantage of using them is that they have substantially higher coverage. In our experiments, more than 40% of the queries have some identified entity. Another relatively subtle advantage is that segment features have no type related errors: the only possible error is a mistake in entity boundaries.

5 Ranking Function Optimization

The ultimate goal of the machine learning approach to web search is to learn a ranking function $h(x_i)$, where x_i is a feature vector of a query-document pair i, such that the error

$$L(h) \equiv \sum_{i=1}^{N} (y_i - h(x_i))^2 \qquad (1)$$

is minimized. Here, y_i is the actual relevance score for the query-document pair i (typically assigned by a human) and N is the number of training samples.

As mentioned in the previous Section, an inherent issue with semantic features is their sparseness. User queries are usually short, with an average length of less than 3 words. Text matching features that are associated with the semantic type of query term or term groups are clearly sparse comparing with traditional, non-entity text matching features – that can be derived for any query. When a feature is very sparse, it is unlikely that it would play a very meaningful role in a machine learned ranking function, since the error L would largely depend on other samples that do not contain the specific semantic features at all. To overcome the spareness issue and take advantage of semantic features, we suggested generalizing our features; but we also exploit a few ranking function modeling techniques.

First, we use a "divide-and-conquer" approach. Long queries usually contain multiple concepts and could be difficult to retrieve relevant documents. Semantic features, however, are rich in this set of queries. We may train special models to further optimize our ranking function for those queries. The loss function over ranking function h becomes

$$L_C(h) \equiv \sum_{i \in C} (y_i - h(x_i))^2 \qquad (2)$$

where C is the training set that falls into a predefined subclass. For example, queries containing both location and business name, queries contains both location and business category, etc, are good candidates to apply semantic features.

To this end, we first classify queries into several classes, each of which has multiple types of entities. The semantic features of those types would be dense for this subclass of queries. We then train models that may rank the specific class of queries well. This approach, however, may suffer from significantly less training samples due to training data partition resulted from the query classification. Increasing the modeling accuracy, then, comes at a cost of reduced data available for training. We apply two techniques to address this issue. The first approach is to over-weight subclass training samples such that the subclass of queries plays a more important role in modeling while still

keeping a large pool of the overall training samples. The second approach is model adaptation: a generalized incremental learning method. Here, instead of being over-weighted in a joint optimization, the subclass of training data is used to modify an existing model such that the new model is "adapted" to the subclass problem. We elaborate on our approaches as follows.

5.1 Weighted Training Samples

To take advantage of both large a pool of training samples and sparse related semantic features for a subclass of queries, we could modify the loss function as follows

$$L_C^w(h) \equiv w \sum_{i \in C} (y_i - h(x_i))^2 + \sum_{i \in \bar{C}} (y_i - h(x_i))^2, \quad (3)$$

where $\bar{C}$ is the complement of set C. Here, the weight w is a compromise between loss function (1) and (2). When $w = 1$, we have

$$L_C^1(h) \equiv L(h);$$

when $w -> \infty$

$$L_C^\infty(h) \equiv L_C(h).$$

A large weight may help optimize the training for a special subclass of queries, and a small weight may help to preserve good generality of the ranker. We could use cross-validation to select the weight w to optimize a the ranking function for a subclass of queries. In practice, a small w is desired to avoid overfitting.

5.2 Model Adaptation

Model adaptation is an emerging machine learning technique that is used for information retrieval applications with limited amount of training data. In this paper, we apply Trada, proposed by Chen et al. (Chen et al., 2008), as our adaptation algorithm.

The Trada algorithm aims at adapting tree-based models. A popular tree based regression approach is Gradient Boosting Trees (GBT) , which is an additive model $h(x) = \sum_{k=1}^{K} \gamma_k h_k(x)$, where each regression tree h_k is sequentially optimized with a hill-climbing procedure. As with other decision trees, a binary regression tree $h_k(x)$ consists of a set of decision nodes; each node is associated with a feature variable and a splitting value that partition the data into two parts, with the corresponding predicted value defined in the leave node. The basic idea of Trada is to apply piecewise linear transformation to the base model based on the new training data. A set of linear transformations are applied to each decision node, either predict or split point or both, such that the new predict or the split point of a node in a decision tree satisfies

$$v = (1 - p_C)\hat{v} + p_C v_C$$

where $\hat{v}$ denotes predict or split point of that node in the base mode and v_C denotes predict or split point of that node using new data set C, and the weight p_C depends on the number of original training data and new training data that fall through the node. For each node, the split or predict can be estimated by

$$p_C = \frac{\beta n_C}{n + \beta n_C},$$

where n is the number of training sample of the base model that fall through the node, n_C is the number of new training sample that fall through the node, and β is a parameter that can be determined using cross validation. The parameter β is used to over-weight new training data, an approach that is very effective in practice. For new features that are not included in the base model, more trees are allowed to be added to incorporate them.

6 Experiments

We now measure the effectiveness of our proposal, and answer related questions, through extensive experimental evaluation. We begin by examining the effectiveness of features as well as the modeling approaches introduced in Section 5 on a particular class of queries—those with a local intent. We proceed by evaluating whether if the *type* associated with each entity really matters by comparing results with type dependent semantic features and segment features. Finally, we examine the robustness of our features by measuring the change in the accuracy of our resulting ranking function when the query analysis is wrong; we do this by introducing simulated noise into the query analysis results.

6.1 Dataset

Our training, validation and test sets are human-labeled query-document pairs. Each item in the

sets consists of a feature vector $\mathbf{x_i}$ representing the query and the document, and a judgment score y_i assigned by a human. There are around 600 features in each vector, including both the newly introduced semantic features and existing features; features are either query-dependent ones, document-dependent ones, or query-and-document-dependent features.

The training set is based on uniformly sampled Web queries from our query log, and top ranked documents returned by commercial search engines for these queries; this set consists of 1.24M query-document pairs.

We use two additional sets for validation and testing. One set is based on uniformly sampled Web queries, and contains 42790 validation samples and 70320 test samples. The second set is based on uniformly sampled *local queries*. By local queries, we mean queries that contain at least two types of semantic tags: a location tag (such as street, city or state name) and a business tag (a business name or business category). We refer to this class of queries "local queries," as users often type this kind of queries in local vertical search. The local query set consists of 11040 validation samples and 39169 test samples. In the training set we described above, there are 56299 training samples out of the 1.24M total number of training samples that satisfy the definition of local queries. We call this set local training subset.

6.2 Evaluation Metrics

To evaluate the effectiveness of our semantic features we use Discounted Cumulative Gain (DCG) (Jarvelin and Kekalainen, 2000), a widely-used metric for measuring Web search relevance. (Jarvelin and Kekalainen, 2000). Given a query and a ranked list of K documents ($K = 5$ in our experiments), the DCG for this query is defined as

$$\mathrm{DCG}(K) = \sum_{i=1}^{K} \frac{y_i}{\log_2(1+i)}. \qquad (4)$$

where $y_i \in [0, 10]$ is a relevance score for the document at position i, typically assigned by a human, where 10 is assigned to the most relevant documents and 0 to the least relevant ones.

To measure statistical significance, we use the Wilcoxon test (Wilcoxon, 1945); when the p-value is below 0.01 we consider a difference to be statistically significant and mark it with a **bold font** in the result table.

6.3 Experimental Results

We use Stochastic Gradient Boosting Trees (SGBT) (Friedman, 2002), a robust none linear regression algorithm, for training ranking functions and, as mentioned earlier, Trada (Chen et al., 2008) for model adaptation.

Training parameters are selected to optimize the relevance on a separated validation set. The best resulting is evaluated against the test set; all results presented here use the test set for evaluation.

6.3.1 Feature Effectiveness with Ranking Function Modeling

We apply the modeling approaches introduced in Section 5 to improve feature effectiveness on "difficult" queries—those more than one entity type; we evaluate these approaches with the semantic-feature-rich set, the local query test set. We split training sets into two parts: one set belongs to the local queries, the other is the rest. We first weight the local queries and use the combined dataset as training data to learn the ranking functions; we train functions with and without the semantic features. We evaluate these functions against the local query test set. The results are summarized in Table 1, where w denotes the weight assigned to the local training set, bolded numbers are statistically significant result compared to the baseline, uniformly weighted training data without semantic features (with superscript b). It is interesting to observe that without semantic features, over-weighted local training data does not have statistically significant impact on the test performance; with semantic features, a proper weight over training samples does improve test performance substantially.

Table 1: Evaluation of Ranking Models Trained Against Over-weighted Local Queries with Semantic Features on the Local Query Test Set

	w/o semantic features		w/ semantic features	
Weight	DCG(5)	Impr.	DCG(5)	Impr.
$w = 0$	8.09^b	-	8.25	$\mathbf{2.0\%}$
$w = 2$	8.09	0.02%	8.26	$\mathbf{2.1\%}$
$w = 4$	8.13	0.49%	8.34	$\mathbf{3.1\%}$
$w = 8$	8.13	0.49%	8.42	$\mathbf{4.1\%}$
$w = 16$	8.13	0.49%	8.30	$\mathbf{2.6\%}$
$w = 32$	8.04	-0.60%	8.27	$\mathbf{2.2\%}$

Next, we use the local query training set as "new data" in the tree adaptation approach. In tree adaptations, all parameters are set to optimize the performance over the local validation set. We com-

pare two major adaptation approaches proposed in (Chen et al., 2008): adapting predict only and adapting both predict and split. We use the model trained with the combined training and uniform weights as the baseline; results are summarized in Table 2.

Table 2: Trada Algorithms with Semantic Features on Local Query Test Set

	w/o semantic feat.		w/ semantic feat.	
Ada. Appr.	DCG(5)	Impr.	DCG(5)	Impr.
Combined data	8.09^b	-	8.25	$\mathbf{2.0}\%$
Ada. predict	8.02	-0.1%	8.14	0.6%
Ada. predict & split	8.00	-0.1%	8.17	$\mathbf{1.0}\%$

Comparing Tables 1 and 2, note that using the combined training data with local query training samples over-weighted achieves better results than tree adaption. The latter approach, however, has the advantage of far less training time, since the adaptation is over a much smaller local query training set. With the same hardware, it takes just a few minutes to train an adaptation model, while it takes days to train a model over the entire, combined training data. Considering that massive model validation tasks are required to select good training parameters, training many different models with over a million training samples becomes prohibitly costly. Applying tree adaptation techniques makes research and prototyping of these models feasible.

6.3.2 Type Dependent Semantic Features vs. Segment Features

Our next experiment compares type-dependent features and segment features, evaluating models trained with these features against the local query test set. No special modeling approach is applied here; results are summarized in Table 3. We observe that by using type-dependent semantic features only, we can achieve as much as by using all semantic features. Since segment features only convey proximity information while the base feature set already contain a systematic set of proximity measures, the improvement through segment features is not as significant as the the type dependent ones.

6.3.3 Robustness of Semantic Features

Our final set of experiments aims at evaluating the robustness of our semantic features by introducing

Table 3: Type-dependent Semantic Features vs. Segment Features

Feature set	DCG(5)
base + type dependent semantic features	8.23
base + segment features	8.19
base + all semantic features	8.25

simulated errors to the output of our query analysis. Concretely, we manipulate the precision and the recall of a specific type of entity tagger, t, on the training and test set. To decrease the *recall* of type t, we uniformly remove a set of $a\%$ tags of type t – preserving precision. To decrease *precision*, we uniformly select a set of query segments (viewing the entity detection as simple segmentation, as detailed earlier) and assign the semantic type t to those segments. Since the newly added term group are selected from query segmentation results, the introduced errors are rather semantic *type* error than boundary error or proximity error. The total number of newly assigned type t tags are $b\%$ of the original number of type t tags in the training set. By doing this, we decrease the precision of type t while keeping the recall of it at the same level.

Suppose the original tagger achieves precision p and recall r. By removing $a\%$ of tags, we have estimated precision $\hat{p}$ and recall $\hat{r}$ defined as follows:

$$\hat{r} = \frac{100r - ar}{100},$$

$$\hat{p} = p.$$

By adding $b\%$ more term group to this type, we have estimated precision and recall as

$$\hat{p} = \frac{100p}{100 + bp},$$

$$\hat{r} = r.$$

In the experiment reported here we use BUSINESS NAME as the target semantic type for this robustness experiment. An editorial test shows that our tagger achieves 74% precision and 66% recall based on a random set of human labeled queries for this entity type. We train ranking models with various values of a and b. When we reduce the estimated recall, we evaluate these models against the local test set since other data are not affected. The results are summarized in Table 4.

When we reduce the precision, we evaluate the resulting models against the general test set as

Table 4: Relevance with simulated error on local query test set

a	b	$\hat{p}$	$\hat{r}$	DCG(5)	Impr.
0	0	0.74	0.66	8.25	–
10	0	0.74	0.594	8.21	0.48%
20	0	0.74	0.528	8.19	**0.72%**
40	0	0.74	0.396	8.18	**0.85%**

Table 5: Search relevance with simulated error for semantic features on general test set

a	b	$\hat{p}$	$\hat{r}$	DCG(5)	Impr.
0	0	0.74	0.66	10.11	-
0	10	0.689	0.66	10.11	0.00%
0	20	0.645	0.66	10.12	0.10%
0	40	0.571	0.66	10.12	0.10%
0	60	0.513	0.66	10.12	0.10%
0	80	0.465	0.66	10.11	0.00%
0	100	0.425	0.66	10.10	−0.10%

simulated errors would virtually affect any samples with certain probability. Results appear in Table 5. The results are quite interesting: when the recall of business name entity decreases, we observe statistically significant relevance degradation: if less entities are discovered, search relevance is hit. The experiments with simulated precision error, however, are less conclusive. One may note the experiments are conducted over the general test set. Therefore, it is not clear if the precision of the NER system really has insignificant impact on the IR relevance or just the impact is diluted in a larger test set.

6.4 Case Analysis

In this section, we take a close look at a few cases where our new semantic features help most and where they fail. For the query *silverado ranch in irving texas*, with no semantic features, the ranking function ranks a local listing page for this business, `http://local.yahoo.com/info-28646193`, as the top document. With semantic features, the ranking function ranks the business home page: `http://www.silveradoranchparties.com/` as top URL. Examining the two documents, the local listing page actually contains much more relevant anchor text, which are the among the most salient features in traditional ranking models. The home page, however, contains almost no relevant anchor text: for a small business home page, this is not a rare situation. Looking at the semantic features of these two pages, the highest resolution of location, the city name "Irving," appears in the document body text 19 times in the local listing page body text, and only 2 times in the home page body text. The training process learns, then, that for a query for a local business name (rather than a business category), home pages—even with fewer location terms in them—are likely to be more relevant than a local listing page that usually contain high frequency location terms.

In some cases, however, our new features do hurt performance. For the query *pa treasurers office*, the ranking function with no semantic features ranks the document `http://www.patreasury.org` highest, while the one with semantic features ranks the page `http://www.pikepa.org/treasurer.htm` higher. The latter page is somewhat relevant: it is a treasurer's office in Pennsylvania. However, it belongs to a specific county, which makes it less relevant than the former page. This is a classic error that we observe: a mismatch of the intended location area. While users are looking for state level business, we provide results of county level. To resolve this type of error, query analysis and semantic text matching are no longer enough: here, the ranking function needs to know that Pike County is a county in Pennsylvania, Milford is a city in Pike County, and neither are referred to by the user. Document-side entity recognition, however, may provide this type of information, helping to address this type of errors.

7 Conclusion and Future Research

In this paper, we investigate how semantic features can improve search relevance in a large-scale information retrieval setting; to our knowledge, it is the first study of this approach on a web scale. We present a set of features that incorporate semantic and vertical knowledge into the retrieval process, propose techniques to handle the sparseness problem for these features, and describe how they fit in the learning process. We demonstrate that these carefully designed features significantly improve relevance, particularly for difficult queries – long queries with multiple entities.

The work reported here focuses on query-side processing, avoiding the indexing cost of document processing. We are currently investigating document-side analysis to complement the query-side work, and believe that this will further boost the retrieval accuracy; we hope to report on this in a follow-up study.

Abstract

Inspired by the success of English grapheme-to-phoneme research in speech synthesis, many researchers have proposed phoneme-based English-to-Chinese transliteration models. However, such approaches have severely suffered from the errors in Chinese phoneme-to-grapheme conversion. To address this issue, we propose a new English-to-Chinese transliteration model and make systematic comparisons with the conventional models. Our proposed model relies on the joint use of Chinese phonemes and their corresponding English graphemes and phonemes. Experiments showed that Chinese phonemes in our proposed model can contribute to the performance improvement in English-to-Chinese transliteration.

1 Introduction

1.1 Motivation

Transliteration, i.e., *phonetic translation*, is commonly used to translate proper names and technical terms across languages. A variety of English-to-Chinese machine transliteration models has been proposed in the last decade (Meng et al., 2001; Gao et al., 2004; Jiang et al., 2007; Lee and Chang, 2003; Li et al., 2004; Li et al., 2007; Wan and Verspoor, 1998; Virga and Khudanpur, 2003). They can be categorized into those based on Chinese phonemes (Meng et al., 2001; Gao et al., 2004; Jiang et al., 2007; Lee and Chang, 2003; Wan and Verspoor, 1998; Virga and Khudanpur, 2003) and those that don't rely on Chinese phonemes (Li et al., 2004; Li et al., 2007).

Inspired by the success of English grapheme-to-phoneme research in speech synthesis, many researchers have proposed phoneme-based English-to-Chinese transliteration models. In these approaches, Chinese phonemes are generated from English graphemes or phonemes, and then the Chinese phonemes are converted into Chinese graphemes (or characters), where Chinese Pinyin strings[1] are used for representing a syllable-level Chinese phoneme sequence. Despite its high accuracy in generating Chinese phonemes from English, this approach has severely suffered from errors in Chinese phoneme-to-grapheme conversion, mainly caused by Chinese homophone confusion – one Chinese Pinyin string can correspond to several Chinese characters (Li et al., 2004). For example, the Pinyin string "LI" corresponds to such different Chinese characters as 利, 莉, and 里. For this reason, it has been reported that English-to-Chinese transliteration without Chinese phonemes outperforms that with Chinese phonemes (Li et al., 2004).

Then "Can Chinese phonemes improve English-to-Chinese transliteration, if we can reduce the errors in Chinese phoneme-to-grapheme conversion?" Our research starts from this question.

1.2 Our Approach

Previous approaches using Chinese phonemes have relied only on Chinese phonemes in Chinese phoneme-to-grapheme conversion. However, the simple use of Chinese phonemes doesn't always provide a good clue to reduce the ambiguity in Chinese phoneme-to-grapheme conversion. Let us explain with an example, the Chinese transliteration of *Greeley* in Table 1, where Chinese phonemes are represented in terms of Chinese Pinyin strings and English phonemes are represented by *ARPAbet* symbols[2].

In Table 1, Chinese Pinyin string "LI" corresponds to two different Chinese characters, 里 and

[1] Pinyin, the most commonly used Romanization system for Chinese characters, faithfully represents Chinese

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 658–667,
Singapore, 6-7 August 2009.

Table 1: Chinese Pinyin string "LI" and its corresponding Chinese characters in Chinese transliteration of *Greeley*

English grapheme	*g*	*ree*	*ley*
English phoneme	G	R IY	L IY
Chinese Pinyin	GE	LI	LI
Chinese character	格	里	利

利. It seems difficult to find evidence for selecting the correct Chinese character corresponding to each Chinese Pinyin string "LI" by just looking at the sequence of Chinese Pinyin strings "GE LI LI." However, English graphemes (*ree* and *ley*) or phonemes ("R IY" and "L IY") corresponding to Chinese Pinyin string "LI", especially their consonant parts (*r* and *l* in the English graphemes and "R" and "L" in the English phonemes), provide strong evidence to resolve the ambiguity. Thus, we can easily find rules for the conversion from Chinese Pinyin string "LI" to 里 and 利 as follows:

- ⟨ "R IY", LI ⟩ → 里
- ⟨ "L IY", LI ⟩ → 利

Based on the observation, we propose an English-to-Chinese transliteration model based on the joint use of Chinese phonemes and their corresponding English graphemes and phonemes. We define a set of English-to-Chinese transliteration models and categorize them into the following three classes:

- $\mathbf{M_I}$: **M**odels **I**ndependent of Chinese phonemes
- $\mathbf{M_S}$: **M**odels based on **S**imple use of Chinese phonemes
- $\mathbf{M_J}$: **M**odels based on **J**oint use of Chinese phonemes and English graphemes and phonemes that correspond to our proposed model.

Our comparison among the three types of transliteration models can be summarized as follows.

- The $\mathbf{M_I}$ models relying on either English graphemes or phonemes could not outperform those based on both English graphemes and phonemes.
- The $\mathbf{M_S}$ models always showed the worst performance due to the severe error rate in Chinese phoneme-to-grapheme conversion.
- The $\mathbf{M_J}$ models significantly reduced errors in Chinese phoneme-to-grapheme conversion; thus they achieved the best performance.

The rest of this paper is organized as follows. Section 2 introduces the notations used throughout this paper. Section 3 describes the transliteration models we compared. Section 4 describes our tests and results. Section 5 concludes the paper with a summary.

2 Preliminaries

Let E_G be an English word composed of *n* English graphemes, and let E_P be a sequence of English phonemes that represents the pronunciation of E_G. Let C_G be a sequence of Chinese graphemes corresponding to the Chinese transliteration of E_G, and let C_P be a sequence of Chinese phonemes that represents the pronunciation of C_G.

C_P corresponds to a sequence of the Chinese Pinyin strings of C_G. Because a Chinese Pinyin string represents the pronunciation of a syllable consisting of consonants and vowels, we divide a Chinese Pinyin string into consonant and vowel parts like "L+I", "L+I+N", and "SH+A." In this paper, we define a *Chinese phoneme* as the vowel and consonant parts in a Chinese Pinyin string (e.g., "L", "SH", and "I"). A Chinese character usually corresponds to multiple English graphemes, English phonemes, and Chinese phonemes (i.e., 里 corresponds to English graphemes *ree*, English phonemes "R IY", and Chinese phonemes "L I" in Table 1). To represent these many-to-one correspondences, we use the well-known BIO labeling scheme to represent a Chinese character, where B and I represent the beginning and inside/end of the Chinese characters, respectively, and O is not used. Each Chinese phoneme corresponds to a Chinese character with B and I labels. For example, Chinese character "里" in Table 1 can be represented as "里:B" and "里:I", where "里:B" and "里:I" correspond to Chinese phonemes "L" and "I", respectively. In this paper, we define a *Chinese grapheme* as a Chinese character represented with a BIO label, e.g., "里:B" and "里:I."

phonemes and syllables (Yin and Felley, 1990).

[2] `http://www.cs.cmu.edu/~laura/pages/arpabet.ps`

Table 2: eg_i and its corresponding ep_i, cp_i, and cg_i in *Greeley* and its corresponding Chinese transliteration "格里利"

i	1	2	3	4	5	6	7
E_G	*g*	*r*	*e*	*e*	*l*	*e*	*y*
E_P	G	R	IY	ϕ	L	IY	ϕ
C_P	GE	L	I	ϕ	L	I	ϕ
	GE	LI		ϕ	LI		ϕ
C_G	格:B	里:B	里:I	ϕ	利:B	利:I	ϕ
	格	里		ϕ	利		ϕ

Then E_P, C_P, and C_G can be segmented into a series of sub-strings, each of which corresponds to an English grapheme in E_G. We can thus write

- $E_G = eg_1, \cdots, eg_n = eg_1^n$
- $E_P = ep_1, \cdots, ep_n = ep_1^n$
- $C_P = cp_1, \cdots, cp_n = cp_1^n$
- $C_G = cg_1, \cdots, cg_n = cg_1^n$

where eg_i, ep_i, cp_i, and cg_i represent the i^{th} English grapheme, English phonemes, Chinese phonemes, and Chinese graphemes corresponding to eg_i, respectively.

Based on the definition, we model English-to-Chinese transliteration so that each English grapheme is tagged with its corresponding English phonemes, Chinese phonemes, and Chinese graphemes. Table 2 illustrates eg_i, ep_i, cp_i, and cg_i with the same example listed in Table 1 (English word *Greeley* and its corresponding Chinese transliteration "格里利")[3], where ϕ represents an empty string.

3 Transliteration Model

We defined eighteen transliteration models to be compared. These transliteration models are classified into three classes, $\mathbf{M_I}$, $\mathbf{M_S}$, and $\mathbf{M_J}$ as described in Section 1.2; each class has three basic transliteration models and three hybrid ones. In this section, we first describe the basic transliteration models in each class by focusing on the main difference among the three classes and then describe the hybrid transliteration models.

[3]We performed alignment between E_G and E_P and between E_P and C_P in a similar manner presented in Li et al. (2004). Then the two alignment results were merged using E_P as a pivot. Finally, we made a correspondence relation among eg_i, ep_i, cp_i, and cg_i using the merged alignment result and the Pinyin table.

3.1 Basic Transliteration Models

The basic transliteration models in each class are denoted as $M(x, y)$.

- $(x, y) \in X \times Y$
- $x \in X = \{E_G, E_P, E_{GP}\}$
- $y \in Y = \{\phi, C_P, JC_P\}$

x is an English-side parameter representing English grapheme (E_G), English phoneme (E_P), and the joint use of English grapheme and phoneme ($E_{GP} = \langle E_G, E_P \rangle$) that contributes to generating Chinese phonemes or Chinese graphemes in a transliteration model. y is a Chinese-phoneme parameter that represents a way of using Chinese phonemes to generate Chinese graphemes in a transliteration model. Since $M(x, \phi)$ represents a transliteration model that does not rely on Chinese phonemes, it falls into $\mathbf{M_I}$, while $M(x, C_P)$ corresponds to a transliteration model in $\mathbf{M_S}$ that only uses Chinese phonemes in Chinese phoneme-to-grapheme conversion. $M(x, JC_P)$ is a transliteration model in the $\mathbf{M_J}$ class that generates Chinese transliterations based on joint use of x and Chinese phoneme C_P, where $x \in X$. Thus, $M(x, JC_P)$ can be rewritten as $M(x, \langle x, C_P \rangle)$, where the joint representation of x and C_P, $\langle x, C_P \rangle$, is used in Chinese phoneme-to-grapheme conversion. The three basic models in $\mathbf{M_J}$ can be interpreted as follows:

- $M(E_G, JC_P) = M(E_G, \langle E_G, C_P \rangle)$
- $M(E_P, JC_P) = M(E_P, \langle E_P, C_P \rangle)$
- $M(E_{GP}, JC_P) = M(E_{GP}, \langle E_{GP}, C_P \rangle)$

$M(E_G, JC_P)$ directly converts English graphemes into Chinese phonemes without the help of English phonemes and then generates Chinese transliterations based on the joint representation of English graphemes and Chinese phonemes. The main difference between $M(E_P, JC_P)$ and $M(E_{GP}, JC_P)$ lies in the use of English graphemes to generate Chinese phonemes and graphemes. English graphemes are only used in English grapheme-to-phoneme conversion, and English phonemes play a crucial role for generating Chinese transliteration in $M(E_P, JC_P)$. Chinese phoneme-to-grapheme conversion that relies on the joint use of English graphemes, English phonemes, and Chinese

$$P_{M(E_G,JC_P)}(C_G|E_G) = \sum_{\forall C_P} P(C_P|E_G) \times P(C_G|E_G, C_P) \quad (1)$$

$$P_{M(E_P,JC_P)}(C_G|E_G) = \sum_{\forall C_P} \sum_{\forall E_P} P(E_P|E_G) \times P(C_P|E_P) \times P(C_G|E_P, C_P) \quad (2)$$

$$P_{M(E_{GP},JC_P)}(C_G|E_G) = \sum_{\forall C_P} \sum_{\forall E_P} P(E_P|E_G) \times P(C_P|E_G, E_P) \times P(C_G|E_G, E_P, C_P) \quad (3)$$

$$P_{M(E_G,C_P)}(C_G|E_G) = \sum_{\forall C_P} P(C_P|E_G) \times P(C_G|C_P) \quad (4)$$

$$P_{M(E_P,C_P)}(C_G|E_G) = \sum_{\forall C_P} \sum_{\forall E_P} P(E_P|E_G) \times P(C_P|E_P) \times P(C_G|C_P) \quad (5)$$

$$P_{M(E_{GP},C_P)}(C_G|E_G) = \sum_{\forall C_P} \sum_{\forall E_P} P(E_P|E_G) \times P(C_P|E_G, E_P) \times P(C_G|C_P) \quad (6)$$

phonemes is the key feature of $M(E_{GP}, JC_P)$. Because $M(x, JC_P)$ can be interpreted as $M(x, \langle x, C_P\rangle)$, English-side parameter x determines the English graphemes and phonemes, or both jointly used with Chinese phonemes in Chinese phoneme-to-grapheme conversion. Then we can represent the three basic transliteration models as in Eqs. (1)–(3), where $P(C_G|E_G, C_P)$, $P(C_G|E_P, C_P)$, and $P(C_G|E_G, E_P, C_P)$ are the key points in our proposed models, $\mathbf{M_J}$.

The three basic transliteration models in $\mathbf{M_S}$ – $M(E_G, C_P)$, $M(E_P, C_P)$, and $M(E_{GP}, C_P)$ – are formulated as Eqs. (4)–(6). Chinese phoneme-based transliteration models in the literature fall into either $M(E_G, C_P)$ or $M(E_P, C_P)$ (Meng et al., 2001; Gao et al., 2004; Jiang et al., 2007; Lee and Chang, 2003; Wan and Verspoor, 1998; Virga and Khudanpur, 2003). The three basic transliteration models in $\mathbf{M_S}$ are identical as those in $\mathbf{M_J}$, except for the Chinese phoneme-to-grapheme conversion method. They only depend on Chinese phonemes in Chinese phoneme-to-grapheme conversion represented as $P(C_G|C_P)$ in Eqs. (4)–(6).

$$P_{M(E_G,\phi)}(C_G|E_G) = P(C_G|E_G) \quad (7)$$

$$P_{M(E_P,\phi)}(C_G|E_G) = \sum_{\forall E_P} P(E_P|E_G) \times P(C_G|E_P) \quad (8)$$

$$P_{M(E_{GP},\phi)}(C_G|E_G) = \sum_{\forall E_P} P(E_P|E_G) \times P(C_G|E_G, E_P) \quad (9)$$

The three basic transliteration models in $\mathbf{M_I}$ are represented in Eqs. (7)–(9). Because the $\mathbf{M_I}$ models are independent of Chinese phonemes, they are the same as the transliteration models in the literature used for machine transliteration from English to other languages without relying on target-language phonemes (Karimi et al., 2007; Malik, 2006; Oh et al., 2006; Sherif and Kondrak, 2007; Yoon et al., 2007). Note that $M(E_G, \phi)$ is the same transliteration model as the one proposed by Li et al. (2004).

3.2 Hybrid Transliteration Models

The hybrid transliteration models in each class are defined by discrete mixture between the probability distribution of the two basic transliteration models, as in Eq. (10) (Al-Onaizan and Knight, 2002; Oh et al., 2006), where $0 < \alpha < 1$. We denote a hybrid transliteration model between two basic transliteration models $M(x_1, y)$ and $M(x_2, y)$ as $M(x_1 + x_2, y, \alpha)$, where $y \in Y = \{\phi, C_P, JC_P\}$, $x_1 \neq x_2$, and $x_1, x_2 \in X = \{E_G, E_P, E_{GP}\}$. In this paper, we define three types of hybrid transliteration models in each class: $M(E_G + E_P, y, \alpha)$, $M(E_G + E_{GP}, y, \alpha)$, and $M(E_P + E_{GP}, y, \alpha)$.

$$P_{M(x_1+x_2,y,\alpha)}(C_G|E_G) = \alpha \times P_{M(x_1,y)}(C_G|E_G) + (1-\alpha) \times P_{M(x_2,y)}(C_G|E_G) \quad (10)$$

3.3 Probability Estimation

Because Eqs. (1)–(9) can be estimated in a similar way, we limit our focus to Eq. (3) in this section. Assuming that $P(E_P|E_G)$, $P(C_P|E_G, E_P)$, and $P(C_G|E_G, E_P, C_P)$ in Eq. (3) depend on the size of the context window, k ($k = 3$ in this paper),

Table 3: Feature functions for $P(cg_i|cg_{i-k}^{i-1}, \langle eg, ep, cp\rangle_{i-k}^{i+k})$ with an example in Table 2, where $i = 2$

f_1	$gram_3(eg_i)$	eg_i^{i+2} = "ree"	cg_i = "里:B"
f_2	$pair_{11}(cp_{i-1}, cg_{i-1})$	cp_{i-1} = "G", cg_{i-1} = "格:B"	cg_i = "里:B"
f_3	$pair_{12}(cg_{i-1}, cp_{i-1})$	cp_{i-1}^i = "GE L", cg_{i-1}= "格:B"	cg_i = "里:B"
f_4	$pair_{22}(cp_{i-1}, cg_{i-2})$	eg_{i-1}^i = "gr", ep_{i-1}^i = "G R"	cg_i = "里:B"
f_5	$triple_1(eg_i, cp_i, cg_{i-1})$	eg_i = "r", cp_{i-1} = "GE", cg_{i-1}= "格:B"	cg_i = "里:B"
f_6	$triple_2(eg_{i-1}, cg_{i-1}, cp_{i-1})$	eg_{i-1} = "g", cp_{i-1}^i= "GE L", cg_{i-1}= "格:B"	cg_i = "里:B"

they can be simplified into a series of products in Eqs. (11)–(13).

The maximum entropy model is used to estimate the probabilities in Eqs. (11)–(13) (Berger et al., 1996). Generally, a conditional maximum entropy model is an exponential model that gives the conditional probability, as described in Eq. (14), where λ_i is the parameter to be estimated and $f_i(a, b)$ is a feature function corresponding to λ_i (Berger et al., 1996; Ratnaparkhi, 1997):

$$P(E_P|E_G) \approx \prod_i P(ep_i|ep_{i-k}^{i-1}, eg_{i-k}^{i+k}) \quad (11)$$

$$P(C_P|E_G, E_P) \quad (12)$$
$$\approx \prod_i P(cp_i|cp_{i-k}^{i-1}, \langle eg, ep\rangle_{i-k}^{i+k})$$

$$P(C_G|E_G, E_P, C_P) \quad (13)$$
$$\approx \prod_i P(cg_i|cg_{i-k}^{i-1}, \langle eg, ep, cp\rangle_{i-k}^{i+k})$$

$$P(b|a) = \frac{exp(\sum_i \lambda_i f_i(a, b))}{\sum_{b'} exp(\sum_i \lambda_i f_i(a, b'))} \quad (14)$$

$f_i(a, b)$ is a binary function returning TRUE or FALSE based on context a and output b. If $f_i(a, b)$=1, its corresponding model parameter λ_i contributes toward conditional probability $P(b|a)$ (Berger et al., 1996; Ratnaparkhi, 1997). The feature functions used here are defined in terms of context predicates — a function returning TRUE or FALSE that depends on the presence of the information in the current context (Ratnaparkhi, 1997). Context predicates and their descriptions used are given in Table 4.

N-GRAM includes $gram_1(u_j)$, $gram_2(u_j)$, and $gram_3(u_j)$ corresponding to a unigram, a bigram, and a trigram, respectively. PAIR includes a pair of unigrams ($pair_{11}$), unigram and bigram ($pair_{12}$), and bigrams ($pair_{22}$). TRIPLE includes a triple of three unigrams ($triple_1$) and a triple of two unigrams and one bigram ($triple_2$). Note that if different context predicates represent the same context, we accept one of them and ignore the others

Table 4: Context predicates and their descriptions

Category	Context predicates	Description
N-GRAM	$gram_1(u_j)$	u_j
	$gram_2(u_j)$	u_j^{j+1}
	$gram_3(u_j)$	u_j^{j+2}
PAIR	$pair_{11}(u_j, v_k)$	u_j, v_k
	$pair_{12}(u_j, v_k)$	u_j, v_k^{k+1}
	$pair_{22}(u_j, v_k)$	u_j^{j+1}, v_k^{k+1}
TRIPLE	$triple_1(u_j, v_k, w_l)$	u_j, v_k, w_l
	$triple_2(u_j, v_k, w_l)$	u_j, v_k, w_l^{l+1}

(e.g., $pair_{12}(u_j, u_{j+1}) = trigram(u_j) = u_j^{j+2}$). Table 3 represents the examples of feature functions for $P(cg_i|cg_{i-k}^{i-1}, \langle eg, ep, cp\rangle_{i-k}^{i+k})$.

We used the "Maximum Entropy Modeling Toolkit"[4] to estimate the probabilities and the LBFGS algorithm to find λ_i in Eq. (14). For each transliteration model, we produced n-best transliterations using a stack decoder (Schwartz and Chow, 1990).

3.4 Summary

In this paper, we defined eighteen transliteration models to be compared. There are six transliteration models, three basic and three hybrid ones, in each class, $\mathbf{M_I}$, $\mathbf{M_S}$, and $\mathbf{M_J}$. We compared the transliteration models from the viewpoint of Chinese phonemes or the class of transliteration models in our experiments.

4 Testing and Results

We used the same test set used in Li et al. (2004) for our testing[5]. It contains 37,694 pairs of English words and their official Chinese transliterations

[4]Available at `http://homepages.inf.ed.ac.uk/s0450736/maxent_toolkit.html`

[5]This test set was also used in "NEWS09 machine transliteration shared task" for English-to-Chinese transliteration (Li et al., 2009)

extracted from the "Chinese Transliteration of Foreign Personal Names" (Xinhua News Agency, 1992), which includes names in English, French, German, and many other foreign languages (Li et al., 2004). We used the same test data as in Li et al. (2004). But we randomly selected 90% of the training data used in Li et al. (2004) as our training data and the remainder as the development data, as shown in Table 5.

Table 5: Number of English-Chinese transliteration pairs in each data set

	Ours	Li et al. (2004)
Training data	31,299	34,777
Development data	3,478	N/A
Blind test data	2,896	2,896

We used the training data for training the transliteration models. For each model, we tuned the parameters including the number of iterations for training the maximum entropy model and a Gaussian prior for smoothing the maximum entropy model using the development data. Further, the development data was used to select parameter α of the hybrid transliteration models. We varied parameter α from 0 to 1 in 0.1 intervals (i.e., α=0, 0.1, 0.2, $\cdots$,1) and tested the performance of the hybrid models with the development data. Then we chose α that showed the best performance in each hybrid model. The blind test data was used for evaluating the performance of each transliteration model. *The CMU Pronouncing Dictionary*[6], which contains about 120,000 English words and their pronunciations, was used for estimating $P(E_P|E_G)$.

We conducted two experiments. First, we compared the overall performance of the transliteration models. Second, we investigated the effect of training data size on the performance of each transliteration model.

The evaluation was done for word accuracy in top-1 (ACC), Chinese pronunciation accuracy (CPA) and a mean reciprocal rank (MRR) metric (Kantor and Voorhees, 2000; Li et al., 2009; Chang et al., 2009). ACC measures how many correct transliterations appeared in the top-1 result of each system. CPA measures the Chinese pronunciation accuracy in the top-1 of the n-best Chinese pronunciation. We used CPA for comparing the performance between systems based on Chinese phonemes. MRR, mean reciprocal ranks of n-best results of each system over the test entries, is an evaluation measure for n-best transliterations. If a transliteration generated by a system matches a reference transliteration[7] at the r^{th} position of the n-best results, its reciprocal rank equals $1/r$; otherwise its reciprocal rank equals 0, where $1 \leq r \leq n$. We produced 10-best Chinese transliterations for each English word in our experiments.

4.1 Comparison of the Overall Performance

Table 6 represents the overall performance of one system in a previous work (Li et al., 2004) and eighteen systems based on the transliteration models defined in this paper. ACC, MRR, and CPA represent the evaluation results for each model trained by our training data. To test transliteration models without the errors introduced by incorrect Chinese phonemes, we carried out the experiments with the correct Chinese pronunciation (or the correct Chinese phoneme sequence) in Chinese phoneme-to-grapheme conversion. In the experiment, we put the correct Chinese pronunciation into the top-1 of the n-best Chinese pronunciation with the highest probability, say $P(C_P|E_G)$=1; thus CPA was assumed to be 100%. The ACC of the transliteration models under this condition is denoted as ACC' in Table 6. TRAIN represents the evaluation results of the transliteration models trained by our training data. To compare Li et al. (2004) and transliteration models defined in this paper under the same condition, we also carried out experiments with the same training data in Li et al. (2004). Since the training data used in Li et al. (2004) is identical as the union of our training and development data, we denoted it as TRAIN+DEV in Table 6. In both TRAIN and TRAIN+DEV, we used the same parameter setting that was obtained by using the development data.

LI04 represents a system in Li et al. (2004), and its ACC' in TRAIN+DEV is taken from the literature. The systems based on the transliteration models defined in our paper are represented from the second row in Table 6. The phoneme-based transliteration models in the literature correspond to either $M(E_G, C_P)$ (Wan and Verspoor, 1998; Lee and Chang, 2003; Jiang et al., 2007) or $M(E_P, C_P)$ (Meng et al., 2001; Gao et al., 2004;

[6]Available at `http://www.speech.cs.cmu.edu/cgi-bin/cmudict`

[7]In our test set, an English word corresponds to one reference Chinese transliteration.

Table 6: Comparison of the overall performance

Virga and Khudanpur, 2003).

A comparison between the basic and hybrid transliteration models showed that the hybrid ones usually performed better (the exception was $M(E_P{+}E_{GP}, y, \alpha)$ but the performance still comparable to the basic ones in each class). Especially, the hybrid ones based on the best two basic transliteration models, $M(E_G{+}E_{GP}, y, \alpha)$, showed the best performance.

A comparison among the $\mathbf{M_I}$, $\mathbf{M_S}$, and $\mathbf{M_J}$ models showed that Chinese phonemes did contribute to the performance improvement of English-to-Chinese transliteration when Chinese phonemes were used together with their corresponding English graphemes and phonemes in Chinese phoneme-to-grapheme conversion. A one-tail paired t-test between the $\mathbf{M_I}$ and $\mathbf{M_J}$ models showed that the results of the $\mathbf{M_J}$ models were always significantly better than those of the $\mathbf{M_I}$ models if the $\mathbf{M_I}$ and $\mathbf{M_J}$ models shared the same English-side parameter, $x \in \{E_G, E_P, E_{GP}\}$ (level of significance = 0.001). In the results obtained by the $\mathbf{M_S}$ and $\mathbf{M_J}$ models, the figures in CPA are the same when the $\mathbf{M_S}$ and our $\mathbf{M_J}$ models share the same English-side parameter. Moreover, the difference between the figures in ACC and CPA can be interpreted as the error rate of Chinese phoneme-to-grapheme conversion. Our proposed $\mathbf{M_J}$ models generated Chinese transliterations with a very low error rate in Chinese phoneme-to-grapheme conversion, while the $\mathbf{M_S}$ models suffered from a significant error rate in Chinese phoneme-to-grapheme conversion. ACC' showed that the $\mathbf{M_J}$ models still outperformed the $\mathbf{M_S}$ models even without errors in generating Chinese pronunciation from the English words. These results indicate that the joint use of Chinese phonemes and their corresponding English graphemes and phonemes significantly improved the performance in Chinese phoneme-to-grapheme conversion and English-to-Chinese transliteration.

Table 7 shows the Chinese transliterations generated by $M(E_G, \phi)$, $M(E_{GP}, \phi)$, $M(E_G, JC_P)$, and $M(E_{GP}, JC_P)$ where English or Chinese phonemes contributed to the correct transliteration. In this table, the first column show the English words and their English phonemes, and the second and third columns represent the Chinese transliterations and their phonemes. Note that the Chinese phonemes in the second and third columns of the $\mathbf{M_I}$ models are not used in transliteration. They are shown in the table to indicate the difference in the Chinese phonemes of Chinese

transliterations between the $\mathbf{M_I}$ and $\mathbf{M_J}$ models.

For *Emily* and *Reinhardt*, the $\mathbf{M_J}$ models generated correct Chinese transliterations, but the $\mathbf{M_I}$ models did not. Figure 1 shows the probability distribution when a transliteration model generates the first Chinese character in the Chinese transliteration of *Reinhardt* with and without Chinese phonemes. Two Chinese characters, 赖 and 莱, were strong candidates and 莱 is the correct one in this case. Without Chinese phonemes, $M(E_G, \phi)$, which is based on P(cg|$Reinhardt$) in Figure 1(a) preferring 赖 to 莱, generated the incorrect transliteration as shown in Table 7. However, Figure 1(b) shows that 莱 can be selected if the correct Chinese phoneme sequence "LAI YIN ..." is given. Three Chinese phoneme sequences starting with "LAI YIN ...", "LAI NA ...", and "LAI NEI ..." were generated from *Reinhardt*, where "LAI YIN ..." was the best Chinese phoneme sequence based on the probability distribution in Figure 1(c). As a result, $M(E_G, JC_P)$, which jointly used Chinese phonemes with English graphemes, generated the correct Chinese transliteration of *Reinhardt* based on two probability distribution in Figures 1(b) and 1(c). In the case of *Ivy*, English phonemes contributed to generating the correct transliteration in the $M(E_{GP}, \phi)$ and $M(E_{GP}, JC_P)$ models.

Chinese transliterations sometimes reflect the English word's pronunciation as well as the Chinese character's meaning (Li et al., 2007). Li et al. (2007) defined such a Chinese transliteration as a phonetic-semantic transliteration (semantic transliteration) to distinguish it from a usual phonetic transliteration. One fact that affects semantic transliteration is gender association (Li et al., 2007). For example, 莉 (meaning *jasmine*) is frequently used in Chinese transliterations of female names but seldom in common person names. Because *Emily* is often used in female names, the results obtained by the $M(E_G, JC_P)$ and $M(E_{GP}, JC_P)$ models are acceptable. This indicates that Chinese phonemes coupled with English graphemes or those coupled with English graphemes and phonemes could provide evidence required for semantic transliteration as well as phonetic transliteration. As a result, $M(E_{GP}, \phi)$, $M(E_G, JC_P)$,

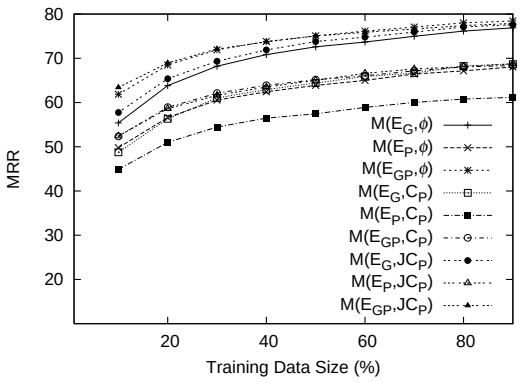
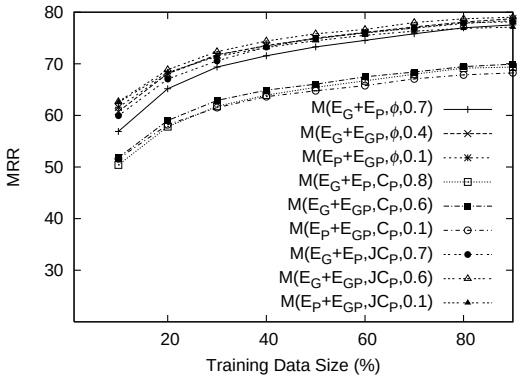
Figure 1: Probability distribution for the first Chinese character in the Chinese transliteration of *Reinhardt*: $M(E_G, \phi)$ vs. $M(E_G, JC_P)$

and $M(E_{GP}, JC_P)$, which used phonemes coupled with English graphemes, achieved higher performance than $M(E_G, \phi)$, which relied only on English graphemes.

4.2 Effect of Training Data Size



(a) Basic transliteration models



(b) Hybrid transliteration models

Figure 2: Performance of each system with different training data size

We investigated the effect of training data size on the performance of each transliteration model. We randomly selected training data with ratios from 10 to 90% and compared the performance of each system trained by different sizes of training data. The results for the basic transliteration models in Figure 2(a) can be categorized into three groups. $M(E_{GP}, \phi)$ and $M(E_{GP}, JC_P)$ fall into the best group, where they showed the best performance regardless of training data size. $M(E_G, \phi)$ and $M(E_G, JC_P)$ belong to the middle group, where they showed lower performance than the best group if the training data size is small, but their performance is comparable to the best group if the size of the training data is large enough. The others always showed lower performance than both the best and middle groups. Figure 2(b) shows that hybrid transliteration models, on average, were less sensitive to the training data size than the basic ones, because the two different basic transliteration models used in the hybrid ones boosted transliteration performance by complementing each other's weak points.

5 Conclusion

We proposed a new English-to-Chinese transliteration model based on Chinese phonemes and their corresponding English graphemes and phonemes. We defined eighteen English-to-Chinese transliteration models including our proposed model and classified them into three classes based on the role of Chinese phonemes in the transliteration models. Experiments showed that Chinese phonemes in our proposed model can contribute to the performance improvement in English-to-Chinese transliteration.

Now we can answer *Yes* to this paper's key question, "Can Chinese phonemes improve machine transliteration?" Actually, this is the second time the same question has been answered. The previous answer, which was unfortunately reported as *No* by Li et al. (2004), has been accepted as true for the last five years; the research issue has been considered closed. In this paper, we found a new answer that contradicts the previous answer. We hope that our answer promotes research on phoneme-based English-to-Chinese transliteration.

Abstract

Many approaches to unsupervised morphology acquisition incorporate the frequency of character sequences with respect to each other to identify word stems and affixes. This typically involves heuristic search procedures and calibrating multiple arbitrary thresholds. We present a simple approach that uses no thresholds other than those involved in standard application of χ^2 significance testing. A key part of our approach is using document boundaries to constrain generation of candidate stems and affixes and clustering morphological variants of a given word stem. We evaluate our model on English and the Mayan language Uspanteko; it compares favorably to two benchmark systems which use considerably more complex strategies and rely more on experimentally chosen threshold values.

1 Introduction

Unsupervised morphology acquisition attempts to learn from raw corpora one or more of the following about the *written* morphology of a language: (1) the segmentation of the set of word types in a corpus (Creutz and Lagus, 2007), (2) the clustering of word types in a corpus based on some notion of morphological relatedness (Schone and Jurafsky, 2000), (3) the generation of out-of-vocabulary items which are morphologically related to other word types in the corpus (Yarowsky et al., 2001).

We take a novel approach to segmenting words and clustering morphologically related words. The approach uses no parameters that need to be tuned on data. The two main ideas of the approach are (a) the filtering of affixes by significant co-occurrence, and (b) the integration of knowledge of document boundaries when generating candidate stems and affixes and when clustering morphologically related words. The main application that we envision for our approach is to produce interlinearized glossed texts for under-resourced/endangered languages (Palmer et al., 2009). Thus, we strive to eliminate hand-tuned parameters to enable documentary linguists to use our model as a preprocessing step for their manual analysis of stems and affixes. To require a documentary linguist–who is likely to have little to no knowledge of NLP methods–to tune parameters is unfeasible. Additionally, data-driven exploration of parameter settings is unlikely to be reliable in language documentation since datasets typically are quite small. To be relevant in this context, a model needs to produce useful results out of the box.

Constraining learning by using document boundaries has been used quite effectively in unsupervised word sense disambiguation (Yarowsky, 1995). Many applications in information retrieval are built on the statistical correlation between documents and terms. However, we are unaware of cases where knowledge of document boundaries has been used for unsupervised learning for morphology. The intuition behind our approach is very simple: if two words in a single document are very similar in terms of orthography, then the two words are likely to be related morphologically. We measure how integrating these assumptions into our model at different stages affects performance.

We define a simple pipeline model. After generating candidate stems and affixes (possibly constrained by document boundaries), a χ^2 test based on global corpus counts filters out unlikely affixes. Mutually consistent affix pairs are then clustered to form affix groups. These in turn are used to build morphologically related word clusters, possibly constrained by evidence from co-occurence of word forms in documents. Following Schone and Jurafsky (2000), clusters are evaluated for

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 668–677,
Singapore, 6-7 August 2009.

whether they capture inflectional paradigms using CELEX (Baayen et al., 1993).

We are unaware of other work on morphology using χ^2 tests despite its wide application across many disciplines.[1] This may be due to the large degree of noise found in the candidate affix sets induced through other candidate generation methods. The χ^2 test has two standard thresholds–a significance threshold and a lower bound on observed counts. These are the only manually set parameters we require—and we in fact use the widely accepted standard values for these thresholds without varying them in our experiments. This is a significant improvement over other approaches that typically require a number of arbitrary thresholds and parameters yet provide little intuitive justification for them. (We give examples of these in §3.)

We evaluate our approach on two languages, English and Uspanteko, and compare its performance to two benchmark systems, Morfessor (Creutz and Lagus, 2007) and Linguistica (Goldsmith, 2001). English is commonly used in other studies and permits the use of CELEX as a gold standard for evaluation. Uspanteko is an endangered Mayan language for which we have a set of interlinearized glossed texts (IGT) (Pixabaj et al., 2007; Palmer et al., 2009). IGT provides word-by-word morpheme segmenation, which we use to create a synthetic gold standard. In addition to evaluation against this standard, Telma Kaan Pixabaj—a Mayan linguist who helped create the annotated corpus—reviewed by hand 100 word clusters produced by our system, Morfessor and Linguistica. Note that because English is suffixal and Uspanteko is both prefixal and suffixal, we use a slightly modified model for Uspanteko.

The approach introduced in this paper compares favorably to Linguistica and Morfessor, two models that employ much more complex strategies and rely on experimentally-tuned language/corpus-specific parameters. In our evaluation, document boundary awareness greatly benefits precision for small datasets, blocking acquisition of spurious affixes. For large datasets, global candidate generation outperforms document-aware candidate generation at the task of filtering out spurious stems, but document-aware clustering improves precision. These findings are promising for the application of this approach to under-resourced languages like Uspanteko.

[1] Monson (2004) suggests, but does not actually use, χ^2.

2 Unsupervised morphology acquisition

Unsupervised morphology acquisition aims to model one or more of three properties of *written* morphology: segmentation, clustering around a common stem, and generation of new word forms with productive affixes. Intuitively, there are straightforward, but non-trivial, challenges that arise when evaluating a model. One large challenge is distinguishing derivational from inflectional morphology. Most approaches deal with tokens without considering context. Since inflectional morphology is virtually always driven by syntax and word context, such approaches are unable to learn only inflectional morphology or only derivational morphology. Even approaches which take context into consideration (Schone and Jurafsky, 2000; Baroni et al., 2002; Freitag, 2005) cannot learn specifically for one or the other.

In addition, the evaluation of both segmentation and clustering involves arbitrary judgment calls. Concerning segmentation, should *altimeter* and *altitude* be one morpheme or two? (The sample English gold standard for MorphoChallenge 2009 provides *alti+meter* but *altitude*.) Similar issues arise when evaluating clusters of related word forms if inflection and derivation are not distinguished. Does *atheism* belong to the same cluster as *theism*? Where is the frequency cutoff point between a productive derivational morpheme and an unproductive one? Yet, many studies have evaluated their segmentations and clusters by going over their results word by word, cluster by cluster and judging by sight whether some segmentation or clustering is good (e.g., Goldsmith (2001)).

Like Schone and Jurafsky (2001), we build clusters that will have both inflectionally and derivationally related stems and evaluate them with respect to a gold standard of *only* inflectionally related stems.

3 Related work

There is a diverse body of existing work on unsupervised morphology acquisition. We summarize previous work, emphasizing some of its more arbitrary and *ad hoc* aspects.

Letter successor variety. Letter successor variety (LSV) models (Hafer and Weiss, 1974; Gaussier, 1999; Bernhard, 2005; Bordag, 2005;

Keshava and Pitler, 2005; Hammarström, 2006; Dasgupta and Ng, 2007; Demberg, 2007) use the hypothesis that there is less certainty when predicting the next character at morpheme boundaries. LSV has several issues that require fine parameter tuning. For example, Hafer and Weiss (1974) counts how many types of characters appear after some initial string (the *successor* count) and how many types of characters appear before some final string (the *predecessor* count). A successful criterion for segmenting a word was if the predecessor count for the second part was greater than 17 and the successor count for the first part was greater than 5. Other studies have similar data specific parameters and restrictions.

MDL and Bayesian models. Minimum description length (MDL) models (Goldsmith, 2001; Creutz and Lagus, 2002; Creutz and Lagus, 2004; Goldsmith, 2006; Creutz and Lagus, 2007) try to segment words by maximizing the probability of a training corpus subject to a penalty based on the size of hypothesized morpheme lexicons they build on the basis of the segmentations. While theoretically elegant, a pure implementation on real data results in descriptions that do not reflect actual morphology. Creutz and Lagus (2005) report that, "frequent word forms remain unsplit, whereas rare word forms are excessively split." In the end, every MDL approach uses probabilistically motivated refinements that restrict the tendency of raw MDL to generate descriptions that do not fit linguistic notions of morphology. Despite the sophistication of the models in this group, there are many parameters that need to be set, and heuristic search procedures are crucial for their success (Goldwater, 2007). Snover et al. (2002) present a Bayesian model that uses a prior distribution to refine disjoint clusters of morphologically related words. It disposes with parameter setting by selecting the highest ranking hypothesis.

Context aware approaches. A word's morphology is strongly influenced by its syntactic and semantic context. Schone and Jurafsky (2000) attempts to cluster morphologically related words starting with an unrefined trie search (but with a parameter of minimum possible stem length and an upper bound on potential affix candidates) that is constrained by semantic similarity in a word context vector space. Schone and Jurafsky (2001) builds on this approach, but adds more *ad hoc* parameters to handle circumfixation. Baroni et al. (2002) takes a similar approach but uses edit distance to cluster words that are similar but do not necessarily share a long, contiguous substring. They remove noise by constraining cluster membership with mutual information derived semantic similarity. Freitag (2005) uses a mutual information derived measure to learn the *syntactic* similarity between words and clusters them. Then he derives finite state machines across words in different clusters and refines them through a graph walk algorithm. This group is the only one to evaluate against CELEX (Schone and Jurafsky, 2000; Schone and Jurafsky, 2001; Freitag, 2005).

Others. Some other models require input such as POS tables and lexicons and use a wider range of information about the corpus (Yarowsky and Wicentowski, 2000; Yarowsky et al., 2001; Chan, 2006). Because of the knowledge dependence of these models, they are able to properly induce inflectional morphology, as opposed to the studies cited above. Snyder and Barzilay (2008) uses a set of aligned phrases across related languages to learn how to segment words with a Bayesian model and is otherwise fully unsupervised.

4 Model[2]

Our goal is to generate *conflation sets*: sets of word types that are related through either inflectional or derivational morphology (Schone and Jurafsky, 2000). Solving this task requires learning how individual types are segmented (though the segmentation itself is not evaluated). For present purposes, we assume that the affixal pattern of the language is known: whether it is prefixal, suffixal, or both. To simplify presentation, we discuss a model that captures suffixes only. Our approach is a four stage process:

1. *Candidate Generation*: generate candidate stems and affixes using an orthographically defined data structure (a trie)

2. *Candidate Filtering*: filter candidate affixes using the statistical significance for pairs of affixes based on their co-occurence counts with shared stems

3. *Affix Clustering*: cluster significant affix pairs into affix groups

[2]The code implementing the model is available from `http://comp.ling.utexas.edu/earl`

4. *Word Clustering*: form conflation sets based on affix clusters

The first and last stages are particularly prone to noise, which has necessitated many of the thresholds and heuristics employed in previous work. We hypothesize that naturally occuring document boundaries provide a strong constraint that should reduce this noise, and we test that hypothesis by using it in those stages.

Our intuition comes from an observation by Yarowsky (1995) regarding multiple tokens of words in documents. He tabulates the *applicability* of using document boundaries to disambiguate word senses, which measures how often a given word occurs more than twice in the same document. For ten potentially ambiguous words, he counts how often they occur more than once in some document and finds that if the words do occur, they do so multiple times in 50.1% of these documents, on average. His counts ignored morphological variation, and it is likely the *applicability* measure would have increased considerably: if a content word is used more than once in some text, it is likely to be repeated in different syntactic contexts, requiring the word to be inflected or to be derived for a different part-of-speech category. [3]

For stage one, we build separate tries for each document rather than a trie for the entire corpus. This should reduce the chance that orthographically similar but morphologically unrelated word pairs lead to bad candidates by reducing the search space for words which share a stem to a local document. For example, *assuage* and *assume* are both likely to occur in a large corpus and suggest that there is a stem *assu* with affixes *-age* and *-me*. They are less likely to occur together in many different documents that form the corpus, whereas *assume*, *assumed*, and *assuming* are. We refer to this document constrained candidate generation as *CandGen-D*, and to the unconstrained generation (a single trie for all documents) as *CandGen-G*.

For stage four, documents are used to constrain potential membership of words in clusters: all pairs of words in a cluster must have occured together in some document. We refer to document-constrained clustering as *Clust-D* and the unconstrained global clustering as *Clust-G*.

[3]For example, in just this *one* paragraph we have {*document,documents*}, {*measure, measures*}, {*occur, occurs, occuring*}, and {*word, words*}.

4.1 Candidate generation

Given a document or collection of documents, we use tries (prefix trees) to identify potential stems and affixes and collect statistics for co-occurrences between affixes and between affixes and stems. A trie G, like the example on the right, can be identified with the set of all words on paths from the root to any leaf, in the case of the example figure the set $G = \{abd, ab\$, ac\}$. (We use \$ to denote an empty affix.) Given a trie G over alphabet L, we define the set of *trunks* of G as all paths from the root to a branching point:

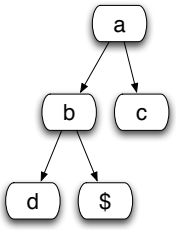

Figure 1

$$\mathit{Tr}(G) = \{w \in L^+ \mid \exists a, b \in L, x_1, x_2 \in L^* : a \neq b \ \wedge \ wax_1, wbx_2 \in G\}$$

Also, we define the set of *branches* of a trunk $t \in \mathit{Tr}(G)$ as the paths from its branching points to the leaves:

$$\mathit{Br}(t, G) = \{x \in L^+ \mid tx \in G\}$$

In our example, $\{a, ab\}$ are the trunks, with $\mathit{Br}(\mathrm{a}, G) = \{bd, b\$, c\}$ and $\mathit{Br}(\mathrm{ab}, G) = \{d, \$\}$. When we use a trie to induce stems and affixes, all induced stems will be trunks, and all induced affixes will be branches.

From a given trie, we induce a set of *stem candidates* and *affix candidates*. A simple criterion is used: if a trunk is longer than all of its branches, the trunk is a stem candidate and its branches are affix candidates. So, the set of stem candidates for a trie G, $\mathit{CStem}(G)$, is the set of trunks $t \in \mathit{Tr}(G)$ such that $|t| > |b|$ for all $b \in \mathit{Br}(t, G)$.

Given a stem candidate $s \in \mathit{CStem}(G)$, its set of affix candidates $\mathit{CAff}(s, G)$ is identical to its set of branches. (To talk about the sets of stem and affix candidates for a whole trie G or a set of tries, we write $\mathit{CAff}(G)$, $StC(G)$, CAff, and CStem.) The *count* of an affix candidate $b \in \mathit{CAff}$ is the number of stem candidates with which it occurs:

$$\mathrm{count}(b) = \sum_G |\{s \in \mathit{CStem}(G) \mid b \in \mathit{CAff}(s, G)\}|$$

For Fig. 1, the set of stem candidates is $\{ab\}$ (since some branches of the trunk a are longer than the

trunk itself). The matching set of affix candidates is *CAff*(ab, G) = $\{d, \$\}$, each with a count of one.

An *affix rule candidate* is an unordered pair of affix candidates $\{b_1, b_2\}$. It states that any stem occurring with b_1 can also occur with b_2. Affix rules implement the assumption that all productive affixes will cooccur with other productive affixes and that these will form a coherent group. The rule candidates for a given stem candidate $s \in$ *CStem*(G) are:

$$\textit{CRule}(s, G) = \left\{ \{b_1, b_2\} \subseteq \textit{CAff}(s, G) \mid b_1 \neq b_2 \right\}$$

For example, the single stem candidate *ab* in Fig. 1 has one rule candidate, $\{d, \$\}$. We also use *CRule*($G$) for the rule candidates of a trie G across all stems, and *CRule* for the union of rule candidates in a set of tries.

The count of a rule candidate r=$\{b_1, b_2\}$ in a trie is the number of stem candidates it appears with:

$$\text{count}(r) = \sum_{G} |\{s \in \textit{CStem}(G) \mid r \in \textit{CRule}(s, G)\}|$$

We also use *CAff*(s) for the set of affix candidates of stem s across several tries, and *CRule*(s) for the set of rule candidates of a stem s across several tries.

Document-specific versus global candidate generation. *CandGen-D* defines separate tries for every document in the corpus and induces stem, affix and rule candidates for each document. *CandGen-G* instead induces these candidates for a global trie over all the words in the corpus. From the perspective of the formalism laid out above, the only difference is that *CandGen-D* has as many tries G_i as there are documents i and *CandGen-G* has only one G. This simple difference leads to different candidate sets and counts over their occurrences. For example, say two documents contain the pair *putt/putts* and another contains *bogey/bogeys*. With *CandGen-D*, count($\$$)=3, count(s)=3, and count($\$, s$)=2. For the same documents, *CandGen-G* would produce count($\$$)=2 and count(s)=2 since *putt/putts* would have occurred only once in the global trie.

Also, consider a rare pair such as *aardvark/aardvarks* where each word is found in a different document. The pair would be identified by *CandGen-G* but not by *CandGen-D*. The pair would contribute a count of one to count($\$, s$) in *CandGen-G* but not in *CandGen-D*. So, *CandGen-G* can provide better coverage, but it is also more likely to identify noisy candidates, such as *assuage/assumed*, than *CandGen-D*.

4.2 Candidate filtering

The sets of candidates *CStem*, *CAff*, *CRule* is expected to be noisy since the only basis for generating them was strings that share a large portion of their substrings. One way of filtering candidates is to find affix candidates whose co-occurence with other candidates is not statistically significant.

We measure correlation between candidate affixes b_1, b_2 in a candidate rule with the paired χ^2 test. By using χ^2, we only consider pairwise correlation between affixes, rather than attempting global inference. Global consistency of affix sets is not ensured, and as such the approach is susceptible to the multiple comparisons problem. We still opt for this approach for its simplicity and because global inference is problematic due to data sparseness.

Correlation between b_1 and b_2 is determined by the following contingency table:[4]

	b_1	$\sim b_1$
b_2	O_{11}	O_{12}
$\sim b_2$	O_{21}	O_{22}

Based on the significance testing, we define the set of valid rules *PairRule* as those for which the χ^2 test is significant at $p < 0.05$. Thus, affix candidates not significantly correlated with any other affix in *CAff* are discarded.

4.3 Affix clustering

The previous stage produces a set of *pairs* of affixes that are significantly correlated. However, inflectional paradigms rarely contain just two affixes, so we would like to group together affix pairs into larger affix sets to improve generalization. We use a bottom up, minimum distance clustering for valid affix pairs (rules). We do not assume that cluster membership is exclusive. For example, it would not make sense to determine that the null affix *-$* can belong to only one cluster. Therefore, we produce non-disjoint affix clusters.

A valid cluster of affixes is a maximal set of affixes forming pairwise valid rules: *Aff* $\subseteq$ *CAff* is a valid cluster of affixes iff

[4] where O_{11} = count($\{b_1, b_2\}$), O_{12} = count(b_2) − O_{11}, O_{21} = count(b_1) − O_{11}, $O_{22} = N - O_{11} - O_{12} - O_{21}$ and $N = \sum_{b \in \textit{CAff}}$ count(b). See table (1) for examples.

	ed	∼ed

Table 1: Affix counts in contingency tables for the valid pair *ed/ing* and spurious pair *le/s* according to *CandGen-D* in (a) and (b) and according to *CandGen-G* in (c) and (d). χ^2 test values are given under each table. Data is from NYT. Total affix token counts induced through *CandGen-D* and *CandGen-G* are N=4178578 and N=156299, respectively. A total of 2054 and 3739 affix *types* were induced for *CandGen-D* and *CandGen-G*, respectively showing that *CandGen-G* does have better coverage though it might have more noise.

1. $\forall b_1, b_2 \in$ *Aff* : $\{b_1, b_2\} \in$ *PairRule*, and
2. If $b \in$ *CAff* with $\forall b' \in$ *Aff* : $\{b, b'\} \in$ *PairRule*, then $b \in$ *Aff*.

The set of all valid affix clusters is *GroupRule*. This formulation does not rule out the existence of clusters with affixes in common.

4.4 Word clustering

We next cluster word forms into morphologically related groups. Our model assumes two word forms to be morphologically related iff (1) they occurred in the same trie *G*, (2) they have a trunk s in common that is a stem in *Stem*(G), and (3) their affixes under this stem s are members in a common valid affix cluster in *GroupRule*. Hence a single stem s can be involved in at most |*GroupRule*| conflation sets, one for each valid affix cluster. Again, the only distinction between clustering with a global trie (*Clust-G*) and clustering with several tries from the documents in a corpus (*Clust-D*) is that the former has only one trie.

We define the conflation set for a given stem $s \in$ *Stem* and valid affix cluster *Aff* $\in$ *GroupRule* as

$$\textit{Wd}(s, \textit{Aff}) = \{sb_1, sb_2 \mid b_1, b_2 \in \textit{Aff} \wedge \exists G.s \in \textit{Stem}(G) \ \wedge \ b_1, b_2 \in \textit{CAff}(s, G)\}$$

One issue that needs clarification is when the candidate generation and clustering stages use different strategies, i.e. the models *CandGen-D +Clust-G* and *CandGen-G +Clust-D*. This simply means that the *statistics*, and thus the valid *GroupRule*, are derived from either *CandGen-D* or *CandGen-G*.

4.5 Induction for languages that are both prefixal and affixal

The above approach would not fit a language that is prefixal and suffixal. Assuming we have induced separate conflation sets over a prefix trie and a suffix trie, we merge clusters between the two if they have at least one word form in common. Formally, given a set of prefix conflation sets *PCS* and a set of suffix conflation sets *SCS*, the final set of conflation sets *CS* is:

$$\textit{CS} = \{p \cup s \mid p \in \textit{PCS}, s \in \textit{SCS} \wedge \ p \cap s \neq \emptyset\}$$

5 Data

We apply our method on English and Uspanteko, an endangered Mayan language.

Learning corpora. For English, we use two subsets of the NYTimes portion in the Gigaword corpus which we will call NYT and MINI-NYT. NYT in the current study is the complete collection of articles in the New York Times from June, 2002. NYT has 10K articles, 88K types and 9M tokens. MINI-NYT is a subset of NYT with 190 articles, 15K types and 187K tokens.

The Uspanteko text, USP has 29 distinct texts, 7K types, and 50K tokens. The texts are from OKMA (Pixabaj et al., 2007) and the segmentation and labels of the interlinear glossed text annotations were checked for consistency and cleaned up (Palmer et al., 2009). All counts are for lowercased, punctuation-removed word forms.

CELEX. The CELEX lexical database (Baayen et al., 1993) has been built for Dutch, English and German and provides detailed entries that list and analyze the morphological properties of words, among other information. Using CELEX, we evaluate on types rather than tokens. The performance of the model is based on how many of the words it judges to be morphologically related overlap with the entries in CELEX. Following previous work (Schone and Jurafsky, 2000; Schone and Jurafsky,

2001; Freitag, 2005), we evaluate on inflectional clusters only, using the CELEX file listing clusters of inflectional variants. [5]

6 Experiments and evaluation

We outline our evaluation methodology, baselines, benchmarks and results, and discuss the results.

6.1 Evaluation metric

Schone and Jurafsky (2000) give definitions for correct ($\mathcal{C}$), inserted ($\mathcal{I}$), and deleted ($\mathcal{D}$) words in model-derived conflation sets in relation to a gold standard. Their formulation does not allow for multiple cluster membership of words. We extend the definition to incorporate this fact about the data. Let w be a word form. We write X_w for the clusters induced by the model that contain w, and Y_w for gold standard clusters containing w. X_w and Y_w only count words which occurred in both model and gold standard clusters. Then

$$\mathcal{C} = \sum_w \sum_{X_w} \sum_{Y_w} (|X_w \cap Y_w|/|Y_w|)$$

$$\mathcal{I} = \sum_w \sum_{X_w} \sum_{Y_w} (|X_w - (X_w \cap Y_w)|/|Y_w|)$$

$$\mathcal{D} = \sum_w \sum_{X_w} \sum_{Y_w} (|Y_w - (X_w \cap Y_w)|/|Y_w|)$$

Based on these definitions, we formulate precision (P), recall (R), and the f-score (F) as: $P = \mathcal{C}/(\mathcal{C}+\mathcal{I})$, $R = \mathcal{C}/(\mathcal{C}+\mathcal{D})$, $F = (2PR)/(P+R)$.

USP evaluation We use two different means to evaluate the performance on USP. One is the f-score derived from the above section with respect to a standard that was automatically generated from the morpheme segment tiers of the OKMA IGT. We generated the standard by taking non-hyphenated segments as the stem and clustering words with shared stems.

We also had an expert in Uspanteko manually evaluate a random subset ($N = 100$) of the model output to compensate for any failings in the standard. The evaluator determined a dominant stem for a cluster and identified words which were not related to that stem. We measured accuracy and full cluster accuracy[6] for the expert evaluations (table 4).

We experimented on Uspanteko with three different assumptions: (1) it is only prefixal; (2) it is only suffixal; (3) it is both prefixal and suffixal. We applied the assumptions of only prefixal or only suffixal to LINGUISTICA as well. The relevant results are given row headers in tables with a corresponding +P(*prefix*) or +S(suffix).

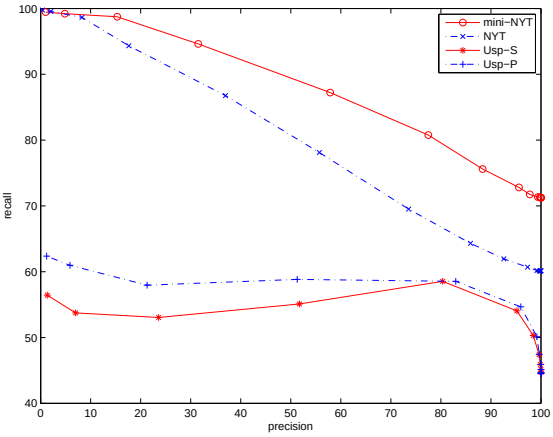

Figure 2: Precision/recall graph for baseline experiments on English, prefix USP (Usp-P) and suffix USP (Usp-S).

6.2 Baselines and benchmarks

In a *set* of baselines, we put words which share the first k characters into the same cluster. We do this for NYT, MINI-NYT, and USP in a prefix tree, and for USP in suffix tree (using the last k characters). We set the values of $0 < k < \max$, where $\max$ is the length of the longest string, and plot the results in a precision-recall graph (Fig. 2). Low k corresponds to high recall and low precision while high k shows the opposite. The contrast in morphological patterns for each language can also be seen. Because Uspanteko is morphologically complex with suffixes and prefixes, a very simple strategy cannot achieve high recall as opposed to English where it is possible to retrieve all variants with a simple prefix tree.

We use Linguistica (Goldsmith, 2001) and Morfessor (Creutz and Lagus, 2007) as benchmarks. We used the default settings for these programs. Note that comparison with these tools is not com-

[5] CELEX does have a second file listing words and their breakup into constituent morphemes for both derivation and inflection, but its use would have required additional processing that could introduce errors.

[6] Given a model cluster C_i and the "misses" for each cluster M_i, accuracy is measured as $1/N \sum_i (|C_i| - |M_i|)/(|C_i|)$ where N is the sample size. Full cluster accuracy is the number of clusters that did not have any misses over N.

pletely fair. Morfessor only generates segmentations. We therefore processed Morfessor output by clustering words by assuming that the longest segment in any segmentation is the stem and evaluated this instead. Linguistica produces stems and associated suffixes so the clusters naturally follow from this output. However, Linguistica only infers either prefix or suffix patterns.

6.3 Results and discussion

The results on English are in table 2 with χ^2 test criteria of $p<0.05$ and each cell in the contingency table >5. *CandGen-G +Clust-D* had the best f-score, and easily beats the benchmarks.

This is different from our expectation that awareness of document boundaries at all stages (i.e., *CandGen-D +Clust-D*) would show the best results. The discrepancy is especially marked for the larger NYT. One important reason for this is the affix criterion itself: trunks must be longer than branches. Consider again the sample contingency tables in Table 1 that were derived from NYT through *CandGen-D* and *CandGen-G*. We had assumed at the outset that *CandGen-D* would be better able to filter out noise and would be sparser, but results show the opposite. The reason is that that short words in a global lexicon are more likely to share trunks with longer, unrelated words. This ensures that short word forms rarely generate candidate affixes. Longer words which are less likely to have spurious long branches generate the bulk of candidate suffixes and stems. This is born out by the stems that were associated with the spurious suffix pair *le/s*: *CandGen-G* has *cliente, cripp, crumb, daniel, ender, label, mccord, nag, oval, sear, stubb, whipp*. *CandGen-D* has *crumb, hand, need, sing, tab, trick, trip*. The word forms that are associated with *le/s* through the *CandGen-D* strategy are *crumble/crumbs, handle/hands, ...* Compare this with the word forms associated with the search strategy *CandGen-G* such as *clientele/clientes, cripple/crips, ...* The majority of them are not common English words; they are most probably proper names such as *LaBelle* and *Searle*. Furthermore, there is no item among the stems from the *CandGen-G* search where concatenating the stems *le* and *s* would result in both word forms being a common noun or verb as is the case with the stems from the *CandGen-D* search where all concatenated word forms are common English words. Though *CandGen-G* finds spurious stems, the counts for the spurious affix pair are suppressed (see table 1) because it is a type count rather than a token count. This results in *le/s* being properly excluded as a rule. This explains why *CandGen-D* has worse precision in general than *CandGen-G*.

The affix criterion has other minor issues. One is that it ignores the few cases where stems are shorter than affixes, such as the very common words *be, do, go*.[7] Assuming that the longest productive inflectional suffix in English is *-ing*[8], the criterion would correctly find stem candidates for *-ing* only when the stem is longer than 3 or 4 letters. Another is that the criterion, when combined with *CandGen-D*, generates candidates from *the/them/then/their/these* which cooccur frequently in documents. This is not an issue when the criterion is applied in *CandGen-G*.

Nonetheless, results show that when data sizes are small, as with USP (Table 3) and MINI-NYT, awareness of document boundaries at the candidate generation stage is beneficial to precision.

[7] The exclusion of such words in a *token* based evaluation as opposed to a *type* based evaluation would heavily penalize our approach. We are not aware, however, of any prior work in unsupervised morphology that evaluates over tokens.

Table 4: Human expert evaluated accuracy (Acc.) and full cluster accuracy (FAcc.) of models on USP and average cluster size in words (Avg. Sz.)

However, it seems that *CandGen-G* has better coverage no matter the size of the corpus, which explains why coupling it with *Clust-D* produces overall better scores. *Clust-D* does provide a useful added constraint to mere orthographic similarity (i.e. shared trunks in a trie).

A worrisome aspect of the results is that performance degrades for large data sets (this is also true for Linguistica). However, it also hints that this method might work well for under-resourced languages. We surmise that since productive suffixes do not suffer from sparsity, even a small data set provides sufficient evidence to reach reliable conclusions about the productive morphology of some language. Increasing the size of the data merely increases the counts of spurious affixes and poses problems for a relative simple measure such as the χ^2 test. A similar result was shown in Creutz and Lagus (2005) where f-score performance of their segmentation method improved as more data was provided then decreased as the input exceeded 250K tokens in English. Their method showed continued improvement with increased data for Finnish. This hints that more data is beneficial for morphologically complex languages but not for morphologically impoverished languages.

Finally, it is also encouraging that the manual evaluation (Table 4) shows very high accuracy, as judged by a documentary linguist. Both our model and Linguistica perform very well under this evaluation.

7 Conclusion

We have presented a novel approach to unsupervised morphology acquisition that uses a very simple pipeline and does not use any thresholds other than standard ones associated with the χ^2 test. The model relies on document boundaries and correlation tests for filtering spurious stems and affixes. The model compares favorably to Linguistica and Morfessor, two models that employ much more complex strategies and rely on fine-tuned parameters. We found that the use of document boundaries is especially beneficial with small datasets, which is promising for the application of this model to under-resourced languages. For large datasets, global candidate generation outperformed document-aware candidate generation at the task of filtering out spurious stems, but document-aware clustering does improve precision and overall performance.

In this paper we have addressed one aspect of morphology acquisition, segmentation and clustering. Extending the approach is straightforward, for example, substituting more sophisticated data structures or statistical tests for the current ones. In particular, we will move from the use of document boundaries to a flexible notion of textual distance to estimate likelihood of morphological relatedness.

Abstract

We extend previous work on fully unsupervised part-of-speech tagging. Using a non-parametric version of the HMM, called the infinite HMM (iHMM), we address the problem of choosing the number of hidden states in unsupervised Markov models for PoS tagging. We experiment with two non-parametric priors, the Dirichlet and Pitman-Yor processes, on the Wall Street Journal dataset using a parallelized implementation of an iHMM inference algorithm. We evaluate the results with a variety of clustering evaluation metrics and achieve equivalent or better performances than previously reported. Building on this promising result we evaluate the output of the unsupervised PoS tagger as a direct replacement for the output of a fully supervised PoS tagger for the task of shallow parsing and compare the two evaluations.

1 Introduction

Many Natural Language Processing (NLP) tasks are commonly tackled using supervised learning approaches. These learning methods rely on the availability of labeled datasets which are usually produced by expensive manual annotation. For some tasks, we have the choice to use unsupervised learning approaches. While they do not necessarily achieve the same level of performance, they are appealing as unlabeled data is usually abundant. In particular, for the purpose of exploring new domains and languages, obtainining labeled material can be prohibitively expensive and unsupervised learning methods are a very attractive choice. Recent work (Johnson, 2007; Goldwater and Griffiths, 2007; Gao and Johnson, 2008) explored the task of part-of-speech tagging (PoS) using unsupervised Hidden Markov Models (HMMs) with encouraging results. PoS tagging is a standard component in many linguistic processing pipelines, so any improvement on its performance is likely to impact a wide range of tasks.

It is important to point out that a completely unsupervised learning method will discover the statistics of a dataset *according to a particular model choice* but these statistics might not correspond exactly to our intuition about PoS tags. Johnson (2007) and Gao & Johnson (2008) assume that words are generated by a hidden Markov model and find that the resulting states strongly correlate with POS tags. Nonetheless, *identifying* the HMM states with appropriate POS tags is hard. Because many evaluation methods often require POS tags (rather than HMM states) this identification problem makes unsupervised systems difficult to evaluate.

One potential solution is to add a small amount of supervision as in Goldwater & Griffiths (2007) who assume a dictionary of frequent words associated with possible PoS tags extracted from a labeled corpus. Although this technique improves performance, in this paper we explore the completely unsupervised approach. The reason for this is that better unsupervised approaches provide us with better starting points from which to explore how and where to incorporate supervision.

In previous work on unsupervised PoS tagging a main question was how to set the number of hidden states appropriately. Johnson (2007) reports results for different numbers of hidden states but it is unclear how to make this choice a priori, while Goldwater & Griffiths (2007) leave this question as future work.

It is not uncommon in statistical machine learning to distinguish between parameters of a model and the capacity of a model. E.g. in a clustering context, the choice for the number of clusters (capacity) and the parameters of each cluster are often

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 678–687,
Singapore, 6-7 August 2009.

treated differently: the latter are estimated using algorithms like EM, MCMC or Variational Bayes while the former is chosen using common sense, heuristics or in a Bayesian framework maybe using evidence maximization.

Non-parametric Bayesian methods are a class of probability distributions which explicitly treat the capacity of a model as "just another parameter". Potential advantages are

- the model capacity can automatically adjust to the amount of data: e.g. when clustering a very small dataset, it is unlikely that many fine grained clusters can be distinguished,

- inference can be more efficient: e.g. instead of running full inference for different model capacities and then choosing the best capacity (according to some choice of "best"), inference in non-parametric Bayesian methods integrates the capacity search in one algorithm. This is particularly advantageous when parameters other than capacity need to be explored, since it reduces signifcantly the number of experiments needed.

None of these potential advantages are guaranteed and in this paper we investigate these two aspects for the task of unsupervised PoS tagging.

The contributions in this paper extend previous work on unsupervised PoS tagging in five ways. First, we introduce the use of a non-parametric version of the HMM, namely the infinite HMM (iHMM) (Beal et al., 2002) for unsupervised PoS tagging. This answers an open problem from Goldwater & Griffiths (2007). Second, we carefully implemented a parallelized version of the inference algorithms for the iHMM so we could use it on the Wall Street Journal Penn Treebank dataset. Third, we introduce a new variant of the iHMM that builds on the Pitman-Yor process. Fourth, we evaluate the results with a variety of clustering evaluation methods and achieve equivalent or better performances than previously reported. Finally, building on this promising result we use the output of the unsupervised PoS tagger as a direct replacement for the output of a fully supervised PoS tagger for the task of shallow parsing. This evaluation enables us to assess the applicability of an unsupervised PoS tagging method and provides us with means of comparing its performance against a supervised PoS tagger.

The rest of the paper is structured as follows: in section 2 we introduce the iHMM as a non-parametric version of the Bayesian HMM used in previous work on unsupervised PoS tagging. Then, in section 3 we describe some details of our implementation of the iHMM. In section 4 we present a variety of evaluation metrics to compare our results with previous work. Finally, in section 5 we report our experimental results. We conclude this paper with a discussion of ongoing work and experiments.

2 The Infinite HMM

In this section, we describe a non-parametric hidden Markov model known as the infinite HMM (iHMM) (Beal et al., 2002; Teh et al., 2006). As we show below, this model is flexible in the number of hidden states which it can accomodate. In other words, *the capacity is an uncertain quantity* with an a priori infinite range that is a posteriori inferred by the data. It is instructive to first review the finite HMM and its Bayesian treatment: for one, it is the model that has been used in previous work on unsupervised PoS tagging, secondly it allows us to better understand the iHMM.

The Bayesian HMM A finite first-order HMM consists of a hidden state sequence $\boldsymbol{s} = (s_1, s_2, \ldots, s_T)$ and a corresponding observation sequence $\boldsymbol{y} = (y_1, y_2, \ldots, y_T)$. Each state variable s_t can take on a finite number of states, say $1 \ldots K$. Transitions between states are governed by Markov dynamics parameterized by the transition matrix $\boldsymbol{\pi}$, where $\pi_{ij} = p(s_t = j | s_{t-1} = i)$, while the initial state probabilities are $\pi_{0i} = p(s_1 = i)$. For each state $s_t \in \{1 \ldots K\}$ there is a parameter ϕ_{s_t} which parameterizes the observation likelihood for that state: $y_t | s_t \sim F(\phi_{s_t})$. Given the parameters $\{\pi_0, \boldsymbol{\pi}, \boldsymbol{\phi}, K\}$ of the HMM, the joint distribution over hidden states $\boldsymbol{s}$ and observations $\boldsymbol{y}$ can be written (with $s_0 = 0$):

$$p(\boldsymbol{s}, \boldsymbol{y} | \pi_0, \boldsymbol{\pi}, \boldsymbol{\phi}, K) = \prod_{t=1}^{T} p(s_t | s_{t-1}) p(y_t | s_t)$$

As Johnson (2007) clearly explained, training the HMM with EM leads to poor results in PoS tagging. However, we can easily treat the HMM in a fully Bayesian way (MacKay, 1997) by introducing priors on the parameters of the HMM. With no further prior knowledge, a typical prior for the transition (and initial) probabilities are symmetric Dirichlet distributions. This corresponds to our

belief that, a priori, each state is equally likely to transition to every other state. Also, it is commonly known that the parameter of a Dirichlet distribution controls how sparse its samples are. In other words, by making the hyperprior on the Dirichlet distribution for the rows of the transition matrix small, we can encode our belief that any state (corresponding to a PoS tag in this application context) will only be followed by a small number of other states. As we explain below, we will be able to include this desirable property in the non-parametric model as well. Secondly, we need to introduce a prior on the observation parameters ϕ_k. Without any further prior knowledge, a convenient choice here is another symmetric Dirichlet distribution with sparsity inducing hyperprior. This encodes our belief that only a subset of the words correspond to a particular state.

The Infinite HMM A first naïve way to obtain a non-parametric HMM with an infinite number of states might be to use symmetric Dirichlet priors over the transition probabilities with parameter α/K and take $K \to \infty$. This approach unfortunately does not work: $\alpha/K \to 0$ when $K \to \infty$ and hence the rows of the matrix will become "infinitely sparse". Since the sum of the entries must sum to one, the rows of the transition matrix will be zero everywhere and all its mass in a random location. Unfortunately, this random location is out of an infinite number of possible locations and hence with probability 1 will be different for all the rows. As a consequence, at each timestep the HMM moves to a new state and will never revisit old states. As we shall see shortly, we can fix this by using a hierarchical Bayesian formalism where the Dirichlet priors on the rows have a shared parameter.

Before moving on to the iHMM, let us look at the finite HMM from a different perspective. The finite HMM of length T with K hidden states can be seen as a sequence of T finite mixture models. The following equation illustrates this idea: conditioned on the previous state s_{t-1}, the marginal probability of observation y_t can be written as:

$$\begin{aligned} p(y_t|s_{t-1}=k) &= \sum_{s_t=1}^{K} p(s_t|s_{t-1}=k)p(y_t|s_t), \\ &= \sum_{s_t=1}^{K} \pi_{k,s_t} p(y_t|\phi_{s_t}). \end{aligned} \quad (1)$$

The variable $s_{t-1} = k$ specifies the mixing weights $\pi_{k,\cdot}$ for the mixture distribution, while s_t indexes the mixture component generating the observation y_t. In other words, equation (1) says that each row of the transition matrix $\boldsymbol{\pi}$ specifies a different mixture distribution over the same set of K mixture components $\boldsymbol{\phi}$.

Our second attempt to define a non-parametric version of the hidden Markov model is to replace the finite mixture by an infinite mixture. The theory of Dirichlet process mixtures (Antoniak, 1974) tells us exactly how to do this. A draw $G \sim DP(\alpha, H)$ from a Dirichlet process (DP) with base measure H and concentration parameter $\alpha \geq 0$ is a discrete distribution which can be written as an infinite mixture of atoms

$$G(\cdot) = \sum_{i=1}^{\infty} \pi_i \delta_{\phi_i}(\cdot)$$

where the ϕ_i are i.i.d. draws from the base measure H, $\delta_{\phi_i}(\cdot)$ represents a point distribution at ϕ_i and $\pi_i = v_i \prod_{l=1}^{i-1}(1 - v_l)$ where each $v_l \sim \mathsf{Beta}(1, \alpha)$. The distribution over π_i is called a stick breaking construction and is essentially an infinite dimensional version of the Dirichlet distribution. We refer to Teh et al. (2006) for more details.

Switching back to the iHMM our next step is to introduce a DP G_j for each state $j \in \{1 \cdots \infty\}$; we write $G_j(\cdot) = \sum_{i=1}^{\infty} \pi_i^j \delta_{\phi_i^j}(\cdot)$. There is now a parameter for each state j and each index $i \in \{1, 2, \cdots, \infty\}$. Next, we draw the datapoint at timestep t given that the previous datapoint was in state s_{t-1} by drawing from DP $G_{s_{t-1}}$. We first select a mixture component s_t from the vector $\pi_{s_{t-1},\cdot}$ and then sample a datapoint $y_t \sim F(\phi_{s_{t-1},s_t})$ so we get the following distribution for y_t

$$p(y_t|\alpha, s_{t-1}) = \sum_{s_t=1}^{\infty} \pi_{s_{t-1},s_t} p(y_t|\phi_{s_{t-1},s_t}).$$

This is almost the non-parametric equivalent of equation (1) but there is a subtle difference: each G_j selects their own set of parameters $\phi_{\cdot}^j$. This is unfortunate as it means that the output distribution would not be the same for each state, it would depend on which state we were moving to! Luckily, we can easily fix this: by introducing an intermediate distribution $G_0 \sim DP(\gamma, H)$ and let $G_j \sim DP(\alpha, G_0)$ we enforce that the i.i.d. draws $\phi_{\cdot}^j$ are draws from a discrete distribution (since G_0

is a draw from a Dirichlet process) and hence all G_j will share the same infinite set of atoms as chosen by G_0. Figure 1 illustrates the graphical model for the iHMM.

The iHMM with Pitman-Yor Prior The Dirichlet process described above defines a very specific distribution over the number of states in the iHMM. One particular generalization of the Dirichlet process that has been studied in the NLP literature before is the *Pitman-Yor* process. Goldwater et al. (2006) have shown that the Pitman-Yor distribution can more accurately capture power-law like distributions that frequently occur in natural language.

More specifically, a draw $G \sim PY(d, \alpha, H)$ from a Pitman-Yor process (PY) with base measure H, discount parameter $0 \leq d < 1$ and concentration parameter $\alpha > -d$ is a discrete distribution which can be written as an infinite mixture of atoms

$$G(\cdot) = \sum_{i=1}^{\infty} \pi_i \delta_{\phi_i}(\cdot)$$

where the ϕ_i are i.i.d. draws from the base measure H, $\delta_{\phi_i}(\cdot)$ represents a point distribution at ϕ_i and $\pi_i = v_i \prod_{l=1}^{i-1}(1 - v_l)$ where each $v_l \sim \mathsf{Beta}(1-d, \alpha+ld)$. Note the similarity to the DP: in fact, the DP is a special case of PY with $d = 0$.

In our experiments, we constructed an iHMM where the $DP(\alpha, H)$ base measure G_0 is replaced with its two parameter generalization $PY(d, \alpha, H)$. Because the Dirichlet and Pitman-Yor processes only differ in the way π is constructed, without loss of generality we will describe hyper-parameter choice and inference in the context of the iHMM with Dirichlet process base measure.

Hyperparameter Choice The description above shows that there are 4 parameters which we must specify: the base measure H, the output distribution $p(y_t|\phi_{s_t})$, the discount[1] and concentration[2] parameters d, γ for G_0 and the concentration parameter α for the DP's G_j. Just as in the finite case, the base measure H is the prior distribution on the parameter ϕ of $p(y_t|\phi_{s_t})$. We chose to use a symmetric Dirichlet distribution with parameter δ over the word types in our corpus. Since we do not know the sparsity level δ of the output distributions we decided to learn this parameter from the data. We initially set a vague Gamma prior over δ but soon realized that as we expect hidden states in the iHMM to correspond to PoS tags, it is unrealistic to expect each state to have the same sparsity level. Hence we chose a Dirichlet process as the prior for δ; this way we end up with a small discrete set of sparsity levels: e.g. we can learn that states corresponding to verbs and nouns share one sparsity level while states correpsonding to determiners have their own (much sparser) sparsity level. For the output distribution $p(y_t|\phi_{s_t})$ we chose a simple multinomial distribution.

The hyperparameters d and γ mostly control the number of states in the iHMM while - as we discussed above - α controls the sparsity of the transition matrix. In the experiments below we report both fixing the two parameters and learning them by sampling (using vague Gamma hyperpriors). Because of computational constraints, we chose to use vague Bayesian priors for all hyperparameters rather than run the whole experiment over a grid of "reasonable" parameter settings and use the best ones according to cross validation.

3 Inference

The Wall Street Journal part of the Penn Treebank that was used for our experiments contains about one million words. In the non-parametric Bayesian literature not many algorithms have been described that scale into this regime. In this section we describe our parallel implementation of the iHMM which can easily handle a dataset of this scale.

There is a wealth of evidence (Scott, 2002; Gao and Johnson, 2008) in the machine learning literature that Gibbs sampling for Markov models leads to slow mixing times. Hence we decided our starting point for inference needs to be based on dynamic programming. Because we didn't have a good idea for the number of states that we were going to end up with, we prefered the beam sampler of Van Gael et al. (2008) over a finite truncation of the iHMM. Moreover, the beam sampler also introduces a certain amount of sparsity in the dynamic program which can speed up computations (potentially at the cost of slower mixing).

The beam sampler is a blocked Gibbs sampler where we alternate between sampling the parameters (transition matrix, output parameters), the state sequence and the hyperparameters. Sam-

[1] for Pitman-Yor base measure

[2] for both Dirichlet and Pitman-Yor base measures

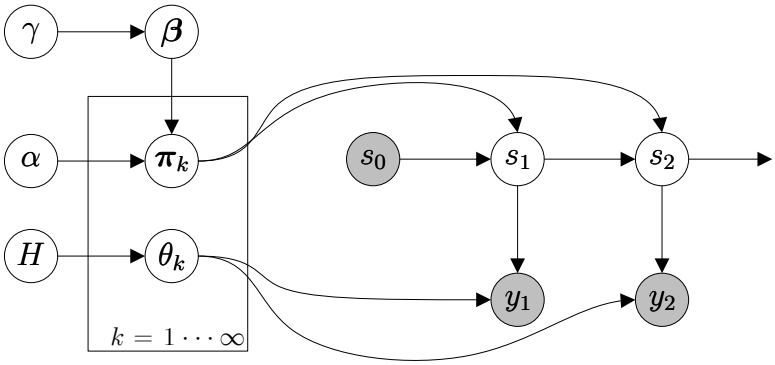

Figure 1: The graphical model for the iHMM. The variable β represents the mixture for the DP G_0.

pling the transition matrix and output distribution parameters requires computing their sufficient statistics and sampling from a Dirichlet distribution; we refer to the beam sampling paper for details. For the hyperparameters we use standard Gibbs sampling. We briefly sketch the resampling step for the state sequence for a single sequence of data (sentence of words). Running standard dynamic programming is prohibitive because the state space of the iHMM is infinitely large. The central idea of the beam sampler is to adaptively truncate the state space of the iHMM and run dynamic programming. In order to truncate the state space, we sample an auxilary variable u_t for each word in the sequence from the distribution $u_t \sim \mathsf{Uniform}(0, \pi_{s_{t-1}s_t})$ where π represents the transition matrix.

Intuitively, when we sample $u_{1:T}|s_{1:T}$ according to the distribution above, the only valid samples are those for which the u_t are smaller than the transition probabilities of the state sequence $s_{1:T}$. This means that when we sample $s_{1:T}|u_{1:T}$ at a later point, it must be the case that the u_t's are still smaller than the new transition probabilities. This significantly reduces the set of valid state sequences that we need to consider. More specifically, Van Gael et al. (2008) show that we can compute $p(s_t|y_{1:t}, u_{1:t})$ using the following dynamic programming recursion $p(s_t|y_{1:t}, u_{1:t}) =$

$$p(y_t|s_t) \sum_{s_{t-1}:u_t<\pi_{s_{t-1},s_t}} p(s_{t-1}|y_{1:t-1}, u_{1:t-1}).$$

The summation $\sum_{s_{t-1}:u_t<\pi_{s_{t-1},s_t}}$ ensures that this computation remains finite. When we compute $p(s_t|y_{1:t}, u_{1:t})$ for $t \in \{1 \cdots T\}$, we can easily sample s_T and using Bayes rule backtrack sample every other s_t. It can be shown that this procedure produces samples from the exact posterior.

Notice that the dynamic program only needs to perform computation when $u_t < \pi_{s_{t-1},s_t}$. A careful implementation of the beam sampler consists of preprocessing the transition matrix π and sorting its elements in descending order. We can then iterate over the elements of the transition matrix starting from the largest element and stop once we reach the first element of the transition matrix smaller than u_t. In our experiments we found that this optimization reduces the amount of computation per sentence by an order of magnitutde.

A second optimization which we introduced is to use the map-reduce paradigm (Dean and Ghemawat, 2004) to parallelize our computations. More specifically, after we preprocess the transition matrix, the dynamic program computations are independent for each sentence in the dataset. This means we can perform each dynamic program in parallel; in other words our "map" consists of running the dynamic program on one sentence in the dataset. Next, we need to resample the transition matrix and output distribution parameters. In order to do so we need to compute their sufficient statistics: the number of transitions from state to state and the number of emissions of each word out of each state. Our "reduce" function consists of computing the sufficient statistics for each sentence and then aggregating the statistics for the whole dataset. Our implementation runs on a quad-core shared memory architecture and we find an almost linear speedup going from one to four cores.

4 Evaluation

Evaluating unsupervised PoS tagging is rather difficult mainly due to the fact that the output of such

systems are not actual PoS tags but state identifiers. Therefore it is impossible to evaluate performance against a manually annotated gold standard using accuracy. Recent work (Goldwater and Griffiths, 2007; Johnson, 2007; Gao and Johnson, 2008) on this task explored a variety of methodologies to address this issue.

The most common approach followed in previous work is to evaluate unsupervised PoS tagging as clustering against a gold standard using the Variation of Information (VI) (Meilă, 2007). VI assesses homogeneity and completeness using the quantities $H(C|K)$ (the conditional entropy of the class distribution in the gold standard given the clustering) and $H(K|C)$ (the conditional entropy of clustering given the class distribution in the gold standard). However, as Gao & Johnson (2008) point out, VI is biased towards clusterings with a small number of clusters. A different evaluation measure that uses the same quantities but weighs them differently is the V-measure (Rosenberg and Hirschberg, 2007), which is defined in Equation 2 by setting the parameter β to 1.

$$h = 1 - \frac{H(C|K)}{H(C)}$$
$$c = 1 - \frac{H(K|C)}{H(K)}$$
$$V_\beta = \frac{(1+\beta)hc}{(\beta h) + c} \quad (2)$$

Vlachos et al. (2009) noted that V-measure favors clusterings with a large number of clusters. Both of these biases become crucial in our experiments, since the number of clusters (states of the iHMM) is not fixed in advance. Vlachos et al. proposed a variation of the V-measure, V-beta, that adjusts the balance between homogeneity and completeness using the parameter β in Eq. 2.

It is worth mentioning that, unlike V-measure and V-beta, VI scores are not normalized and therefore they are difficult to interpret. Meilă (2007) presented two normalizations, acknowledging the potential disadvantages they have. The first one normalizes VI by $2\log(max(|K|,|C|))$, which is inappropriate when the number of clusters discovered $|K|$ changes between experiments. The second normalization involves the quantity $\log N$ which is appropriate when comparing different algorithms on the same dataset (N is the number of instances). However, this quantity depends exclusively on the size of the dataset and hence if the dataset is very large it can result in normalized VI scores misleadingly close to 100%. This does not affect rankings, i.e. a better VI score will also be translated into a better normalized VI score. In our experiments, we report results only with the un-normalized VI scores, V-measure and V-beta.

All the evaluation measures mentioned so far evaluate PoS tagging as a clustering task against a manually annotated gold standard. While this is reasonable, it still does not provide means of assessing the performance in a way that would allow comparisons with supervised methods that output actual PoS tags. Even for the normalized measures V-measure and V-beta, it is unclear how their values relate to accuracy levels. Gao & Johnson (2008) partially addressed this issue by mapping states to PoS tags following two different strategies, cross-validation accuracy, and greedy 1-to-1 mapping, which both have shortcomings. We argue that since an unsupervised PoS tagger is trained without taking any gold standard into account, it is not appropriate to evaluate against a particular gold standard, or at least this should not be the sole criterion. The fact that different authors use different versions of the same gold standard to evaluate similar experiments (e.g. Goldwater & Griffiths (2007) versus Johnson (2007)) supports this claim. Furthermore, PoS tagging is seldomly a goal in itself, but it is a component in a linguistic pipeline.

In order to address these issues, we perform an extrinsic evaluation using a well-explored task that involves PoS tags. While PoS tagging is considered a pre-processing step in many natural language processing pipelines, the choice of task is restricted by the lack of real PoS tags in the output of our system. For our purposes we need a task that relies on discriminating between PoS tags rather than the PoS tag semantics themselves, in other words, a task in which knowing whether a word is tagged as noun instead of a verb is equivalent to knowing it is tagged as state 1 instead of state 2. Taking these considerations into account, in Section 5 we experiment with shallow parsing in the context of the CoNLL-2000 shared task (Tjong Kim Sang and Buchholz, 2000) in which very good performances were achieved using only the words with their PoS tags. Our intuition is that if the iHMM (or any unsupervised PoS tagging

method) has a reasonable level of performance, it should improve on the performance of a system that does not use PoS tags. Moreover, if the performance is very good indeed, it should get close to the performance of a system that uses real PoS tags, provided either by human annotation or by a good supervised system. Similar extrinsic evaluation was performed by Biemann et al. (2007). It is of interest to compare the results between the clustering evaluation and the extrinsic one.

A different approach in evaluating non-parametric Bayesian models for NLP is state-splitting (Finkel et al., 2007; Liang et al., 2007). In this setting, the model is used in order to refine existing annotation of the dataset. While this approach can provide us with some insights and interpretable results, the use of existing annotation influences the output of the model. In this work, we want to verify whether the output of the iHMM (without any supervision) can be used instead of that of a supervised system.

5 Experiments

In all our experiments, the Wall Street Journal (WSJ) part of the Penn Treebank was used. As explained in Section 4, we evaluate the output of the iHMM in two ways, as clustering with respect to a gold standard and as direct replacement of the PoS tags in the task of shallow parsing. In each experiment, we obtain a sample from the iHMM over all the sections of WSJ. The states for sections 15-18 and 20 of the WSJ (training and testing sets respectvely in the CoNLL shared task) are used for the evaluation based on shallow parsing, while the remaining sections are used for evaluation against the WSJ gold standard PoS tags using clustering evaluation measures.

As described in Section 2 we performed three runs with the iHMM: one run with DP prior and fixed γ, α, one with PY prior and fixed d, γ, α and one with DP prior but where we learn the hyperparameters γ, α from the data. Our inference algorithm uses 1000 burn-in iterations after which we collect a sample every 1000 iterations. Our inference procedure is annealed during the first 1000 burnin and 2400 iterations by powering the likelihood of the output distribution with a number that smoothly increases from 0.4 to 1.0 over the 3400 first iterations. The numbers of iterations reported in the remainder of the section refer to the iterations after burn-in. We initialized the sampler by: a) sampling the hyperparameters from the prior where applicable, b) uniformly assign each word one out of 20 iHMM states. For the DP run with fixed parameters, we chose $\alpha = 0.8$ to encourage some sparsity in the transition matrix and $\gamma = 5.0$ to allow for enough hidden states. For the PY run with fixed parameters, we chose $\alpha = 0.8$ for similar reasons and $d = 0.1$ and $\gamma = 1.0$. We point out that one weakness of MCMC methods is that they are hard to test for convergence. We chose to run the simulations until they became prohibitively expensive to obtain a new sample.

First, we present results using clustering evaluation measures which appear in the figures of Table 1. The three runs exhibit different behavior. The number of states reached by the iHMM with fixed parameters using the DP prior stabilizes close to 50 states, while for the experiment with learnt hyperparameters the number of states grows more rapidly, reaching 194 states after 8,000 iterations. With the PY prior, the number of states reached grows less rapidly reaching 90 states. All runs achieve better performances with respect to all the measures used as the number of iterations grows. An exception is that VI scores tend to increase (lower VI scores are better) when the number of states grows larger than the gold standard. It is interesting to notice how the measures exhibit different biases, in particular that VI penalizes the larger numbers of states discovered in the DP run with learnt parameters as well as the run with the PY prior, compared to the more lenient scores provided by V-measure and V-beta. The latter though assigns lower scores to the DP run with learnt parameters because it takes into account that the high homogeneity is achieved using even more states. Finally, the interpretability of these scores presents some interest. For example, in the run with fixed parameters using the DP prior, after burn-in VI was 4.6, which corresponds to 76.65% normalized VI score, while V-measure and V-beta were 12.7% and 9% respectively. In 8,000 iterations after burn-in, VI was 3.94 (80.3% when normalized), while V-measure and V-beta were 53.3%, since the number of states was almost the same as the number of unique PoS tags in the gold standard.

The closest experiment to ours is the one by Gao & Johnson (2008) who run their Bayesian HMM over the whole WSJ and evaluated against the full gold standard, the only difference being is that we exclude the CoNLL shared task sec-

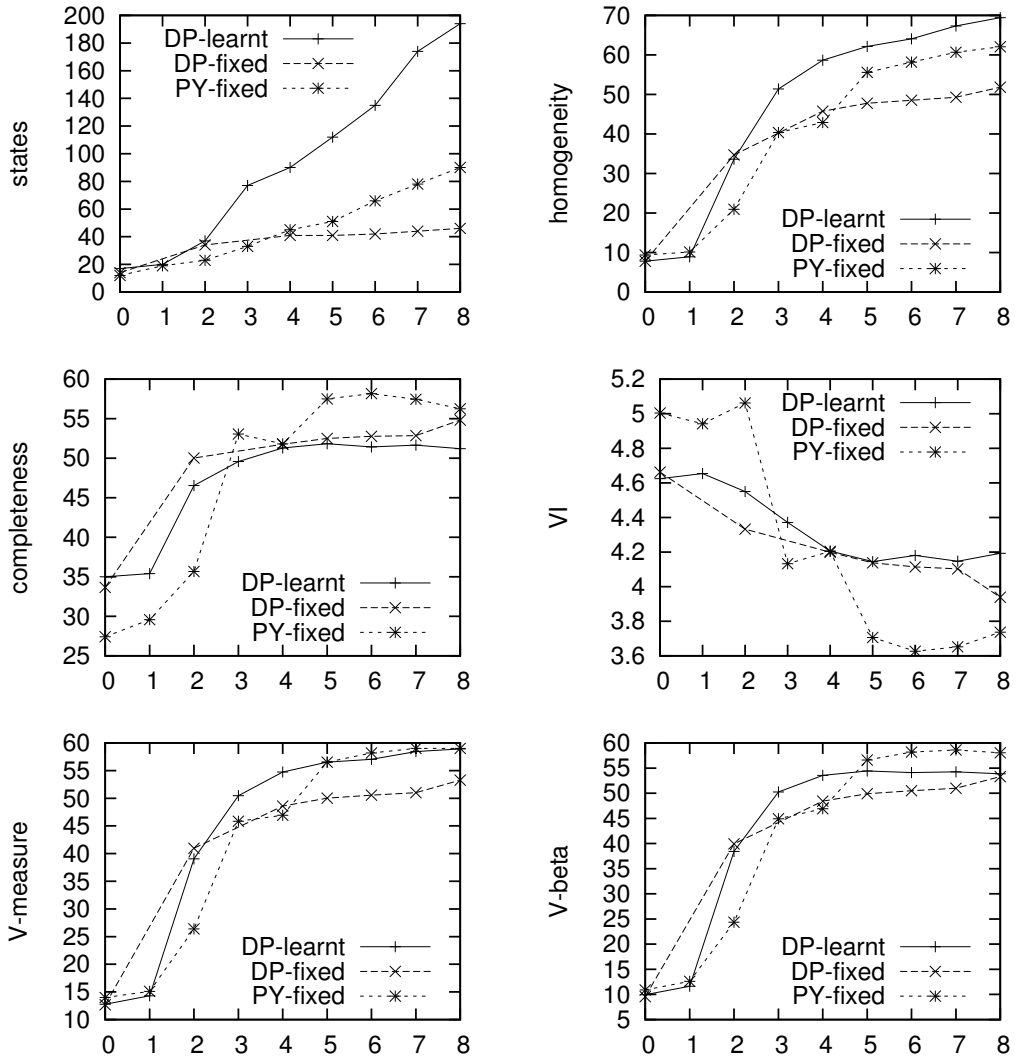

Table 1: Performance of the three iHMM runs according to clustering evaluation measures against number of iteretions (in thousands).

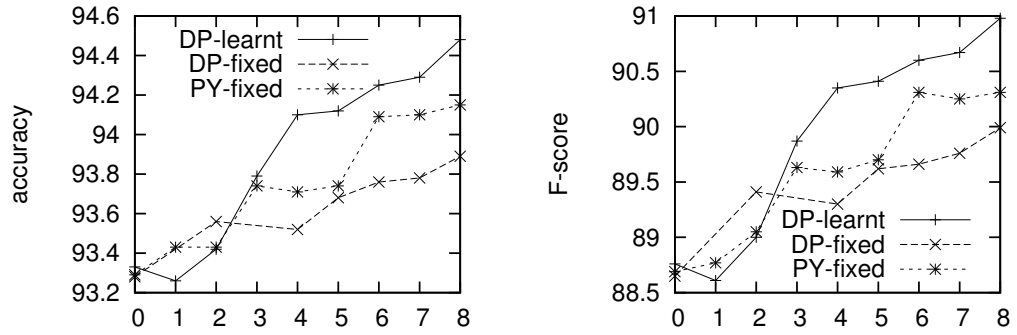

Table 2: Performance of the output of the three iHMM runs when used in shallow parsing against number of iteretions (in thousands).

tions from our evaluation, which leaves us with 19 sections instead of 24. Their best VI score was 4.03886 which they achieved using the collapsed, sentence-blocked Gibbs sampler with the number of states fixed to 50. The VI score achieved by the iHMM with fixed parameters using the PY prior reaches 3.73, while using the DP prior VI reaches 4.32 with learnt parameters and 3.93 with fixed

parameters. These results, even if they are not directly comparable, are on par with the state-of-the-art, which encouraged us to proceed with the extrinsic evaluation.

For the experiments with shallow parsing we used the CRF++ toolkit[3] which has an efficient implementation of the model introduced by Sha & Pereira (2003) for this task. First we ran an experiment using the words and the PoS tags provided in the shared task data and the performances obtained were 96.07% accuracy and 93.81% F-measure. The PoS tags were produced using the Brill tagger (Brill, 1994) which employs tranformation-based learning and was trained using the WSJ corpus. Then we ran an experiment removing the PoS tags altogether, and the performances were 93.25% accuracy and 88.58% F-measure respectively. This gave us some indication as to what the contribution of the PoS tags is in the context of the shallow parsing task at hand.

The experiments using the output of the iHMM as PoS tags for shallow parsing are presented in Table 2. The best performance achieved was 94.48% and 90.98% in accuracy and F-measure, which is 1.23% and 2.4% better respectively than just using words, but worse by 1.57% and 2.83% compared to using the supervised PoS tagger output. Given that the latter is trained on WSJ we believe that this is a good result. Interestingly, this was obtained by using the last sample from the iHMM run using the DP prior with learnt parameters which has worse overall clustering evaluation scores, especially in terms of VI. This sample though has the best homogeneity score (69.39%). We believe that homogeneity is more important than the overall clustering score due to the fact that, in the application considered, it is probably worse to assign tokens that belong to different PoS tags to the same state, e.g. verb and adverbs, rather than generate more than one state for the same PoS. This is likely to be the case in tasks where we are interested in distinguishing between PoS tags rather than the actual tag itself. Also, clustering evaluation measures tend to score leniently consistent mixing of members of different classes in the same cluster. However, such mixing results in consistent noise when the clustering output becomes input to a machine learning method, which is harder to deal with.

6 Conclusions - Future Work

In the context of shallow parsing we saw that the performance of the iHMM does not match the performance of a supervised PoS tagger but does lead to a performance increase over a model using only words as features. Given that it was constructed without any need for human annotation, we believe this is a good result. At the same time though, it suggests that it is still some way from being a direct drop-in replacement for a supervised method. We argue that the extrinsic evaluation of unsupervised PoS tagging performed in this paper is quite informative as it allowed us to assess our results in a more realistic context. In this work we used shallow parsing for this, but we are considering other tasks in which we hope that PoS tagging performance will be more crucial.

Our experiments also suggest that the number of states in a Bayesian non-parametric model can be rather unpredictable. On one hand, this is a strong warning towards inference algorithms which perform finite truncation of non-parametric models. On the other hand, the remarkable difference in behavior between the DP with fixed and learned priors suggests that more research is needed towards understanding the influence of hyperparameters in Bayesian non-parametric models.

We are currently experimenting with a semi-supervised PoS tagger where we let the transition matrix of the iHMM depend on annotated PoS tags. This model allows us to: a) use annotations whenever they are available and do unsupervised learning otherwise; b) use the power of non-parametric methods to possibly learn more fine grained statistical structure than tag sets created manually.

On the implementation side, it would be interesting to see how our methods scale in a distributed map-reduce architecture where network communication overhead becomes an issue.

Finally, the ultimate goal of our investigation is to do unsupervised PoS tagging using web-scale datasets. Although the WSJ corpus is reasonably sized, our computational methods do not currently scale to problems with one or two order of magnitude more data. We will need new breakthroughs to unleash the full potential of unsupervised learning for NLP.

A Simple Unsupervised Learner for POS Disambiguation Rules Given Only a Minimal Lexicon

Qiuye Zhao **Mitch Marcus**
Dept. of Computer & Information Science
University of Pennsylvania
qiuye, mitch@cis.upenn.edu

Abstract

We propose a new model for unsupervised POS tagging based on linguistic distinctions between open and closed-class items. Exploiting notions from current linguistic theory, the system uses far less information than previous systems, far simpler computational methods, and far sparser descriptions in learning contexts. By applying simple language acquisition techniques based on counting, the system is given the closed-class lexicon, acquires a large open-class lexicon and then acquires disambiguation rules for both. This system achieves a 20% error reduction for POS tagging over state-of-the-art unsupervised systems tested under the same conditions, and achieves comparable accuracy when trained with much less prior information.

1 Introduction

All recent research on unsupervised tagging, as well as the majority of work on supervised taggers, views POS tagging as a sequential labeling problem and treats all POS tags, both closed- and open-class, as roughly equivalent. In this work we explore a different understanding of the tagging problem, viewing it as a process of first identifying functional syntactic contexts, which are flagged by closed-class items, and then using these functional contexts to determine the POS labels. This disambiguation model differs from most previous work in three ways: 1) it uses different encodings over two distinct domains (roughly open- and closed-class words) with complementary distribution (and so decodes separately); 2) it is deterministic and 3) it is non-lexicalized. By learning disambiguation models for open- and closed- classes separately, we found that the deterministic, rule-based model can be learned from unannotated data by a simple strategy of selecting a rule in each appropriate context with the highest count.

In contrast to this, most previous work on unsupervised tagging (especially for English) concentrates on improving the parameter estimation techniques for training statistical disambiguation models from unannotated data. For example, (Smith&Eisner, 2005) proposes contrastive estimation (CE) for log-linear models (CRF), achieving the current state-of-the-art performance of 90.4%; (Goldwater&Griffiths, 2007) applies a Bayesian approach to improve maximum-likelihood estimation (MLE) for training generative models (HMM). In the main experiments of both of these papers, the disambiguation model is learned, but the algorithms assume a complete knowledge of the lexicon with all possible tags for each word. In this work, we propose making such a large lexicon unnecessary by learning the bulk of the lexicon along with learning a disambiguation model.

Little previous work has been done on this natural and simple idea because the clusters found by previous induction schemes are not in line with the lexical categories that we care about. (Chan, 2008) is perhaps the first with the intention of generating "a discrete set of clusters." By applying similar techniques to (Chan, 2008), which we discuss later, we can generate clusters that closely approximate the central open-class lexical categories, a major advance, but we still require a closed-class lexicon specifying possible tags for these words. This asymmetry in our lexicon acquisition model conforms with our understanding of natural language as structured data over two distinct domains with complementary distribution: open-class (lexical) and closed-class (functional).

Provided with only a closed-class lexicon of 288 words, about 0.6% of the full lexicon, the system acquires a large open-class lexicon and then acquires disambiguation rules for both closed- and

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 688–697,
Singapore, 6-7 August 2009.

open-class words, achieving a tagging accuracy of 90.6% for a 24k dataset, as high as the current state-of-the-art (90.4%) achieved with a complete dictionary. In the test condition where both algorithms are provided with a full lexicon, and are trained and evaluated over the same 96k dataset, we reduce the tagging error by up to 20%.

In Section 2 we explain our understanding of the POS tagging problem in detail and define the notions of functional context and open- and closed-class elements. Then we will introduce our methods for acquiring the lexicon (Section 3) and learning disambiguation models (Section 4, 5 and 6) step by step. Results are reported in Section 7 followed by Section 8 which discusses the linguistic motivation behind this work and the simplicity and efficiency of our model.

2 The Tagging Problem

In most work on both unsupervised and supervised problem, tagging is viewed as a sequential labeling problem. In this work, however, we would like to explore another view on tagging especially considering language as structured data.

The engineering concept of POS tags derives from the linguistic notion of syntactic category which specifies the combinatorial properties of a word in an underlying (syntactic) structure. Given the parse structure for a given word sequence which breaks the input into recursive functional domains such as IP, VP and NP, the POS tag of each word can be directly inferred. Of course, assuming a pre-parsed structure as input to POS tagging is somewhat ridiculous, but it strongly motivates us to highlight the features of structural information for POS tagging. Without resorting to any intermediate representations richer than the input string, we propose for engineering purposes to capture the features of interest for POS tagging by the functional items in language themselves. Then tagging is considered to be a process of identifying the functional contexts (functional items in context) in which the categorical property of the target item can be inferred.

Following ideas in current linguistic theory discussed in Section 8, we observe that the functional categories and some morphological endings serve as markers of the functional domains themselves (discussed above) and sit abstractly at the edge of those domains; the open-class (lexical) items must sit within appropriate functional domains. More specifically, although long distance dependencies are not at all rare, for a token in sequence, we only consider adjacent closed-class words and the verbal categorical feature (but not morphology) as *functional contexts*, the core concept in our disambiguation model.

Our system uses five open-class categories: three basic lexical categories verb, noun and adverb, and two derived Nominal categories (the two kinds of participles in English); and consider all other words not included in those categories to be closed-class items.

Overall, for the task of unsupervised tagging, we use a rule-based disambiguation model containing disambiguation rules conditioned on functional contexts, and the model is learned from unannotated data constrained by much less lexical knowledge than most previous work, namely the closed-class lexicon as introduced below.

2.1 Closed-class Lexicon

A dictionary containing all possible tags for each word is very useful to constrain the unsupervised learning of a POS disambiguation model, and in most previous work, a full lexicon computed from the WSJ corpus (the source of both training and test datasets) is used for both learning and tagging. Since a full lexicon is not a reasonable resource, we aim to limit the required knowledge to functional (closed-class) words only.

It is hard to define functional words in a linguistically strict sense, but this category is close to the notion within the engineering field of NLP of closed-class words, classes of words that are not open for new members. From the engineering point of view, this implies that a closed class has a finite and static number of members, so its members can be listed once and for all.

For English, lists of closed-class categories such as preposition, pronoun or even degree adverb, are obtainable resources, but this is not necessarily the case for other languages. In this paper, we leave the automatic acquisition of a closed-class lexicon for future work. For experiments in this work, we automatically compute a closed-class lexicon from the WSJ treebank 00-24 sections by picking out those words that are labeled predominantly with closed-class tags[1]. For each word selected as a closed-class word, all possible tags encountered

[1]For each word, if the number of instances labeled by closed-class tags is greater than by open-class tags, we select it as a closed-class word.

more than twice in the WSJ corpus are reserved in the closed-class lexicon, so closed-class words may also have open-class tags in our data set, a source of noise in our results. As a core part of language, this closed-class lexicon containing 288 entries, about 0.6% of the full lexicon by types, should be invariant over various genres, which is confirmed in experiments on both WSJ and Brown corpus[2].

2.2 Tagset

The 45 tags in the Penn Tagset (Marcus *et al.*, 2003) contain more information than just basic lexical categories. In recent work on unsupervised learning of POS taggers following (Smith&Eisner, 2005), the Penn tagset is reduced to 17 tags which nicely improves the tagging performance.

Based on our view of POS tags as local markers of underlying syntactic structure, we derive 27 tags from a feature-based analysis of the original Penn tagset. The main principle for reduction is that we collapse any two tags which are not distinguishable by structural features; such features include +/-N, +/-V for predication and +/-wh, +/-en for movement[3]. For example, under our analysis, the tag 'VBG' has the features [+V, +N, -tense, -en], tag 'VBD' [+V, +tense(past), -en], and 'VB' [+V, -tense(finite), -en]. However, since we do not consider the tense feature to be a structural feature, we do not distinguish 'VBD' from 'VB'; since N(ominal) is a structural feature, 'VBG' remains distinct from both 'VBD' and 'VB'. The 27 tags do not cover all cases of ambiguities of closed-class words in the original Penn tagset. Most notably, adjectives are not separated from nouns.

This reduction naturally follows the crucial properties of our disambiguation model. First of all, our model is not lexicalized, so it can only capture basic interactive relations between categories but cannot capture lexical dependencies, which are heavily required to disambiguate 'RP' with 'IN' or 'PDT' with 'DT' (so these two pairs are collapsed). More importantly, the structural information carried by the closed-class items is the key feature of our disambiguation model, but nouns and adjectives are not distinguishable by their structural positions (in NP), so they are not to be distinguished in our tagset[4].

Table 2: N/V categories of 27 POS tags

We use this new reduced tagset with 27 tags in our experiments[5]. For the purposes of comparison, we map the results using our 27 tag tagset to the commonly-used 17 tag tagset[6], and evaluate our algorithms for both tagsets. Table 1 compare the three tagsets, and the ambiguity column shows the average number of ambiguous tags per token in WSJ corpus section 00-24.

2.3 NV category

By using the reduced 27 tags, we found in this work that the heart of the disambiguation task for open-class words is to distinguish them in the Nominal vs. Verbal domains; and for the closed-class words, the Nominal vs. Verbal property of the adjacent context words is also very helpful for

[2]There are two special classes of words worthy of discussion with respect to being closed or open. 1. While the morphological ending '-ly' freely introduces adverbs, this category is otherwise essentially closed class; and 2. There are obviously unboundedly many numbers(CD), but all these match some regular pattern. So we include adverbs without explicit morphological marking in the closed-class lexicon (we frankly doubt adverbs can be acquired by distributional clustering); and as for numbers, we embed exactly such a regular pattern in our model.

[3]Not all features of tags are listed here, and further discussion of the feature-based analysis of the tagset is to be reported in other work. This analysis of tags is motivated by Chomsky.

[4]Due to the indistinguishable roles of adjectives and nouns in Noun Phrase, it is also hard to extract the adjectives from nouns for lexicon acquisition.

[5]For open-class categories, we keep VB (for VB*), NN for (NN*), VBG, VBN and RB (for RB*), and we reduce the JJ* tags to the tag NN and for closed-class tags, we keep almost all the original distinctions, except for two pairs: 'PDT' and 'DT'; 'RP' and 'IN'. Also 'WRB' is reduced to 'RB'.

[6]In our tagset, there are two coarser tags which stand for more than one tag in the 17 tags: 'NN' stands for both 'N' and 'ADJ' and 'IN' for both 'RP' and 'IN'. So to map the output of coarser tags to the finer ones, we need to look up the full-lexicon, since adjectives are not extracted from nouns in the lexicon acquisition process. For a word tagged as 'NN' with a possible tag of 'JJ', if the following word is also tagged as 'NN', then the current 'NN' is mapped to 'JJ'. On the other hand, no action is done for mapping 'IN', so gold 'RP' is always mis-tagged as 'IN' after mapping. If our tagging system outputs a finer tag (e.g. WDT) then it is reduced to the corresponding coarser one (e.g. 'W') in mapping to 17 tags.

disambiguation. The Nominal vs. Verbal property is defined through N/V categories of POS tags, and we list each category containing both closed-class and open-class tags in table 2.

3 Acquiring the open-class lexicon

Not being equipped with a full lexicon, our system takes the closed-class lexicon as given, and automatically computes possible tags, which must be open class, for all other words in the acquisition process as described below. There are five open-class tags in our reduced tagset, as we describe above: 'VBG' and 'VBN' represent two kinds of derived Nominal elements, with corresponding morphological endings attached to the verbal roots; and 'RB' represents the adverbial class into which new words can only be introduced if affixed with the special ending '-ly'. Taking into account this special morphology, we divide our construction of the open-class lexicon into two steps: N/V-Clustering and Morphing. At the N/V-clustering step, we classify the base-forms (roots) of open-class words into two clusters in a sparse feature space. At the Morphing step, we count on the embedded functional elements (i.e. morphology) to derive specific tags for words in each cluster.

3.1 Clustering

Inducing syntactic categories is a language acquisition task on which there has been extensive research, e.g. (Clark, 2003) and (Schütze, 1993), based largely on variants of distributional clustering. In a standard setup of POS clustering, each target word to be clustered, w_i, is represented as a vector, *<count(w_i,C_1), count(w_i,C_2),...,count(w_i,C_m)>*, collecting counts of occurrences of w_i in each context, C_j. Then the chosen algorithm clusters the feature vectors according to similarity.

In previous work, the contextual features are lexical, so the length of a feature vector varies from hundreds to thousands of features. The clustering algorithm then runs over this high-dimensional space, which is computationally quite intensive. Unlike previous work, our system only employs seven features, all functional, to represent target words, and we are paid back by a substantial improvement in efficiency. Each open-class word is represented in the feature space by the following seven component vector: *<left:DT, left:MD, mid:-ϕ, mid:-ed, mid:-ing, right:DT, right:MD>*. The first two values in this vector represent the counts of modal verbs (MD) and determiners (DT) occurring to the left of all forms of a base form; the three values in the middle represent the counts of three possible morphological forms of a word; and the last two values represent the counts of an immediately following MD and DT. This radical reduction of the feature space eliminates any need for sophisticated clustering techniques. For the purpose of convenience, we use a basic k-means clustering algorithm which allows us to specify the number of output clusters (Maffi, 2007).

As is well known, clustering all words in a corpus using distributional clustering results in a high number of clusters. For example, (Schütze, 1993) induces 200 clusters and (Clark, 2003) chooses between 16-128; and most of these induced categories are difficult to associate with a specific POS tag. Chan's recent thesis work (Chan, 2008) provides us with a solution to this problem. In the first pass of Chan's model for unsupervised lexical category induction, verbs are separated from all other categories with a high level of purity; the second pass separates adjectives from nouns by using the categorical results from the first pass as an additional feature[7]. His experiments for a wide range of languages show that the *"restriction to cluster base forms only*[8]*"* is crucial to induce clusters more in line with the definition of the open-class syntactic categories we care about here.

Here, we follow a variant of Chan's approach, grouping words with their base-forms for clustering. For example, we group all occurrences of the transformed (morphological) forms, (*start, starts, starting and started*), in a particular context, C_j, together with the base form *start* to form a single count for $(start, C_j)$, in forming the corresponding feature vectors. Given this, since all inflections of one base form share the same feature vector, all inflections enter into the same class of their base-form. In (Chan, 2008), morphological base forms are the output of a new morphology induction algorithm he develops. Here, we simply extract the base form of a word by stripping three possible forms of endings: *-s*, *-ing* and *-ed*[9].

[7] For simplicity, we don't run a second pass but reduce adjectives to noun.

[8] See p.139 in (Chan, 2008)

[9] This simple strategy, as well as more complex morphological analyzers, cannot deal with irregular verbs, so we list in memory the corresponding 'regular' ending of each irregular verb. For example, we know that the ending of *ran* is '-ed', but we DO NOT know that *ran* is only the past tense

3.2 Morphing

After the clustering step, which we intend to separate the Nominal and Verbal classes, two clusters as desired are induced, but we still need a method to automatically decide which one is which. A trick that works well in practice is simply to pick the smaller class as the Verbal class. These two classes reflect the basic categories of the roots; by a generative mechanism observed in most languages, roots (base-forms) are transformed into derived categories by fusing with functional elements, which surface as the few morphological endings in English.

For all words in the Nominal class, except for those with the ending *-ly*, the only possible tag for each is 'NN', since no finer categories of 'NN' exist in our reduced tagset. On the other hand, for a word with ending *-ly* falling into the N class, we simply assume that its tag must be 'RB', although this assumption may have a few exceptions.

The Verbal class contains all words with verbal roots. There are two specific endings in English serving as morphological markers of derived Nominal categories, -ed and -ing, corresponding to derived categories 'VBN' and 'VBG' respectively. So for each word ending with -ed, we assign two possible tags to it, 'VB'(our reduced form of 'VBD') and 'VBN'; and for each word ending with -ing we assume only one possible tag, 'VBG', although this assumption may systematically introduce tagging error confusing 'VBG' and 'NN'. For example, if the feature vector representing the base-form group *start, starts, started,starting* is classified into the verbal class, then both *starts* and *start* will receive one possible tag 'VB'; *starting* will receive one possible tag 'VBG'; but *started* will receive two possible tags 'VBN' and 'VB'.

As one may notice, *start* and *starts* should have two senses, noun and verb, but the Nominal sense is lost in the Morphing step. For such cases, we introduce a simple supplemental process to compensate for the missing Nominal sense. For a word with the possible tag 'VB' (not 'VBG' or 'VBN') as determined in the Morphing step, if it is ever seen following a determiner in context, another possible tag 'NN' will be assigned to it.

Remember that, as introduced in Sect 2.2, 'VBN', 'VBG' and 'NN' are of category N and 'VB' is of category V. Then for each word in the resulting lexicon, there is maximally one possible tag of it falling in either category N or V, so the category information (N or V) is enough for the disambiguation task, as specified in Section 6.

form of *run*, because the ending '-ed' is ambiguous for both past tense and past participle. The list of irregular verbs is obtained from *http://www.englishpage.com*.

4 Unsupervised Tagging

Taking a dictionary as input, the task of unsupervised tagging is to learn a disambiguation model from unannotated data and apply this model for disambiguating the occurrences of words in context. In this section, we are going to introduce the representation of our disambiguation model first, and then discuss how it affects the system design. In the following two sections, we will describe the algorithms for learning and decoding the language model respectively.

4.1 Disambiguation Model

Again, we view tagging as a process of identifying functional context, from which the proper tagging simply follows. Given this, we represent the language model as a set of disambiguation rules conditioned on functional contexts that predict categorical information, with each rule of the form of $r = (con : cat)$ with con and cat the functional context and categorical information respectively.

In both open- and closed-class domains, given a pair of words (W_l, W_r), the disambiguation rules check the functional property of W_l and predicts the N/V category of W_r. However, in the open-class disambiguation model, con represents closed-class items as well as verbal feature, but in the closed-class disambiguation model, con represents closed-class categories (closed-class POS tags). In disambiguating an open-class word, con is checked against the preceding closed-class word or verbal feature (if any), and cat of the following open-class word is predicted. In disambiguating a closed-class word cw, each possible tag of cw may invoke a rule and each rule will predict a N/V category of the following item; if some rule makes the right prediction, the corresponding tag is assigned to cw. For example, *he:V*, a disambiguation rule for open-class words, says that if an open-class token follows the closed-class item *he*, then the Verbal tag should be assigned to this token. On the other hand, *IN:N*, a disambiguation rule for closed-class words, says that if a closed-class token precedes a Nominal word (open- or

closed- class) in context and has a possible tag of 'IN', then tag it with 'IN'.

This rule-based disambiguation model is deterministic in the sense that for each token in context there is maximally one tag that can be predicted. Not being statistically parameterized, this greedy prediction requires that 1) each rule is deterministic and 2) in each context, only one rule is invoked (which is guaranteed by the selection step introduced in Section 5.2). Moreover, this disambiguation model is non-lexicalized in that it is only conditioned on the functional items in context but not the target word itself.

4.2 System Design

Ideally, we should use closed-class tags in context for disambiguating open-class words because closed-class words are potentially ambiguous; but this would cause a chicken-egg problem. If we did this, then the learning of disambiguation rules for closed-class words requires category information for open-class items and vice versa, but none of the required category information is available from the unannotated data[10]. Thanks to how language works (including principally the low degree of ambiguity of closed-class words), it is good enough practically, as shown by our experiments, to encode the disambiguation model for open-class words using closed-class items without categorical information.

In this way, we can learn the disambiguation model of open-class items from raw data; however, closed-class disambiguation model is better learned after open-class words are disambiguated. Then there are four models in the system for learning and tagging over two distinct domains: Model-LC and Model-LO for learning the disambiguation model of closed- and open-class words respectively; Model-DC and Model-DO for disambiguating closed- and open-class words respectively; and they must be executed in a strict order as follows: Model-LO → Model-DO → Model-LC → Model-DC, as illustrated in Figure 1.

5 Learning Disambiguation Rules

In this section, we describe the learning algorithm used in both Model-LO and Model-LC. Although there is no annotated data available for learning,

[10]Our disambiguation model is not statistically parameterized, so this problem can not be resolved by any kind of parameter estimation technique as in previous work on unsupervised tagging.

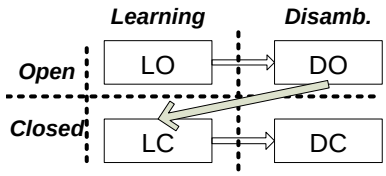

Figure 1: The order of the four models in system.

we can use the unambiguous events in data to establish the disambiguation rules and apply the rules to ambiguous events. The only difference in implementation of the two models lies in the 'rule-extraction', corresponding to different interpretations of unambiguous events for learning open- and closed-class disambiguation models. After being extracted from pairs of adjacent words in the input sequence, the rules are counted and selected using the same algorithm in both models.

5.1 Rule-extraction

For open-class words, disambiguation rules are extracted from raw data. A pair of adjacent words (W_l, W_r) is considered unambiguous if it satisfies the following two conditions: 1. W_l is in the closed class or an unambiguous type with only possible tag of 'VB'; and 2. all possible tags of W_r fall in the same N/V category (Nominal or Verbal but not mixed). If (W_l, W_r) is unambiguous in this sense, then extract rule $r = (con : cat)$, where con is W_l (for closed-class words) or 'V' (for unambiguous verbal words), and cat is the N/V category of W_r. For example, in the sequence *(...he has claimed..)*, the pair *(he, has)* is unambiguous in that *he* is a closed-class item and *has* has only one possible tag, 'VB', so a rule $((he : V)$ is extracted; but *(has, claimed)* is not usable since *claimed* has two possible tags: 'VB' of category V and 'VBN' of category N.

Disambiguation rules for closed-class words are extracted after open-class disambiguation. A pair of adjacent words (W_l, W_r) is considered unambiguous if it satisfies the following two conditions: 1. W_l is in the closed class and has only one possible tag in the closed-class lexicon; 2. W_r is either disambiguated or all possible tags of W_r fall in the same N/V category. If (W_l, W_r) is unambiguous in the above sense, then extract rule $r = (con : cat)$, where con is the single tag of W_l, and cat is the N/V category of W_r. For example, in the sequence *"...for his stepping..."*, the pair *(for his)* is unambiguous in that *for* has only

one possible tag 'IN' and both possible tags of *his*, 'PRP' and 'PRP$', fall into the Nominal category, then a rule $(IN : N)$ is extracted; but *(his about)* is not usable since *his* has more than one possible tag and *about* has two possible tags, 'RB' and 'IN', which are neither both 'N' nor both 'V'.

5.2 Counting and Selecting

In the counting step, a set of rules R is first initialized to be empty, and then, as each disambiguation rule r is generated while passing through the data, if not already in R, it is added with an initial count of one; otherwise, N_r, the count of r, is incremented by one. Note that we know that for a rule, $(con : cat)$, the prediction cat can only be either N or V; then for each context con, there are two forms of rules counted, $(con : N)$ or $(con : V)$. By selecting the rule with a greater count for each context, we guarantee that the resulting disambiguation model is deterministic.

6 Tagging

Given our rule-based, deterministic language model, tagging is a straightforward process of decoding the disambiguation rules. Recall that there are two separate tagging models in the system, Model-DO and Model-DC for disambiguating open- and closed-class respectively.

The inputs to Model-DO are the open-class lexicon, the disambiguation rules learned in Model-LO and raw data in sequence. For each ambiguous open-class word w in sequence if the preceding closed-class word (if any) invokes a disambiguation rule, $r = (con : cat)$, then pick the possible tag of w that falls in the category of cat (N or V), as discussed in Section 3.2. If no rule is triggered our default choice is 'NN'; but if 'NN' is not a possible tag, we assume the default domain is Verbal (so the 'VB' tag is favored).

The application of disambiguation rules in Model-DC is a little more complex. For each ambiguous closed-class word cw in sequence followed by a token of category cat, N or V, pick a possible tag of cw, con, such that $(con : cat)$ is a rule learned in Model-LC. If no tag is picked, a random choice is made. While there are residual cases that no functional context can help with tagging, the disambiguation model proposed here combined with random choice results in a good overall performance, as shown in section 7.3.

	dict. with words of count $> d$				
d (percent lex.)	1 (100%)	2 (55%)	3 (41%)	∞ (0.6%)	#tag -

model-27	*93.2*	...	...	*92.1*	27
LDA+AC	93.4	91.2	89.7	-	17

Table 3: Tagging accuracy with partial dictionaries over 24k dataset; our closed-class lexicon is the closest approximation to the ∞ column .

7 Results

Our unsupervised tagging system is compared to the following models As reported in (Banko&Moore, 2004), 'the quality of the lexicon made available to unsupervised learner made the greatest difference to tagging accuracy'. So we only compare our experiments to recent work built over the same dataset and a full lexicon automatically extracted from the Penn Treebank. As described in section 2.1, the closed-class lexicon, special in our experiments, is also automatically constructed from the WSJ corpus, and will be used in experiments on both WSJ and Brown corpora below[11]. CRF/CE (Smith&Eisner, 2005) and BHMM2 (Goldwater&Griffiths, 2007) have been discussed briefly in the introduction. LDA+AC (Toutanova&Johnson, 2007) is actually a semi-unsupervised model given the prior on $p(t|w)$; despite this additional information, our model outperforms it in experiments with partial dictionaries. For the purpose of comparison, our experiments use the same dataset as in these previous work, varying in sizes from 12K to 96K. In addition to reporting on our own tagset with 27 tags, we also map the results onto the 17 tags used in other models as explained above.

7.1 Unsupervised Tagging over Partial Dictionaries

As shown in Table 3, reducing the dictionary by filtering rare words (with count$<= d$) has not been a promising track to follow for accomplishing the task with as little information as possible. However, by introducing a lexicon acquisition step, we achieve a tagging accuracy of 90.6% for the 24K test data with no prior open-class lexicon, provided with only a minimal lexicon of closed-class items (about 0.6% of the full lexicon), as high as

[11] If we control the quality of the closed-class lexicon (but still leave the full-lexicon untouched) by filtering out errors in the Treebank, the performance is considerably higher.

size	12K	24k	48k	96K	#tag	lex.
BHMM2	85.8	84.4	85.7	85.8	17	full
CRF/CE	86.2	88.6	88.4	89.4	17	full
Model-17	**91.0**	**91.6**	**91.6**	**91.5**	17	full
Model-27	*93.1*	*93.6*	*93.5*	*93.4*	27	full

model-27	*90.9*	*91.2*	*92.0*	*92.2*	27	closed

Table 4: Tagging Accuracy of models trained over dataset varying in sizes with full/closed-class lexicon

the best previous performance of 90.4 given a full lexicon (CRF/CE with $d = 1$)[12].

One other work that investigates the use of a limited lexicon is (Haghighi&Klein, 2006), which develops a prototype-drive approach to propagate the categorical property using distributional similarity features; using only three exemplars of each tag, they achieve a tagging accuracy of 80.5% using a somewhat larger dataset but also the full Penn tagset, which is much larger.

7.2 Varying in sizes

As shown in Table 4, our new algorithm reduces tagging error by up to 20% over the state-of-the-art given a full lexicon, from 89.4% to 91.5% over the 96k dataset[13].

To better understand the learning property of our system and to get an estimate of the variance of our results above, we repeated the experiments above, starting with either the full lexicon or just the closed-class lexicon, with datasets varying from 0.5K to 96K in size, and repeated each experiment 60 times on different sequences, with four samples randomly selected from the Brown corpus, one from the training data reported above and the others from the WSJ corpus. As shown in Figure 2, for the closed-class lexicon experiments, the standard deviation of tagging accuracy over the dataset of each size sharply decreases as the size of the data increases, as expected. It is also clear that

[12]Since we are facing an unsupervised task, the training set is unannotated, and hence there is no reason not to use it as the test set as well. For the sake of comparison, we use the same split of the dataset for training as previous work. In Table 3 the tagging model is trained over 96k and evaluated on 24k, but in Table 4, the tagging model is trained and evaluated over test and training sets of the same size.

[13]With a full lexicon, we need to disambiguate between open-class tags which fall into the same N/V category, which is beyond the ability of our disambiguation rules which predict N or V only. When more than one possible tag in the same category predicted by the disambiguation rule, we simply make a random choice. Although not as constrained as the acquired lexicon, a full lexicon does improve the tagging performance, since the automatic lexicon acquisition is far from perfect.

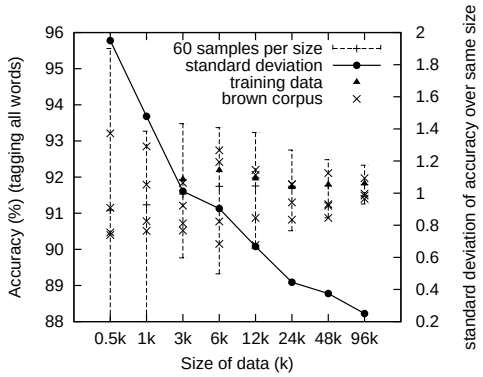

Figure 2: Standard Deviation of Tagging Accuracy with closed-class lexicon; 60 samples for each size, randomly selected from both Brown and WSJ corpus.

	system with closed-class lexicon		system with full lexicon	
sub-model	#errors	accuracy	#errors	accuracy
Model-DO	1089	87.3%	3546	78.9%
Model-DC	1694	89.6%	1709	89.7%
random	1148	44.2%	981	44.9%
recall	3650	-	75	-
total	7581	75.2%	6311	82.1%
#ambiguous	30563		35229	

Table 5: The number of errors and percent *ambiguous* tokens tagged correctly in the 96k dataset with 27 tags. For either system built upon closed-class lexicon or full lexicon, the table shows the disambiguation accuracy and number of errors for each sub-model in the system: Model-DO for disambiguating open-class, Model-DC for disambiguating Closed-class and random choice. The numbers of recall errors (gold tag not in dictionary) and total errors for each system are also shown.

the performance of our algorithm on the Brown corpus is as strong as on the WSJ corpus. Results for the full-lexicon are similar.

7.3 Error Analysis

There are certainly cases that no functional context can help with tagging, since our disambiguation models are encoded by functional context only. Thus it is worth a closer look to how often the system resorts to random choice, as well as to the disambiguation accuracy of either disambiguation model for open- and closed- class learned from unannotated data. We show the disambiguation accuracy of ambiguous words only for each model in Table 5, and also the number of errors due to imperfect lexicons or random choice.

8 Discussion and Future Work

In this work on unsupervised tagging, we combine lexicon acquisition with the learning of a

POS disambiguation model. Moreover, the disambiguation model we used is deterministic, non-lexicalized and defined over two distinct domains with complementary distribution (open- and closed-class).

Building a lexicon based on induced clusters requires our morphological knowledge of three special endings in English: *-ing*, *-ed* and *-s*; on the other hand, to reduce the feature space used for category induction, we utilize vectors of functional features only, exploiting our knowledge of the role of determiners and modal verbs. However, the above information is restricted to the lexicon acquisition model. Taking a lexicon as input, which either consists of a known closed-class lexicon together with an acquired open-class lexicon or is composed by automatic extraction from the Penn Treebank, we need NO language-specific knowledge for learning the disambiguation model.

We would like to point the reader to (Chan, 2008) for more discussion on Category induction[14]; and discussions below will concentrate on the proposed disambiguation model.

Current Chomskian theory, developed in the Minimalist Program (MP) (Chomsky, 2006), argues (very roughly speaking) that the syntactic structure of a sentence is built around a scaffolding provided by a set of functional elements[15]. Each of these provides a large tree fragment (roughly corresponding to what Chomsky calls a *phase*) that provide the piece parts for full utterances. Chomsky observes that when these fragments combine, only the very edge of the fragments can change and that the internal structure of these fragments is rigid (he labels this observation the Phase Impenetrability Condition, PIC). With the belief in PIC, we propose the concept of functional context, in which category property can be determined; also we notice the distinct distribution of the elements (functional) on the edge of *phase* and those (lexical) assembled within the *phase*.

Instead of chasing the highest possible performance by using the strongest method possible, we wanted to explore how well a deterministic, non-lexicalized model, following certain linguistic intuitions, can approach the NLP problem. For the unsupervised tagging task, this simple model, with less than two hundred rules learned, even outperforms non-deterministic generative models with ten of thousands of parameters.

Another motivation for our pursuit of this deterministic, non-lexicalized model is computational efficiency[16]. It takes less than **3 minutes** total for our model to acquire the lexicon, learn the disambiguation model, tag raw data and evaluate the output for a 96k dataset on a small laptop[17]. And a model using only counting and selecting is common in the research field of language acquisition and perhaps more compatible to the way humans process language.

We are certainly aware that our work does not yet address two problems: 1). How the system can be adapted to work for other languages and 2) How to automatically obtain the knowledge of functional elements. We believe that, given the proper understanding of functional elements, our system will be easily adapted to other languages, but we clearly need to test this hypothesis. Also, we are highly interested in completing our system by incorporating the acquisition of functional elements. (Chan, 2008) presents an extensive discussion of his work on morphological induction and (Mintz *et al.*, 2002) presents interesting psychological experiments we can build on to acquire closed-class words.

9 Acknowledgments

We thank the National Science Foundation for its support of this work under grant IIS-0415138. We greatly appreciate the comments of the anonymous reviewers; section 7.3 is newly added and two more paragraphs are added to section 2.2 in response to their comments. Also, we would like to thank an anonymous reviewer of a earlier version of this paper, whose thoughtful suggestion led to a restructuring of the current version. We benefited greatly from our discussions with Dr. Charles Yang. Noah Smith provided the data sets and details of the 17 tag tagset used in previous work. Finally, we thank Constantine Lignos for his careful editing of earlier versions.

[14] In our experiment, using the base-forms and adding a compensation process improves the coverage rate of the acquired lexicon from 79% to 93%.

[15] Such as determiners (for NPs), complementizers like *that* (for clauses), and case assigning elements associated with transitive verbs (for propositions).

[16] In some sense, the Minimalist Program was proposed to explore the idea that the existence of Syntax is especially motivated by efficient language processing.

Abstract

Structured syntactic knowledge is important for phrase reordering. This paper proposes using convolution tree kernel over source parse tree to model structured syntactic knowledge for BTG-based phrase reordering in the context of statistical machine translation. Our study reveals that the structured syntactic features over the source phrases are very effective for BTG constraint-based phrase reordering and those features can be well captured by the tree kernel. We further combine the structured features and other commonly-used linear features into a composite kernel. Experimental results on the NIST MT-2005 Chinese-English translation tasks show that our proposed phrase reordering model statistically significantly outperforms the baseline methods.

1 Introduction

Phrase-based method (Koehn et al., 2003; Och and Ney, 2004; Koehn et al., 2007) and syntax-based method (Wu, 1997; Yamada and Knight, 2001; Eisner, 2003; Chiang, 2005; Cowan et al., 2006; Marcu et al., 2006; Liu et al., 2007; Zhang et al., 2007c, 2008a, 2008b; Shen et al., 2008; Mi and Huang, 2008) represent the state-of-the-art technologies in statistical machine translation (SMT). As the two technologies are complementary in many ways, an interesting research topic is how to combine the strengths of the two methods. Many research efforts have been made to address this issue, which can be summarized into two ideas. One is to add syntax into phrase-based model while another one is to enhance syntax-based model to handle non-syntactic phrases. In this paper, we bring forward the first idea by studying the issue of how to utilize structured syntactic features for phrase reordering in a phrase-based SMT system with BTG (Bracketing Transduction Grammar) constraints (Wu, 1997).

Word and phrase reordering is a crucial component in a SMT system. In syntax-based method, word reordering is implicitly addressed by translation rules, thus the performance is subject to parsing errors to a large extent (zhang et al., 2007a) and the impact of syntax on reordering is difficult to single out (Li et al., 2007). In phrase-based method, local word reordering[1] can be effectively captured by phrase pairs directly while local phrase reordering is explicitly modeled by phrase reordering model and distortion model. Recently, many phrase reordering methods have been proposed, ranging from simple distance-based distortion model (Koehn et al., 2003; Och and Ney, 2004), flat reordering model (Wu, 1997; Zens et al., 2004), lexicalized reordering model (Tillmann, 2004; Kumar and Byrne, 2005), to hierarchical phrase-based model (Chiang, 2005; Setiawan et al., 2007) and classifier-based reordering model with linear features (Zens and Ney, 2006; Xiong et al., 2006; Zhang et al., 2007a; Xiong et al., 2008). However, one of the major limitations of these advances is the structured syntactic knowledge, which is important to global reordering (Li et al., 2007; Elming, 2008), has not been well exploited. This makes the phrase-based method particularly weak in handling global phrase reordering. From machine learning viewpoint (Vapnik, 1995), it is computationally infeasible to explicitly generate features involving structured information in many NLP applica-

[1] This paper follows the term convention of global reordering and local reordering of Li et al. (2007), between which the distinction is solely defined by reordering distance (whether beyond four source words) (Li et al., 2007).

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 698–707,
Singapore, 6-7 August 2009.

tions. For example, one cannot enumerate efficiently all the sub-tree features for a full parse tree. This would be the reason why structured features are not fully utilized in previous statistical feature-based phrase reordering model.

Thanks to the nice property of kernel-based machine learning method that can implicitly explore (structured) features in a high dimensional feature space (Vapnik, 1995), in this paper we propose using convolution tree kernel (Haussler, 1999; Collins and Duffy, 2001) to explore the structured syntactic knowledge for phrase reordering and further combine the tree kernel with other diverse linear features into a composite kernel to strengthen the model's predictive ability. Indeed, using tree kernel methods to mine structured knowledge has shown success in some NLP applications like parsing (Collins and Duffy, 2001), semantic role labeling (Moschitti, 2004; Zhang et al., 2007b), relation extraction (Zhang et al., 2006), pronoun resolution (Yang et al., 2006) and question classification (Zhang and Lee, 2003). However, to our knowledge, such technique still remains unexplored for phrase reordering.

In this paper, we look into the phrase reordering problem in two aspects: 1) how to model and optimize structured features, and 2) how to combine the structured features with other linear features and further integrate them into the log-linear model-based translation framework. Our study shows that: 1) the structured syntactic features are very useful and 2) our kernel-based model can well explore diverse knowledge, including previously-used linear features and the structured syntactic features, for phrase reordering. Our model displays one advantage over the previous work that it is able to utilize the structured syntactic features without the need for extensive feature engineering in decoding a parse tree into a set of linear syntactic features.

To have a more insightful evaluation, we design three experiments with three different evaluation metrics. Experimental results on the NIST MT-2005 Chinese-English translation tasks show that our method statistically significantly outperforms the baseline methods in term of the three different evaluation metrics.

The rest of the paper is organized as follows. Section 2 introduces the baseline method of BTG-based phrase translation method while section 3 discusses the proposed method in detail. The experimental results are reported and discussed in section 4. Finally, we conclude the paper in section 5.

2 Baseline System and Method

We use the MaxEnt-based BTG translation system (Xiong et al., 2006) as our baseline. It is a phrase-based SMT system with BTG reordering constraint. The system uses the BTG lexical translation rules ($A \rightarrow x/y$) to translate the source phrase x into target phrase y, and the BTG merging rules ($A \rightarrow [A, A] | < A, A >$) to combine two neighboring phrases with a straight or inverted order. In the translation model, the BTG lexical rules are weighted with several features, such as phrase translation, word penalty and language models, in a log-linear form. With the BTG constraint, the reordering model Ω is defined on the two neighboring phrases A^1 and A^2 and their order $o \in \{straight, inverted\}$ as follows:

$$\Omega = \mathrm{f}(o, A^1, A^2) \quad (1)$$

In the baseline system, a MaxEnt-based classifier with boundary words of the two neighboring phrases as features is used to model the merging/reordering order. The baseline MaxEnt-based reordering model is formulized as follows:

$$\Omega = p_\theta(o|A^1, A^2) = \frac{exp(\sum_i \theta_i h_i(o, A^1, A^2))}{\sum_o exp(\sum_i \theta_i h_i(o, A^1, A^2))} \quad (2)$$

where the functions $h_i(o, A^1, A^2) \in \{0,1\}$ are model feature functions using the boundary words of the two neighboring phrases as features, and θ_i are feature weights that are trained based on the MaxEnt-based criteria.

3 Tree Kernel-based Phrase Reordering Model

3.1 Kernel-based Classifier Solution to Phrase Reordering

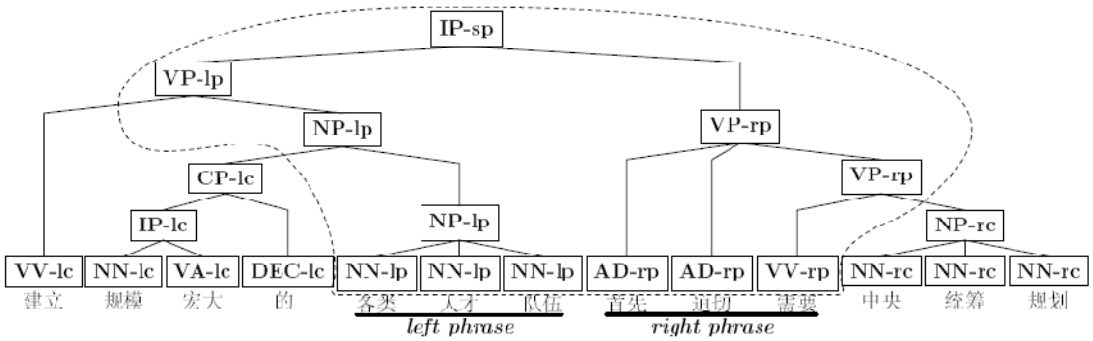
In this paper, phrase reordering is recast as a classification issue as done in previous work (Xiong et al., 2006 & 2008; Zhang et al., 2007a). In training, we use a machine learning algorithm training on the annotated phrase reordering instances that are automatically extracted from word-aligned, source sentence parsed training corpus, to learn a classifier. In testing (decoding), the learned classifier is applied to two adjacent source phrases to decide whether they should be merged (straight) or reordered (inverted) and what their probabilities are, and then these probabilities are used as one feature in the log-linear model in a phrase-based decoder.

In addition to the previously-used linear features, we are more interested in the value of structured syntax in phrase reordering and how to capture it using kernel methods. However, not

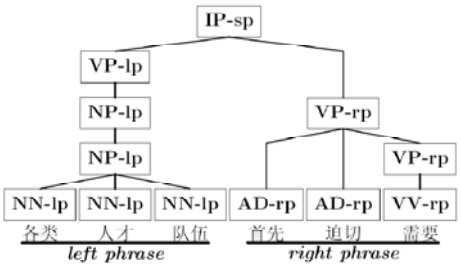
all classifiers are able to work with kernel methods. Only those dot-product-based classifiers can work with kernels by replacing the dot product with a kernel function, where the kernel function is able to directly calculate the similarity between two (structured) objects without enumerating them into linear feature vectors. In this paper, we select SVM as our classifier. In this section, we first define the structured syntactic features and introduce the commonly used linear features, and then discuss how to utilize these features by kernel methods together SVM for phrase reordering

3.2 Structured Syntactic Features

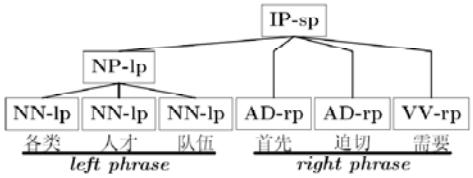
A reordering instance $x = \{A^1, A^2\}$ (see Eq.1) in this paper refers to two adjacent source phrases A^1 and A^2 to be translated. The structured syntactic feature spaces of a reordering instance are defined as the portion of a parse tree of the source sentence that at least covers the span of the reordering instance (i.e. the two neighboring phrases). The syntactic features are defined as all



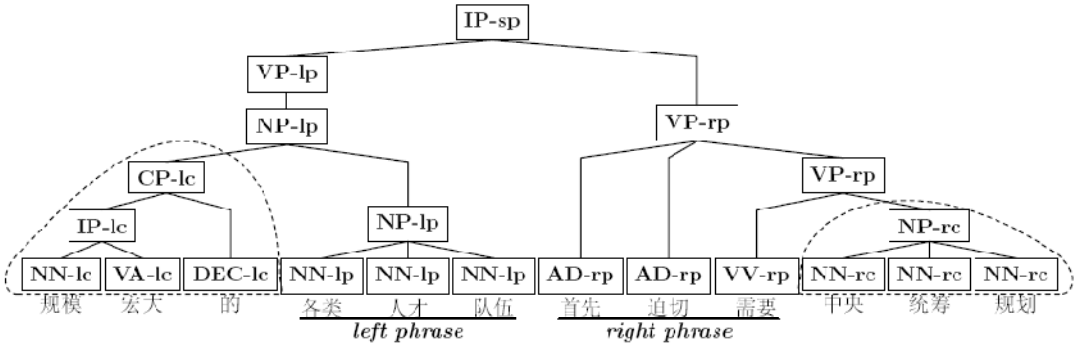
T_1) **Minimum Sub-Tree (MST)**



T_2) **Minimum Sub-Structure (MSS)**



T_4) **Chunking Tree (CT)**



T_3) **Context-sensitive Minimum Sub-Structure (CMSS)**

Figure 1. Different representations of structured syntactic features of a reordering instance in the example sentence excerpted from our training corpus "…建立/build 规模/scale 宏大/mighty 的/of 各类/various types 人才/qualified personnel 队伍/contingent 首先/above all 迫切/urgently 需要/necessary 中央/central authorities 统筹/overall 规划/planning…(To build a mighty contingent of qualified personnel of various types, it is necessary, above all, for the central authorities to make overall planning.) ", where "各类/various types 人才/qualified personnel 队伍/contingent (contingent of qualified personnel of various types)" is the 1st/left phrase and "首先/above all 迫切/urgent 需要/necessary (it is necessary, above all, …)" is the 2nd/right phrase. Note that different function tags are attached to the grammar tag of each internal node.

the possible subtrees in the structured feature spaces. We can see that the structured feature spaces and their features are encapsulated by a full parse tree of source sentences. Thus, it is critical to understand which portion of a parse tree (i.e. structured feature space) is the most effective to represent a reordering instance. Motivated by the work of (Zhang et al., 2006), we here examine four cases that contain different sub-structures as shown in Fig. 1.

(1) Minimum Sub-Tree (MST): the sub-tree rooted by the nearest common ancestor of the two phrases. This feature records the minimum sub-structure covering the two phrases and its left and right contexts as shown in Fig 1.T_1.

(2) Minimum Sub-Structure (MSS): the smallest common sub-structure covering the two phrases. It is enclosed by the shortest path linking the two phrases. Thus, its leaf nodes exactly consist of all the phrasal words.

(3) Context-sensitive Minimum Sub-Structure (CMSS): the **MSS** extending with the 1st left sibling node of the left phrase and the 1st right sibling node of the right phrase and their descendants. If sibling is unavailable, then we move to the parent of current node and repeat the same process until the sibling is available or the root of the **MST** is reached.

(4) Chunking Tree (CT): the base phrase list extracted from the **MSS**. We prune out all the internal structures of the **MSS** and only keep the root node and the base phrase list for generating the chunking tree.

Fig. 1 illustrates the different representations of an example reordering instance. T_1 is the **MST** for the example instance, where the sub-structure circled by a dotted line is the **MSS**, which is also shown in T_2 for clarity. We can see that the **MSS** is a subset of the **MST**. By T_2 we would like to evaluate whether the structured information is effective for phrase reordering while by comparing the system performance when using T_1 and T_2, we would like to evaluate whether the structured context information embedded in the **MST** is useful to phrase reordering. T_3 is the **CMSS**, where the two sub-structures circled by dotted lines are included as the context to T_2 and make T_3 limited context-sensitive. This is to evaluate whether the limited context information in the **CMSS** is helpful. By comparing the performance of T_1 and T_3, we would like to see whether the larger context in T_1 is a noisy feature. T_4 is the **CT**, where only the basic structured information is kept. By comparing the performance of T_2 and T_4, we would like to study whether the high-level structured syntactic features in T_2 are useful to phrase reordering.

After defining the four structured feature spaces, we further partition each feature space into five parts according to their functionalities. Because it only makes sense to evaluate two partitions of the same functionality between two reordering instances, the feature space partition leads to a more precise similarity calculation. As shown in Fig 1, all the internal nodes in each partition are labeled with a unique function tag in the following way:

- **Left Context (-lc):** nodes in this partition do not cover any phrase word and they are all in the left of the left phrase.
- **Right Context (-rc):** nodes in this partition do not cover any phrase word and they are all in the right of the right phrase.
- **Left Phrase (-lp):** nodes in this partition only cover the first phrase and/or its left context.
- **Right Phrase (-rp):** nodes in this partition only cover the second phrase and/or its right context.
- **Shared Part (-sp):** nodes in this partition at least cover both of the two phrases partially.

No lexical word is tagged since it is not a part of the structured features, and therefore not participating in the tree kernel computing.

3.3 Linear Features

In our study, we define the following lexicalized linear features which are easily to be extracted and integrated to our composite kernel:

- Leftmost and rightmost boundary words of the left and right source phrases
- Leftmost and rightmost boundary words of the left and right target phrases
- Internal words of the four phrases (excluding boundary words)
- Target language model (LM) score difference (monotone-inverted)

In total, we arrive at 13 features, including 8 boundary word features, 4 (kinds of) internal word features and 1 LM feature. The first 12 features have been proven useful (Xiong et al., 2006; Zhang et al., 2007a) to phrase reordering. LM score is certainly a strong evidence for modeling word orders and lexical selection. Although it is already used as a standalone feature in the log-linear model, we also would like to explicitly re-optimize it together with other reordering features in our reordering model.

3.4 Tree Kernel, Composite Kernel and Integrating into our Reordering Model

As discussed before, we use convolution tree kernel to capture the structured syntactic feature implicitly by directly computing similarity between the parse-tree representations of two reordering instances with explicitly enumerating all the features one by one. In convolution tree kernel (Collins and Duffy, 2001), a parse tree T is implicitly represented by a vector of integer counts of each sub-tree type (regardless of its ancestors):

$$\phi(T) = (\#\ subtree_1(T), \ldots, \#\ subtree_n(T))$$

where $\#\ subtree_i(T)$ is the occurrence number of the i^{th} sub-tree type ($subtree_i$) in T. Since the number of different sub-trees is exponential with the parse tree size, it is computationally infeasible to directly use the feature vector $\phi(T)$. To solve this computational issue, Collins and Duffy (2001) proposed the following parse tree kernel to calculate the dot product between the above high dimensional vectors implicitly.

$$\begin{aligned} K(T_1,T_2) &= <\phi(T_1),\phi(T_2)> \\ &= \sum_i \left(\left(\sum_{n_1\in N_1} I_{subtree_i}(n_1)\right)\cdot\left(\sum_{n_2\in N_2} I_{subtree_i}(n_2)\right)\right) \\ &= \sum_{n_1\in N_1}\sum_{n_2\in N_2}\Delta(n_1,n_2) \end{aligned}$$

where N_1 and N_2 are the sets of nodes in trees T_1 and T_2, respectively, and $I_{subtree_i}(n)$ is a function that is 1 iff the $subtree_i$ occurs with root at node n and zero otherwise, and $\Delta(n_1,n_2)$ is the number of the common *subtrees* rooted at n_1 and n_2, i.e.,

$$\Delta(n_1,n_2) = \sum_i I_{subtree_i}(n_1)\cdot I_{subtree_i}(n_2)$$

$\Delta(n_1,n_2)$ can be further computed efficiently by the following recursive rules:

Rule 1: if the productions (CFG rules) at n_1 and n_2 are different, $\Delta(n_1,n_2)=0$;

Rule 2: else if both n_1 and n_2 are pre-terminals (POS tags), $\Delta(n_1,n_2)=1\times\lambda$;

Rule 3: else,

$$\Delta(n_1,n_2) = \lambda\prod_{j=1}^{nc(n_1)}(1+\Delta(ch(n_1,j),ch(n_2,j)))$$

where $nc(n_1)$ is the child number of n_1, $ch(n,j)$ is the j^{th} child of node n and λ ($0<\lambda<1$) is the decay factor in order to make the kernel value less variable with respect to the *subtree* sizes. In addition, the recursive **Rule 3** holds because given two nodes with the same children, one can construct common sub-trees using these children and common sub-trees of further offspring. The time complexity for computing this kernel is $O(|N_1|\cdot|N_2|)$ and in practice in near to linear computational time without the need of enumerating all subtree features.

In our study, the linear feature-based similarity is simply calculated using dot-product. We then define the following composite kernel to combine the structured features-based and the linear features-based similarities:

$$K_c(x_1,x_2) = \alpha\cdot K_t(x_1,x_2) + (1-\alpha)\cdot K_l(x_1,x_2) \quad (3)$$

where K_t is the tree kernel over the structured features and K_l is the linear kernel (dot-product) over the linear features. The composite kernel K_c is a linear combination of the two individual kernels, where the coefficient α is set to its default value 0.3 as that in Moschitti (2004)'s implementation. The kernels return the similarities between two reordering instances based on their features used. Our basic assumption is, the more similar the two reordering instances of x_1 and x_2 are, the more chance they share the same order.

Now let us see how to integrate the kernel functions into SVM. The linear classifier learned by SVM is formulized as:

$$f(x) = \mathrm{sgn}(\textstyle\sum_i y_i a_i x\bullet x_i + b) \quad (4)$$

where a_i is the weight of a support vector x_i (i.e., a support reordering instance $x_i = \{A^1, A^2\}$in our study), y_i is its class label (1: $straight$ or -1: $inverted$ in our study) and b is the intercept of the hyperplane. An input reordering instance x is classified as positive (negative) if $f(x)>0$ ($f(x)<0$).

Based on the linear classifier, a kernelized SVM can be easily implemented by simply replacing the dot product $x*x_i$ in Eq (4) with a kernel function $K(x,x_i)$. Thus, the kernelized SVM classifier is formulated as:

$$f(x) = \mathrm{sgn}(\textstyle\sum_i y_i a_i K(x,x_i) + b) \quad (5)$$

where $K(x,x_i)$ is either $K_c(x,x_i)$, $K_t(x,x_i)$ or $K_l(x,x_i)$ in our study. Following Eq (1), our reordering model (implemented by the kernelized SVM) can be formulized as follows:

$$\begin{aligned} \Omega &= \mathrm{f}(o,A^1,A^2) = p_{svm}(o|x=\{A^1,A^2\}) \\ &= sgn(\textstyle\sum_i(y_i a_i K(x,x_i)+b)) \end{aligned} \quad (6)$$

A reordering instance x is classified as *straight* (or *inverted*) if $p_{svm}(o|x)>0$ (or $p_{svm}(o|x)<0$). Eq (6) and Eq (2) show the difference between our kernalized SVM-based reordering

model and the MaxEnt-based reordering model. The main difference between them lies in that our model is able to utilize structured syntactic features by kernalized SVM while the previous work can only use lexicalized word features by MaxEnt-based classifier.

Finally, because the return value of $p_{svm}(o|x)$ is a distance function rather than a probability, we use a sigmoid function to convert $p_{svm}(o|x)$ to a posterior probability as shown using the following to functions and apply it as one feature to the log-linear model in the decoding.

$$P(straight \mid x) = \frac{1}{1+e^{-p_{svm}(o|x)}} \quad \text{and}$$

$$P(inverted \mid x) = \frac{1}{1+e^{p_{svm}(o|x)}}$$

where *straight* represents a positive instance and *inverted* represents a negative instance.

4 Experiments and Discussion

4.1 Experimental Settings

Basic Settings: we evaluate our method on Chinese-English translation task. We use the FBIS corpus as training set, the NIST MT-2002 test set as development (dev) set and the NIST MT-2005 test set as test set. The Stanford parser (Klein and Manning, 2003) is used to parse Chinese sentences on the training, dev and test sets. GIZA++ (Och and Ney, 2004) and the heuristics "grow-diag-final-and" are used to generate *m-to-n* word alignments. The translation model is trained on the FBIS corpus and a 4-gram language model is trained on the Xinhua portion of the English Gigaword corpus using the SRILM Toolkits (Stolcke, 2002) with modified Kneser-Ney smoothing (Kenser and Ney, 1995). For the MER training (Och, 2003), we modify Koehn's MER trainer (Koehn, 2004) to train our system. For significance test, we use Zhang et al's implementation (Zhang et al, 2004).

Baseline Systems: we set three baseline systems: **B1**) Moses (Koehn et al., 2007) that uses lexicalized unigram reordering model to predict three orientations: monotone, swap and discontinuous; **B2**) MaxEnt-based reordering model with lexical boundary word features only (Xiong et al., 2006); **B3**) Linguistically annotated reordering model for BTG-based (LABTG) SMT (Xiong et al., 2008). For Moses, we used the default settings. We build a CKY-style decoder and integrate the corresponding reordering modelling methods into the decoder to implement the 2nd and the 3rd baseline systems and our system. Except reordering models, all the four systems use the same features in translation model, language model and distortion model as Moses in the log-linear framework. We tune the four systems using the strategies as discussed previously in this section.

Reordering Model Training: we extract all reordering instances from the *m-to-n* word-aligned training corpus. The reordering instances include the two source phrases, two target phrases, order label and its corresponding parse tree. We generate the boundary word features from the extracted reordering instances in the same way as discussed in Xiong et al. (2006) and use Zhang's MaxEnt Tools[2] to train a reordering model for the 2nd baseline system. Similarly, we use the algorithm 1 in Xiong et al. (2008) to extract features and use the same MaxEnt Tools to train a reordering model for the 3rd baseline system. Based on the extracted reordering instances, we generate the four structured features and the linear features, and then use the Tree Kernel Tools (Moschitti, 2004) to train our kernel-based reordering model (linear, tree and composite).

Experimental Design and Evaluation Metrics: we design three experiments and evaluate them using three metrics.

Classification-based: in the first experiment, we extract all reordering instances and their features from the dev and test sets, and then use the reordering models trained on the training set to classify (label) those instances extracted from the dev and test sets. In this way, we can isolate the reordering problem from the influence of others, such as translation model, pruning and decoding strategies, to better examine the reordering models' ability and to give analytical insights into the features. Classification Accuracy (CAcc), the percentage of the correctly labeled instances over all trials, is used as the evaluation metric.

Forced decoding[3]-based and normal decoding-based: the two experiments evaluate the reordering models through a real SMT system. The reordering model and the language model are the same in the two experiments. However, in forced decoding, we train two translation models, one using training data only while another using both

[2] http://homepages.inf.ed.ac.uk/s0450736/maxent.html

[3] A normal SMT decoder filters a translation model according to the source sentences, whereas in forced decoding, a translation model is filtered based on both source sentence and target references. In other words, in forced decoding, the decoder is forced to use those phrases whose translations are already in the references.

training, dev and test data. By forced decoding, we aim to isolate the reordering problem from those of OOV and lexical selections resulting from imperfect translation model in the context of a real SMT task. Besides the the case-sensitive BLEU-4 (Papineni et al., 2002) used in the two experiments, we design another evaluation metrics Reordering Accuracy (RAcc) for forced decoding evaluation. RAcc is the percentage of the adjacent word pairs with correct word order[4] over all words in one-best translation results. Similar to BLEU score, we also use the similar Brevity Penalty BP (Papineni et al., 2002) to penalize the short translations in computing RAcc. Finally, please note for the three evaluation metrics, the higher values represent better performance.

Feature Spaces	CAcc (%)	
	Dev	**Test**
Minimum Sub-Tree (**MST**)	89.87	89.92
Minimum Sub-Structure (**MSS**)	87.95	87.88
Context-Sensitive MSS (**CMSS**)	89.11	89.01
Chunking Tree (**CT**)	86.17	86.21
Linear Features (K_l)	90.79	90.46
K_l w/o using LM feature ($K_{l\text{-}LM}$)	84.24	84.06
Composite Kernel (K_c: **MST**+K_l)	92.98	92.67
MST w/o the 5 function tags	86.94	87.03
All are *straight* (*monotonic*)	78.92	78.67

Table 1: Performance of our methods on the dev and test sets with different feature combinations

4.2 Experimental Results

Classification of Instances: Table 1 reports the performance of our defined four structured features, linear feature and the composite kernel. The results are summarized as follows.

The last row reports the performance without using any reordering features. We just suppose that all the translations are monotonic, no reordering happens. The CAccs of 78.92% and 78.67% serve as the bottom line in our study. Compared with the bottom line, the tree kernels over the 4 structured features are very effective for phrase reordering since only structured information is used in the tree kernel[5].

The **CT**s performs the worst among the 4 structured features. This suggests that the middle and high-level structures beyond base phrases are very useful for phrase reordering. The **MSS**s show lower performance than the **CMSS**s and the **MST**s achieve the best performance. This clearly indicates that the structured context information is useful for phrase reordering. For this reason, the subsequent discussions are focused on the **MST**s, unless otherwise specified. The **MSS**s without using the 5 function tags perform much worse than the original ones. This suggests that the partitions of the structured feature spaces are very helpful, which can effectively avoid the undesired matching between partitions of different functionalities. Comparison of K_l and $K_{l\text{-}LM}$ shows the LM plays an important role in phrase reordering. The composite kernel (K_c) performs much better than the two individual kernels. This suggests that the structured and linear features are complementary and the composite kernel can well integrate them for phrase reordering.

Methods	CAcc (%)	
	Dev	**Test**
Minimum Sub-Tree (**MST**)	89.87	89.92
Linear Features (K_l)	90.79	90.46
Composite Kernel (K_c: **MST**+K_l)	92.98	92.67
MaxEnt+boundary word (**B2**)	88.33	86.97
MaxEnt+linguistic features (**B3_1**)	84.83	83.92
MaxEnt+LABTG (**B3: B2+ B3_1**)	88.82	88.18

Table 2: Performance comparison of different methods

Table 2 compares the performance of the baseline methods with ours. Comparison between **B3_1** and **MST** clearly demonstrates that the structured syntactic features are much more effective than the linear syntactic features that are manually extracted via heuristics. It also suggests that the tree kernel can well capture the structured features implicitly. K_l outperforms **B2**. This is mainly due to the contribution of LM features. **B2** (MaxEnt-based) significantly outperforms $K_{l\text{-}LM}$ in Table 1 (SVM-based). This suggests that phrase reordering may not be a good linearly binary-separable task if only boundary word features are used. Our composite kernel (K_c) significantly outperforms LABTG (**B3**). This mainly

[4] An adjacent word pair $w_i w_{i+1}$ in a translation have correct word order if and only if w_i appears before w_{i+1} in translation references. Note than the two words may not be adjacent in the references even if they have correct word order.

[5] The tree kernel algorithm only compares internal structures. It does not concern any lexical leaf nodes.

attributes to the contributions of structured syntactic features, LM and the tree kernel.

Forced Decoding: Table 3 compares the performance of our composite kernel with that of the LABTG (Baseline 3) in forced decoding. As discussed before, here we try two translation models.

The composite kernel outperforms the LABTG in all test cases. This further validates the effectiveness of the kernel methods in phrase reordering. There are still around 30% words reordered incorrectly even if we use the translation model trained on both training, dev and test sets. This reveals the limitations of current SMT modeling methods and suggests interesting future work in this area. The source language OOV[6] rate in forced decoding (13.6%) is much higher that in normal decoding (6.22%, see table 4). This is mainly due to the fact that the phrase table in forced decoding is filtered out based on both source and target languages while in normal decoding it is based on source language only. As a result, more phrases are filtered out in the forced decoding. There is 1.4% OOV even if the translation model is trained on the test set. This is due to the incorrect word alignment, large-span word alignment and different English tokenization strategies used in BLEU-scoring tool and ours.

Methods	Test Set (%)		
	RAcc	OOV	BLEU
Composite Kernel (K_c)	51.03	13.6	38.56
+translation model on Training, dev and test	72.67	1.41	62.87
MaxEnt+LABTG (**B3**)	48.96	13.6	37.32
+translation model on training, dev and test	71.45	1.41	62.14

Table 3: Performance comparison of forced decoding

Methods	Test Set	
	BLEU(%)	OOV(%)
Composite Kernel (K_c)	27.65	6.26
Moses (**B1**)	25.71	6.17
MaxEnt+boundary word(**B2**)	25.99	6.22
MaxEnt+LABTG (**B3**)	26.63	6.22

Table 4: Performance comparison

[6] OOV means a source words has no any English translation according to the translation model. OOV rate is the percentage of the number of OOV words over all the source words.

Normal Decoding/Translation: Table 4 reports the translation performance of our system and the three baseline systems.

Moses (**B1**) and the MaxEnt-based boundary word model (**B2**) achieve comparable performance. This means the lexicalized orientation-based reordering model in Moses performs similarly to the boundary word-based reordering model since the two models are both lexical word-based. However, theoretically, the MaxEnt-based model may suffer less from data sparseness issue since it does not depends on internal phrasal words and uses MaxEnt to optimize feature weights while the orientation-based model uses relative frequency of the entire phrases to compute the posterior probabilities. s. The MaxEnt-based LABTG model significantly outperforms (p<0.05) the MaxEnt-based boundary word model and the lexicalized orientation-based reordering model. This indicates that the linearly linguistically syntactic information is a useful feature to phrase reordering.

Our composite kernel-based model significantly outperforms (p<0.01) the three baseline methods. This again proves that the structured syntactic features are much more effective than the linear syntactic features for phrase reordering and the tree kernel method can well capture the informative structured features. The four methods show very slight difference in OOV rates. This is mainly due to the difference in implementation detail, such as different OOV penalties and other pruning thresholds.

5 Conclusion and Future Work

Structured syntactic knowledge is very useful to phrase reordering. This paper provides insights into how the structured feature can be used for phrase reordering. In previous work, the structured features are selected manually by heuristics and represented by a linear feature vector. This may largely compromise the contribution of the structured features to phrase reordering. Thanks to the nice properties of kernel-based learning method and SVM classifier, we propose leveraging on the kernelized SVM learning algorithm to address the problem. Specifically, we propose using convolution tree kernel to capture the structured features and design a composite kernel to combine the structured features and other linear features for phrase reordering. The tree kernel is able to directly take the structured reordering instances as inputs and compute their similarities without enumerating them into a set of liner

features. In addition, we also study how to find the optimal structured feature space and how to partition the structured feature spaces according to their functionalities. Finally, we evaluate our method on the NIST MT-2005 Chinese-English translation tasks. To provide insights into the model, we design three kinds of experiments together with three different evaluation metrics. Experimental results show that the structured features are very effective and our composite kernel can well capture both the structured and the linear features without the need for extensive feature engineering. It also shows that our method significantly outperforms the baseline methods.

The tree kernel-based phrase reordering method is not only applicable to adjacent phrases. It is able to work with any long phrase pairs with gap of any length in-between. We will study this case in the near future. We would also like to use one individual tree kernel for one partition in a structured feature space. In doing so, we are able to give different weights to different partitions according to their functionalities and contributions. Note that these weights can be automatically tuned and optimized easily against a dev set.

Discriminative Corpus Weight Estimation for Machine Translation

Spyros Matsoukas and **Antti-Veikko I. Rosti** and **Bing Zhang**

Abstract

Current statistical machine translation (SMT) systems are trained on sentence-aligned and word-aligned parallel text collected from various sources. Translation model parameters are estimated from the word alignments, and the quality of the translations on a given test set depends on the parameter estimates. There are at least two factors affecting the parameter estimation: domain match and training data quality. This paper describes a novel approach for automatically detecting and down-weighing certain parts of the training corpus by assigning a weight to each sentence in the training bitext so as to optimize a discriminative objective function on a designated tuning set. This way, the proposed method can limit the negative effects of low quality training data, and can adapt the translation model to the domain of interest. It is shown that such discriminative corpus weights can provide significant improvements in Arabic-English translation on various conditions, using a state-of-the-art SMT system.

1 Introduction

Statistical machine translation (SMT) systems rely on a training corpus consisting of sentences in the source language and their respective reference translations to the target language. These parallel sentences are used to perform automatic word alignment, and extract translation rules with associated probabilities. Typically, a parallel training corpus is comprised of collections of varying quality and relevance to the translation problem of interest. For example, an SMT system applied to broadcast conversational data may be trained on a corpus consisting mostly of United Nations and newswire data, with only a very small amount of in-domain broadcast news/conversational data. In this case, it would be desirable to down-weigh the out-of-domain data relative to the in-domain data during the rule extraction and probability estimation. Similarly, it would be good to assign a lower weight to data of low quality (e.g., poorly aligned or incorrectly translated sentences) relative to data of high quality.

In this paper, we describe a novel discriminative training method that can be used to estimate a weight for each sentence in the training bitext so as to optimize an objective function – expected translation edit rate (TER) (Snover et al., 2006) – on a held-out development set. The training bitext typically consists of millions of (parallel) sentences, so in order to ensure robust estimation we express each sentence weight as a function of sentence-level features, and estimate the parameters of this mapping function instead. Sentence-level features may include the identifier of the collection or genre that the sentence belongs to, the number of tokens in the source or target side, alignment information, etc. The mapping from features to weights can be implemented via any differentiable function, but in our experiments we used a simple perceptron. Sentence weights estimated in this fashion are applied directly to the phrase and lexical counts unlike any previously published method to the author's knowledge. The tuning framework is developed for phrase-based SMT models, but the tuned weights are also applicable to the training of a hierarchical model. In cases where the tuning set used for corpus weight estimation is a close match to the test set, this method yields significant gains in TER, BLEU (Papineni et al., 2002), and METEOR (Lavie and Agarwal, 2007) scores over a state-of-the-art hierarchical baseline.

The paper is organized as follows. Related work on data selection, data weighting, and model adaptation is presented in Section 2. The corpus weight

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 708–717,
Singapore, 6-7 August 2009.

approach and estimation algorithm are described in Section 3. Experimental evaluation of the approach is presented in Sections 4 and 5. Section 6 concludes the paper with a few directions for future work.

2 Related Work

Previous work related to corpus weighting may be split into three categories: data selection, data weighting, and translation model adaptation. The first two approaches may improve the quality of the word alignment and prevent phrase-pairs which are less useful for the domain to be learned. The model adaptation, on the other hand, may boost the weight of the more relevant phrase-pairs or introduce translations for unseen source phrases.

Resnik and Smith (2003) mined parallel text from the web using various filters to identify likely translations. The filtering may be viewed as a data selection where poor quality translation are discarded before word alignment. Yasuda et al. (2008) selected subsets of an existing parallel corpus to match the domain of the test set. The discarded sentence pairs may be valid translations but they do not necessarily improve the translation quality on the test domain. Mandal et al. (2008) used active learning to select suitable training data for human translation. Hildebrand et al. (2005) selected comparable sentences from parallel corpora using information retrieval techniques.

Lu et al. (2007) proposed weighting comparable portions of the parallel text before word alignment based on information retrieval. The relevant portions of the parallel text were given a higher integer weight in GIZA++ word alignment. Similar effect may be achieved by replicating the relevant subset in the training data.

Lu et al. (2007) also proposed training adapted translation models which were interpolated with a model trained on the entire parallel text. Snover et al. (2008) used cross-lingual information retrieval to identify possible bias-rules to improve the coverage on the source side. These rules may cover source phrases for which no translations were learned from the available parallel text.

Koehn and Schroeder (2007) described a procedure for domain adaptation that was using two translation models in decoding, one trained on in-domain data and the other on out-of-domain data. Phrase translation scores from the two models where combined in a log-linear fashion, with weights estimated based on minimum error rate training (Och, 2003) on a designated tuning set.

The method described in this paper can also be viewed as data filtering or (static) translation adaptation, but it has the following advantages over previously published techniques:

1. The estimated corpus weights are *discriminative* and are computed so as to directly optimize an MT performance metric on a pre-defined development set. Unlike the domain adaptation technique in (Koehn and Schroeder, 2007), which also estimates the adaptation parameters discriminatively, our proposed method does not require a manual specification of the in-domain and out-of-domain training data collections. Instead, it automatically determines which collections are most relevant to the domain of interest, and increases their weight while decreasing the weight assigned to less relevant collections.

2. All sentences in the parallel corpus can influence the translation model, as opposed to filtering/discarding data. However, the proposed method can still assign very low weights to parts of the corpus, if it determines that it helps improve MT performance.

3. The framework used for estimating the corpus weights can be easily extended to support discriminative alignment link-level weights, thus allowing the system to automatically identify which portions of the training sentences are most useful.

Naturally, as with any method, the proposed technique has certain limitations. Specifically, it is only concerned with influencing the translation rule probabilities via the corpus weights; it does not change the set of rules extracted. Thus, it is unable to add new translation rules as in Snover et al. (2008). Also, it can potentially lead to parameter over-fitting, especially if the function that maps sentence features to weights is complex and based on a large number of parameters, or if the development set used for estimating the mapping function does not match the characteristics of the test set.

3 Corpus Weights Estimation

3.1 Feature Extraction

The purpose of feature extraction is to identify, for each sentence in the parallel training data, a set of features that can be useful in estimating a weight that is correlated with quality or relevance to the MT task at hand. Starting from sentence-aligned, word-aligned parallel training data, one could extract various types of sentence-level features. For example, we could specify features that describe the two sides of the parallel data or the alignment between them, such as collection id, genre id, number of source tokens, number of target tokens, ratio of number of source and target tokens, number of word alignment links, fraction of source tokens that are unaligned, and fraction of target tokens that are unaligned. Additionally, we could include information retrieval (IR) related features that reflect the relevance of a training sentence to the domain of interest, e.g., by measuring vector space model (VSM) distance of the sentence to the current tuning set, or its log likelihhod with respect to an in-domain language model.

Note that the collection and genre identifiers (ids) mentioned above are bit vectors. Each collection in the training set is mapped to a number. A collection may consist of sentences from multiple genres (e.g., newswire, web, broadcast news, broadcast conversations). Genres are also mapped to a unique number across the whole training set. Then, given a sentence in the training bitext, we can extract a binary vector that contains two non-zero bits, one indicating the collection id, and another denoting the genre id.

It is worth mentioning that in the experiments reported later in this paper we made use of only the collection and genre ids as features, although the framework supports general sentence-level features.

3.2 Mapping Features to Weights

As mentioned previously, one way to map a feature vector to a weight is to use a perceptron. A multi-layer neural network may also be used, but at the expense of slower training. In this work, all of the experiments carried out made use of a perceptron mapping function. However, it is also possible to cluster the training sentences into classes by training a Gaussian mixture model (GMM) on their respective feature vectors[1]. Then, given a feature vector we can compute the (posterior) probability that it was generated by one of the *N* Gaussians in the GMM, and use this N-dimensional vector of posteriors as input to the perceptron. This is similar to having a neural network with a static hidden layer and Gaussian activation functions.

Given the many choices available in mapping features to weights, we will describe the mapping function in general terms. Let $\mathbf{f}_i$ be the $n \times 1$ feature vector corresponding to sentence i. Let $\phi(\mathbf{x}; \boldsymbol{\lambda})$ denote a function $\mathbb{R}^n \rightarrow (0, 1)$ that is parameterized in terms of the parameter vector $\boldsymbol{\lambda}$ and maps a feature vector $\mathbf{x}$ to a scalar weight in $(0, 1)$. The goal of the automatic corpus weight estimation procedure is to estimate the parameter vector $\boldsymbol{\lambda}$ so as to optimize an objective function on a development set.

3.3 Training with Weighted Corpora

Once the sentence features have been mapped to weights, the translation rule extraction and probability estimation can proceed as usual, but with weighted counts. For example, let $w_i = \phi(\mathbf{f}_i; \boldsymbol{\lambda})$ be the weight assigned to sentence i. Let (s, t) be a source-target phrase pair that can be extracted from the corpus, and $\mathcal{A}(s)$ and $\mathcal{B}(t)$ indicating the sets of sentences that s and t occur in. Then,

$$P(s|t) = \frac{\sum_{j \in \mathcal{A}(s) \cap \mathcal{B}(t)} w_j c_j(s, t)}{\sum_{j \in \mathcal{B}(t)} w_j c_j(t)} \qquad (1)$$

where $c_j(\cdot)$ denotes the number of occurrences of the phrase (or phrase-pair) in sentence j.

3.4 Optimizing the Mapping Function

Estimation of the parameters $\boldsymbol{\lambda}$ of the mapping function ϕ can be performed by directly optimizing a suitable objective function on a development set. Ideally, we would like to estimate the parameters of the mapping function so as to directly optimize an automatic MT performance evaluation metric, such as TER or BLEU on the full translation search space. However, this is extremely computationally intensive for two reasons: (a) optimizing in the full translation search space requires a new decoding pass for each iteration of optimization; and (b) a direct optimization of TER or

[1] Note that in order to train such a GMM it may be necessary to first apply a decorrelating, dimensionality reducing, transform (e.g., principal component analysis) to the features.

BLEU requires the use of a derivative free, slowly converging optimization method such as MERT (Och, 2003), because these objective functions are not differentiable.

In our case, for every parameter vector update we need to essentially retrain the translation model (reestimate the phrase and lexical translation probabilities based on the updated corpus weights), so the cost of each iteration is significantly higher than in a typical MERT application. For these reasons, in this work we chose to minimize the expected TER over a translation N-best on a designated tuning set, which is a continuous and differentiable function and can be optimized with standard gradient descent methods in a small number of iterations. Note, that using expected TER is not the only option here; any criterion that can be expressed as a continuous function of the phrase or lexical translation probabilities can be used to optimize $\boldsymbol{\lambda}$.

Given an N-best of translation hypotheses over a development set of S sentences, we can define the expected TER as follows

$$\mathcal{T} = \frac{\sum_{s=1}^{S} \sum_{j=1}^{N_s} p_{sj} \epsilon_{sj}}{\sum_{s=1}^{S} r_s} \tag{2}$$

where N_s is the number of translation hypotheses available for segment s; ϵ_{sj} is the minimum raw edit distance between hypothesis j of segment s (or h_{sj}, for short) and the reference translation(s) corresponding to segment s; r_s is the average number of reference translation tokens in segment s, and p_{sj} is the posterior probability of hypothesis h_{sj} in the N-best. The latter is computed as follows

$$p_{sj} = \frac{e^{\gamma L_{sj}}}{\sum_{k=1}^{N_s} e^{\gamma L_{sk}}} \tag{3}$$

where L_{sj} is the total log likelihood of hypothesis h_{sj}, and γ is a tunable scaling factor that can be used to change the dynamic range of the likelihood scores and hence the distribution of posteriors over the N-best. The hypothesis likelihood L_{sj} is typically computed as a dot product of a decoding weight vector and a vector of various "feature" scores, such as log phrase translation probability, log lexical translation probability, log n-gram language model probability, and number of tokens in the hypothesis. However, in order to simplify this presentation we will assume that it contains a single translation model score, the log phrase translation probability of source given target. This score is a sum of log conditional probabilities, similar to the one defined in Equation 1. Therefore, L_{sj} is indirectly a function of the training sentence weights.

In order to minimize the expected TER $\mathcal{T}$, we need to compute the derivative of $\mathcal{T}$ with respect to the mapping function parameters $\boldsymbol{\lambda}$. Using the chain rule, we get equations (4)-(8), where the summation in Equation 6 is over all source-target phrase pairs in the derivation of hypothesis h_{sm}, ξ is the decoding weight assigned to the log phrase translation score, and the summation in Equation 7 is over all training sentences[2].

Thus, in order to compute the derivative of the objective function we first need to calculate $\frac{\partial \ln P(s_k|t_k)}{\partial \boldsymbol{\lambda}}$ for every phrase pair (s_k, t_k) in the translation N-best based on Equations 7 and 8, which requires time proportional to the number of occurrences of these phrases in the parallel training data. After that, we can compute $\frac{\partial L_{sm}}{\partial \boldsymbol{\lambda}}$ for each hypothesis h_{sm}, based on Equation 6. Finally, we calculate $\frac{\partial \ln p_{sj}}{\partial \boldsymbol{\lambda}}$ and $\frac{\partial \mathcal{T}}{\partial \boldsymbol{\lambda}}$ based on Equations 5 and 4, respectively.

3.5 Implementation Issues

In our system, the corpus weights were trained based on N-best translation hypotheses generated by a phrase-based MT system on a designated tuning set. Each translation hypothesis in the N-best has a score that is a (linear) function of the following log translation probabilities: target phrase given source phrase, source phrase given target phrase, and lexical smoothing term. Additionally, each hypothesis specifies information about its derivation, i.e., which source-target phrase pairs it consists of. Therefore, given an N-best, we can identify the set of unique phrase pairs and use this information in order to perform a filtered accumulation of the statistics needed for calculating the derivative in Equation 8. This reduces the storage needed for the sufficient statistics significantly.

Minimization of the expected TER of the N-best hypotheses was performed using the limited-memory BFGS algorithm (Liu and Nocedal, 1989). Typically, the parameter vector $\boldsymbol{\lambda}$ required about 30 iterations of LBFGS to converge.

Since the N-best provides only a limited representation of the MT hypothesis search space, we regenerated the N-best after every 30 iterations

[2] In the general case where L_{sj} includes other translation scores, e.g., lexical translation probabilities, the derivative $\frac{\partial L_{sm}}{\partial \boldsymbol{\lambda}}$ will have to include additional terms.

$$\frac{\partial \mathcal{T}}{\partial \boldsymbol{\lambda}} = \sum_{s=1}^{S} \sum_{j=1}^{N_s} \frac{\partial \mathcal{T}}{\partial \ln p_{sj}} \frac{\partial \ln p_{sj}}{\partial \boldsymbol{\lambda}} = \left(\frac{1}{\sum_{s=1}^{S} r_s} \right) \sum_{s=1}^{S} \sum_{j=1}^{N_s} p_{sj} \epsilon_{sj} \frac{\partial \ln p_{sj}}{\partial \boldsymbol{\lambda}} \tag{4}$$

$$\frac{\partial \ln p_{sj}}{\partial \boldsymbol{\lambda}} = \sum_{m=1}^{N_s} \frac{\partial \ln p_{sj}}{\partial L_{sm}} \frac{\partial L_{sm}}{\partial \boldsymbol{\lambda}} = \gamma \left(\frac{\partial L_{sj}}{\partial \boldsymbol{\lambda}} - \sum_{m=1}^{N_s} p_{sm} \frac{\partial L_{sm}}{\partial \boldsymbol{\lambda}} \right) \tag{5}$$

$$\frac{\partial L_{sm}}{\partial \boldsymbol{\lambda}} = \sum_{(s_k,t_k) \in h_{sm}} \frac{\partial L_{sm}}{\partial \ln P(s_k|t_k)} \frac{\partial \ln P(s_k|t_k)}{\partial \boldsymbol{\lambda}} = \sum_{(s_k,t_k) \in h_{sm}} \xi \frac{\partial \ln P(s_k|t_k)}{\partial \boldsymbol{\lambda}} \tag{6}$$

$$\frac{\partial \ln P(s_k|t_k)}{\partial \boldsymbol{\lambda}} = \sum_i \frac{\partial \ln P(s_k|t_k)}{\partial w_i} \frac{\partial w_i}{\partial \boldsymbol{\lambda}} \tag{7}$$

$$\frac{\partial \ln P(s_k|t_k)}{\partial w_i} = \frac{\sum_{j \in \mathcal{A}(s_k) \cap \mathcal{B}(t_k)} \delta\left(j-i\right) c_j(s_k,t_k)}{\sum_{j \in \mathcal{A}(s_k) \cap \mathcal{B}(t_k)} w_j c_j(s_k,t_k)} - \frac{\sum_{j \in \mathcal{B}(t_k)} \delta\left(j-i\right) c_j(t_k)}{\sum_{j \in \mathcal{B}(t_k)} w_j c_j(t_k)} \tag{8}$$

$$\delta(x) = \begin{cases} 1 & x = 0 \\ 0 & x \neq 0 \end{cases} \tag{9}$$

of LBFGS training, merging new hypotheses with translations from previous iterations. The overall training procedure is described in more detail below:

1. Initialize parameter vector $\boldsymbol{\lambda}$ to small random values, so that all training sentences receive approximately equal weights.
2. Initialize phrase-based MT decoding weights to previously tuned values.
3. Perform weighted phrase rule extraction as described in Equation 1, to estimate the phrase and lexical translation probabilities.
4. Decode the tuning set, generating N-best.
5. Merge N-best hypotheses from previous iterations to current N-best.
6. Tune decoding weights so as to minimize TER on merged N-best, using a derivative free optimization method. In our case, we used Powell's algorithm (Powell, 1964) modified by Brent as described in (Brent, 1973) [3].
7. Identify set of unique source-target phrase pairs in merged N-best.
8. Extract sufficient statistics from training data for all phrases identified in step 7.
9. Run the LBFGS algorithm to minimize the expected TER in the merged N-best, using the derivative equations described previously.
10. Assign a weight to each training sentence based on the $\boldsymbol{\lambda}$ values optimized in 9.
11. Go to step 3.

Typically, the corpus weights converge in about 4-5 main iterations. The calculation of the derivative is parallelized to speed up computation, requiring about 10 minutes per iteration of LBFGS.

4 Experimental Setup

In this section we describe the setup that was used for all experiments reported in this paper. Specifically, we provide details about the training data, development sets, and MT systems (phrase-based and hierarchical).

4.1 Training Data

All MT training experiments made use of an Arabic-English corpus of approximately 200 million tokens (English side). Most of the collections in this corpus are available through the Linguistic Data Consortium (LDC) and are regularly part of the resources specified for the constrained data track of the NIST MT evaluation[4].

[3] This method was first used for N-best based parameter optimization in (Ostendorf et al., 1991).

[4] For a list of the NIST MT09 constrained training condition resources, see `http://www.itl.nist.gov/iad/mig/tests/mt/2009/MT09_ConstrainedResources.pdf`

The corpus includes data from multiple genres, as shown in Table 1. The "Sakhr" newswire collection is a set of Arabic-to-English and English-to-Arabic data provided by Sakhr Software, totaling about 30.8 million tokens, and is only available to research teams participating in the Defense Advanced Research Projects Agency (DARPA) Global Autonomous Language Exploitation (GALE) program. The "LDC Gigaword (ISI)" collection was produced by automatically detecting and extracting portions of parallel text from the monolingual LDC Arabic and English Gigaword collections, using a method developed at the Information Sciences Institute (ISI) of the University of Southern California.

Table 1: Composition of the Arabic-English parallel corpus used for MT training.

It is easy to see that most of the parallel training data are either newswire or from United Nations. The amount of web text or broadcast news/conversations is only a very small fraction of the total corpus. In total, there are 31 collections in the training bitext. Some collections (especially those released recently by LDC for the GALE project) consist of data from multiple genres. The total number of unique genres (or data types) in the training set is 10.

Besides the above bitext, we also used approximately 8 billion words of English text for language model (LM) training (3.7B words from the LDC Gigaword corpus, 3.3B words of web-downloaded text, and 1.1B words of data from CNN archives). This data was used to train two language models: an entropy-pruned trigram LM, used in decoding, and an unpruned 5-gram LM used in N-best rescoring. Kneser-Ney smoothing was applied to the n-grams in both cases.

4.2 Development Sets

The development sets used for tuning and testing the corpus weights and other MT settings were comprised of documents from previous Arabic-English NIST MT evaluation sets and from GALE development/evaluation sets.

Specifically, the newswire Tune and Test sets consist of documents from the following collections: the newswire portion of NIST MT04, MT05, MT06, and MT08 evaluation sets, the GALE Phase 1 (P1) and Phase 2 (P2) evaluation sets, and the GALE P2 and P3 development sets. The web Tune and Test sets are made of documents from NIST MT06 and MT08, the GALE P1 and P2 evaluation sets, the GALE P2 and P3 development sets, and a held-out portion of the GALE year 1 quarter 4 web training data release.

The audio Tune and Test sets consist of roughly equal parts of news and conversations broadcast from November 2005 through May 2007 by major Arabic-speaking television and radio stations (e.g., Al-Jazeera, Al-Arabiya, Syrian TV), totaling approximately 14 hours of speech. The audio was processed through automated speech recognition (ASR) in order to produce (errorful) transcripts that were used as input to all MT decoding experiments reported in this paper. However, the corpus weight estimation was carried out based on N-best MT of the Arabic audio reference transcriptions (i.e., the transcripts had no speech recognition errors, and contained full punctuation).

It is important to note that some of the documents in the above devsets have multiple reference translations (usually 4), while others have only one. Most of the documents in the newswire sets have 4 references, but unfortunately the web and audio sets have, on average, less than 2 reference translations per segment. More details are listed in Table 2.

Another important note is that, although the audio sets consist of both broadcast news (BN) and broadcast conversations (BC), we did not perform BN or BC-specific tuning. Corpus weights and MT decoding parameters were optimized based on a single Tune set, on a mix of BN and BC data. However, when we report speech translation results in later sections, we break down the perfor-

mance by genre.

4.3 MT Systems

Experiments were performed using two types of statistical MT systems: a phrase-based system, similar to Pharaoh (Koehn, 2004), and a state-of-the-art, hierarchical string-to-dependency-tree system, similar to (Shen et al., 2008).

The phrase-based MT system employs a pruned 3-gram LM in decoding, and can optionally generate N-best unique translation hypotheses which are used to estimate the corpus weights, as described in Section 3.

The hierarchical MT system performs decoding with the same 3-gram LM, generates N-best of unique translation hypotheses, and then rescores them using a large, unpruned 5-gram LM in order to select the best scoring translation. It is worth mentioning that this hierarchical MT system provides a very strong baseline; it achieves a case-sensitive BLEU score of 52.20 on the newswire portion of the NIST MT08 evaluation set, which is similar to the score of the second-best system that participated in the unconstrained data track of the NIST MT08 evaluation.

Both types of models were trained on the same word alignments generated by GIZA++ (Och and Ney, 2003).

5 Results

In this section we report results on the Arabic newswire, web, and audio development sets, using both phrase-based and hierarchical MT systems, in terms of TER, BLEU[5], and METEOR (Lavie and Agarwal, 2007). Whenever corpus weights are used, they were estimated on the designated Tune set using the phrase-based MT system. Only the collection and genre ids were used as sentence features in order to estimate the corpus weights. As mentioned in Section 4.1, the training bitext consists of 31 collections and 10 genres, so each training sentence was assigned a 41-dimensional binary vector indicating its particular collection/genre combination. That vector was then mapped into a single weight using a perceptron.

5.1 Phrase-based MT

Results using the phrase-based MT system are shown in Table 3. In all cases, the decoding weights were optimized so as to minimize TER on the designated Tune set. On newswire, the discriminative corpus weights provide 0.8% absolute gain in TER, in both Tune and Test sets. On web, the TER gain is 0.9% absolute on Tune and 0.5% on Test. On the audio Test set, the TER gain is 0.5% on BN and 1.4% on BC. Significant improvements were also obtained in the BLEU and METEOR scores, on all sets and conditions.

5.2 Hierarchical MT

Results using the hierarchical MT system are shown in Table 4. The hierarchical system used different tuning criteria in each genre. On newswire, the decoding weights were optimized so as to maximize BLEU, while on web and audio the tuning was based on $0.5\text{TER} + 0.5(1 - \text{BLEU})$ (referred to as TERBLEU in what follows). Note that these were the criteria for tuning the decoding weights; whenever corpus weights were used, they were taken from the phrase-based system.

It is interesting to see that gains from discriminative corpus weights carry over to the more powerful hierarchical MT system. On newswire Test, the gain in BLEU is 0.8; on web Test, the gain in TERBLEU is 0.3. On the audio Test set, the corpus weights provide 0.7 and 0.75 TERBLEU reduction on BN and BC, respectively. As with the

phrase-based system, all metrics improve from the use of corpus weights, in all sets/conditions.

6 Conclusions

We have described a novel approach for estimating a weight for each sentence in a parallel training corpus so as to optimize MT performance of a phrase-based statistical MT system. The sentence weights influence MT performance by being applied to the phrase and lexical counts during translation rule extraction and probability estimation.

In order to ensure robust training of the weights, we expressed them as a function of sentence-level features. Then, we defined the process for optimizing the parameters of that function based on the expected TER of a translation hypothesis N-best on a designated tuning set.

The proposed technique was evaluated in the context of Arabic-English translation, on multiple conditions. It was shown that encouraging results were obtained by just using collection and genre ids as features. Interestingly, the discriminative corpus weights were found to be generally applicable and provided gains in a state-of-the-art hierarchical string-to-dependency-tree MT system, even though they were trained using the phrase-based MT system.

Next step is to include other sentence-level features, as described in Section 3.1. Finally, the technique described in this paper can be extended to address the estimation of weights at the alignment link level, based on link-level features. We believe that this will have a larger impact on the lexical and phrase translation probabilities, since there is a large number of parallel training sentences that are partially correct, i.e., they contain parts that are aligned and translated correctly, and parts that are wrong. The current procedure tries to assign a single weight to such sentences, so there is no way to distinguish between the "good" and "bad" portions of each sentence. Pushing the weight estimation at the alignment link level will alleviate this problem and will make the discriminative training more targeted.

Unsupervised Tokenization for Machine Translation

Tagyoung Chung and **Daniel Gildea**

University of Rochester
Rochester, NY 14627

Abstract

Training a statistical machine translation starts with tokenizing a parallel corpus. Some languages such as Chinese do not incorporate spacing in their writing system, which creates a challenge for tokenization. Moreover, morphologically rich languages such as Korean present an even bigger challenge, since optimal token boundaries for machine translation in these languages are often unclear. Both rule-based solutions and statistical solutions are currently used. In this paper, we present unsupervised methods to solve tokenization problem. Our methods incorporate information available from parallel corpus to determine a good tokenization for machine translation.

1 Introduction

Tokenizing a parallel corpus is usually the first step of training a statistical machine translation system. With languages such as Chinese, which has no spaces in its writing system, the main challenge is to segment sentences into appropriate tokens. With languages such as Korean and Hungarian, although the writing systems of both languages incorporate spaces between "words", the granularity is too coarse compared with languages such as English. A single word in these languages is composed of several morphemes, which often correspond to separate words in English. These languages also form compound nouns more freely. Ideally, we want to find segmentations for source and target languages that create a one-to-one mapping of words. However, this is not always straightforward for two major reasons. First, what the optimal tokenization for machine translation should be is not always clear. Zhang et al. (2008b) and Chang et al. (2008) show that getting the tokenization of one of the languages in the corpus close to a gold standard does not necessarily help with building better machine translation systems. Second, even statistical methods require hand-annotated training data, which means that in resource-poor languages, good tokenization is hard to achieve.

In this paper, we explore unsupervised methods for tokenization, with the goal of automatically finding an appropriate tokenization for machine translation. We compare methods that have access to parallel corpora to methods that are trained solely using data from the source language. Unsupervised monolingual segmentation has been studied as a model of language acquisition (Goldwater et al., 2006), and as model of learning morphology in European languages (Goldsmith, 2001). Unsupervised segmentation using bilingual data has been attempted for finding new translation pairs (Kikui and Yamamoto, 2002), and for finding good segmentation for Chinese in machine translation using Gibbs sampling (Xu et al., 2008). In this paper, further investigate the use of bilingual information to find tokenizations tailored for machine translation. We find a benefit not only for segmentation of languages with no space in the writing system (such as Chinese), but also for the smaller-scale tokenization problem of normalizing between languages that include more or less information in a "word" as defined by the writing system, using Korean-English for our experiments. Here too, we find a benefit from using bilingual information, with unsupervised segmentation rivaling and in some cases surpassing supervised segmentation. On the modeling side, we use dynamic programming-based variational Bayes, making Gibbs sampling unnecessary. We also develop and compare various factors in the model to control the length of the tokens learned, and find a benefit from adjusting these parameters directly to optimize the end-to-end translation quality.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 718–726,
Singapore, 6-7 August 2009.

2 Tokenization

Tokenization is breaking down text into lexemes — a unit of morphological analysis. For relatively isolating languages such as English and Chinese, a word generally equals a single token, which is usually a clearly identifiable unit. English, especially, incorporates spaces between words in its writing system, which makes tokenization in English usually trivial. The Chinese writing system does not have spaces between words, but there is less ambiguity where word boundaries lie in a given sentence compared to more agglutinative languages. In languages such as Hungarian, Japanese, and Korean, what constitutes an optimal token boundary is more ambiguous. While two tokens are usually considered two separate words in English, this may be not be the case in agglutinative languages. Although what is considered a single morphological unit is different from language to language, if someone were given a task to align words between two languages, it is desirable to have one-to-one token mapping between two languages in order to have the optimal problem space. For machine translation, one token should not necessarily correspond to one morphological unit, but rather should reflect the morphological units and writing system of the other language involved in translation.

For example, consider a Korean "word" *meok-eoss-da*, which means *ate*. It is written as a single word in Korean but consists of three morphemes *eat-past-indicative*. If one uses morphological analysis as the basis for Korean tokenization, *meok-eoss-da* would be split into three tokens, which is not desirable if we are translating Korean to English, since English does not have these morphological counterparts. However, a Hungarian word *szekrényemben*, which means *in my closet*, consists of three morphemes *closet-my-inessive* that are distinct words in English. In this case, we do want our tokenizer to split this "word" into three morphemes *szekrény em ben*.

In this paper, we use segmentation and tokenization interchangeably as blanket terms to cover the two different problems we have presented here. The problem of segmenting Chinese sentences into words and the problem of segmenting Korean or Hungarian "words" into tokens of right granularity are different in their nature. However, our models presented in section 3 handle the both problems.

3 Models

We present two different methods for unsupervised tokenization. Both are essentially unigram tokenization models. In the first method, we try learning tokenization from word alignments with a model that bears resemblance to Hidden Markov models. We use IBM Model 1 (Brown et al., 1993) for the word alignment model. The second model is a relatively simpler monolingual tokenization model based on counts of substrings which serves as a baseline of unsupervised tokenization.

3.1 Learning tokenization from alignment

We use expectation maximization as our primary tools in learning tokenization form parallel text. Here, the observed data provided to the algorithm are the tokenized English string $\mathbf{e}_1^n$ and the untokenized string of foreign characters $\mathbf{c}_1^m$. The unobserved variables are both the word-level alignments between the two strings, and the tokenization of the foreign string. We represent the tokenization with a string $\mathbf{s}_1^m$ of binary variables, with $s_i = 1$ indicating that the ith character is the final character in a word. The string of foreign words $\mathbf{f}_1^\ell$ can be thought of as the result of applying the tokenization $\mathbf{s}$ to the character string $\mathbf{c}$:

$$\mathbf{f} = \mathbf{s} \circ \mathbf{c} \quad \text{where} \quad \ell = \sum_{i=1}^{m} s_i$$

We use IBM Model 1 as our word-level alignment model, following its assumptions that each foreign word is generated independently from one English word:

$$\begin{aligned} P(\mathbf{f}|\mathbf{e}) &= \sum_{\mathbf{a}} P(\mathbf{f}, \mathbf{a} \mid \mathbf{e}) \\ &= \sum_{\mathbf{a}} \prod_i P(f_i \mid e_{a_i}) P(\mathbf{a}) \\ &= \prod_i \sum_j P(f_i \mid e_j) P(a_i = j) \end{aligned}$$

and that all word-level alignments $\mathbf{a}$ are equally likely: $P(a) = \frac{1}{n}$ for all positions. While Model 1 has a simple EM update rule to compute posteriors for the alignment variables $\mathbf{a}$ and from them learn the lexical translation parameters $P(f \mid e)$, we cannot apply it directly here because $\mathbf{f}$ itself is unknown, and ranges over an exponential number of possibilities depending on the hidden segmentation $\mathbf{s}$. This can be addressed by applying dynamic programing over the sequence $\mathbf{s}$. We compute the

posterior probability of a word beginning at position i, ending at position j, and being generated by English word k:

$$P(\mathbf{s}_{i...j} = (1, 0, \ldots, 0, 1), a = k \mid \mathbf{e}) = \frac{\alpha(i)P(f \mid e_k)P(a = k)\beta(j)}{P(\mathbf{c} \mid \mathbf{e})}$$

where $f = c_i \ldots c_j$ is the word formed by concatenating characters i through j, and a is a variable indicating which English position generated f. Here α and β are defined as:

$$\alpha(i) = P(\mathbf{c}_1^i, s_i = 1 \mid \mathbf{e})$$
$$\beta(j) = P(\mathbf{c}_{j+1}^m, s_j = 1 \mid \mathbf{e})$$

These quantities resemble forward and backward probabilities of hidden Markov models, and can be computed with similar dynamic programming recursions:

$$\alpha(i) = \sum_{\ell=1}^{L} \alpha(i - \ell) \sum_a P(a)P(c_{i-\ell}^i \mid e_a)$$
$$\beta(j) = \sum_{\ell=1}^{L} \sum_a P(a)P(c_j^{j+\ell} \mid e_a)\beta(j + \ell)$$

where L is the maximum character length for a word.

Then, we can calculate the expected counts of individual word pairs being aligned (c_i^j, e_k) by accumulating these posteriors over the data:

$$ec(c_i^j, e_k) \mathrel{+}= \frac{\alpha(i)P(a)P(c_i^j \mid e_k)\beta(j)}{\alpha(m)}$$

The M step simply normalizes the counts:

$$\tilde{P}(f \mid e) = \frac{ec(f, e)}{\sum_e ec(f, e)}$$

Our model can be compared to a hidden Markov model in the following way: a target word generates a source token which spans a zeroth order Markov chain of characters in source sentence, where a "transition" represents a segmentation and a "emission" represents an alignment. The model uses HMM-like dynamic programming to do inference. For the convenience, we refer to this model as the bilingual model in the rest of the paper. Figure 1 illustrates our first model with an small example. Under this model we are not learning segmentation directly, but rather we are learning alignments between two sentences. The segmentation is by-product of learning the alignment. We can find the optimal segmentation of a new source language sentence using the Viterbi algorithm. Given two sentences $\mathbf{e}$ and $\mathbf{f}$,

$$\mathbf{a}^* = \operatorname*{argmax}_{\mathbf{a}} P(\mathbf{f}, \mathbf{a} \mid \mathbf{e})$$

and segmentation $\mathbf{s}^*$ implied by alignment $\mathbf{a}^*$ is the optimal segmentation of $\mathbf{f}$ found by this model.

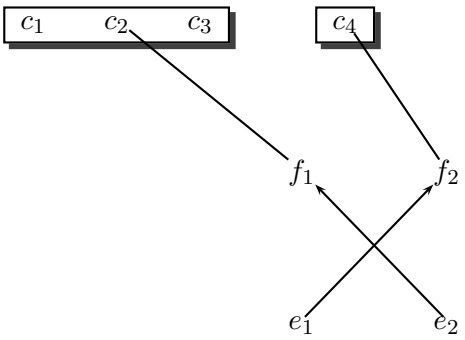

Figure 1: The figure shows a source sentence $\mathbf{f} = f_1, f_2 = \mathbf{s} \circ c_1 \ldots c_4$ where $\mathbf{s} = (0, 0, 1, 1)$ and a target sentence $\mathbf{e} = e_1, e_2$. There is a segmentation between c_3 and c_4; thus c_1, c_2, c_3 form f_1 and c_3 forms f_2. f_1 is generated by e_2 and f_2 is generated by e_1.

3.2 Learning tokenization from substring counts

The second tokenization model we propose is much simpler. More sophisticated unsupervised monolingual tokenization models using hierarchical Bayesian models (Goldwater et al., 2006) and using the minimum description length principle (Goldsmith, 2001; de Marcken, 1996) have been studied. Our model is meant to serve as a computationally efficient baseline for unsupervised monolingual tokenization. Given a corpus of only source language of unknown tokenization, we want to find the optimal $\mathbf{s}$ given $\mathbf{c}$ — $\mathbf{s}$ that gives us the highest $P(\mathbf{s} \mid \mathbf{c})$. According to Bayes' rule,

$$P(\mathbf{s} \mid \mathbf{c}) \propto P(\mathbf{c} \mid \mathbf{s})P(\mathbf{s})$$

Again, we assume that all $P(\mathbf{s})$ are equally likely. Let $\mathbf{f} = \mathbf{s} \circ \mathbf{c} = f_1 \ldots f_\ell$, where f_i is a word under some possible segmentation $\mathbf{s}$. We want to find the $\mathbf{s}$ that maximizes $P(\mathbf{f})$. We assume that

$$P(\mathbf{f}) = P(f_1) \times \ldots \times P(f_\ell)$$

To calculate $P(f_i)$, we count every possible

substring — every possible segmentation of characters — from the sentences. We assume that

$$P(f_i) = \frac{count(f_i)}{\sum_k count(f_k)}$$

We can compute these counts by making a single pass through the corpus. As in the bilingual model, we limit the maximum size of f for practical reasons and to prevent our model from learning unnecessarily long f. With $P(f)$, given a sequence of characters $\mathbf{c}$, we can calculate the most likely segmentation using the Viterbi algorithm.

$$\mathbf{s}^* = \underset{\mathbf{s}}{\operatorname{argmax}}\, P(\mathbf{f})$$

Our rationale for this model is that if a span of characters $f = c_i \dots c_j$ is an independent token, it will occur often enough in different contexts that such a span of characters will have higher probability than other spans of characters that are not meaningful. For the rest of the paper, this model will be referred to as the monolingual model.

3.3 Tokenizing new data

Since the monolingual tokenization only uses information from a monolingual corpus, tokenizing new data is not a problem. However, with the bilingual model, we are learning $P(f \mid e)$. We are relying on information available from **e** to get the best tokenization for **f**. However, the parallel sentences will not be available for new data we want to translate. Therefore, for the new data, we have to rely only on $P(f)$ to tokenize any new data, which can be obtained by calculating

$$P(f) = \sum_e P(f \mid e)P(e)$$

With $P(f)$ from the bilingual model, we can run the Viterbi algorithm in the same manner as monolingual tokenization model for monolingual data. We hypothesize that we can learn valuable information on which token boundaries are preferable in language f when creating a statistical machine translation system that translates from language f to language e.

4 Preventing overfitting

We introduce two more refinements to our word-alignment induced tokenization model and monolingual tokenization model. Since we are considering every possible token f that can be guessed from our corpus, the data is very sparse. For the bilingual model, we are also using the EM algorithm to learn $P(f \mid e)$, which means there is a danger of the EM algorithm memorizing the training data and thereby overfitting. We put a Dirichlet prior on our multinomial parameter for $P(f \mid e)$ to control this situation. For both models, we also want a way to control the distribution of token length after tokenization. We address this problem by adding a length factor to our models.

4.1 Variational Bayes

Beal (2003) and Johnson (2007) describe variational Bayes for hidden Markov model in detail, which can be directly applied to our bilingual model. With this Bayesian extension, the emission probability of our first model can be summarized as follows:

$$\theta_{\mathbf{e}} \mid \alpha \sim \mathrm{Dir}(\alpha),$$
$$f_i \mid e_i = e \sim \mathrm{Multi}(\theta_{\mathbf{e}}).$$

Johnson (2007) and Zhang et al. (2008a) show having small α helps to control overfitting. Following this, we set our Dirichlet prior to be as sparse as possible. It is set at $\alpha = 10^{-6}$, the number we used as floor of our probability.

For the model incorporating the length factor, which is described in the next section, we do not place a prior on our transition probability, since there are only two possible states, i.e. $P(s = 1)$ and $P(s = 0)$. This distribution is not as sparse as the emission probability.

Comparing variational Bayes to the traditional EM algorithm, the E step stays the same but the M step for calculating the emission probability changes as follows:

$$\tilde{P}(f \mid e) = \frac{\exp(\psi(ec(f, e) + \alpha))}{\exp(\psi(\sum_e ec(f, e) + s\alpha))}$$

where ψ is the digamma function, and s is the size of the vocabulary from which f is drawn. Since we do not accurately know s, we set s to be the number of all possible tokens. As can be seen from the equation, by setting α to a small value, we are discounting the expected count with help of the digamma function. Thus, having lower α leads to a sparser solution.

4.2 Token length

We now add a parameter that can adjust the tokenizer's preference for longer or shorter tokens.

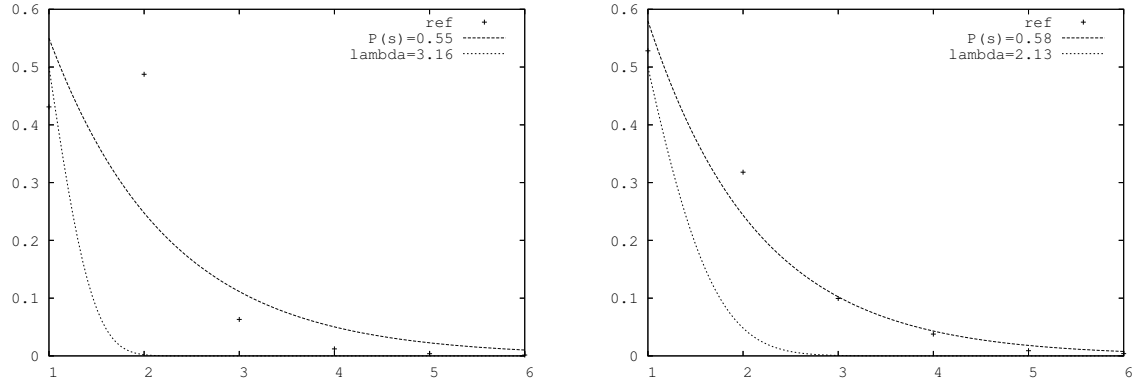

Figure 2: Distribution of token length for (from left to right) Chinese, and Korean. "ref" is the empirical distribution from supervised tokenization. Two length factors — ϕ_1 and ϕ_2 are also shown. For ϕ_1, the parameter to geometric distribution $P(s)$ is set to the value learned from our bilingual model. For ϕ_2, λ is set using the criterion described in the experiment section.

This parameter is beneficial because we want our distribution of token length after tokenization to resemble the real distribution of token length. This parameter is also useful because we also want to incorporate information on the number of tokens in the other language in the parallel corpus. This is based on the assumption that, if tokenization creates a one-to-one mapping, the number of tokens in both languages should be roughly the same. We can force the two languages to have about the same number of tokens by adjusting this parameter. The third reason is to further control overfitting. Our observation is that certain morphemes are very common, such that they will be always observed attached to other morphemes. For example, in Korean, a noun attached with nominative case marker is very common. Our model is likely to learn a noun attached with the morpheme — nominative case marker — rather than noun itself. This is not desirable when the noun occurs with less common morphemes; in these cases the morpheme will be split off creating inconsistencies.

We have experimented with two different length factors, each with one adjustable parameter:

$$\phi_1(\ell) = P(s)(1 - P(s))^{\ell-1}$$
$$\phi_2(\ell) = 2^{-\ell^\lambda}$$

The first, ϕ_1, is the geometric distribution, where l is length of a token and $P(s)$ is probability of segmentation between two characters. The second length factor ϕ_2 was acquired through several experiments and was found to work well. As can been seen from Figure 2, the second factor discounts longer tokens more heavily than the geometric distribution. We can adjust the value of λ and $P(s)$ to increase or decrease number of tokens after segmentation.

For our monolingual model, incorporating these factors is straightforward. We assume that

$$P(\mathbf{f}) \propto P(f_1)\phi(\ell_1) \times \ldots \times P(f_n)\phi(\ell_n)$$

where ℓ_i is the length of f_i. Then, we use the same Viterbi algorithm to select the $f_1 \ldots f_n$ that maximizes $P(\mathbf{f})$, thereby selecting the optimal $\mathbf{s}$ according to our monolingual model with a length factor. We pick the value of λ and $P(s)$ that produces about the same number of tokens in the source side as in the target side, thereby incorporating some information about the target language.

For our bilingual model, we modify our model slightly to incorporate ϕ_1, creating a hybrid model. Now, our forward probability of forward-backward algorithm is:

$$\alpha(i) = \sum_{\ell=1}^{L} \alpha(i-l)\phi_1(\ell) \sum_a P(a)P(c_{i-\ell}^{i} \mid e_a)$$

and the expected count of (c_i^j, e_k) is

$$ec(c_i^j, e_k) \mathrel{+}= \frac{\alpha(i)P(a)P(c_i^j \mid e_k)\beta(j)\phi_1(j-i)}{\alpha(m)}$$

For ϕ_1, we can learn $P(s)$ for the geometric distribution from the model itself:[1]

$$P(s) = \frac{1}{m}\sum_{i}^{m} \frac{\alpha(i)\beta(i)}{\alpha(m)}$$

[1]The equation is for one sentence, but in practice, we sum over all sentences in the training data to calculate $P(s)$.

We can also fix $P(s)$ instead of learning it through EM. We incorporate ϕ_2 into the bilingual model as follows: after learning $P(f)$ from the bilingual model, we pick the λ in the same manner as the monolingual model and run the Viterbi algorithm.

After applying the length factor, what we have is a log-linear model for tokenization, with two feature functions with equal weights: the length factor and $P(f)$ learned from model.

5 Experiments

5.1 Data

We tested our tokenization methods on two different language pairs: Chinese-English, and Korean-English. For Chinese-English, we used FBIS newswire data. The Korean-English parallel data was collected from news websites and sentence-aligned using two different tools described by Moore (2002) and Melamed (1999). We used subsets of each parallel corpus consisting of about 2M words and 60K sentences on the English side. For our development set and test set, Chinese-English had about 1000 sentences each with 10 reference translations taken from the NIST 2002 MT evaluation. For Korean-English, 2200 sentence pairs were randomly sampled from the parallel corpus, and held out from the training data. These were divided in half and used for test set and development set respectively. For all language pairs, very minimal tokenization — splitting off punctuation — was done on the English side.

5.2 Experimental setup

We used Moses (Koehn et al., 2007) to train machine translation systems. Default parameters were used for all experiments except for the number of iterations for GIZA++ (Och and Ney, 2003). GIZA++ was run until the perplexity on development set stopped decreasing. For practical reasons, the maximum size of a token was set at three for Chinese, and four for Korean.[2] Minimum error rate training (Och, 2003) was run on each system afterwards and BLEU score (Papineni et al., 2002) was calculated on the test sets.

For the monolingual model, we tested two versions with the length factor ϕ_1, and ϕ_2. We picked λ and $P(s)$ so that the number of tokens on source side (Chinese, and Korean) will be about the same as the number of tokens in the target side (English).

For the bilingual model, as explained in the model section, we are learning $P(f \mid e)$, but only $P(f)$ is available for tokenizing any new data. We compared two conditions: using only the source data to tokenize the source language training data according to $P(f)$ (which is consistent with the conditions at test time), and using both the source and English data to tokenize the source language training data (which might produce better tokenization by using more information). For the first length factor ϕ_1, we ran an experiment where the model learns $P(s)$ as described in the model section, and we also had experiments where $P(s)$ was pre-set at 0.9, 0.7, 0.5, and 0.3 for comparison. We also ran an experiment with the second length factor ϕ_2 where λ was picked as the same manner as the monolingual model.

We varied tokenization of development set and test set to match the training data for each experiment. However, as we have implied in the previous paragraph, in the one experiment where $P(f \mid e)$ was used to segment training data, directly incorporating information from target corpus, tokenization for test and development set is not exactly consistent with tokenization of training corpus. Since we assume only source corpus is available at the test time, the test and the development set was tokenized only using information from $P(f)$.

We also trained MT systems using supervised tokenizations and tokenization requiring a minimal effort for the each language pair. For Chinese-English, the minimal effort tokenization is maximal tokenization where every Chinese character is segmented. Since a number of Chinese tokenizers are available, we have tried four different tokenizations for the supervised tokenizations. The first one is the LDC Chinese tokenizer available at the LDC website[3], which is compiled by Zhibiao Wu. The second tokenizer is a maxent-based tokenizer described by Xue (2003). The third and fourth tokenizations come from the CRF-based Stanford Chinese segmenter described by Chang et al. (2008). The difference between third and fourth tokenization comes from the different gold standard, the third one is based on Beijing University's segmentation (pku) and the fourth one is based on Chinese Treebank (ctb). For Korean-

[2] In the Korean writing system, one character is actually one syllable block. We do not decompose syllable blocks into individual consonants and vowels.

English, the minimal effort tokenization splitting off punctuation and otherwise respecting the spacing in the Korean writing system. A Korean morphological analysis tool[4] was used to create the supervised tokenization.

For Chinese-English, since a gold standard for Chinese segmentation is available, we ran an additional evaluation of tokenization from each methods we have tested. We tokenized the raw text of Chinese Treebank (Xia et al., 2000) using all of the methods (supervised/unsupervised) we have described in this section except for the bilingual tokenization using $P(f \mid e)$ because the English translation of the Chinese Treebank data was not available. We compared the result against the gold standard segmentation and calculated the F-score.

6 Results

Results from Chinese-English and Korean-English experiments are presented in Table 1. Note that nature of data and number of references are different for the two language pairs, and therefore the BLEU scores are not comparable. For both language pairs, our models perform equally well as supervised baselines, or even better. We can observe three things from the result. First, tokenization of training data using $P(f \mid e)$ tested on a test set tokenized with $P(f)$ performed worse than any other experiments. This affirms our belief that consistency in tokenization is important for machine translation, which was also mentioned by Chang et al. (2008). Secondly, we are learning valuable information by looking at the target language. Compare the result of the bilingual model with ϕ_2 as the length factor to the result of the monolingual model with the same length factor. The bilingual version consistently performed better than the monolingual model in all language pairs. This tells us we can learn better token boundaries by using information from the target language. Thirdly, our hypothesis on the need for heavy discount for longer tokens is confirmed. The value for $P(s)$ learned by the model was 0.55, and 0.58 for Chinese, and Korean respectively. For both language pairs, this accurately reflects the empirical distribution of token length, as can be seen in Figure 2. However, experiments where $P(s)$ was directly optimized performed better, indicating that this parameter should be optimized within the context of a complete system. The second length factor ϕ_2, which discounts longer tokens even more heavily, generally performed bet-

Figure 3: Sample tokenization results for Korean-English data. The underscores are added to clearly visualize where the breaks are.

ter than the first length factor when used in conjunction with the bilingual model. Lastly, F-scores of Chinese segmentations compared against the gold standard shows higher segmentation accuracy does not necessarily lead to higher BLEU score. F-scores presented in Table 1 are not directly comparable for all different experiments because the test data (Chinese Treebank) is used in training for some of the supervised segmenters, but these numbers do show how close unsupervised segmentations are to the gold standard. It is interesting to note that our highest unsupervised segmentation result does make use of bilingual information.

Sample tokenization results for Korean-English experiments are presented in Figure 3. We observe that different configurations produce different tokenizations, and the bilingual model produced generally better tokenizations for translation compared to the monolingual models or the supervised tokenizer. In this example, the tokenization obtained from the supervised tokenizer, although morphologically correct, is too fine-grained for the purpose of translation to English. For example, it correctly tokenized the attributive suffix ㄴ *-n* however, this is not desirable since English has no such counterpart. Both variations of the monolingual tokenization have errors such as incorrectly not segmenting 결과를 *gyeol-gwa-reul*, which is a compound of a noun and a case marker, into 결과␣를 *gyeol-gwa␣reul* as the bilingual model was able to do.

6.1 Conclusion and future work

We have shown that unsupervised tokenization for machine translation is feasible and can outperform rule-based methods that rely on lexical analysis, or supervised statistical segmentations. The approach can be applied both to morphological analysis of Korean and the segmentation of sentences into words for Chinese, which may at first glace appear to be quite different problems. We have only shown how our methods can be applied to one language of the pair, where one language is generally isolating and the other is generally synthetic. However, our methods could be extended to tokenization for both languages by iterating between languages. We also used the most simple word-alignment model, but more complex word alignment models could be incorporated into our bilingual model.

Abstract

Tree Adjoining Grammars have well-known advantages, but are typically considered too difficult for practical systems. We demonstrate that, when done right, adjoining improves translation quality without becoming computationally intractable. Using adjoining to model optionality allows general translation patterns to be learned without the clutter of endless variations of optional material. The appropriate modifiers can later be spliced in as needed.

In this paper, we describe a novel method for learning a type of Synchronous Tree Adjoining Grammar and associated probabilities from aligned tree/string training data. We introduce a method of converting these grammars to a weakly equivalent tree transducer for decoding. Finally, we show that adjoining results in an end-to-end improvement of +0.8 BLEU over a baseline statistical syntax-based MT model on a large-scale Arabic/English MT task.

1 Introduction

Statistical MT has changed a lot in recent years. We have seen quick progress from manually crafted linguistic models to empirically learned statistical models, from word-based models to phrase-based models, and from string-based models to tree-based models. Recently there is a swing back to incorporating more linguistic information again, but this time linguistic insight carefully guides the setup of empirically learned models.

Shieber (2007) recently argued that probabilistic Synchronous Tree Adjoining Grammars (Shieber and Schabes, 1990) have the right combination of properties that satisfy both linguists and empirical MT practitioners. So far, though, most work in this area has been either more linguistic than statistical (Abeille et al., 1990) or statistically-based, but linguistically light (Nesson et al., 2006).

Current tree-based models that integrate linguistics and statistics, such as GHKM (Galley et al., 2004), are not able to generalize well from a single phrase pair. For example, from the data in Figure 1, GHKM can learn rule (a) to translate nouns with two pre-modifiers, but does not generalize to learn translation rules (b) - (d) without the optional adjective or noun modifiers. Likewise, none of these rules allow extra material to be introduced, e.g. "Pakistan's national defense minister". In large enough training data sets, we see many examples of all the common patterns, but the rarer patterns have sparse statistics or poor coverage.

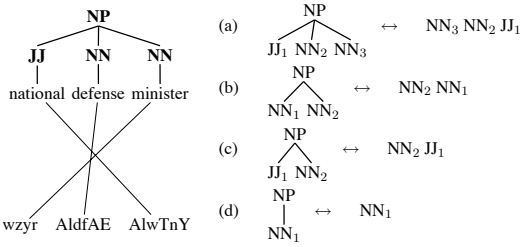

Figure 1: Rule (a) can be learned from this training example. Arguably, the more general rules (b) - (d) should also be learnable.

To mitigate this problem, the parse trees used as training data for these systems can be binarized (Wang et al., 2007). Binarization allows rules with partial constituents to be learned, resulting in more general rules, richer statistics, and better phrasal coverage (DeNeefe et al., 2007), but no principled required vs. optional decision has been made. This method's key weakness is that binarization always keeps adjacent siblings together, so there is no way to group the head with a required complement if optional information intervenes between the two. Furthermore, if all kinds of children are considered equally optional, then we have removed important syntactic constraints, which may end up permitting too much freedom. In addition, spurious alignments may limit the binarization tech-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 727–736,
Singapore, 6-7 August 2009.

nique's effectiveness.

In this paper, we present a method of learning a type of probabilistic Synchronous Tree Adjoining Grammar (STAG) automatically from a corpus of word-aligned tree/string pairs. To learn this grammar we use linguistic resources to make the required vs. optional decision. We then directly model the optionality in the translation rules by learning statistics for the required parts of the rule independently from the optional parts. We also present a method of converting these rules into a well-studied tree transducer formalism for decoding purposes. We then show that modeling optionality using adjoining results in a statistically significant BLEU gain over our baseline syntax-based model with no adjoining.

2 Translation Model

2.1 Synchronous Tree Insertion Grammars

Tree Adjoining Grammars (TAG), introduced by Joshi et al. (1975) and Joshi (1985), allow insertion of unbounded amounts of material into the structure of an existing tree using an adjunction operation. Usually they also include a substitution operation, which has a 'fill in the blank' semantics, replacing a substitution leaf node with a tree. Figure 2 visually demonstrates TAG operations. Shieber and Schabes (1990) offer a synchronous version of TAG (STAG), allowing the construction of a pair of trees in lockstep fashion using the TAG operations of substitution and adjunction on tree *pairs*. To facilitate this synchronous behavior, links between pairs of nodes in each tree pair define the possible *sites* for substitution and adjunction to happen. One application of STAG is machine translation (Abeille et al., 1990).

One negative aspect of TAG is the computational complexity: $O(n^6)$ time is required for monolingual parsing (and thus decoding), and STAG requires $O(n^{12})$ for bilingual parsing (which might be used for training the model directly on bilingual data). Tree Insertion Grammars (TIG) are a restricted form of TAG that was introduced (Schabes and Waters, 1995) to keep the same benefits as TAG (adjoining of unbounded material) without the computational complexity—TIG parsing is $O(n^3)$. This reduction is due to a limitation on adjoining: auxiliary trees can only introduce tree material to the left or the right of the node adjoined to. Thus an auxiliary tree can be classified by direction as left or right adjoining.

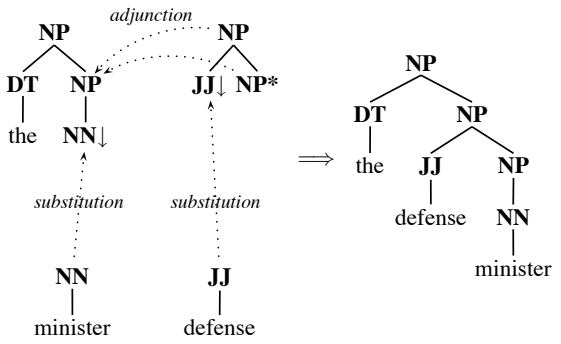

Figure 2: TAG grammars use substitution and adjunction operations to construct trees. Substitution replaces the substitution node (marked with ↓) with another tree. Adjunction inserts an auxiliary tree—a special kind of tree fragment with a foot node (marked with *)—into an existing tree at a permitted non-terminal node. Note that in TAG, adjunctions are permitted at *any* non-terminal with the same label as the root and foot node of the auxiliary tree, while in STAG adjunctions are restricted to linked sites.

Nesson et al. (2006) introduce a probabilistic, synchronous variant of TIG and demonstrate its use for machine translation, showing results that beat both word-based and phrase-based MT models on a limited-vocabulary, small-scale training and test set. Training the model uses an $O(n^6)$ bilingual parsing algorithm, and decoding is $O(n^3)$. Though this model uses trees in the formal sense, it does not create Penn Treebank (Marcus et al., 1993) style linguistic trees, but uses only one non-terminal label (**X**) to create those trees using six simple rule structures.

The grammars we use in this paper share some properties in common with those of Nesson et al. (2006) in that they are of the probabilistic, synchronous tree-insertion variety. All pairs of sites (both adjunction and substitution in our case) are explicitly linked. Adjunction sites are restricted by direction: at each linked site, the source and target side each specify one allowed direction. The result is that each synchronous adjunction site can be classified into one of four direction classes: {LR, LL, RR, RL}. For example, LR means the source side site only allows left adjoining trees and the target side site only allows right adjoining trees.

There are several important differences between our grammars and the ones of Nesson et al. (2006):

Richer, Linguistic Trees: Our grammars have a

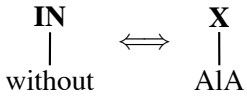
Penn Treebank-style linguistic tree on the English (target) side, and a hierarchical structure using only a single non-terminal symbol (**X**) on the source side. We believe this provides the rich information needed in the target language without over-constraining the model.

Substitution Sites/Non-lexical trees: We use both substitution and adjunction (Nesson et al. (2006) only used adjunction) and do not require all trees to contain lexical items as is commonly done in TIG (Schabes and Waters, 1995).

Single Adjunction/Multiple Sites: Each non-terminal node in a tree may allow multiple adjunction sites, but every site only allows at most one adjunction,[1] a common assumption for TAG as specified in the Vijay-Shanker (1987) definition.

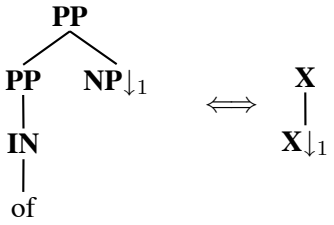
Here are some examples of automatically learned translation rules with interpretations of how they work:

1. simple lexical rules for translating words or phrases:



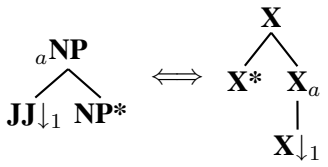
interpretation: translate the Arabic word "AlA" as the preposition "without"

2. rules with substitution for translating phrases with holes (substitution sites are designated by an arrow and numeric subscript, e.g. **NP**$\downarrow_1$):



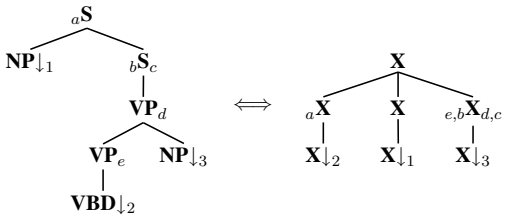
interpretation: insert "of" to turn a noun phrase into a prepositional phrase

3. simple adjoining rules for inserting optional modifiers (adjoining sites are designated by an alphabetic subscript before *or* after a non-terminal to indicate direction of adjoining, e.g. $_a$**NP**):



interpretation: adjoin an adjective before a noun in English but after in Arabic, and allowing further adjoinings in those same directions afterward

4. rules with multiple adjunction and substitution sites:



interpretation: translate an Arabic sentence in VSO form into an English sentence in SVO form, with multiple adjoining options

2.2 Generative Story

When we use these rules to translate from a foreign sentence f into an English sentence e, we use several models together in a log-linear fashion, but our primary model is a joint model of $P(e_{tree}, f_{tree})$, which is our surrogate for directly modeling $P(e|f)$. This can be justified because $P(e|f) = \frac{P(e,f)}{P(f)}$, and $P(f)$ is fixed for a given foreign sentence. Therefore:

$$\begin{aligned}\underset{e}{\operatorname{argmax}} P(e|f) &= \underset{e}{\operatorname{argmax}} P(e,f) \\ &\approx \operatorname{yield}(\underset{e_{tree}}{\operatorname{argmax}} P(e_{tree}, f_{tree})) \\ &\approx \operatorname{yield}(\underset{e_{tree}}{\operatorname{argmax}} P(d_{e_{tree},f_{tree}}))\end{aligned}$$

where $d_{e_{tree},f_{tree}}$ is a derivation tree of rules that generates e_{tree} and f_{tree}. In other words, e, the highest probability translation of f, can be approximated by taking the yield of the highest probability tree e_{tree} that is a translation of the highest probability tree of f. This can further be approximated by the highest probability derivation of rules translating between f and e via trees.

Now we define the probability of generating $d_{e_{tree},f_{tree}}$. Starting with an initial symbol pair

[1] An adjoined rule may itself have adjoining sites allowing further adjunction.

representing a rule with a single substitution site,[2] $\langle$TOP$\downarrow$, X$\downarrow\rangle$, a tree pair can be generated by the following steps:

1. For each substitution site s_i in the current rule r_1:
   (a) Choose with probability $P_{sub}(r_2|\langle \text{label}_L(s_i), \text{label}_R(s_i)\rangle)$ a rule r_2 having root node labels $\text{label}_L(s_i)$ and $\text{label}_R(s_i)$ that match the left and right labels at s_i.
2. For each adjunction site s_{i,r_1} in the current rule r_1:
   (a) Choose with rule-specific probability $P_{\text{if}adj}(\text{decision}_{adjoin}|s_{i,r_1}, r_1)$ choose whether or not to adjoin at the current site s_{i,r_1}.
   (b) If we *are* adjoining at site s_{i,r_1}, choose with probability $P_{adj}(r_2|d, \langle \text{label}_L(s_{i,r_1}), \text{label}_R(s_{i,r_1})\rangle)$ a rule r_2 of direction class d having root node labels $\text{label}_L(s_{i,r_1})$ and $\text{label}_R(s_{i,r_1})$ that match the left and right labels at s_{i,r_1}.
3. Recursively process each of the added rules

For all substitution rules r_s, adjoining rules r_a, and adjoining sites $s_{i,r}$, the probability of a derivation tree using these rules is the product of all the probabilities used in this process, i.e.:

$$P_{deriv} = \prod_{r_s} \left(P_{sub}(r_s|\langle \text{root}_L(r_s), \text{root}_R(r_s)\rangle) \cdot \prod_{s_{i,r_s}} P_{\text{if}adj}(\text{decision}_{adjoin}|s_{i,r_s}, r_s) \right) \cdot \prod_{r_a} \left(P_{adj}(r_a|\text{dir}(r_a), \langle \text{root}_L(r_a), \text{root}_R(r_a)\rangle) \cdot \prod_{s_{i,r_a}} P_{\text{if}adj}(\text{decision}_{adjoin}|s_{i,r_a}, r_a) \right)$$

Note that while every new substitution site requires an additional rule to be added, adjunction sites may or may not introduce an additional rule based on the rule-specific $P_{\text{if}adj}$ probability. This allows adjunction to represent linguistic optionality.

[2]Here and in the following, we use *site* as shorthand for synchronous site pair.

3 Learning the Model

Instead of using bilingual parsing to directly train our model from strings as done by Nesson et al. (2006), we follow the method of Galley et al. (2004) by dividing the training process into steps. First, we word align the parallel sentences and parse the English (target) side. Then, we transform the aligned tree/string training data into derivation trees of minimal translation rules (Section 3.1). Finally, we learn our probability models P_{sub}, $P_{\text{if}adj}$, and P_{adj} by collecting counts over the derivation trees (Section 3.2). This method is quick enough to allow us to scale our learning process to large-scale data sets.

3.1 Generating Derivation Trees and Rules

There are four steps in transforming the training data into derivation trees and rules, the first two operating only on the English parse tree itself:[3]

A. Marking Required vs. Optional. For each constituent in the English parse tree, we mark children as (H)ead, (R)equired, or (O)ptional elements (see step (a) in Figure 3). The choice of head, required, or optional has a large impact on the generality and applicability of our grammar. If all children are considered required, the result is the same as the GHKM rules of Galley et al. (2004) and has the same problem—lots of low count, syntactically over-constrained rules. Too many optional children, on the other hand, allows ungrammatical output. Our proposed model is a linguistically motivated middle ground: we consider the linguistic heads and complements selected by Collins' (2003) rules to be required and all other children to be optional.

B. Parse tree to TIG tree. Next, we restructure the English tree to form a TIG derivation where head and required elements are substitutions, and optional elements are adjunctions (see step (b) in Figure 3). To allow for adjoining between siblings under a constituent, we first do a head-out binarization of the tree. This is followed by excising[4] any children marked as optional and replacing them with an adjunction site, as shown in Figure 4. Note that we excise a chain of optional children as one site with each optional child

[3]These first two steps were inspired by the method Chiang (2003) used to automatically extract a TIG from an English parse tree.

[4]Excising is the opposite of adjoining: extracting out an auxiliary rule from a tree to form two smaller trees.

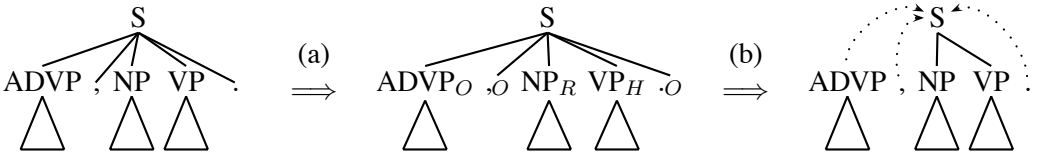


Figure 3: Parse tree to TIG transformation: (a) mark constituent children with (H)ead, (R)equired, and (O)ptional, then (b) restructure the tree so that head and required elements are substitutions, while optional elements are adjoined (shown with dotted lines).

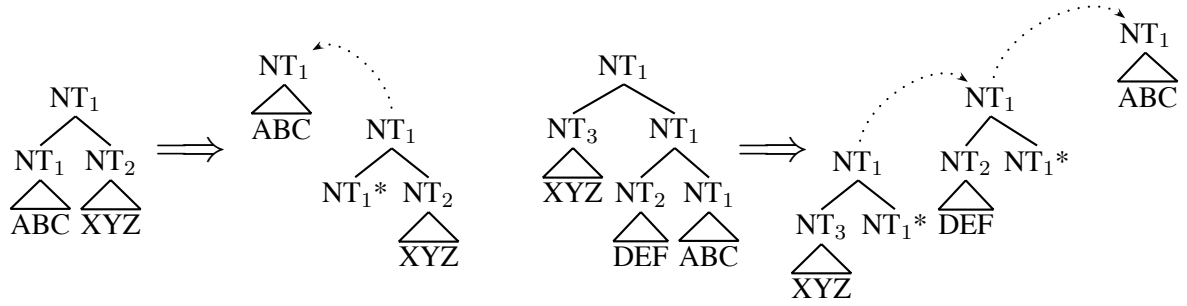

(a) excising one optional child (XYZ) (b) excising a series of optional children (DEF, then XYZ)

Figure 4: Two examples of excising auxiliary trees from a head-out binarized parse tree: (a) excising one optional left branch, (b) excising a chain of optional branches in the same (right) direction into a series of adjunctions. In both examples, the 'ABC' child is the head, while the other children are optional.

adjoined to the previous child, as in Figure 4(b).

C. Extracting rules and derivation trees. We now have a TIG derivation tree, with each elementary tree attached to its parent by a substitution or adjunction link. We can now extract synchronous rules allowed by the alignments and syntactic constituents. This can be done using a method inspired by the rule-extraction approach of Galley et al. (2004), but instead of directly operating on the parse tree we process the English TIG derivation tree. In bottom-up fashion, we visit each elementary tree in the derivation, allowing a rule rooted at this tree to be extracted if its words or those of its descendants are aligned such that they are the English side of a self-contained parallel phrase (i.e., the foreign text of this phrase is not aligned to English leaves outside of the set of descendants). Otherwise, this elementary tree is rejoined with its parent to form a larger elementary tree. At the end of this process we have a new set of linked elementary trees which make up the English side of the grammar, where each substitution or adjunction link becomes a substitution or adjunction site in the synchronous grammar.

On the foreign side we start with the foreign text of the self-contained parallel phrase and replace any parts of this phrase covered by substituted or adjoined children of the English side tree with substitution sites or adjunction site markers. From this, we produce a tree with a simple, regular form by placing all items under a root node labeled X. In the case of more than one foreign word or substitution site, we introduce an intermediate level of X-labeled non-terminals to allow for possible adjunction between elements, otherwise the adjoining sites attach to the single root node. We attach all foreign-side adjoining sites to be left adjoining, except on the right side of the right-hand child.

It is possible to have the head child tree on the English side not aligned to anything, while the adjoined children are. This may lead to rules with no foreign non-terminal from which to anchor the adjunctions, so in this case, we attach adjoined child elementary trees starting from the head and moving out until we attach a some child with a non-empty foreign side.

D. Generalizing rules. We need to clarify what makes one rule distinct from another. Consider the example in Figure 5, which shows selected rules learned in the case of two different noun phrases. If the noun phrase consists of just a single noun, we learn rule (a), while if the noun phrase also has an adjective, we learn rules (b) and (c). Since adjoining the adjective is optional, *we*

consider rules (a) and (c) to be the same rule, the latter with an adjoining seen, and the former with the same adjoining not seen.

3.2 Statistical Models

Once we have the derivation trees and list of rules, we learn our statistical models using maximum likelihood estimation. By counting and normalizing appropriately over the entire corpus, we can straightforwardly learn the P_{sub} and P_{adj} distributions. However, recall that in our model $P_{\text{if}adj}$ is a rule-specific probability, which makes it more difficult to estimate accurately. For common rules, we see plenty of examples of adjoining, while for other rules, we need to learn from only a handful of examples. Smoothing and generalization are especially important for these low frequency cases.

Two options present themselves for how to estimate adjoining:

(a) A joint model of adjoining. We assume that adjoining decisions are made in combination with each other, and so learn non-zero probabilities only for adjoining combinations seen in data

(b) An independent model of adjoining. We assume adjoining decisions are made independently, and learn a model for each adjoining site separately

Option (a) may be sufficient for frequent rules, and will accurately model dependencies between different kinds of adjoining. However, it does not allow us to generalize to unseen patterns of adjoining. Consider the low frequency situation depicted in Figure 6, rules (d)-(f). We may have seen this rule four times, once with adjoining site a, twice with adjoining sites a and b, and once with a third adjoining site c. The joint model will give a zero probability to unseen patterns of adjoining, e.g. no adjoining at any site or adjoining at site b alone. Even if we use a discounting method to give a non-zero probability to unseen cases, we still have no way to distinguish one from another.

Option (b) allows us to learn reasonable estimates for these missing cases by separating out adjoining decisions and letting each speak for itself. To properly learn non-zero probabilities for unseen cases[5] we use add k smoothing ($k = \frac{1}{2}$).

[5]For example, low frequency rules may have always been observed with a single adjoining pattern, and never without adjoining.

A weakness of this approach still remains: adjoining is not a truly independent process, as we observe empirically in the data. In real data, frequent rules have many different observed adjoining sites (10 or 20 in some cases), many of which represent already infrequent sites in combinations never seen together. To reduce the number of invalid combinations produced, we only allow adjoinings to be used at the same time if they have occurred together in the training data. This restriction makes it possible to do less adjoining than observed, but not more. For the example in Figure 6, in addition to the observed patterns, we would also allow site b to be used alone, and we would allow no adjoinings, but we would not allow combinations of site c with either a or b. Later, we will see that this makes the decoding process more efficient.

Because both option (a) and (b) above have strengths and weaknesses, we also explore a third option which builds upon the strengths of each:

(c) A log-linear combination of the joint model and independent model. We assume the probability has both a dependent and independent element, and learn the relative weight between them automatically

To help smooth this model we add two additional binary features: one indicating adjoining patterns seen in data and one indicating previously unseen patterns.

4 Decoding

To translate with these rules, we do a monolingual parse using the foreign side of the rules (constraining the search using non-terminal labels from both sides), while keeping track of the English side string and structure for language modeling purposes. This produces all valid derivations of rules whose foreign side yield is the input string, from which we simply choose the one with the highest log-linear model score. Though this process could be done directly using a specialized parsing algorithm, we note that these rules have weakly equivalent counterparts in the Synchronous Tree Substitution Grammar (STSG) and Tree-to-string transducer (xLNTs[6]) worlds, such that each STIG rule can be translated into one equivalent rule, plus some helper rules to model the adjoin/no-adjoin

[6]xLNTs is shorthand for extended linear non-deleting top-down tree-to-string transducer.

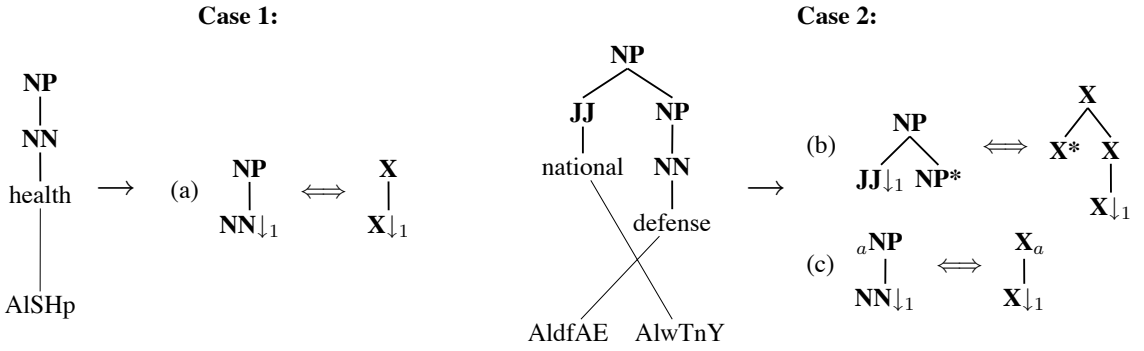

Figure 5: Selected rules learned in two cases. Rule (a) and (c) are considered the same rule, where (c) has the optional synchronous adjoining site marked with a. From these (limited) examples alone we would infer that adjective adjoining happens half the time, and is positioned before the noun in English, but after the noun in Arabic (thus the positioning of site a).

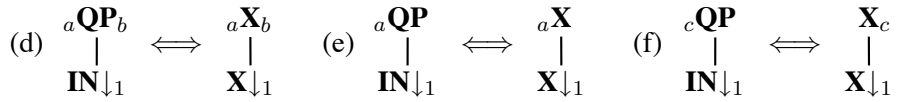

(seen once) (seen twice) (seen once)

Figure 6: For a low frequency rule, we may see only a few different adjoining patterns, but we want to infer more.

decision. Conversion to a better known and explored formalism allows us to take advantage of existing code and algorithms. Here we describe the conversion process to xLNTs rules, though conversion to STSG is similar.

Algorithm 1 describes the process of converting one of our automatically learned STIG rules. On each side of the rule, we traverse the tree in a top-down, left-to-right order, recording words, substitution sites, and adjoining sites in the order encountered (left adjoinings before the node's children and right adjoinings after). We make these words and sites as the children under a single root node. The substitution sites are given states made up of a combination of their source and target labels as are the roots of non-adjoining rules. Adjoining sites are labeled with a combination of the rule id and a site id. Adjoining rule roots are labeled with a combination of the source and target root labels and the direction class. To allow for the adjoining/no-adjoining decision, two helper rules are created for each adjoining site, their root state a combination of the rule and site ids. One of these rules has only epsilon leaf nodes (representing no adjoining), while the other has leaf nodes and a state that match with the corresponding adjoining rule root (labeled with the site's source and target labels and the direction class).

For each rule, the algorithm generates one main rule and pairs of helper rules to facilitate adjoining/non-adjoining. For computational efficiency reasons, our decoder supports neither epsilon rules nor non-binary rules. So we remove epsilons using an exponential expansion of the rules: combine each main rule with an adjoining or non-adjoining helper rule for each adjunction site, then remove epsilon-only branches. For k adjunction sites this could possibly results in 2^k rules. But as discussed previously (at the end of Section 3.2), we only allow subsets of adjoining combinations seen in training data, so this number is substantially lower for large values of k.

5 Experiments

All experiments are trained with a subset (171,000 sentences or 4 million words) of the Arabic-English training data from the constrained data track of the NIST 2008 MT Evaluation, leaving out LDC2004T18, LDC2007E07, and the UN data. The training data is aligned using the LEAF technique (Fraser and Marcu, 2007). The English side of the training data is parsed with an implementation of Collins Model 2 (Collins, 2003) then head-out binarized. The tuning data (1,178 sentences) and devtest data (1,298 sentences) are

Input: Synchronous TIG rule r with j adjoining sites, $S \leftrightarrow T$, where S and T are trees

end

Algorithm 1: Conversion from synchronous TIG rules to weakly equivalent xLNTs rules

		BLEU	
	description	**DevTest**	**NIST06**
(1)	baseline: all required (GHKM minimal, head-out binarized parse trees)	48.0	47.0
(2)	joint adjoining prob model alone (only observed adjoining patterns)	48.0	46.6
(3)	independent adjoining prob model alone (only observed adjoining patterns)	48.1	46.7
(4)	independent adjoining prob model alone (with new adjoining patterns)	48.5	47.6
(5)	independent model alone + features (adjoining pattern, direction)	48.4	47.7
(6)	log-linear combination of joint & independent models + features	48.7	47.8

Table 1: End-to-end MT results show that the best adjoining model using a log-linear combination of joint and independent models (line 6) outperforms the baseline (line 1) by +0.7 and +0.8 BLEU, a statistically significant difference at the 95% confidence level.

made up of newswire documents drawn from the NIST MT evaluation data from 2004, 2005, and 2006 (GALE part). We use the newswire documents from the NIST part of the 2006 evaluation data (765 sentences) as a held-out test set.

We train our feature weights using max-BLEU (Och, 2003) and decode with a CKY-based decoder that supports language model scoring directly integrated into the search.

In addition to P_{sub}, P_{adj}, and $P_{\text{if}adj}$, we use several other features in our log-linear model during decoding, including: lexical and phrase-based translation probabilities, a model similar to conditional probability on the trees ($P(f_{tree}(rule)|e_{tree}(rule))$), a probability model for generating the top tree non-terminal, a 5-gram language model[7], and target length bonus. We also have several binary features—lexical rule, rule with missing or spurious content words—and several binary indicator features for specialized rules: unknown word rules; name, number, and date translation rules; and special fail-safe monotone translation rules in case of parse failures and extremely long sentences.

Table 1 shows the comparison between our baseline model (minimal GHKM on head-out binarized parse trees) and different models of adjoining, measured with case-insensitive, NIST-tokenized BLEU (IBM definition). The top section (lines 1–4) compares the joint adjoining probability model to the independent adjoining probability model and seen vs. unseen adjoining combinations. While the joint model results in a BLEU score at the same level as our baseline (line 2), the independent model (line 4) improves BLEU by +0.5 and +0.6, which are significant differences at the 95% confidence level. Since with the independent model we introduce both new adjoining patterns and a different probability model for adjoining (each site is independent), we also use the independent model with only previously seen adjoining patterns (line 3). The insignificant difference in BLEU between lines 2 and 3 leads us to think that the new adjoining patterns are where the improvement comes from, rather than the independent probability model alone.

We also test several other features and combinations. First, we add binary features to indicate a new adjoining combination vs. one previously seen in data. We also add features to indicate the direction class of adjoining to test if there is a systematic bias toward particular directions. These features cause no significant difference in score (line 5). We also add the joint-adjoining probability as a feature, allowing it to be combined in a log-linear fashion with the independent probability (line 6). This results in our best BLEU gain: +0.7 and +0.8 over our non-adjoining baseline.

[7]The 5-gram LM was trained on 2 billion words of automatically selected collections taken from the NIST 08 allowable data.

6 Conclusion

We have presented a novel method for learning the rules and probabilities for a new statistical, linguistically-informed, syntax-based MT model that allows for adjoining. We have described a method to translate using this model. And we have demonstrated that linguistically-motivated adjoining improves the end-to-end MT results.

There are many potential directions for research to proceed. One possibility is to investigate other methods of making the required vs. optional decision, either using linguistic resources such as COMLEX or automatically learning the distinction using EM (as done for tree binarization by Wang et al. (2007)). In addition, most ideas presented here are extendable to rules with linguistic trees on both sides (using insights from Lavie et al. (2008)). Also worth investigating is the direct integration of bilingual dictionaries into the grammar (as suggested by Shieber (2007)). Lastly, rule composition and different amounts of lexicalization (Galley et al., 2006; Marcu et al., 2006; DeNeefe et al., 2007) or context modeling (Mariño et al., 2006) have been successful with other models.

Acknowledgments

We thank David Chiang for suggestions about adjoining models, Michael Pust and Jens-Sönke Vöckler for developing parts of the experimental framework, and other colleagues at ISI for their helpful input. We also thank the anonymous reviewers for insightful comments and suggestions. This research is financially supported under DARPA Contract No. HR0011-06-C-0022, BBN subcontract 9500008412.

Word Buffering Models for Improved Speech Repair Parsing*

Tim Miller
University of Minnesota – Twin Cities
tmill@cs.umn.edu

Abstract

This paper describes a time-series model for parsing transcribed speech containing disfluencies. This model differs from previous parsers in its explicit modeling of a buffer of recent words, which allows it to recognize repairs more easily due to the frequent overlap in words between errors and their repairs. The parser implementing this model is evaluated on the standard Switchboard transcribed speech parsing task for overall parsing accuracy and edited word detection.

1 Introduction

Speech repair is a phenomenon in spontaneous speech where a speaker interrupts the flow of speech (at what's called the *interruption point*), backtracks some number of words (the *reparandum*), and continues the utterance with material meant to replace the reparandum (the *alteration*).[1] The utterance can be rendered syntactically correct by excising all the words that the speaker skipped over when backtracking. Speech with repair is difficult for machines to process because in addition to detecting repair, a system must know what words are meant to be excised, and parsing systems must determine how to form a grammatical structure out of the set of words comprising both the error speech and the correct speech.

Recent approaches to syntactic modeling of speech with repairs have shown that significant gains in parsing accuracy can be achieved by modeling the syntax of repairs (Hale et al., 2006; Core and Schubert, 1999). In addition, others have shown that a parser based on a time-series model that explicitly represents the incomplete constituents in fluent and disfluent speech can also improve parsing accuracy (Miller and Schuler, 2008). However, these parsing approaches are still not as accurate at detecting reparanda as classification systems which use a variety of features to detect repairs (Charniak and Johnson, 2001; Johnson and Charniak, 2004; Heeman and Allen, 1999).

One highly salient feature which classification systems use to detect repair is the repetition of words between the error and the repair. Johnson and Charniak report that 60% of words in the alterations are copies of words in reparanda in the Switchboard corpus. Typically, this information is not available to a parser trained on context-free grammars.

Meanwhile, psycholinguistic models suggest that the human language system makes use of buffers both to keep track of recent input (Baddeley et al., 1998) and to smooth out generation (Levelt, 1989). These buffers are hypothesized to contain representations of recent phonological events, suggesting that there is a short window where new input might be compared to recent input. This could be represented as a buffer which predicts or detects repeated input in certain constrained circumstances.

This paper describes a hybrid parsing system operating on transcribed speech which combines an incremental parser implemented as a probabilistic time-series model, as in Miller and Schuler, with a buffer of recent words meant to loosely model something like a phonological loop, which should better account for word repetition effects in speech repair.

2 Background

This work uses the Switchboard corpus (Godfrey et al., 1992) for both training and testing. This corpus contains transcribed and syntactically annotated conversations between human interlocutors. The reparanda in speech repairs are ulti-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 737–745,
Singapore, 6-7 August 2009.

mately dominated by the EDITED label, and in cases where the reparandum ends with an unfinished constituent, the lowest constituent label is augmented with the -UNF tag. These annotations provide necessary but not sufficient information for parsing speech with repairs, and thus many improvements in performing this task come as the result of modifying these annotations in the training data.

As mentioned above, both Hale and colleagues (2006) and Miller and Schuler (2008) showed that speech repairs contain syntactic regularities, which can improve the parsing of transcribed speech with repairs when modeled properly. Hale et al. used 'daughter annotation', which adds the label of an EDITED node's child to the EDITED label itself, and '-UNF propagation', which labels every node between an original -UNF node and the EDITED with an -UNF tag. Miller and Schuler used a 'right-corner transform' to convert standard phrase structure trees of the Penn Treebank into 'right-corner trees', which have highly left-branching structure and non-standard tree categories representing incomplete constituents being recognized. These trees can be mapped into a fixed-depth Hierarchical Hidden Markov Model to achieve improved parsing and reparandum-finding results over standard CYK parsers.

Work by Johnson and Charniak (2004; 2001) uses much of the same structure, but is not a parsing approach per se. In earlier work, they used a boosting algorithm using word identity and category features to classify individual words as part of a reparandum or not, and achieved very impressive accuracy. More recent work uses a tree-adjoining grammar (TAG) to model the overlap in words and part-of-speech tags between reparandum and alteration as context sensitive syntax trees. A parser is then used to rank the multiple outputs of the TAG model with reparandum words removed.

Another approach that makes use of the correspondence between words in the reparandum and alteration is Heeman and Allen (1999). This approach uses several sources of evidence, including word and POS correspondence, to predict repair beginnings and correct them (by predicting how far back they are intended to retrace). This model includes random variables between words that correspond to repair state, and in a repair state, allows words in the reparandum to 'license' words in the alteration with high probability, accounting for the high percentage of copied words and POS tags between reparandum and alteration.

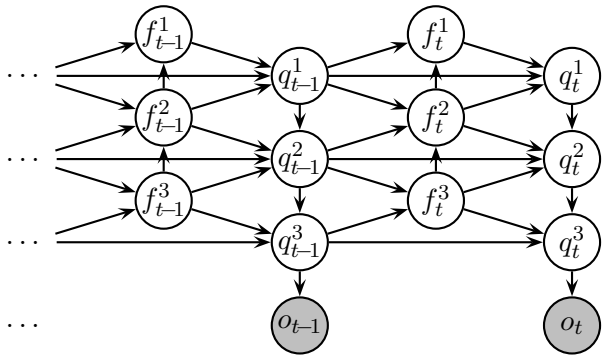

Figure 1: Graphical representation of the dependency structure in a standard Hierarchic Hidden Markov Model with $D = 3$ hidden levels that can be used to parse syntax. Circles denote random variables, and edges denote conditional dependencies. Shaded circles denote variables with observed values.

3 Model Description

This work is based on a standard Hierarchical Hidden Markov Model parser (Schuler, 2009), with the addition of two new random variables for tracking the state of speech repair. The HHMM framework is a desirable starting point for this work for two reasons: First, its definition in terms of a graphical model makes it easy to think about and to add new random variables. Second, the HHMM parser operates incrementally in a left-to-right fashion on word input, which allows this system to run in a single pass, conditioning current words on a hypothesized buffer and interruption point variable. The incremental nature of this system is a constraint that other systems are not bound by, but makes this model more psycholinguistically plausible. In comparison, a CYK parsing framework attempting to use the same probabilistic model of word dependency between reparanda and alterations would need to do a second pass after obtaining the most likely parses, in order to tell if a particular word's generation probability in a specific parse is influenced by a recent repair.

The graphical model representation of this framework is illustrated in Figures 1 and 4. The original model, shown in Figure 1, has complex variables Q and F broken down into several q^d_t and f^d_t for time step t and depth d. These ran-

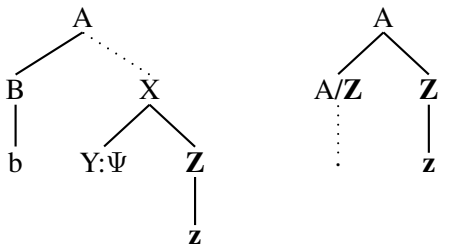
dom variables will be explained shortly, but for now suffice it to say that in this work they are unaltered from the original HHMM parsing framework, while those labeled I and B (Figure 4) are additions specific to the system described in this paper. This section will next describe the standard HHMM parsing framework, before describing how this work augments it.

3.1 Right-corner Transform

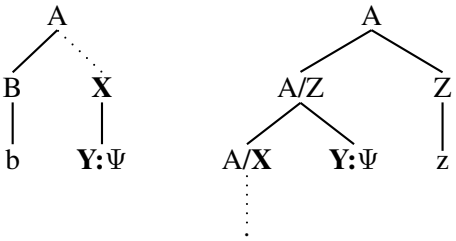
The HHMM parser consists of stacks of a fixed depth, which contain hypotheses of constituents that are being processed. In order to minimize the number of stack levels needed in processing, the phrase structure trees in the training set are modified using a 'right-corner transform', which converts right expansion in trees to left expansion, leaving heavily left-branching structure requiring little depth. The right-corner transform used in this paper is simply the left-right dual of a left-corner transform (Johnson, 1998a).

The right-corner transform can be defined as a recursive algorithm on phrase-structure trees in Chomsky Normal Form (CNF). Trees are converted to CNF first by binarizing using standard linguistically-motivated techniques (Klein and Manning, 2003; Johnson, 1998b). Remaining unbinarized structure is binarized in a brute force fashion, creating right-branching structure by creating a single node which dominates the two right-most children of a 'super-binary' tree, with the label being the concatenation of its children's labels (see Figure 2).

Taking this CNF phrase structure tree as input, the right-corner transform algorithm keeps track of two separate trees, the original and the new right-corner tree it is building. This process begins at the right-most preterminal of the original tree, and works its way up along the right 'spine', while building its way down a corresponding left spine of the new right-corner tree. The trees below shows the first step of the algorithm, with the tree on the left being disassembled, the tree on the right being built from its parts, and the working positions in the trees shown in bold.



The bottom right corner of the original tree is made the top right corner of the new tree, and the left corner of the new tree is made the new working position and given a 'slash' category A/Z. The 'slash' category label A/Z represents a tree that is the start of a constituent of type A that needs a right-child of type Z in order to complete. The new right-corner of the original tree is the parent (X) of the previous right corner, and its subtree is now added to the right-corner derivation:



After the first step, the subtrees moved over to the right-corner tree may have more complex substructure than a single word (in this case, Ψ represents that possibly complex structure). After being attached to the right-corner tree in the correct place, the algorithm is recursively applied to that now right-branching substructure.

Again, the left child is given a new slash category: The 'active constituent' (the left side of a slash category) is inherited from the root, and the 'awaited constituent' (the right side of a slash category) is taken from the constituent label of the right-corner it came from.

This algorithm proceeds iteratively up the right spine of the original tree, moving structure to the right-corner tree and recursively transforming it as it is added. The final step occurs when the original root (A in this case) is reduced to having a single child, in which case its child is added as a child of the leftmost current branch of the right-corner tree, and it is transformed recursively.

Figures 2 and 3 show an example tree from the Switchboard corpus before and after the right-corner transform is applied.

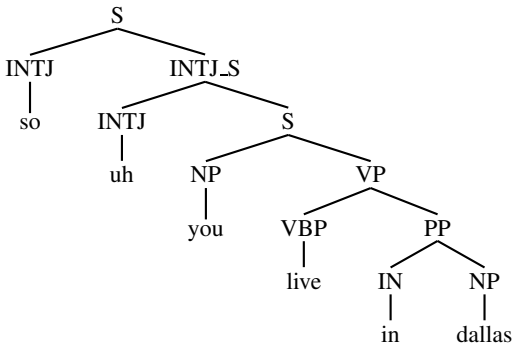


Figure 2: Input to the right-corner transform. This tree also shows an example of the 'brute-force' binarization done on super-binary branches that cannot be otherwise be binarized with linguistically-motivated rules.

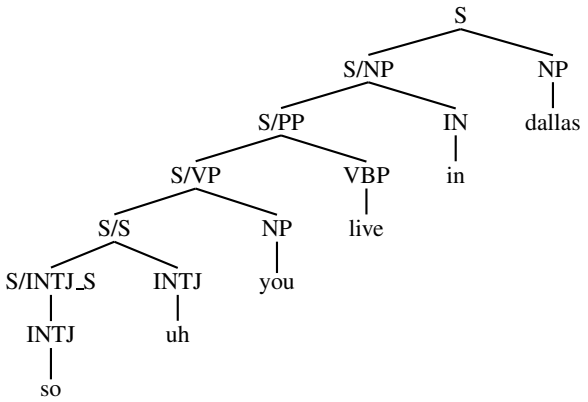

Figure 3: Right-corner transformed version of the tree in Figure 2.

3.2 Hierarchical Hidden Markov Model

A Hierarchical Hidden Markov Model is essentially an HMM with a specific factorization that is useful in many domains — the hidden state at each time step is factored into d random variables which function as a stack, and d additional random variables which regulate the operations of the stack through time. For the model of speech repair presented here, an interruption point is identified by one of these regulator variables firing earlier than it would in fluent speech. This concept will be formalized below. The stack regulating random variables are typically marginalized out when performing inference on a sequence.

While the vertical direction of the hidden sub-states (at a fixed t) represents a stack at a single point in time, the horizontal direction of the hidden sub-states (at a fixed d) can be viewed as a simple HMM at depth d, expanding the state from the HMM above it across multiple time steps and causing the HMM below it to expand its own states. This interpretation will be useful when formally defining the transitions between the stack elements at different time steps below.

Formally, HMMs characterize speech or text as a sequence of hidden states q_t (which may consist of speech sounds, words, and/or other hypothesized syntactic or semantic information), and observed states o_t at corresponding time steps t (typically short, overlapping frames of an audio signal, or words or characters in a text processing application). A most likely sequence of hidden states $\hat{q}_{1..T}$ can then be hypothesized given any sequence of observed states $o_{1..T}$, using Bayes' Law (Equation 2) and Markov independence assumptions (Equation 3) to define a full $\mathsf{P}(q_{1..T} \mid o_{1..T})$ probability as the product of a *Language Model* (Θ_{L}) prior probability and an *Observation Model* (Θ_{O}) likelihood probability:

$$\hat{q}_{1..T} = \underset{q_{1..T}}{\operatorname{argmax}}\, \mathsf{P}(q_{1..T} \mid o_{1..T}) \tag{1}$$

$$= \underset{q_{1..T}}{\operatorname{argmax}} \mathsf{P}(q_{1..T}) \cdot \mathsf{P}(o_{1..T} \mid q_{1..T}) \tag{2}$$

$$\stackrel{\text{def}}{=} \underset{q_{1..T}}{\operatorname{argmax}} \prod_{t=1}^{T} \mathsf{P}_{\Theta_{\mathrm{L}}}(q_t \mid q_{t-1}) \cdot \mathsf{P}_{\Theta_{\mathrm{O}}}(o_t \mid q_t) \tag{3}$$

Language model transitions $\mathsf{P}_{\Theta_{\mathrm{L}}}(q_t \mid q_{t-1})$ over complex hidden states q_t can be modeled using synchronized levels of stacked-up component HMMs in a Hierarchic Hidden Markov Model (HHMM) (Murphy and Paskin, 2001). HHMM transition probabilities are calculated in two phases: a 'reduce' phase (resulting in an intermediate, marginalized state f_t), in which component HMMs may terminate; and a 'shift' phase (resulting in a modeled state q_t), in which unterminated HMMs transition, and terminated HMMs are re-initialized from their parent HMMs. Variables over intermediate f_t and modeled q_t states are factored into sequences of depth-specific variables — one for each of D levels in the HMM hierarchy:

$$f_t = \langle f_t^1 \dots f_t^D \rangle \tag{4}$$

$$q_t = \langle q_t^1 \dots q_t^D \rangle \tag{5}$$

Transition probabilities are then calculated as a product of transition probabilities at each level, using level-specific 'reduce' Θ_{F} and 'shift' Θ_{Q} mod-

els:

$$\mathsf{P}_{\Theta_{\text{L}}}(q_t|q_{t\text{-}1}) = \sum_{f_t} \mathsf{P}(f_t|q_{t\text{-}1}) \cdot \mathsf{P}(q_t|f_t\, q_{t\text{-}1}) \quad (6)$$

$$\stackrel{\text{def}}{=} \sum_{f_t^{1..D}} \prod_{d=1}^{D} \mathsf{P}_{\Theta_{\text{F}}}(f_t^d|\, f_t^{d+1} q_{t\text{-}1}^d q_{t\text{-}1}^{d-1}) \cdot \mathsf{P}_{\Theta_{\text{Q}}}(q_t^d|f_t^{d+1} f_t^d\ q_{t\text{-}1}^d q_t^{d-1}) \quad (7)$$

with f_t^{D+1} and q_t^0 defined as constants.

Shift and reduce probabilities are now defined in terms of finitely recursive FSAs with probability distributions over transition, recursive expansion, and final-state status of states at each hierarchy level. In the HHMM used in this paper, each intermediate state variable is a reduction state variable $f_t^d \in G \cup \{\mathbf{0}, \mathbf{1}\}$ (where G is the set of all nonterminal symbols from the original grammar), representing a reduction to the final syntactic state in G, a horizontal transition to a new awaited category, or a top-down transition to a new active category. Each modeled state variable is a syntactic element ($q_t^d \in G \times G$) with an active and awaited category represented with the slash notation.

The intermediate variable f_t^d is probabilistically determined given a reduction at the stack level below, but is deterministically $\mathbf{0}$ in the case of a non-reduction at the stack level below. [2]

$$\mathsf{P}_{\Theta_{\text{F}}}(f_t^d \mid f_t^{d+1} q_{t\text{-}1}^d q_{t\text{-}1}^{d-1}) \stackrel{\text{def}}{=} \begin{cases} \text{if } f_t^{d+1} \notin G : [f_t^d = \mathbf{0}] \\ \text{if } f_t^{d+1} \in G : \mathsf{P}_{\Theta_{\text{F-Reduce}}}(f_t^d \mid q_{t\text{-}1}^d, q_{t\text{-}1}^{d-1}) \end{cases} \quad (8)$$

where $f^{D+1} \in G$ and $q_t^0 = \mathbf{ROOT}$.

Shift probabilities at each level are defined using level-specific transition $\Theta_{\text{Q-T}}$ and expansion $\Theta_{\text{Q-E}}$ models:

$$\mathsf{P}_{\Theta_{\text{Q}}}(q_t^d \mid f_t^{d+1} f_t^d\ q_{t\text{-}1}^d q_t^{d-1}) \stackrel{\text{def}}{=} \begin{cases} \text{if } f_t^{d+1} \notin G, f_t^d \notin G\text{: } [q_t^d = q_{t\text{-}1}^d] \\ \text{if } f_t^{d+1} \in G, f_t^d \notin G\text{: } \mathsf{P}_{\Theta_{\text{Q-T}}}(q_t^d \mid f_t^{d+1} f_t^d q_{t\text{-}1}^d q_t^{d-1}) \\ \text{if } f_t^{d+1} \in G, f_t^d \in G\text{: } \mathsf{P}_{\Theta_{\text{Q-E}}}(q_t^d \mid q_t^{d-1}) \end{cases} \quad (9)$$

where $f^{D+1} \in G$ and $q_t^0 = \mathbf{ROOT}$. This model is conditioned on final-state switching variables at and immediately below the current HHMM level. If there is no final state immediately below the current level (the first case above), it deterministically copies the current HHMM state forward to the next time step. If there is a final state immediately below the current level (the second case above), it transitions the HHMM state at the current level, according to the distribution $\Theta_{\text{Q-T}}$. And if the state at the current level is final (the third case above), it re-initializes this state given the state at the level above, according to the distribution $\Theta_{\text{Q-E}}$. The overall effect is that higher-level HMMs are allowed to transition only when lower-level HMMs terminate. An HHMM therefore behaves like a probabilistic implementation of a pushdown automaton (or 'shift-reduce' parser) with a finite stack, where the maximum stack depth is equal to the number of levels in the HHMM hierarchy.

All of the probability distributions defined above can be estimated by training on a corpus of right-corner transformed trees, by mapping tree elements onto the random variables in the HHMM and computing conditional probability tables at each random variable. This process is described in more detail in other work (Schuler et al., in press).

3.3 Interruption Point and Word Buffer

This paper expands upon this standard HHMM parsing model by adding two new sub-models to the hidden variables described above, an interruption point (I) variable, and a word buffer (B) . This model is illustrated in Figure 4, which takes Figure 1 as a starting point and adds random variables just mentioned.

Buffers are hypothesized to be used in the human language system to smooth out delivery of speech (Levelt, 1989). In this work, a buffer of that sort is placed between the syntax generating elements and the observed evidence (words). Its role in this model is not to smooth the flow of speech, but to keep a short memory that enables the speaker to conveniently and helpfully restart when a repair is produced. This in turn gives assistance to a listener trying to understand what the speaker is saying, since the listener also has the last few words in memory.

The I variable implements a state machine that keeps track of the repair status at each time point. The domain of this variable is $\{\mathbf{0}, \mathbf{1}, \mathbf{ET}\}$, where $\mathbf{1}$ indicates the first word of an alteration, $\mathbf{ET}$ indicates editing terms in between reparandum and alteration, and $\mathbf{0}$ indicating no repair.[3]

[2] Here $[\cdot]$ is an indicator function: $[\phi] = 1$ if ϕ is true, 0 otherwise.

[3] Actually, $\mathbf{0}$ can occur during an alteration, but in those cases that fact is indicated by the state of the buffer.

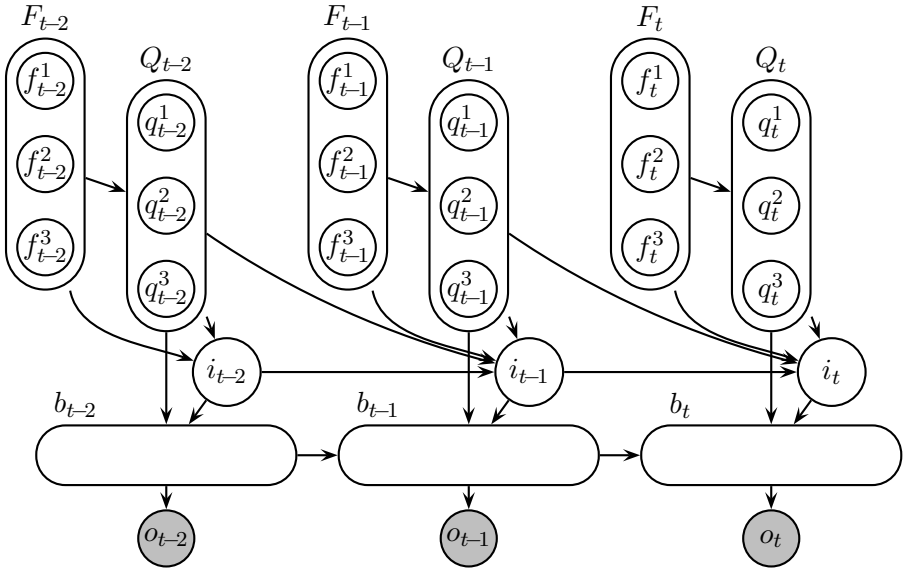

Figure 4: Extended HHMM parsing model with variables for interruption points (I) and a modeled word buffer (B). Arrows within and between complex hidden variables F and Q have been removed for clarity.

The value of I is deterministically constrained in this work by its inputs, but it can be conceived as a conditional probability $\mathsf{P}(i_t \mid i_{t-1}, q_t, q_{t-1}, r_t)$ to allow footholds for future research.[4] While depending formally on many values, in practice its dependencies are highly context-dependent and constrained:

$$\mathsf{P}(i_t \mid i_{t-1}, q_t, q_{t-1}, q_t) \stackrel{\text{def}}{=}$$

$$\begin{cases} \text{if } i_{t-1} = \mathbf{1} & : [i_t = \mathbf{0}] \\ \text{if } i_{t-1} = \mathbf{ET} \wedge (INTJ \vee PRN) \in q_t & : [i_t = \mathbf{ET}] \\ \text{if } i_{t-1} = \mathbf{ET} & : [i_t = \mathbf{1}] \\ \text{if } i_{t-1} = \mathbf{0} \wedge EDITED \in (q_{t-1} \cup f_t) & \\ \quad \wedge (INTJ \vee PRN) \in q_t & : [i_t = \mathbf{ET}] \\ \text{if } i_{t-1} = \mathbf{0} \wedge EDITED \in (q_{t-1} \cup f_t) & : [i_t = \mathbf{1}] \\ \text{if } i_{t-1} = \mathbf{0} & : [i_t = \mathbf{0}] \end{cases}$$

These conditions are meant to be evaluated in a short-circuiting fashion, i.e., the first condition which is true starting from the top is applied. The default (last) case is most common, going from non-repair to non-repair state. When the syntax generated something with the category EDITED at the last time step (as evidenced by either the modeled state variable q_{t-1} or the reduction state variable f_t depending on the length of the reparandum), the interruption point variable is triggered to change, either to $\mathbf{ET}$ if an interjection (INTJ) or parenthetical (PRN) followed, otherwise to $\mathbf{1}$ for the first word of an alteration. The $\mathbf{ET}$ state continues as long as the syntax at the current level is generating something containing INTJ or PRN.

The random variable for the word buffer is more complex, containing at each time step t an integer index for keeping track of a current position in the buffer ($c_t \in \langle 0, 1, \ldots, n-1 \rangle$ for buffer size n), and an array of several recently generated words ($\vec{w}_t$). This can be represented as the following conditional probability:

$$\mathsf{P}(b_t \mid b_{t-1}, i_t, q_t) = \mathsf{P}(c_t \mid c_{t-1}, i_t) \cdot \mathsf{P}(\vec{w}_t \mid \vec{w}_{t-1}, c_t) \qquad (10)$$

The operation of the buffer is governed by four cases:

Case 1: During normal operation (i.e. for fluent speech), the interruption point variable is $\mathbf{0}$ and at the previous time step the buffer index points at the end of the buffer ($i_t = \mathbf{0} \wedge c_{t-1} = n-1$). In this simple case, the buffer pointer remains pointing at the end position in the buffer ($c_t = n-1$), and the last $n-1$ items in the buffer are deterministically copied backwards one position. A new word is generated probabilistically to occupy the last position in the buffer (where c_t is pointing). This probability is estimated empirically using the same model used in a standard HHMM to generate words, by conditioning the word on the deepest non-empty q_t value in the stack.

Case 2: When an editing term is being generated, ($i_t = \mathbf{ET}$), the buffer is not in use. Practi-

[4] Most obviously, this variable could be made prior to its conditions to be their cause, if a suitable model for the causation of interruption points was designed using prosodic cues. For this work, it is simply an intermediary that is not strictly necessary but makes the model design more intuitive.

cally, this means that the value of the index c and all w^j are just copied over from time $t-1$ to time t. This makes sense psycholinguistically, because a buffer used to smooth speech rates would by definition not be used when speech is interrupted by a repair. It also makes sense from a purely engineering point of view, since words used as editing terms are usually stock phrases and filled pauses that are not likely to have much predictive value for the alteration, and are thus not worth keeping in the buffer. The probability of the actual observed word is modeled the same way word probabilities are modeled in a standard HHMM, conditioned on the deepest non-empty q_t value, and ignoring the buffer.

Case 3: The alteration case applies to the first word after the reparandum and optional editing terms ($i_t = \mathbf{1}$). In this case, the index c_t for the current position of the buffer is obtained by subtracting a number of words to replace, with that number drawn from a prior distribution. This distribution is based on the function $f(k) = 1.22 \cdot 0.45^k$. This function was taken from Shriberg (1996), where it was estimated based on several different training corpora, and provided a remarkable fit to all of them. Since this model uses a fixed size buffer, the values are precomputed and renormalized to form a probability distribution. With a buffer size of only $n = 4$, approximately 96% of the probability mass of the original function is accounted for.

After the indices are computed, the buffer at position c_t is given a word value. The model first decides whether to substitute or copy the previous word over. The probability governing this decision is also determined empirically, by computing how often the first word in a alteration in the Switchboard training set is a copy of the first word it is meant to replace. If the copy operation is selected, the word is added to the buffer without further diluting its probability. If, however, the substitution operation was selected, the word is added to the buffer with probability distributed across all possible words.

Case 4: The final case to account for is alterations of length greater than one ($i_t = \mathbf{0} \wedge c_{t-1} \neq n-1$). This occurs when the current index was moved back more than one position, and so even though i is set to $\mathbf{0}$, the current index into the buffer is not pointing at the end. In this case, again the index c_t is selected according to a prior probability distribution. The value selected from the distribution corresponds to different actions that may be selected when retracing the words in the reparandum to generate the alteration.

The first option is that the current index remains in place, which corresponds to an *insertion* operation, where the alteration is given an extra word relative to the reparandum at its current position. Following an insertion, a new word is generated and placed in the buffer at the current index, with probability conditioned on the syntax at the most recent time step. The second option is to continue the alignment, moving the current index forward one position in the buffer, and then either performing a *substitution* or *copy* operation in alignment with a word from the alteration. Word probabilities for the copy and substitution operations are generated in the same way as for the first word of an alteration. Finally, the current index may skip forward more than one value, performing a *deletion* operation. Deletion skips over words in the reparandum that do not correspond to words in the alteration. After the deletion moves the current index pointer forward, a word is again either copied or substituted against the newly aligned word.

The prior probability distributions over alignment operations is estimated from data in the Switchboard in a similar manner to Johnson and Charniak (2004). Briefly, using the disfluency-annotated section of the Switchboard corpus (.dps files), a list of reparanda and alterations corresponding to one another are compiled. For each pair, the minimal cost alignment is computed, where a copy operation has cost 0, substitution has cost 4, and deletion and insertion each have cost 7. Using these alignments, probabilities are computed using relative frequency counts for both the first word of an alteration, and for subsequent operations. Copy and substitution are the most frequent operations (copying gives information about the repair itself, while substitution can correct the reason for the error), insertion is somewhat less frequent (presumably for specifying further information), and deletion is relatively rare (usually a repair is not made to remove information).

4 Evaluation

This model was evaluated on the Switchboard corpus (Godfrey et al., 1992) of conversational telephone speech between two human interlocu-

System	*Precision*	*Recall*	*F-Score*

tors. The input to this system is the gold standard word transcriptions, segmented into individual utterances. The standard train/test breakdown was used, with sections 2 and 3 used for training, and subsections 0 and 1 of section 4 used for testing. Several held-out sentences from the end of section 4 were used during development.

For training, the data set was first standardized by removing punctuation, empty categories, typos, all categories representing repair structure, and partial words – anything that would be difficult or impossible to obtain reliably with a speech recognizer.

The two metrics used here are the standard Parseval F-measure, and Edit-finding F. The first takes the F-score of labeled precision and recall of the non-terminals in a hypothesized tree relative to the gold standard tree. The second measure marks words in the gold standard as edited if they are dominated by a node labeled EDITED, and measures the F-score of the hypothesized edited words relative to the gold standard.

Results are shown in Tables 1 and 2. Table 1 shows detailed results on edited word finding, with two test systems and several related approaches.

The first two lines show results from a reimplementation of Hale et al. parsers. In both those cases, gold standard part-of-speech (POS) tags were supplied to the parser. The following two lines are reported results of a lexicalized parser from Hale et al. and the TAG system of Johnson and Charniak. The final three lines are evaluations of HHMM systems. The first is an implementation of Miller and Schuler, run without gold standard POS tags as input. The second HHMM result is a system much like that described in this paper, but designed to approximate the best result that can come from simply trying to match the first word of an alteration with a recent word. Levelt (1989) notes that in over 90% of repairs, the first word of the alteration is either identical or a member of the same category as the first word of the reparandum, and this clue is enough for listeners to understand what the alteration is meant to replace. This implementation keeps the I variable to model repair state, but rather than a modeled buffer being part of the hidden state, it keeps an observed buffer that simply tracks the last n words seen ($n = 4$ in this experiment). This buffer is used only to generate the first word of a repair, and only when the syntactic state allows the word. Finally, the system described in Section 3 is shown on the final line.

Table 2 shows overall parsing accuracy results, with the same set of systems, with the exception of the TAG system which did not report parsing results.

5 Discussion and Conclusion

These results first show that the main contribution of this paper, a model for a buffer of recent words which influences speech repairs, results in drastic improvements in the ability of an HHMM system to discover edited words. This model does this in a single pass through the observed words, incrementally forming hypotheses about the state of the syntactic process as well as the state of repair, just as humans must recognize spontaneous speech.

Another interesting result is the relative effectiveness of a buffer that is not modeled, but rather just a collection of words used to condition the first words of repair ('HHMM-Back'). While this result is superior to the plain HHMM system, it still falls well short of the retracing model using a modeled buffer. This suggests that, though one word is sufficient to align a reparandum and alteration when the existence of a repair is given, more information is often necessary when the task is not just alignment of repair but also detection of re-

pair. A model that takes into account information sources that identify the existence of repair, such as prosodic cues (Hale et al., 2006; Lickley, 1996), may thus result in improved performance for the simpler unmodeled buffer.

These results also confirm that parsing spontaneous speech with an HHMM can be far superior to a CKY parser, even when the CKY parser is given the advantage of correct POS tags as input. Second, even the baseline HHMM system also improves over the CYK parser in finding edited words, again without the advantage of correct POS tags as input.

In conclusion, the model described here uses a buffer inspired by the phonological loop used in the human auditory system to keep a short memory of recent input. This model, when used to assist in the detection and correction of repair, results in a large increase in accuracy in detection of repair over other most basic parsing systems. This system does not reach the performance levels of lexicalized parsers, nor multi-pass classification systems. Future work will explore ways to apply additional features of these systems or other sources of information to account for the remainder of the performance gap.

Less is More: Significance-Based N-gram Selection for Smaller, Better Language Models

Abstract

The recent availability of large corpora for training N-gram language models has shown the utility of models of higher order than just trigrams. In this paper, we investigate methods to control the increase in model size resulting from applying standard methods at higher orders. We introduce significance-based N-gram selection, which not only reduces model size, but also improves perplexity for several smoothing methods, including Katz backoff and absolute discounting. We also show that, when combined with a new smoothing method and a novel variant of weighted-difference pruning, our selection method performs better in the trade-off between model size and perplexity than the best pruning method we found for modified Kneser-Ney smoothing.

1 Introduction

Statistical language models are potentially useful for any language technology task that produces natural-language text as a final (or intermediate) output. In particular, they are extensively used in speech recognition and machine translation. Despite the criticism that they ignore the structure of natural language, simple N-gram models, which estimate the probability of each word in a text string based on the $N-1$ preceding words, remain the most widely-used type of model.

Until the late 1990s, N-gram language models of order higher than trigrams were seldom used. This was due, at least in part, to the fact the amounts of training data available did not produce significantly better results from higher-order models. Since that time, however, increasingly large amounts of language model training data have become available ranging from approximately one billion words (the Gigaword corpora from the Linguistic Data Consortium) to trillions of words (Brants et al., 2007). With these larger resources, the use of language models based on 5-grams to 7-grams is becoming increasingly common.

The problem we address here is that, even when relatively modest amounts of training data are used, high-order N-gram language models estimated by standard techniques can be impractically large. Hence, we investigate ways of building high-order N-gram language models without dramatically increasing model size. This is, of course, the same goal behind much previous work on language model pruning, including that of Seymore and Rosenfeld (1996), Stolcke (1998), and Goodman and Gao (2000). We take a novel approach, however, which we refer to as significance-based N-gram selection. We reject a higher-order estimate of the probability of a particular word in a particular context whenever the distribution of observations for the higher-order estimate provides no evidence that the higher-order estimate is better than our backoff estimate.

Perhaps our most surprising result is that significance-based N-gram selection not only reduces language model size, but it also improves perplexity when applied to a number of widely-used smoothing methods, including Katz backoff and several variants of absolute discounting.[1] In contrast, experiments applying previous pruning methods to Katz backoff (Seymore and Rosenfeld, 1996; Stolcke, 1998) and absolute discounting (Goodman and Gao, 2000) always found the lowest perplexity model to be the unpruned model.

We tested significance-based selection on only one smoothing method without obtaining improved perplexity: modified Kneser-Ney (KN)

[1] For most of the standard smoothing methods mentioned here, we refer the reader to the excellent comparative study of smoothing methods by Chen and Goodman (1998). References to the original sources may be found there.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 746–755,
Singapore, 6-7 August 2009.

smoothing (Chen and Goodman, 1998). This is unfortunate, because modified KN smoothing generally seems to have the lowest perplexity of any known smoothing method for N-gram language models; in our tests it had a lower perplexity than any of the other models, with or without significance-based N-gram selection. However, when we compared modified KN smoothing to our best results applying N-gram selection to other smoothing methods for multiple N-gram orders, two of our models outperformed modified KN in terms of perplexity for a given model size.

Of course, the trade-off between perplexity and model size for modified KN can also be improved by pruning. So, in a final set of experiments we found the best combinations we could for pruned modified KN models, and we did the same for our best model using significance-based selection. The best pruning method for the latter turned out to be a novel modification of weighted-difference pruning (Seymore and Rosenfeld, 1996) that was especially convenient to compute given our method for performing significance-based N-gram selection. The final result is that our best model using significance-based selection and modified weighted difference pruning always had a better size/perplexity trade-off than pruned modified KN, with up to about 8% perplexity reduction for a given model size.

2 Significance-Based N-gram Selection

The idea of using a statistical test to decide whether to use a higher- or lower-order estimate of an N-gram probablity is not new. It was perhaps first proposed by Ron, et al. (1996), who suggested using a threshold on relative entropy (Kullback-Liebler divergence) as an appropriate test to decide whether to extend the context used to predict the next token in a sequence. Stolcke (1998) used the same metric in his work on language model pruning, and he also pointed out that weighted difference pruning is, in fact, an approximation of relative entropy pruning. However, while relative entropy pruning is based on a statistical test, it is not a *significance* test. The difference in probability represented by a certain relative entropy value can be statistically significant when measured on a large corpus, but not significant when measured on a small corpus.

The primary test we use to choose between higher- or lower-order estimates of an N-gram probablity is inspired by an insight of Jedynak and Khudanpur (2005). They note that, given a set of y observations of a multinomial distribution, the observed counts will have the highest probabilty of any possible set of y observations for the maximum likelihood estimate (MLE) model derived from the relative frequencies of those observations. In general, however, the MLE model will not be the only model for which this set of observations is the most probable set of y observations. Jedynak and Khudanpur call the set of such models the maximum likelihood set (MLS) for the observations.

Jedynak and Khudanpur argue that the observations alone do not support choosing the MLE over other members of the MLS. The MLE may assign the observations a higher probability than other members of the MLS, but that may be an accident of what outcomes are possible given the number of observations. If we flip a coin 9 times and get 5 heads, is there any reason to believe that the probability of heads is closer to the MLE $5/9$ than it is to $5/10$? No, because $5/9$ is as close as we can come to $5/10$, given 9 observations.

We apply this insight to the problem of N-gram selection as follows: For each word w_n in a context $w_1...w_{n-1}$ with a backoff estimate for the probability of that word in that context $\beta\, p(w_n|w_2...w_{n-1})$,[2] we do not include an explicit estimate of $p(w_n|w_1...w_{n-1})$ in our model, if the backoff estimate is within the MLS of the counts for $w_1...w_n$ and $w_1...w_{n-1}$.

This requires finding the MLS of a set of observations only for binomial distributions (rather than the general multinomial distributions studied by Jedynak and Khudanpur), which has a very simple solution:

$$MLS(x,y) = \left\{ p \;\middle|\; \frac{x}{y+1} \leq p \leq \frac{x+1}{y+1} \right\}$$

where x is the count for $w_1...w_n$, y is the count for $w_1...w_{n-1}$, and p is a possible backoff probabilty estimate for $p(w_n|w_1...w_{n-1})$. In this case, the MLS is the set of binomial distributions that have x successes as their mode given y trials, which is well-known to be specified by this formula.

We describe this method as "significance-based" because we can consider our criterion as a significance test in which we take the backoff

[2] $p(w_n|w_2...w_{n-1})$ being the next lower-order estimate, and β being the backoff weight for the context $w_1...w_{n-1}$.

probability estimate as the null hypothesis for the estimate in the higher-order model, and we set the rejection threshold to the lowest possible value; we reject the null hypothesis (the backoff probability) if there are *any* outcomes for the given number of trials that are more likely, according to the null hypothesis, than the one we observed.

We make a few refinements to this basic idea. First, we never add an explicit higher-order estimate to our model, if the next lower-order estimate is not explicitly stored in the model. This enables us to keep only the next lower-order model available while performing N-gram selection.

Next, we observe that in some cases the higher-order estimate for $p(w_n|w_1...w_{n-1})$ may not fall within the MLS for the observed counts, due to smoothing. In this case, we prefer the backoff probability estimate if it lies within the MLS or between the smoothed higher-order estimate and the MLS. Otherwise, we would reject the backoff estimate for being outside the MLS, only to replace it with a higher-order estimate even farther outside the MLS.

Finally, we note that the backoff probability estimate for an N-gram not observed in the training data sometimes falls outside the corresponding MLS, which in the 0-count case simplifies to

$$MLS(0, y) = \left\{ p \;\middle|\; 0 \leq p \leq \frac{1}{y+1} \right\}$$

When this happens, we include an explicit higher-order estimate $p(w_n|w_1...w_{n-1}) = 1/(y+1)$, which is the upper limit of the MLS. This is similar to Rosenfeld and Huang's (1993) "confidence interval capping" method for reducing unreasonably high backoff estimates for unobserved N-grams.

In order to apply this treatment of 0-count N-grams, we sort the explicitly-stored N-grams for each backoff context by decreasing probability. For each higher-order context, to find the 0-count N-grams subject to the $1/(y+1)$ limit, we traverse the sorted list of explicitly-stored N-grams for its backoff context. When we encounter an N-gram whose extension to the higher-order context was not observed in the training data, we give it an explicit probability of $1/(y+1)$, if its weighted backoff probability is greater than that. We stop the traversal as soon as we encounter an N-gram for the backoff context that has a weighted backoff probability less than or equal to $1/(y+1)$, which in practice means we actually examine only a small number of backoff probabilities for each context.

3 Finding Backoff Weights by Iterative Search

The approach described above is very attractive from a theoretical perspective, but it has one practical complication. To decide which N-grams for each context to explicitly include in the higher-order model, we need to know the backoff weight for the context, but we cannot compute the backoff weight until we know exactly which higher-order N-grams are included in the model.

We address this problem by iteratively solving for a backoff weight that yields a normalized probability distribution. For each context, we guess an initial value for the backoff weight and keep track of the sum of the probabilites resulting from applying our N-gram selection method with that backoff weight. If the sum is greater than 1.0, by more than a convergence threshold, we reduce the estimated backoff weight and iterate. If the sum is less than 1.0, by more than the threshold, we increase the estimated weight and iterate.

It is easy to see that, for all standard smoothing methods, the function from backoff weights to probability sums is piece-wise linear. Within a region where no decision changes about which N-grams to include in the model, the probability sum is a linear function of the backoff weight. At values of the backoff weight where the set of selected N-grams changes, the function can be discontinous. With a little more effort, one can see that the linear segments overlap with respect to the probability sum in such a way that there will always be one or more values of the backoff weight that make the probability sum equal 1.0, with one specific exception.

The exception arises because of the capping of backoff probabilites for unobserved N-grams. It is possible for there to be a context for which all observed N-grams are included in the higher-order model, the probabilities for all unobserved N-grams are either capped at $1/(y+1)$ or effectively 0 due to arithmetic underflow, and the probability sum is less than 1.0. For some smoothing methods, the probability sum cannot be increased in this situation by increasing the backoff weight. We check for this situation, and if it arises, we increase the cap on the 0-count probability just enough to make the probability sum equal 1.0.

That exception aside, we iteratively find backoff weights as follows: For an initial estimate of the backoff weight for a context, we compute

what the backoff weight would be for the base smoothing method without N-gram selection. If that value is less than 1.0, we use it as our initial estimate, otherwise we use 1.0, which annecdotally seems to produce better models than initial estimates greater than 1.0, in situations where there are multiple solutions. If the first iteration of N-gram selection produces a probability sum less than 1.0, we repeatedly double the estimated backoff weight until we obtain a sum greater than or equal to 1.0, or we encounter the special situation previously described. If the initial probability sum is greater than 1.0, we repeatedly halve the estimated backoff weight until we obtain a sum less than or equal to 1.0.

Once we have values for the backoff weight that produce probability sums on both sides of 1.0, we have a solution bracketed, and we can use standard numerical search techniques to find that solution. At every subsequent iteration, we try a value for the backoff weight between the largest value we have tried that produces a sum less than 1.0 and the smallest value we have tried that produces a sum greater than 1.0. We stop when the difference between these values of the backoff weight is less than a convergence threshold.

We use a combination of simple techniques to choose the next value of the backoff weight to try. The primary technique we use is called the "false position method", which basically solves the linear equation defined by the two current bracketing values and corresponding probability sums. The advantage of this method is that, if our bracketing points lie on the same linear segment of our function, we obtain a solution in one step. The disadvantage of the method is that it sometimes approaches the solution by a long sequence of tiny steps from the same side.

We try to detect the latter situation by keeping track of the number of consecutive iterations that make a step in the same direction. If this number reaches 10, we take the next step by the bisection method, which simply tries the value of the backoff weight halfway between our two current bracketing values. In practice, this combined search method works very well, taking an average of less than four iterations per backoff weight.

4 Modified Weighted-Difference Pruning

While the N-gram selection method described above considerably reduces the number of parameters in a high-order language model, we may wish to reduce language model size even more. The concept of significance-based N-gram selection to produce smaller models could be extended by relaxing our criterion for using backoff distributions in place of explicit higher-order probability estimates, but true significance tests at more relaxed thresholds that are accurate for small counts are expensive to compute; so we resort to more conventional language model pruning methods.

In our experiments, we tried four methods for additional pruning: simple count cutoffs, relative entropy pruning (REP) (Stolcke, 1998), and two modified versions of Seymore and Rosenfeld's (1996) weighted-difference pruning (WDP). In the notation we have been using, Seymore and Rosenfeld's WDP criterion for using a backoff estimate, in place of an explicit higher-order estimate, is that the quantity

$$K \times \left(\begin{array}{l} \log(p(w_n|w_1...w_{n-1})) - \\ \log(\beta_u \, p(w_n|w_2...w_{n-1})) \end{array} \right)$$

be less than a pruning threshold, where K is the Good-Turing-discounted training set count for $w_1...w_n$, and β_u is the backoff weight for the unpruned model.

The first of our modified version of WDP uses the following quantity instead:

$$p(w_1...w_n) \times \left| \begin{array}{l} \log(p(w_n|w_1...w_{n-1})) - \\ \log(\beta_p \, p(w_n|w_2...w_{n-1})) \end{array} \right|$$

where $p(w_1...w_n)$ is an estimate of the probability of $w_1...w_n$ and β_p is the backoff weight for the pruned model.

We make three modifications to WDP in this formula. First, we follow a suggestion of Stolcke (1998) by replacing the discounted training set count K of $w_1...w_n$ with an estimate the joint probability of $w_1...w_n$, computed by chaining the explicit probability estimates, according to our model, for all N-gram lengths up to n.

The second modification to WDP is that we use the absolute value of the difference of the log probabilities. By using the signed difference of the log probabilities, Seymore and Rosenfeld will always prune a higher-order probability estimate if it is less than the backoff estimate. But the backoff estimate may well be too high. Using the absolute value of the difference avoids this problem.

$$p(w_n|w_1 \dots w_{n-1}) = \begin{cases} \alpha_{w_1 \dots w_{n-1}} \frac{C(w_1 \dots w_n) - D_{n,C(w_1 \dots w_n)}}{C(w_1 \dots w_{n-1})} & \\ \quad + \beta_{w_1 \dots w_{n-1}} p(w_n|w_2 \dots w_{n-1}) & \text{if } C(w_1 \dots w_n) > 0 \\ \\ \gamma_{w_1 \dots w_{n-1}} p(w_n|w_2 \dots w_{n-1}) & \text{if } C(w_1 \dots w_n) = 0 \end{cases}$$

$$\beta_{w_1 \dots w_{n-1}} = \delta \frac{|\{w' | C(w_1 \dots w_{n-1} w') > 0\}|}{C(w_1 \dots w_{n-1})}$$

$$\alpha_{w_1 \dots w_{n-1}} = 1 - \beta_{w_1 \dots w_{n-1}}$$

Figure 1: New language model smoothing method

The final modification is that we compute the difference in log probability with respect to the backoff weight for the pruned model rather than the unpruned model, which we are able to do by performing the pruning inside our iterative search for the value of the backoff weight. We do this because, if the backoff weight is changed significantly by pruning, backoff estimates that meet the pruning criterion with the old backoff weight may no longer meet the criterion with the new backoff weight, and vice versa. Since the new backoff weight is the one that will be used in the pruned model, that seems to be the one that should be used to make pruning decisions.

Our second variant of modified WDP is like the first, but it estimates $p(w_1 ... w_n)$ simply by dividing Seymore and Rosenfeld's discounted N-gram count K by the total number of highest-order N-grams in the training corpus. This is equivalent to smoothing only the highest-order conditional N-gram model in estimating $p(w_1 ... w_n)$, estimating all the lower-order probabilities in the chain by the corresponding MLE model. We refer to this joint probability estimate as "partially-smoothed", and the one suggested by Stolcke as "fully-smoothed".

5 Evaluation

We carried out three sets of evaluations to test the new techniques described above. First we compared the perplexity of full models and models reduced by significance-based N-gram selection for seven language model smoothing methods. For the best three results in that comparison, we looked at the trade-off between perplexity and model size over a range of N-gram orders. Finally, we tried various pruning methods to further reduce model size, and then compared the best result we obtained using previous techniques with the best result we obtained using our new techniques.

5.1 Data and Base Smoothing Methods

For training, parameter optimzation, and test data we used English text from the WMT-06 Europarl corpus (Koehn and Monz, 2006). We trained on the designated 1,003,349 sentences (27,493,499 words) of English language model training data, and used 2000 sentences each for testing and parameter optimization, from the English half of the English-French dev and devtest data sets.

We conducted our experiments on seven language model smoothing methods. Five of these are well-known: (1) interpolated absolute discounting with one discount per N-gram length, estimated according to the formula derived by Ney et al. (1994); (2) Katz backoff with Good-Turing discounts for N-grams occurring 5 times or less; (3) backoff absolute discounting with Ney et al. formula discounts; (4) backoff absolute discounting with one discount used for all N-gram lengths, optimized on held-out data; (5) modified interpolated Kneser-Ney smoothing with three discounts per N-gram length, estimated according to the formulas suggested by Chen and Goodman (1998).

We also experimented with two variants of a new smoothing method that we have recently developed. Full details of the new method are given elsewhere (Moore and Quirk, 2009), but since it is not well-known, we summarize the method here. Smoothed N-gram probabilities are defined by the formulas shown in Figure 1, for all n such that $N \geq n \geq 2$,[3] where N is the greatest N-gram length used in the model. The novelty of this model is that, while it is an interpolated model, the interpolation weights β for the lower-order model

[3]For $n = 2$, we take the expression $p(w_n|w_2 \dots w_{n-1})$ to denote a unigram probability estimate $p(w_2)$.

	Method	base PP	select PP	percent change
1	interp-AD-fix	62.6	61.6	-1.6
2	Katz backoff	59.8	56.1	-7.9
3	backoff-AD-fix	59.9	54.3	-9.3
4	backoff-AD-opt	58.8	54.4	-7.5
5	KN-mod-fix	51.6	54.6	+5.8
6	new-fix	56.1	52.1	-7.1
7	new-opt	53.7	52.0	-3.3

Table 1: Perplexity results for N-gram selection

are not constrained to match the backoff weights γ for the lower-order model. This allows the interpolation weights to be set independently of the discounts D, with the backoff weights being adjusted to normalize the resulting distributions.

The motivation for this is to let the D parameters correct for potential overestimation of the probabilities for observed N-grams, while the δ parameter (which determines the α and β interpolation parameters) somewhat independently corrects for quantization errors caused by the fact that only certain probabilities can be derived from integer observed counts, even after discounting. δ is interpretable as the estimated mean quantization error for each distinct count for a given context.

We tested two variants of the new method, (6) one in which the D parameters and the δ parameter are set by fixed criteria, and (7) one in which a single value for all D parameters and the value of the δ parameter are optimized on held-out data. For the fixed value of δ, we assume that, since the distance between possible N-gram counts, after discounting, is approximately 1.0, their mean quantization error would be approximately 0.5. For the fixed discount parameters, we use three values for each N-gram length: D_1 for N-grams whose count is 1, D_2 for N-grams whose count is 2, and D_3 for N-grams whose count is 3 or more. We set these values to be the discounts for 1-counts, 2-counts, and 3-counts estimated by the Good-Turing method. This yields the formula

$$D_r = r - (r+1)\frac{N_{r+1}}{N_r},$$

for $1 \leq r \leq 3$, where N_r is the number of distinct N-grams of the length in question occuring r times in the training set.

In all experiments, the unigram language model is an un-smoothed, closed-vocabulary MLE model. We use this unigram model, because there is no simple, principled way of assigning probabilities to individual out-of-vocabulary (OOV) words. The only principled solution to this problem that we are aware of is to use a character-based model, but this seems overly complicated for something that is orthogonal to the main points of this study, and of minor practical importance. Since we make no provision for OOV words in the models, OOV words are also omitted from all perplexity measurements. Thus, the perplexity numbers are systematically lower than they would be if OOVs were taken into account, but they are all comparable in this regard.

5.2 Results for Significance-Based N-gram Selection

Table 1 shows the minimum perplexity (with respect to N-gram order) of language models up to 7-grams for each of the seven smoothing methods discussed above, with and without significance-based N-gram selection. N-gram selection improved the perplexity of all models, except for modified KN. The lowest overall perplexity remains that of the base modified KN method, but with N-gram selection, the two variants of the new smoothing method come very close to it.

If we cared only about perplexity, that would be the end of the story, but we also care about language model size. The results in Table 1 were obtained on models estimated using just the counts needed to cover the parameter optimization and test sets; so to accurately measure model size, we trained full language models using base modifed KN, and the two variants of the new method with N-gram selection. The resulting sizes of the models represented in backoff form (in terms of total number of probability and backoff parameters) are shown in Figure 2 as function of N-gram length, from trigrams up to 7-grams for KN and up to 10-grams for the two new models. We see that beyond 4-grams the model sizes diverge dramatically, with the new models incorporating N-gram selection leveling off, but the modified KN model (or any standard model) continuing to grow in size, apparently linearly in the N-gram order.

In Figure 3, we show the relationship between perplexity and model size for the same three models, varying N-gram order. We see that between about 20 million and 45 million parameters, both of the new models incorporating significance-

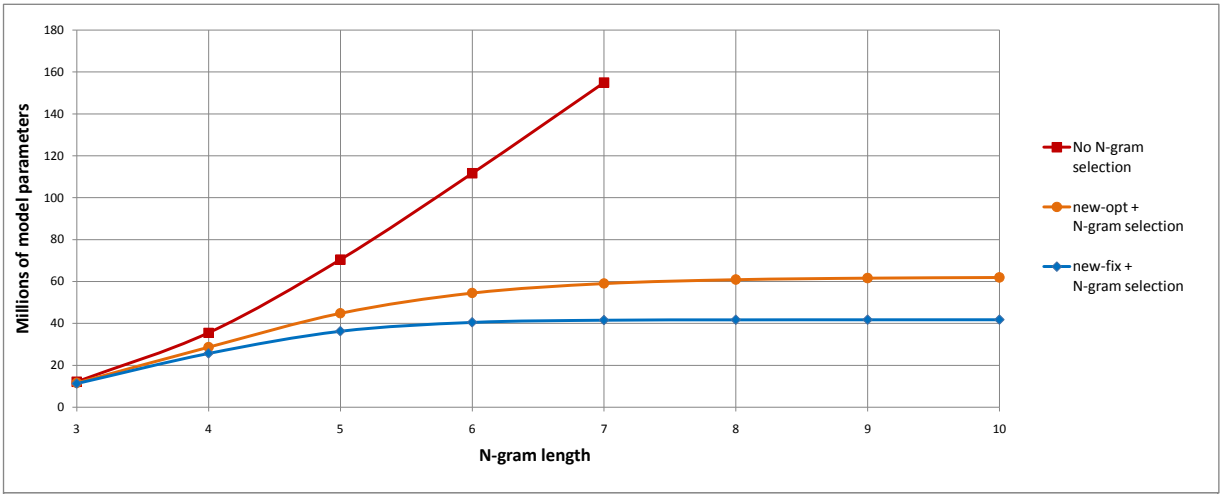

Figure 2: Model size vs. N-gram length

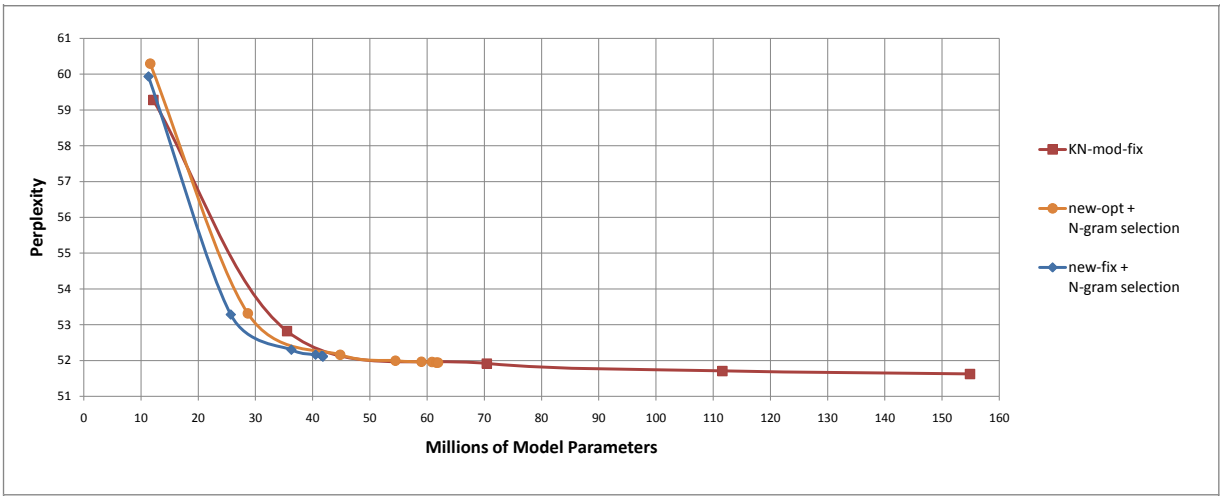

Figure 3: Perplexity vs. model size

based N-gram selection seem to outperform modified KN, and that the best of the three is, in fact, the new model with fixed parameter values.

5.3 Results for Additional Pruning

We further tested modified KN smoothing, and our new smoothing method with fixed parameter values and significance-based N-gram selection, with additional pruning. We compared several pruning methods on trigram models: count cutoffs, REP,[4] and our two modified versions of WDP.

Figure 4 shows the resulting combinations of perplexity and model size for REP and modified WDP at various pruning thresholds, and for count cutoffs of 1, 2, and 3 for both bigrams and trigrams ($n > 1$) and for trigrams only ($n > 2$), applied to our new smoothing method with fixed parameter values, together with significance-based N-gram selection. Overall, modified WDP with fully-smoothed joint probability estimates performs the best. It is has lower perplexity than count cutoffs at all model sizes tested, and is about equal to REP at very severe pruning levels and superior to REP with less pruning. Modified WDP with fully-smoothed joint probabilities is about equal to modified WDP with partially-smoothed joint probabilities at the highest and lowest pruning levels tested, but superior in between.

Figure 4 also shows the result of applying modified WDP with fully-smoothed joint probabilities to our new smoothing method *without* significance-based N-gram selection, to test whether the former subsumes the gains from the latter. We see that modified WDP does not render

[4]Thanks to Asela Gunawardana for the use of his REP tool.

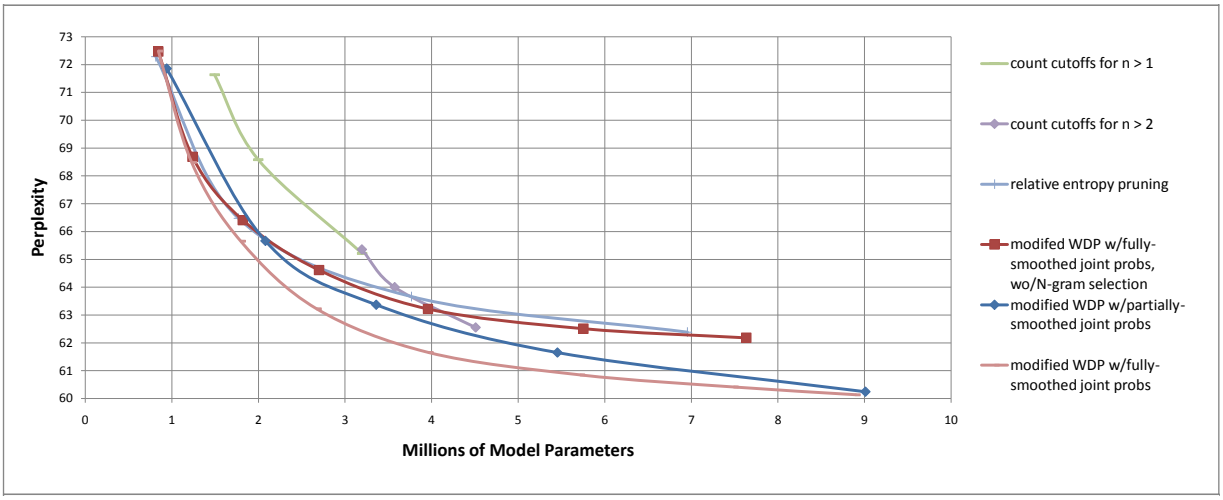

Figure 4: Pruning methods for new smoothing technique with N-gram selection

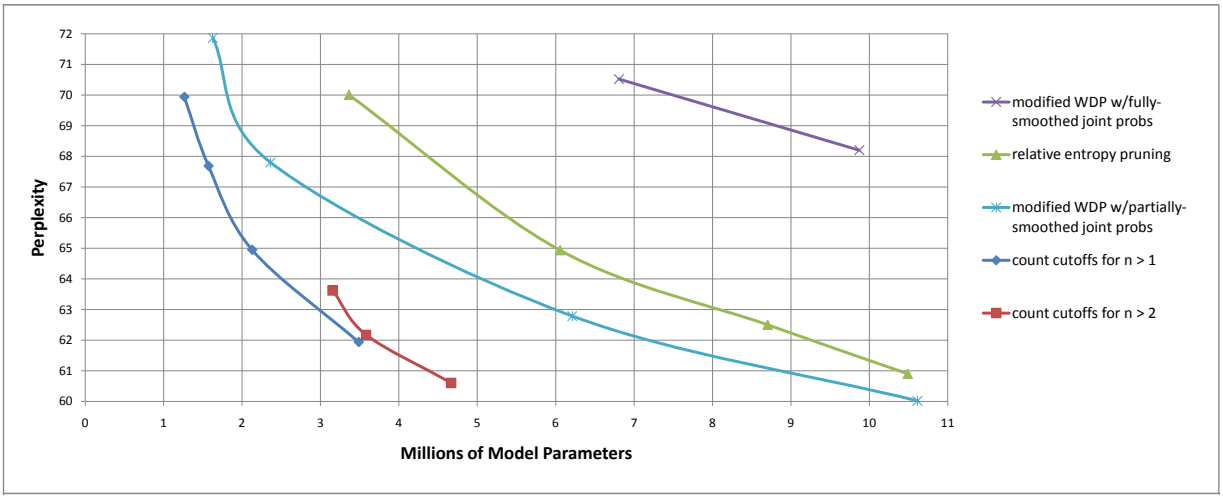

Figure 5: Pruning methods for modified KN smoothing

N-gram selection redundant except at very severe pruning levels, much like REP.

Figure 5 shows the results of applying the same four pruning methods to KN smoothing. Count cutoffs clearly perform the best with KN smoothing. It is interesting to note, however, that—contrary to the results for our new smoothing method—with KN smoothing, modified WDP with partially-smoothed joint probabilities is significantly better than either REP or modified WDP with fully-smoothed joint probabilities. We believe this is due to the fact that the latter two methods both estimate the joint probabilities by chaining the lower-order conditional probabilities from the fully-smoothed model, which in the case of KN smoothing are designed specifically to cover N-grams that have not been observed, and are poor estimates for the probabilities of lower-order N-grams that do occcur in the training data.

Finally, we compared the new smoothing method with N-gram selection and modified WDP with fully-smoothed joint probabilities against modified KN smoothing with count cutoffs, using combinations of pruning parameter values and N-gram order that yielded the best size/perplexity trade-offs. The results are shown in Figure 6. At all model sizes within the range of these experiments, the new method with significance-based N-gram selection and modified WDP had lower perplexity than modifed KN with count cutoffs—up to about 8% lower at greater pruning levels.

This experiment also suggests that the size/perplexity trade-off is easier to optimize for our new combination of smoothing, N-gram selection, and modified WDP, than for KN smoothing with count cut-offs. Table 2 shows the

56.4	10	$10^{-7.25}$
54.6	10	$10^{-7.5}$
53.7	10	$10^{-7.75}$
53.2	10	$10^{-8.0}$

Table 3: Optimal pruning parameters for new-fix with N-gram selection and modified WDP

perplexity (PP), maximum N-gram length (N), count cutoff (CC), and N-gram lengths to which the count cutoffs are applied ($n >$) for the points on the curve for pruned KN in Figure 6. Although some tendencies are discernable, it seems clear that a significant part of the space of combinations of N, CC, and "$n >$" parameter values must be searched to find the best points for trading off perplexity against model size. Table 3 shows maximum N-gram length and pruning threshold values for the points on the corresponding curve for our new approach. Here the situation is much simpler. The best trade-off points are found by varying the pruning threshold, and including in the model all N-grams that pass the pruning threshold, regardless of N-gram length.

6 Conclusions

We have shown that significance-based N-gram selection can simultaneously reduce both model size and perplexity when applied to a number of language model smoothing methods, including the widely-used Katz backoff and absolute discounting methods. We are not aware of any other technique that does this. We also found that, when combined with a new smoothing method and a novel variant of weighted difference pruning, our N-gram selection method outperformed modified Kneser-Ney smoothing—using the best form of pruning we found for that approach—with respect to the trade-off between model size and model quality.

As our next steps, first, we need to verify that the results obtained on a moderate-sized training corpus are repeatable on much larger corpora. Second, we plan to extend this work to incorporate language model size reduction by word clustering, which has been shown by Goodman and Gao (2000) to produce additional gains when combined with previous methods of language model pruning.

Abstract

Randomised techniques allow very big language models to be represented succinctly. However, being batch-based they are unsuitable for modelling an unbounded stream of language whilst maintaining a constant error rate. We present a novel randomised language model which uses an *online perfect hash* function to efficiently deal with unbounded text streams. Translation experiments over a text stream show that our online randomised model matches the performance of batch-based LMs without incurring the computational overhead associated with full retraining. This opens up the possibility of randomised language models which continuously adapt to the massive volumes of texts published on the Web each day.

1 Introduction

Language models (LM) are an integral feature of statistical machine translation (SMT) systems. They assign probabilities to generated hypotheses in the target language informing lexical selection. The most common form of LMs in SMT systems are smoothed n-gram models which predict a word based on a contextual history of $n-1$ words. For some languages (such as English) trillions of words are available for training purposes. This fact, along with the observation that machine translation quality improves as the amount of monolingual training material increases, has lead to the introduction of randomised techniques for representing large LMs in small space (Talbot and Osborne, 2007; Talbot and Brants, 2008).

Randomised LMs (RLMs) solve the problem of representing large, static LMs but they are *batch* oriented and cannot incorporate new data without fully retraining from scratch. This property makes current RLMs ill-suited for modelling the massive volume of textual material published daily on the Web. We present a novel RLM which is capable of incremental (re)training. We use random hash functions coupled with an online perfect hashing algorithm to represent n-grams in small space. This makes it well-suited for dealing with an unbounded stream of training material. To our knowledge this is the first stream-based RLM reported in the machine translation literature. As well as introducing the basic stream-based RLM, we also consider adaptation strategies. Perplexity and translation results show that populating the language model with material chronologically close to test points yields good results. As with previous randomised language models, our experiments focus on machine translation but we also expect that our findings are general and should help inform the design of other stream-based models.

Section 2 introduces the incrementally retrainable randomised LM and section 3 considers related work; Section 4 then considers the question of how unbounded text streams should be modelled. Sections 5 and 6 show stream-based translation results and properties of our novel data-structure. Section 7 concludes the paper.

2 Online Bloomier Filter LM

Our online randomised LM (O-RLM) is based on the dynamic Bloomier filter (Mortensen et al., 2005). It is a variant of the batch-based Bloomier filter LM of Talbot and Brants (2008) which we refer to as the TB-LM henceforth. As with the TB-LM, the O-RLM uses random hash functions to represent n-grams as *fingerprints* which is the main source of space savings for the model.

2.1 Online Perfect Hashing

The key difference in our model as compared to the TB-LM is we use an *online perfect hashing*

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 756–764,
Singapore, 6-7 August 2009.

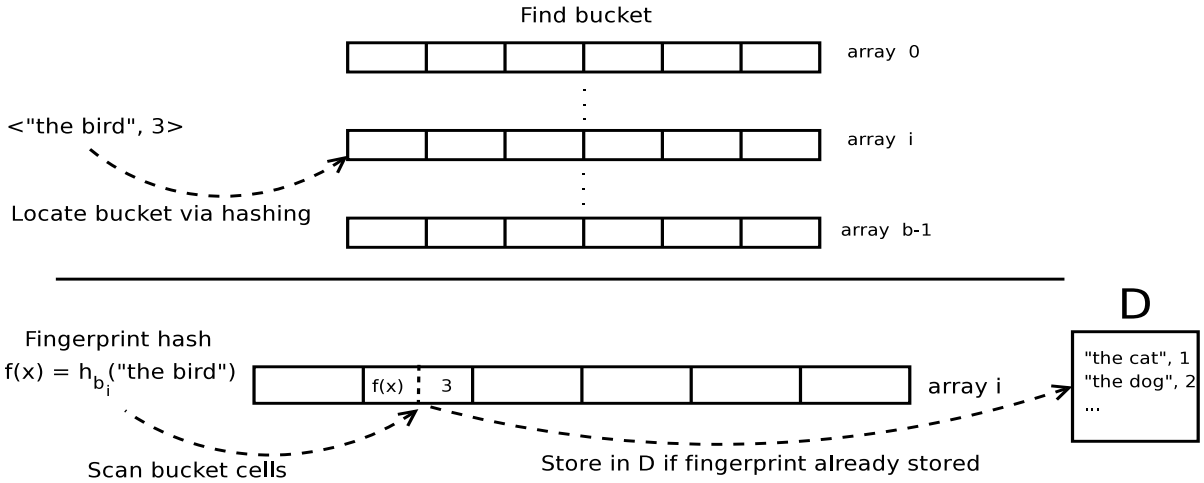

Figure 1: Inserting an n-gram into the dynamic Bloomier filter. Above: an n-gram is hashed to its target bucket. Below: the n-gram is transformed into a fingerprint and the same target bucket is scanned. If a collision occurs that n-gram is diverted to the overflow dictionary; otherwise the fingerprint is stored in the bucket.

function instead of having to precompute the perfect hash offline prior to data insertion.

The online perfect hash function uses two data structures: A and D. A is the main, randomised data structure and is an array of b dictionaries $A_0, \ldots, A_{b-1}$. D is a lossless data structure which handles collisions in A. Each of the dictionaries in A is referred to as a 'bucket'. In our implementation the buckets are equally sized arrays of w-bit cells. These cells hold the fingerprints and values of n-grams (one n-gram-value pair per cell).

To **insert** an n-gram x and associated value $v(x)$ into the model, we select a bucket A_i by hashing x into the range $i \rightarrow [0, \ldots, b-1]$. Each bucket has an associated random hash function, h_{A_i}, drawn from a universal hash function (UHF) family h (Carter and Wegman, 1977), which is then used to generate the n-gram fingerprint: $f(x) = h_{A_i}(x)$.

If the bucket A_i is not full we conduct a scan of its cells. If the fingerprint $f(x)$ is not already encoded in the bucket A_i we add the fingerprint and value to the first empty cell available. We allocate a preset number of the least significant bits of each w-bit cell to hold $v(x)$ and the remaining most significant bits for $f(x)$ but this is arbitrary. Any encoding scheme, such as the packed representation of Talbot and Brants (2008), is viable here.

However, if $f(x) \in A_i$ already (there is a collision) we store the n-gram x and associated value $v(x)$ in the lossless overflow dictionary D instead. D also holds the n-grams that were hashed to any buckets that are already full.

To **query** for the value of an n-gram, we first check if the gram is in the overflow dictionary D. If it is, we return the associated value. Otherwise we query A using the same hash functions and procedure as insertion. If we find a matching fingerprint in the appropriate bucket A_i we have a hit with high probability. **Deletions** and **updates** are symmetric to querying except we reset the cell to the null value or update its value respectively. As with other randomised models we construct queries with the appropriate *sanity checks* to lower the error rate efficiently (Talbot and Brants, 2008).

2.2 Data Insertion

Initially we seed the language model with a large corpus S in the usual manner associated with batch LMs. Then, when processing the stream, we aggregate n-gram counts for some consecutive portion, or *epoch*, of the input stream. We can vary the size of stream window. For example we might batch-up a day or week's worth of material. Intuitively, smaller windows produce results that are sensitive to small variation in the stream, while longer windows (corresponding to data over a longer time period) average out local spikes. The exact window size is a matter of experimentation. In our MT experiments (section 5) we can compute counts within the streaming window exactly but randomised approaches (such as the approximate counting schemes from section 3) can easily be employed instead.

These n-grams and counts are then considered for insertion into the online model. If we decide to insert an n-gram, we either update the count of that n-gram if we previously inserted it or else we insert it as a new entry. Note that there is some probability we may encounter a false positive and update some other n-gram in the model.

2.3 Properties

The online perfect hash succeeds by associating each n-gram with only **one** cell in A rather than having it depend on cells (or bits) which may be shared by other n-grams as with the TB-LM. Since each n-gram's encoding in the model uses distinct bits and is independent of all other events it can not corrupt other n-grams when deleted.

Adding the overflow dictionary D means that we use more space than the TB-LM for the same support. It is shown in Mortensen et al. (2005) that the expected size of D is a small fraction of the total number of events and its space usage comprises less than $O(|S|)$ bits with high probability.

There is a nonzero probability for false positives. Since the overflow dictionary D has no errors, the expected error rate for our dynamic structure is the probability of a random collision in the hash range of each h_{A_i} for each bucket cell compared. In our setup we have

$$\Pr(falsepos) = \frac{|A_i|}{2^{|f(x)|}}$$

where $|f(x)|$ is the number of bits of each w-bit cell used for the fingerprint $f(x)$. w also primarily governs space used in the model. The O-RLM assumes only valid updates and deletions are performed (i.e. we do not remove or update entries that were never inserted prior).

The O-RLM takes time linear to the input size for training and uses worst-case constant time for querying and deletions where the constant is dependent on the number of cells per bucket in A. The number of bucket cells also effects the overall error rate significantly since smaller ranges reduce the probability of a collision. However, too few cells per bucket will result in many full buckets when the bucket hash function is not highly IID.

2.4 Basic RLM Comparisons

Table 1 compares expected versus observed false positive rates for the Bloom filter, TB-LM, and O-RLM obtained by querying a model of approximately 280M events with 100K unseen n-grams.

LM	Expected	Observed	RAM
Lossless	0	0	7450MB
Bloom	0.0039	0.0038	390MB
TB-LM	0.0039	0.0033	640MB
O-RLM	0.0039	0.0031	705MB

Table 1: Example false postive rates and corresponding memory usage for all randomised LMs.

We see the bit-based Bloom filter uses significantly less memory than the cell-based alternatives and the O-RLM consumes more memory than the TB-LM for the same expected error rate.

3 Related Work

3.1 Randomised Language Models

Talbot and Osborne (2007) used a *Bloom filter* (Bloom, 1970) to encode a smoothed LM. A Bloom filter (BF) represents a set S from arbitrary domain U and supports membership queries such as"Is $x \in S$?". The BF uses an array of m bits and k independent UHFs each with range $0, \ldots, m-1$. For insertion, each item is hashed through the k hash functions and the resulting target bits are set to one. During testing, an event $x \in U$ is passed through the same k hash functions and if any bit tested is zero then x was not in the support S.

The *Bloomier filter* directly represents key-value pairs by using a table of cells and a family of k associated hash functions (Chazelle et al., 2004). Each key-value pair is associated with k cells in the table via a perfect hash function. Talbot and Brants (2008) used a Bloomier filter to encode a LM. Before data can be added to the Bloomier filter, a greedy perfect hashing of all entries needs to be computed in advance; this attempts to associate each event in the support with one unique table cell so no other entry collides with it. The procedure can fail and might need to be repeated many times.

Neither of these two randomised language models are suitable for modelling a stream. Given the fact that the stream is of unbounded size, we are forced to delete items if we wish to maintain a constant error rate and account for novel n-grams. However, the Bloom filter LM nor the Bloomier Filter LM support deletions. The bit sharing of the Bloom filter (BF) LM (Talbot and Osborne, 2007) means deletions may corrupt shared stored events. The Bloomier filter LM (Talbot and Brants, 2008) has a precomputed matching of keys shared between a constant number of cells in the filter array.

Deleting items from a Bloomier Filter without recomputing the perfect hash will corrupt it.

3.2 Probabilistic Counting

Concurrent work has used approximate counting schemes based on Morris (1978) to estimate in small space frequencies over a high volume input text stream (Van Durme and Lall, 2009; Goyal et al., 2009). The space savings are due to compact storage of counts and retention of only a small subset of the available n-grams in the data stream. Since the final LMs are still lossless (modulo counts), the resulting LM needs significant space. It is trivial to use probabilistic counting within our framework.

3.3 Compact Exact Language Models

Randomised algorithms are not the only compact representation schemes. Church et al. (2007) looked at Golomb Coding and Brants et al. (2007) used tries in a distributed setting. These methods are less succinct than randomised approaches.

3.4 Adaptive Language Models

There is a large literature on adaptive LMs from the speech processing domain (Bellegarda, 2004). The primary difference between the O-RLM and other adaptive LMs is that we add and remove n-grams from the model instead of adapting only the parameters of the current support set.

3.5 Domain adaptation in Machine Translation

Within MT there has been a variety of approaches dealing with domain adaption (for example (Wu et al., 2008; Koehn and Schroeder, 2007). Typically LMs are interpolated with one another, yielding good results. These models are usually statically trained, exact and unable to deal with an unbounded stream of monolingual data. Domain adaptation has similarities with streaming, in that our stream may be non-stationary. A crucial difference however is that the stream is of unbounded length, whereas domain adaptation usually assumes some finite and fixed training set.

4 Stream-based translation

Streaming algorithms have numerous applications in mainstream computer science (Muthukrishnan, 2003) but to date there has been very little awareness of this field within computational linguistics.

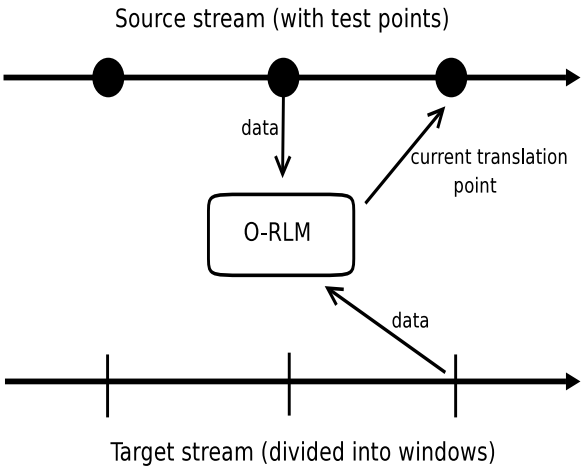

Figure 2: Stream-based translation. The online RLM uses data from the target stream and the last test point in the source stream for adaptation.

A *text stream* can be thought of as a unbounded sequence of documents that are time-stamped and we have access to them in strict chronological order. The volume of the stream is so large we can afford only a limited number of passes over the data (typically one).

Text streams naturally arise on the Web when millions of new documents are published each day in many languages. For instance, 18 thousand websites continuously publish news stories in 40 languages and there are millions of multilingual blog postings per day. There are over 30 billion e-mails sent daily and social networking sites, including services such as Twitter, generate an adundance of textual data in real time. Web crawlers that spidered all these new documents would produce an unbounded input stream.

The stream-based translation scenario is as follows: we assume that each day we see a source stream of many new newswire stories that need translation. We also assume a stream of newswire stories in the target language. Intuitively, since the concurrent streams are from the same domain, we can use the contexts provided in the target stream to help with the translation of the source stream (Figure 2). From a theoretical perspective, since we cannot represent the entirety of the stream and wish to maintain a constant error rate, we are forced to throw some information away.

Given that the incoming text stream contains far too much data to store in its entirety an immediate question we would like to answer is: within our LM, which subset of the target text stream should

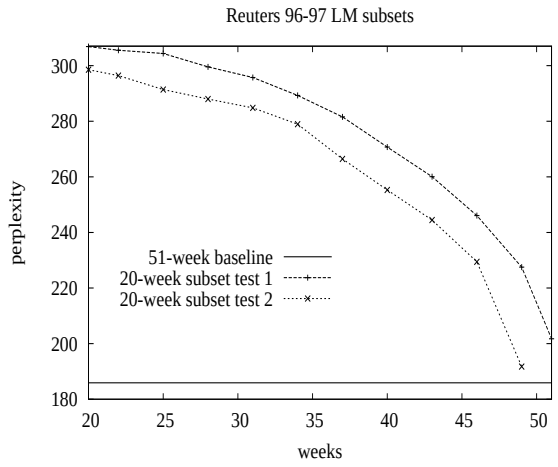

Figure 3: Perplexity results using streamed data. Perplexity decreases as we retrain LMs using data chronologically closer to the (two) test dates.

we represent in our model?

Using perplexity, we investigated this question using a text stream based on Reuter's RCV1 text collection (Rose et al., 2002). This contains 800k time-stamped newswire stories from a full calender year (8.20.1996 - 8.19.1997). We used the SRILM (Stolcke, 2002) to construct an exact trigram model built using all the RCV1 data with the exception of the final week which we held out as test data. This served as an oracle since we store all of the stream.

We then trained multiple exact LMs of much smaller sizes, coined *subset LMs*, to simulate memory constraints. For a given date in the RCV1 stream, these subset LMs were trained using a fixed window of previously seen documents up to that data. Then we obtained perplexity results for each subset LM against our test set.

Figure 3 shows an example. For this experiment subset LMs were trained using a sliding window of 20 weeks with the window advancing over a period of three weeks each time. The two arcs correspond to two different test sets drawn from different days. The arcs show that **recency** has a clear effect: populating LMs using material closer to the test data date produces improved perplexity performance. The LM chronologically closest to a given test set has perplexity closest to the results of the significantly larger baseline LM which uses all the stream. As expected, using all of the data yields the lowest perplexity.

We note that this is a robust finding, since we also observe it in other domains. For example, we conducted the same tests over a stream of 18 billion tokens drawn from 80 million time-stamped blog posts downloaded from the web with matching results. The effect of recency on perplexity has also been observed elsewhere (see, for example, Rosenfeld (1995) and Whittaker (2001)).

Epoch	Stream Window
1	08.20.1996 to 01.01.1997
2	01.02.1997 to 04.23.1997
3	04.24.1997 to 08.18.1997

Table 2: The stream timeline is divided into windowed epochs for our recency experiments.

Our experiments show that a possible way to tackle stream-based translation is to always focus the attention of the LM on the most recent part of the stream. This means we remove data from the model that came from the receding parts of the stream and replace it with the present.

5 SMT Experiments

5.1 Experimental Setup

We used publicly available resources for all our tests: for decoding we used Moses (Koehn and Hoang, 2007) and our parallel data was taken from the Spanish-English section of Europarl. For test material, we translated 63 documents (800 sentences) from three randomly selected dates spaced throughout the RCV1 year (January 2nd, April 24, and August 19).[1] This effectively divided the stream into three *epochs* between the test dates (table 2). We held out 300 sentences for minimum error rate training (MERT) (Och, 2003) and optimised the parameters of the feature functions of the decoder for each experimental run.

The RCV1 is not a large corpus when compared to the entire web but it is multilingual, chronological, and large enough to enable us to test the effect of recency in a translation setting.

5.2 Adaption

We looked at a number of ways of adapting the O-RLM:

1. (**Random**) Randomly sample the stream and for each new n-gram encountered, insert

[1] As RCV1 is not a parallel corpus we translated the reference documents ourselves. This parallel corpus is available from the authors.

Order	Full	Epoch 1	Epoch 3
1	1.25M	0.6M	0.7M
2	14.6 M	6.8M	7.0M
3	50.6 M	21.3M	21.7M
4	90.3 M	34.8M	35.4M
5	114.7M	41.8M	42.6M
Total	271.5M	105M	107.5M

Table 3: Distinct n-grams (in millions) encountered in the full stream and example epochs.

it and remove some previously inserted n-gram, irrespective of whether it was ever requested by the decoder or is a prefix.

2. (**Conservative**) For each new n-gram encountered in the stream, insert it in the filter and remove one previously inserted n-gram which was never requested by the decoder. To preserve consistency we do not remove lower-order grams that are needed to estimate backoff probability for higher-order smoothing. Counts are updated for n-grams already in the model if the new count observed is larger than the current one.

3. (**Severe**) Differs from the conservative approach only in that we delete *all* unused n-grams (i.e. all those not requested by the decoder in the previous translation task) from the O-RLM before adapting with data from the stream. This means the data structure is sparsely populated for all runs.

All the TB-LMs and O-RLMs were unpruned 5-gram models and used *Stupid-backoff* smoothing (Brants et al., 2007) [2] with the backoff parameter set to 0.4 as suggested. The number of distinct n-grams encountered in the stream for two epochs is shown in Table 3.

Table 6 shows translation results using these adaption strategies. In practice, the random approach does not work while the conservative and severe adaption techniques produce equivalent results due to the small proportion of data in the model that is queried during decoding. All the MT experiments that follow use the severe method and the overflow dictionary always holds less than 1% of the total elements in the model.

[2] Smoothing text input data streams poses an interesting problem we hope to investigate in the future.

Date	Lossless	TB-LM	O-RLM

Aug	29.05	28.52	28.44
Avg	33.92	33.28	33.46

Table 4: Baseline translation results in BLEU using data from the first stream epoch with a lossless LM (4.5GB RAM), the TB-LM and the O-RLM (300MB RAM). All LMs are static.

5.3 Training Regimes

We now consider stream-based translation. Our first *naive approach* is to continually add new data from the stream to the training set without deleting anything. Given a constant memory bound this strategy only increases the error rate over time as discussed. Our second, computationally demanding approach is, before each test point, to rebuild the TB-LM from scratch using the stream data from the most recent epoch as the training set. This is *batch retraining*. The final approach incrementally retrains online. This utilizes the same training data as above (the stream data from the last epoch) but instead of full retraining it replaces n-grams currently in the model with unseen n-grams and counts encountered in the data stream.

5.4 Streaming Translation Results

Each table shows translation results for the three different test times in the stream. All results reported use the case-sensitive BLEU score.

For our baselines we use *static* LMs trained on the first epoch's data to test all three translation points in the source stream. This is the traditional approach. We trained an exact, modified Kneser-Ney smoothed LM (here we do not enforce a memory constraint) and also used the TB-LM and O-RLM to verify our structures adequecy. Results are shown in table 4. The exact model gives better performance overall due to the more sophisticated smoothing used.

Table 5 shows results for a set of *stream-based* LMs using the TB-LM and the O-RLM with memory bounds of 200MB and 300MB. As expected, the naive models performance degrades over time as we funnel more data into the TB-LM and the error rises. The batch retrained TB-LMs and O-RLMs have constant error rates of $\frac{1}{2^8}$ and $\frac{1}{2^{12}}$ and so outperform the naive approach. Since the training data is identical we see (approximately) equal

	Naive TB-LM		Batch Retrained TB-LM		O-RLM	
Date	200MB	300MB	200MB	300MB	200MB	300MB
Jan	35.94	37.12	35.94	37.12	36.44	37.17
Apr	33.55	35.79	36.01	35.99	35.87	36.10
Aug	22.44	26.07	28.97	29.38	29.00	29.18
Avg	30.64	32.99	33.64	34.16	33.77	34.15

Table 5: Translation results for stream-based LMs in BLEU. Performance degrades with time using the Naive approach. The batch retrained TB-LM and stream-based O-RLM use constant error rates of $\frac{1}{2^8}$ and $\frac{1}{2^{12}}$.

performance from the batch retrained and online models. We also see some improvement compared to the static baselines when the LMs use the most recent data from the target language stream with respect to the current translation point.

The key difference is that each time we batch retrain the TB-LM, we must compute a perfect hashing of the new training set. This is computationally demanding since the perfect hashing algorithm uses Monte Carlo randomisation which fails routinely and must be repeated. To make the algorithm tractable the training data set must be divided into lexically sorted subsets as well. This requires extra passes over the data which may not be trivial in a streaming environment.

In contrast, the O-RLM is incrementally retrained online. This makes it more resource efficient since we find bits in the model for the n-grams dynamically without using more memory than we intially set. Note that even though the O-RLM is theoretically less space efficient than the TB-LM, when using the same amount of memory translation performance is comparable.

6 O-RLM Properties

The previous experiments confirm that the O-RLM can be employed as a LM in an SMT setting but it is useful to get insight into the intrinsic properties of the data structure. Many of the properties of the model, such as the number of bits per fingerprint, follow directly from the TB-LM but the relationship between the overflow dictionary and the randomised buckets is novel.

Figures 4 and 5 shows properties of the O-RLM while varying only the number of cells in each bucket and keeping all other model parameters constant. We test membership of n-grams in an unseen corpus against those stored in the table. Our tests were conducted over a larger stream of 1.25B n-grams from the Gigaword corpus(Graff, 2003). We set our space usage to match the 3.08 bytes per n-gram reported in Talbot and Brants (2008) and held out just over 1M unseen n-grams to test the error rates of our models.

Date	Severe	Random	Conservative
Jan	36.44	36.44	36.44
Apr	35.87	31.08	35.51
Aug	29.00	19.31	29.14
Avg	33.77	29.11	33.70

Table 6: Adaptation results measured in BLEU. Random deletions degrade performance when adapting a 200MB O-RLM.

In Figure 4 we see a direct correlation between model error and cells per buckets. As the number of cells decreases the false positive rate drops as well since fewer cells to compare against per bucket means a lower chance of producing collisions. If the range is decreased too much though more data is diverted to the overflow dictionary due to many buckets reaching capacity when inserting and adapting. Clearly this is less space efficient. Figure 5 shows the relationship between the percent of data in the overflow dictionary and the total cells per bucket.

7 Conclusions

Our experiments have shown that for stream-based translation, using recent data can benefit performance but simply adding entries to a randomised representation will only reduce translation performance over time. We have presented a novel randomised language model based on dynamic perfect hashing that supports online insertions and deletions. As a consequence, it is considerably faster and more efficient than batch retraining.

While not advocating the idea that only small amounts of data are needed for language mod-

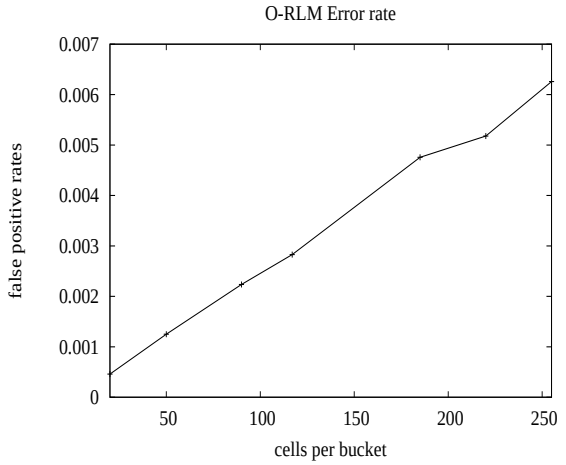

Figure 4: The O-RLM error rises in correlation with the number of cells per bucket.

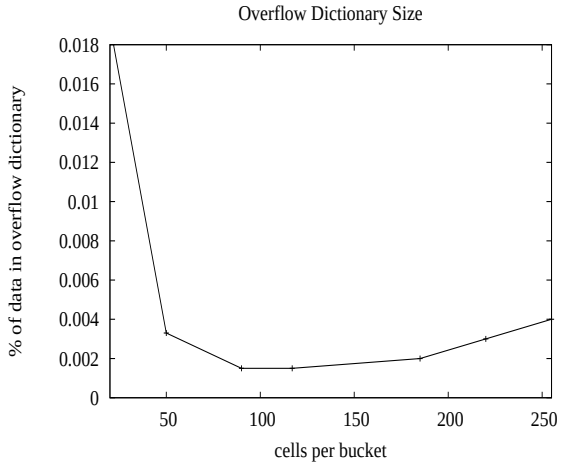

Figure 5: Too few cells per bucket causes a higher percentage of the data to be stored in the overflow dictionary due to full buckets.

elling, within a bounded amount of space our results show that it is better to have a low error rate and store a wisely chosen fraction of the data than having a high error rate and storing more of it. Clearly tradeoffs will vary between applications.

This is the first stream-based randomised language model and associated machine translation system reported in the literature. Clearly there are many interesting open questions for future work. For example, can we use small randomised representations called *sketches* to compactly represent side-information on the stream telling us which aspects of it we should insert into our data? How can we efficiently deal with smoothing in this setting? Our adaptation scheme is simple and our data stream is tractable. Currently we are conducting tests over much larger, higher variance text streams from crawled blog data. In the future we will also consider randomised representations of other adaptive LMs in the literature using a static background LM in conjunction with our online one. We ultimately hope to deploy large-scale LMs which continuously adapt to the vast amount of material published on the Web without incurring significant computational overhead.

Abstract

While speaking spontaneously, speakers often make errors such as self-correction or false starts which interfere with the successful application of natural language processing techniques like summarization and machine translation to this data. There is active work on reconstructing this errorful data into a clean and fluent transcript by identifying and removing these simple errors.

Previous research has approximated the potential benefit of conducting word-level reconstruction of simple errors only on those sentences known to have errors. In this work, we explore new approaches for automatically identifying speaker construction errors on the utterance level, and quantify the impact that this initial step has on word- and sentence-level reconstruction accuracy.

1 Introduction

A system would accomplish reconstruction of its spontaneous speech input if its output were to represent, in flawless, fluent, and content-preserving text, the message that the speaker intended to convey. While full speech reconstruction would likely require a range of string transformations and potentially deep syntactic and semantic analysis of the errorful text (Fitzgerald, 2009), in this work we will attempt only to resolve less complex errors, correctable by deletion alone, in a given manually-transcribed utterance.

The benefit of conducting word-level reconstruction of simple errors only on those sentences known to have errors was approximated in (Fitzgerald et al., 2009). In the current work, we explore approaches for automatically identifying speaker-generated errors on the utterance level, and calculate the gain in accuracy that this initial step has on word- and sentence-level accuracy.

1.1 Error classes in spontaneous speech

Common simple disfluencies in sentence-like utterances (SUs) include *filler words* (i.e., "um", "ah", and discourse markers like "you know"), as well as speaker edits consisting of a *reparandum*, an *interruption point (IP)*, an optional *interregnum* (like "I mean"), and a *repair* region (Shriberg, 1994), as seen in Figure 1.

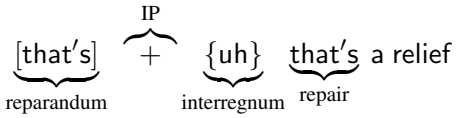

Figure 1: Typical edit region structure.

These reparanda, or *edit regions*, can be classified into three main groups:

1. In a **repetition** (above), the repair phrase is approximately identical to the reparandum.
2. In a **revision**, the repair phrase alters reparandum words to correct the previously stated thought.

   EX1: but [when he] + {i mean} when she put it that way

   EX2: it helps people [that are going to quit] + that would be quitting anyway
3. In a **restart fragment** an utterance is aborted and then restarted with a new train of thought.

   EX3: and [i think he's] + he tells me he's glad he has one of those

   EX4: [amazon was incorporated by] {uh} well i only knew two people there

In *simple cleanup* (a precursor to full speech reconstruction), all detected filler words are deleted, and the reparanda and interregna are deleted while the repair region is left intact. This is a strong initial step for speech reconstruction, though more

complex and less deterministic changes may be required for generating fluent and grammatical speech text in all cases.

1.2 Related Work

Stochastic approaches for simple disfluency detection use features such as lexical form, acoustic cues, and rule-based knowledge. State-of-the-art methods for edit region detection such as (Johnson and Charniak, 2004; Zhang and Weng, 2005; Kahn et al., 2005; Honal and Schultz, 2005) model speech disfluencies as a noisy channel model, though direct classification models have also shown promise (Fitzgerald et al., 2009; Liu et al., 2004). The final output is a word-level tagging of the error condition of each word in the sequence, as seen in line 2 of Figure 2.

The Johnson and Charniak (2004) approach, referred to in this document as JC04, combines the noisy channel paradigm with a tree-adjoining grammar (TAG) to capture approximately repeated elements. The TAG approach models the crossed word dependencies observed when the reparandum incorporates the same or very similar words in roughly the same word order, which JC04 refer to as a *rough copy*. Line 3 of Figure 2 refines "edits" (E) into rough copies (RC) and *non-copies* (NC).

As expected given the assumptions of the TAG approach, JC04 identifies repetitions and most revisions in spontaneous data, but is less successful in labeling false starts and other speaker self-interruptions without cross-serial correlations. These non-copy errors hurt the edit detection recall and overall accuracy.

Fitzgerald et al. (2009) (referred here as FHJ) used conditional random fields (CRFs) and the Spontaneous Speech Reconstruction (SSR) corpus (Fitzgerald and Jelinek, 2008) corpus for word-level error identification, especially targeting improvement of these non-copy errors. The CRF was trained using features based on lexical, language model, and syntactic observations along with features based on JC04 system output.

Alternate experimental setup showed that training and testing only on SUs known from the labeled corpus to contain word-level errors yielded a notable improvement in accuracy, indicating that the described system was falsely identifying many non-error words as errors.

Improved sentence-level identification of errorful utterances was shown to help improve word-level error identification and overall reconstruction accuracy. This paper describes attempts to extend these efforts.

2 Approach

2.1 Data

We conducted our experiments on the recently released Spontaneous Speech Reconstruction (SSR) corpus (Fitzgerald and Jelinek, 2008), a medium-sized set of disfluency annotations atop Fisher conversational telephone speech data (Cieri et al., 2004)[1]. Advantages of the SSR data include

- aligned parallel original and cleaned sentences
- several levels of error annotations, allowing for a coarse-to-fine reconstruction approach
- multiple annotations per sentence reflecting the occasional ambiguity of corrections

As reconstructions are sometimes non-deterministic, the SSR provides two manual reconstructions for each utterance in the data. We use these dual annotations to learn complementary approaches in training and to allow for more accurate evaluation.

The Spontaneous Speech Reconstruction corpus is partitioned into three subcorpora: 17,162 training sentences (119,693 words), 2,191 sentences (14,861 words) in the development set, and 2,288 sentences (15,382 words) in the test set. Approximately 17% of the total utterances contain a reparandum-type error. In constructing the data, two approaches were combined to filter out the utterances considered most likely to be errorful (6,384 in total) and only those SUs were manually reconstructed. However the entire data set was included in the distribution – and used in training for this work – to maintain data balance.

[1]The Spontaneous Speech Reconstruction corpus can be downloaded from http://www.clsp.jhu.edu/PIRE/ssr.

The training of the TAG model for JC04, used as a feature in this work, requires a very specific data format, and thus is trained not with SSR but with Switchboard (SWBD) data (Godfrey et al., 1992). Key differences in these corpora, besides the granularity and form of their annotations, include:

- SSR aims to correct speech output, while SWBD edit annotation aims to identify reparandum structures specifically. SSR only marks those reparanda which annotators believe must be deleted to generate a grammatical and content-preserving reconstruction.
- SSR includes more complex error identification and correction, not considered in this work.

While the SWBD corpus has been used in some previous simple disfluency labeling work (e.g., Johnson and Charniak, 2004; Kahn et al., 2005), we consider the SSR for its fine-grained error annotations.

3 Identifying poor constructions

Prior to reconstruction, it is to our advantage to automatically identify poorly constructed sentences, defined as being ungrammatical, incomplete, or missing necessary sentence boundaries. Accurately extracting ill-formed sentences prior to subsentential error correction helps to minimize the risk of information loss posed by unnecessarily and incorrectly reconstructing well-formed text.

To evaluate the efforts described below, we manually label each SU s in the SSR test set S (including those not originally annotated with reconstructions but still included in the SSR distribution) as *well-formed* or *poorly-formed*, forming the set of poorly constructed SUs $P \subset S$, $|P| = 531$ and $|S| = 2288$ utterances.

To identify speaker errors on the sentence level, we consider and combine a collection of features into a single framework using a maximum entropy model (implemented with the Daumé III (2004) MEGA Model toolkit).

3.1 SU-level error features

Six feature types are presented in this section.

- Features #1 and #2 are the two methods included in a similar though less exhaustive effort by (Fitzgerald and Jelinek, 2008) in error filtering for the creation of the SSR corpus itself.
- Feature types #3 and #4 extract features from automatic parses assigned to the given sentence. It is expected that these parses will contain some errors and the usefulness of these features may be parser-specific. The value of these features though is the consistent, if not always accurate, treatment of similar construction errores given a particular state-of-the-art parser.
- Feature type #5 investigates the relationship between the probability of a SU-internal error and the number of words it contains.
- Feature type #6 serves to bias the probability against assigning a backchannel acknowledgement SU as an error instance.

Feature #1 (JC04): Consider only sentences with JC04 detected edit regions. This approach takes advantage of the high precision, low recall JC04 disfluency detection approach described in Section 1.2. We apply the out-of-box JC04 system and consider any sentence with one or more labeled reparanda as a "poor" indicator. Since speakers repairing their speech once are often under a higher cognitive load and thus more likely to make more serious speech errors (in other words, there is a higher probability of making an error given that an error has already been made (Bard et al., 2001)). This is a reasonable first order approach for finding deeper problems.

Feature #2 (HPSG): Use deep linguistic parsers to confirm well-formedness. Statistical context-free parsers are highly robust and, due to smoothing, can assign a non-zero probability syntactic structure even for text and part-of-speech sequences never seen during training. However, sometimes no output is preferable to highly errorful output. Hand-built rule-based parsers can produce extremely accurate and context-sensitive syntactic structures, but are also brittle and do not adapt well to never before seen input. We use this inflexibility to our advantage.

Head-driven Phrase Structure Grammar (HPSG) is a deep-syntax phrase structure grammar which produces rich, non-context-free syntactic analyses of input sentences based on a collection of carefully constructed rules and lexical item structures (Pollard and Sag, 1994; Wahlster, 2000). Each utterance is parsed using

the PET deep parser produced by the inter-institutional DELPH-IN group[2]. The manually compiled English Resource Grammar (ERG) (Flickinger, 2002) rules have previously been extended for the Verbmobil (Wahlster, 2000) project to allow for the parsing of basic conversational elements such as SUs with no verb or basic backchannel acknowledgements like "last thursday" or "sure", but still produce strict HPSG parses based on these rules. We use the binary result of whether or not each SU is parsable by the HPSG ERG as binary indicator functions in our models.

There has been some work on producing partial parses for utterances for which a full HPSG analysis is not deemed possible by the grammar (Zhang et al., 2007). This work has shown early promise for identifying coherent substrings within errorful SUs given subjective analysis; as this technology progresses, HPSG may offer informative subsentential features for word-level error analysis as well.

Feature #3 (Rules): Mark unseen phrase rule expansions. Phrase-based parses are composed of a recursive sequence of non-terminal (NT) rule expansions, such as those detailed for the example parse shown in Figure 3. These rules are learned from training data such as the Switchboard treebank, where telephone conversation transcripts were manually parsed. In many statistical parsers, new structures are generated based on the relative frequencies of such rules in the training treebank, conditioned on the terminal words and some local context, and the most probable parse (roughly the joint probability of its rule expansions) is selected.

Because parsers are often required to produce output for words and contexts never seen in the training corpus, smoothing is required. The Charniak (1999) parser accomplishes this in part through a *Markov grammar* which works top-down, expanding rules to the left and right of an expansion head M of a given rule. The non-terminal (NT) M is first predicted from the parent P, then – in order – L_1 through L_m (stopping symbol '#') and R_1 through R_n (again '#'), as shown in Equation 1.

$$\text{parent } P \rightarrow \#L_m \dots L_1 M R_1 \dots R_n \# \qquad (1)$$

In this manner, it is possible to produce rules never before seen in the training treebank. While this may be required for parsing grammatical sentences with rare elements, this SU-level error prediction feature indicates whether the automatic parse for a given SU includes an expansion never seen in the training treebank. If an expansion rule in the one-best parse was not seen in training (here meaning in the SWBD treebank after EDITED nodes have been removed), the implication is that new rule generation is an indicator of a speaker error within a SU.

Feature #4 (C-comm): Mark unseen rule c-commanding NTs. In X' theory (Chomsky, 1970), lexical categories such as nouns and verbs are often modified by a specifier (such as the DT "a" modifying the NN "lot" in the NP_3 phrase in Figure 3 or an auxiliary verb for a verb in a verb phrase (VBZ for VP_3) and a complement (such as the object of a verb NP_3 for VBG in the phrase VP_3).

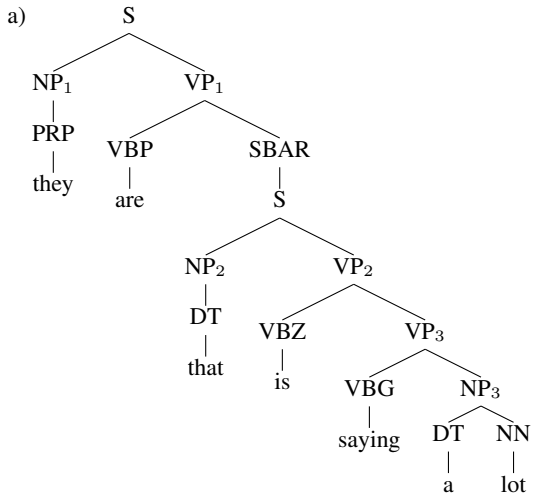
In each of these cases, an NT tree node A has the following relationship with a second NT P:

- Neither does node A *dominate* P nor node P dominate A, (i.e., neither is directly above the other in the parse tree), and
- Node A immediately *precedes* P in the tree (precedence is represented graphically in left-to-right order in the tree).

Given these relationships, we say that A *locally c-commands* P and its descendants. We further extend this definition to say that, if node $\hat{A}$ is the only child of node A (a unary expansion) and A locally c-commands P, then $\hat{A}$ locally c-commands P (so both [SBAR $\rightarrow$ S] and [S $\rightarrow$ NP_2 VP_2] are c-commanded by VBP). See Figure 3 for other examples of non-terminal nodes in c-commanding relationships, and the phrase expansion rule they c-command.

The c-command relationship is fundamental in syntactic theory, and has uses such as predicting the scope of pronoun antecedents. In this case, however, we use it to describe two nodes which are in a specifier–category relationship or a category–complement relationship (e.g., subject–verb and verb–object, respectively). This is valuable to us because it takes advantage of a weakness of statistical parsers: the context used to condition the probability of a given rule expansion generally does not reach beyond dominance relationships, and thus parsers rarely penalize for the juxtaposition of A c-commanding P and its children as

[2]The DEep Linguistic Processing with HPSG INitiative (see http://www.delph-in.net/)



b) Rules expansions:
S → NP VP
NP_1 → PRP
VP_1 → VBP SBAR
SBAR → S
S → NP_2 VP_2
NP_2 → DT
VP_2 → VBZ VP
VP_3 → VBG NP
NP_3 → DT NN

c) Rule expansions + c-commanding NT:	
S → NP VP	*no local c-command*
NP_1 → PRP	*no local c-command*
VP_1 → V SBAR	NP_1
SBAR → S	VBP
S → NP_2 VP_2	VBP
NP_2 → DT	*no local c-command*
VP_2 → VBZ VP	NP_2
VP_3 → VBG NP	VBZ
NP_3 → DT NN	VBG

Figure 3: The automatically generated parse (a) for an errorful sentence-like unit (SU), with accompanying rule expansions (b) and local c-commands (c). Non-terminal indices such as NP_2 are for reader clarification only and are not considered in the feature extraction process.

long as they have previously seen NT type A preceding NT type P. Thus, we can use the children of a parent node P as a way to enrich a NT type P and make it more informative.

For example, in Figure 3, the rule [S → NP_2 VP_2] is routinely seen in the manual parses of the SWBD treebank, as is [VP_1 → VBP SBAR]. However, it is highly unusual for VBP to immediately precede SBAR or S when this rule expands to NP_2 VP_2. So, not only does SBAR/S complement VBP, but a very specific type of [SBAR/S → NP VP] is the complement of VBP. This conditional infrequency serves as an indication of deeper structural errors.

Given these category relationship observations, we include in our maximum entropy model a feature indicating whether a given parse includes a c-command relationship not seen in training data.

Feature #5 (Length): Threshold sentences based on length. Empirical observation indicates that long sentences are more likely to contain speaker errors, while very short sentences tend to be backchannel acknowledgments like "yeah" or "I know" which are not considered errorful. Oviatt (1995) quantifies this, determining that the disfluency rate in human-computer dialog increases roughly linearly with the number of words in an utterance.

The length-based feature value for each sentence therefore is defined to be the number of word tokens in that sentence.

Feature #6 (Backchannel): Bias backchannel acknowledgements as non-errors A backchannel acknowledgement is a short sentence-like unit (SU) which is produced to indicate that the speaker is still paying attention to the other speaker, without requesting attention or adding new content to the dialog. These SUs include "uh-huh", "sure", or any combination of backchannel acknowledgements with fillers (ex. "sure uh uh-huh").

To assign this feature, fifty-two common backchannel acknowledgement tokens are considered. The indicator feature is one (1) if the SU in question is some combination of these backchannel acknowledgements, and zero (0) otherwise.

3.2 SU-level error identification results

We first observe the performance of each feature type in isolation in our maximum entropy framework (Table 1(a)). The top-performing individual

Setup	Features included						F_1-score

12	√	√	√	√	√	–	82.9 (-0.4)
13	√	√	√	√	–	√	83.2 (-0.1)

Table 1: Comparison of poor construction identification features, tested on the SSR test corpus.

feature is the JC04 edit indicator, which is not surprising as this is the one feature whose existence was designed specifically to predict speaker errors. Following JC04 in individual performance are the HPSG parsability feature, length feature, and unseen c-command rule presence feature. Backchannel acknowledgements had no predictive power on their own. This was itself unsurprising as the feature was primarily meant to reduce the probability of selecting these SUs as errorful.

Combining all rules together (Table 1(b)), we note an F_1-score gain of 3.4 as compared to the top individual feature JC04. (JC04 has a precision of 97.6, recall of 67.6, and F of 79.9; the combined feature model has a precision of 93.0, a recall of 75.3, and an F of 83.3, so unsurprisingly our gain primarily comes from increased error recall).

In order to understand the contribution of an individual feature, it helps not only to see the prediction results conditioned only on that feature, but the loss in accuracy seen when only that feature is removed from the set. We see in Table 1(c) that, though the c-command prediction feature was only moderately accurate in predicting SU errors on its own, it has the second largest impact after JC04 (an F-score loss of 2.1) when removed from the set of features. Such a change indicates the orthogonality of the information within this feature to the other features studied. Length, on the other hand, while moderately powerful as a single indicator, had negligible impact on classification accuracy when removed from the feature set. This indicates that the relationship between errorful sentences and length can be explained away by the other features in our set.

We also note that the combination of all features excluding JC04 is competitive with JC04 itself. Additional complementary features seem likely to further compete with the JC04 prediction feature.

4 Combining efforts

The FHJ work shows that the predictive power of a CRF model could greatly improve (given a restriction on only altering SUs suspected to contain errors) from an F-score of 84.7 to as high as 88.7 for rough copy (RC) errors and from an F-score of 47.5 to as high as 73.8 for non-copy (NC) errors.

Now that we have built a model to predict construction errors on the utterance level, we combine the two approaches to analyze the improvement possible for word-level identification (measured again by precision, recall, and F-score) and for SU-level correction (measured by the SU_Match metric defined in Section 4.2).

4.1 Word-level evaluation of error identification, post SU filtering

We first evaluate edit detection accuracy on those test SUs predicted to be errorful on a per-word basis. To evaluate our progress identifying word-

level error classes, we calculate precision, recall and F-scores for each labeled class c in each experimental scenario. As usual, these metrics are calculated as ratios of correct, false, and missed predictions. However, to take advantage of the double reconstruction annotations provided in SSR (and more importantly, in recognition of the occasional ambiguities of reconstruction) we modified these calculations slightly to account for all references.

Analysis of word-level label evaluation, post SU filtering. Word-level F_1-score results for error region identification are shown in Table 2.

By first automatically selecting testing as described in Section 3 (with a sentence-level F-score of 83.3, Table 1(b)), we see in Table 2 some gain in F-score for all three error classes, though much potential improvement remains based on the oracle gain (rows indicated as having "Gold errors" testing data). Note that there are no results from training only on errorful data but testing on all data, as this was shown to yield dramatically worse results due to data mismatch issues.

Unlike in the experiments where all data was used for testing and training, the best NC and RC detection performance given the automatically selected testing data was achieved when training a CRF model to detect each class separately (RC or NC alone) and not in conjunction with filler word detection FL. As in FHJ, training RC and NC models separately instead of in a joint FL+RC+NC model yielded higher accuracy.

We notice also that the F-score for RC identification is lower when automatically filtering the test data. There are two likely causes. The most likely issue is that the automatic SU-error classifier filtered out some SUs with true RC errors which had previously been correctly identified, reducing the overall precision ratio as well as recall (i.e., we no longer receive accuracy credit for some easier errors once caught). A second, related possibility is that the errorful SUs identified by the Section 3 method had a higher density of errors that the current CRF word-level classification model is unable to identify (i.e. the more difficult errors are now a higher relative percentage of the errors we need to catch). While the former possibility seems more likely, both causes should be investigated in future work.

The F-score gain in NC identification from 42.5 to 54.6 came primarily from a gain in precision (in the original model, many non-errorful SUs were mistakenly determined to include errors). Though capturing approximately 55% of the non-copy NC errors (for SUs likely to have errors) is an improvement, this remains a challenging and unsolved task which should be investigated further in the future.

4.2 Sentence-level evaluation of error identification and region deletion, post SU identification

Depending on the downstream task of speech reconstruction, it may be imperative not only to identify many of the errors in a given spoken utterance, but indeed to identify *all* errors (and only those errors), yielding the exact cleaned sentence that a human annotator might provide.

In these experiments we apply *simple cleanup* (as described in Section 1.1) to both JC04 output and the predicted output for each experimental setup, deleting words when their error class is a filler, rough copy or non-copy.

Taking advantage of the dual annotations provided for each sentence in the SSR corpus, we can report double-reference evaluation. Thus, we judge that if a hypothesized cleaned sentence exactly matches *either* reference sentence cleaned in the same manner we count the cleaned utterance as correct, and otherwise we assign no credit. We report double-reference exact match evaluation between a given SU s and references $r \in R$, as defined below.

$$\text{SU\_match} = \frac{1}{S} \sum_{s \in S} \max_{r \in R} \delta(s, r) \qquad (2)$$

Analysis of sentence level evaluation, post SU identification. Results from this second evaluation of rough copy and non-copy error reconstruction can be seen in Table 3.

As seen in word-level identification results (Table 2), automatically selecting a subset of testing data upon which to apply simple cleanup reconstruction does not perform at the accuracy shown to be possible given an oracle filtering. While measuring improvement is difficult (here, non-filtered data is incomparable to filtered test data results since a majority of these sentences require no major deletions at all), we note again that our methods (MaxEnt/FHJ-x) outperform the baseline of deleting nothing but filled pauses like "eh" and "um", as well as the state-of-the-art baseline JC04.

Class labeled	Training	SUs for Testing	FL	RC	NC
FL+RC+NC	All data	All SU data	71.0	80.3	47.4
	Errorful only	Auto ID'd SU errors	87.9	79.9	49.0
	Errorful only	Gold SU errors	91.6	84.1	52.2
NC	All data	All SU data	-	-	42.5
	Errorful only	Auto ID'd SU errors	-	-	**54.6**
	Errorful only	Gold SU errors	-	-	73.8
NC+FL	All data	All SU data	70.8	-	47.5
	Errorful only	Auto ID'd SU errors	**88.8**	-	53.3
	Errorful only	Gold SU errors	90.7	-	69.8
RC	All data	All SU data	-	*/84.2/*	-
	Errorful only	Auto ID'd SU errors	-	**81.3**	-
	Errorful only	Gold SU errors	-	88.7	-
RC+FL	All data	All SU data	67.8	*/84.7/*	-
	Errorful only	Auto ID'd SU errors	88.1	80.5	-
	Errorful only	Gold SU errors	92.3	87.4	-

Table 2: Error predictions, post-SU identification: F_1-score results. Automatically identified "SUs for testing" were determined via the maximum entropy classification model described earlier in this paper, and feature set #7 from Table 1. Filler (FL), rough copy error (RC) and non-copy error (NC) results are given in terms of word-level F_1-score. **Bold** numbers indicate the highest performance post-automatic filter for each of the three classes. *Italicized* values indicate experiments where no filtering outperformed automatic filtering (for RC errors).

Setup	Classed deleted	Testing	# SUs (filt/unfilt)	# SUs that match ref	% accuracy
Baseline-1	only filled pauses	All data	2288	1800	78.7%
JC04-1	E+FL	All data	2288	1858	81.2%
MaxEnt/FHJ-1	FL+RC+NC	All data	2288	1922	84.0%
Baseline-2	**only filled pauses**	**Auto ID'd**	**430**	**84**	**19.5%**
JC04-2	**E+FL**	**Auto ID'd**	**430**	**187**	**43.5%**
MaxEnt/FHJ-2	**FL+RC+NC**	**Auto ID'd**	**430**	**223**	**51.9%**
Baseline-3	only filled pauses	Gold errors	281	5	1.8%
JC04-3	E+FL	Gold errors	281	126	44.8%
MaxEnt/FHJ-3	FL+RC+NC	Gold errors	281	156	55.5%

Table 3: Error predictions, post-SU identification: Exact Sentence Match Results.
For the baseline, we delete only filled pause filler words like "eh" and "um". For JC04 output, we deleted any word assigned the class E or FL. Finally, for the MaxEnt/FHJ models, we used the jointly trained FL+RC+NC CRF model and deleted all words assigned any of the three classes.

5 Future Work

While some success and improvements for the automatic detection and deletion of fillers and reparanda (i.e., "simple cleanup") have been demonstrated in this work, much remains to be done to adequately address the issues and criteria considered here for full reconstruction of spontaneous speech.

Included features for both the word level and SU-level error detection have only skimmed the surface of potentially powerful features for spontaneous speech reconstruction. There should be continued development of complementary parser-based features (such as those from dependency parsers or even deep syntax parsers such as implementations of HPSG as well as additional syntactic features based on automatic constituent or context-free grammar based parsers). Prosodic

features, though demonstrated to be unnecessary for at least moderately successful detection of simple errors, also hold promise for additional gains. Future investigators should evaluate the gains possible by integrating this information into the features and ideas presented here.

6 Summary and conclusions

This work was an extension of the results in FHJ, which showed that automatically determining which utterances contain errors before attempting to identify and delete fillers and reparanda has the potential to increase accuracy significantly.

In Section 3, we built a maximum entropy classification model to assign binary error classes to spontaneous speech utterances. Six features – JC04, HPSG, unseen rules, unseen c-command relationships, utterance length, and backchannel acknowledgement composition – were considered. The combined model achieved a precision of 93.0, a recall of 75.3, and an F_1-score of 83.3.

We then, in Section 4, cascaded the sentence-level error identification system output into the FHJ word-level error identification and simple cleanup system. This combination lead to non-copy error identification with an F_1-score of 54.6, up from 47.5 in the experiments conducted on all data instead of data identified to be errorful, while maintaining accuracy for rough copy errors and increasing filler detection accuracy as well. Though the data setup is slightly different, the true errors are common across both sets of SUs and thus the results are comparable.

This work demonstrates that automatically selecting a subset of SUs upon which to implement reconstruction improves the accuracy of non-copy (restart fragment) reparanda identification and cleaning, though less improvement results from doing the same for rough copy identification.

Abstract

Strictly corpus-based measures of semantic distance conflate co-occurrence information pertaining to the many possible senses of target words. We propose a corpus–thesaurus hybrid method that uses soft constraints to generate word-sense-aware distributional profiles (DPs) from coarser "concept DPs" (derived from a Roget-like thesaurus) and sense-unaware traditional word DPs (derived from raw text). Although it uses a knowledge source, the method is not vocabulary-limited: if the target word is not in the thesaurus, the method falls back gracefully on the word's co-occurrence information. This allows the method to access valuable information encoded in a lexical resource, such as a thesaurus, while still being able to effectively handle domain-specific terms and named entities. Experiments on word-pair ranking by semantic distance show the new hybrid method to be superior to others.

1 Introduction

Semantic distance is a measure of the closeness in meaning of two concepts. People are consistent judges of semantic distance. For example, we can easily tell that the concepts of "exercise" and "jog" are closer in meaning than "exercise" and "theater". Studies asking native speakers of a language to rank word pairs in order of semantic distance confirm this—average inter-annotator correlation on ranking word pairs in order of semantic distance has been repeatedly shown to be around 0.9 (Rubenstein and Goodenough, 1965; Resnik, 1999).

A number of natural language tasks such as machine translation (Lopez, 2008) and word sense disambiguation (Banerjee and Pedersen, 2003; McCarthy, 2006), can be framed as semantic distance problems. Thus, developing automatic measures that are in-line with human notions of semantic distance has received much attention. These automatic approaches to semantic distance rely on manually created lexical resources such as WordNet, large amounts of text corpora, or both.

WordNet-based information content measures have been successful (Hirst and Budanitsky, 2005), but there are significant limitations on their applicability. They can be applied only if a WordNet exists for the language of interest (which is not the case for the "low-density" languages); and even if there is a WordNet, a number of domain-specific terms may not be encoded in it. On the other hand, corpus-based distributional measures of semantic distance, such as cosine and α-skew divergence (Dagan et al., 1999), rely on raw text alone (Weeds et al., 2004; Mohammad, 2008). However, when used to rank word pairs in order of semantic distance or correct real-word spelling errors, they have been shown to perform poorly (Weeds et al., 2004; Mohammad and Hirst, 2006).

Mohammad and Hirst (2006) and Patwardhan and Pedersen (2006) argued that word sense ambiguity is a key reason for the poor performance of traditional distributional measures, and they proposed hybrid approaches that are distributional in nature, but also make use of information in lexical resources such as published thesauri and WordNet. However, both these approaches can be applied to estimate the semantic distance between two terms *only* if both terms exist in the lexical resource they rely on. We know lexical resources tend to have limited vocabulary and a large number of domain-

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 775–783,
Singapore, 6-7 August 2009.

specific terms are usually not included.

It should also be noted that similarity values from different distance measures are not comparable (even after normalization to the same scale), that is, a similarity score of .75 as per one distance measure does not correspond to the same semantic distance as a similarity score of .75 from another distance measure.[1] Thus if one uses two independent distance measures, in this case: one resource-reliant and one only corpus-dependent, then these two measures are not comparable (and hence cannot be used in tandem), even if both rely—partially or entirely—on distributional corpus statistics.

We propose a hybrid semantic distance method that *inherently* combines the elements of a resource-reliant measure and a strictly corpus-dependent measure by imposing resource-reliant soft constraints on the corpus-dependent model. We choose the Mohammad and Hirst (2006) method as the resource-reliant method and not one of the WordNet-based measures because, unlike the WordNet-based measures, the Mohammad and Hirst method is distributional in nature and so lends itself immediately for combination with traditional distributional similarity measures. Our new hybrid method combines concept–word co-occurrence information (the Mohammad and Hirst distributional profiles of thesaurus concepts (DPC)) with word–word co-occurrence information, to generate word-sense-biased distributional profiles. The "pure" corpus-based distributional profile (a.k.a. *co-occurrence vector*, or *word association vector*), for some target word u, is biased with soft constraints towards each of the concepts c that list u in the thesaurus, to create a distributional profile that is specific to u in the sense that is most related to the other words listed under c.

Thus, this method can make more fine-grained distinctions than the Mohammad and Hirst method, and yet uses word sense information.[2] Our proposed method falls back gracefully to rely only on word-word co-occurrence information if any of the target terms is not listed in the lexical resource. Experiments on the word-pair ranking task on three different datasets show that the our proposed hybrid measure outperforms all other comparable distance measures.

Mohammad and Hirst (2007) show that their method can be used to compute semantic distance in a resource poor language L_1 by combining its text with a thesaurus in a resource-rich language L_2 using an L_1–L_2 bilingual lexicon to create cross-lingual distributional profiles of concepts, that is, L_2 word co-occurrence profiles of L_1 thesaurus concepts. Since our method makes use of the Mohammad and Hirst DPCs, it can just as well make use of their cross-lingual DPCs, to compute semantic distance in a resource-poor language, just as they did. We leave that for future work.

2 Background and Related Work

Strictly speaking, semantic distance/closeness is a property of lexical units—a combination of the surface form and word sense.[3] Two terms are considered to be semantically close if there is a lexical semantic relation between them. Such a relation may be a classical relation such as hypernymy, troponymy, meronymy, and antonymy, or it may be what have been called an ad-hoc non-classical relation, such as cause-and-effect (Morris and Hirst, 2004). If the closeness in meaning is due to certain specific classical relations such as hypernymy and troponymy, then the terms are said to be semantically *similar*. Semantic *relatedness* is the term used to describe the more general form of semantic closeness caused by any semantic relation (Hirst and Budanitsky, 2005). So the nouns *liquid* and *water* are both semantically similar and semantically related, whereas the nouns *boat* and *rudder* are semantically related, but not similar.

The next three sub-sections describe three kinds of automatic distance measures: (1) lexical-resource-based measures that rely on a manually created resource such as WordNet; (2) corpus-based measures that rely only on co-occurrence statistics from large corpora; and (3) hybrid measures that are distributional in nature, and that also exploit the information in a lexical resource.

2.1 Lexical-resource-based measures

WordNet is a manually-created hierarchical network of nodes (taxonomy), where each node in

[1] All we can infer is that if w_1 and w_2 have a similarity score of .75 and w_3 and w_4 have a score of .5 by the *same* distance measure, then w_1–w_2 are closer in meaning than w_3–w_4.

[2] Even though Mohammad and Hirst (2006) use thesaurus categories as coarse concepts, their algorithm can be applied using more finer-grained thesaurus word groupings (paragraphs and semicolon units), as well.

[3] The notion of semantic distance can be generalized, of course, to larger units such as phrases, sentences, passages, and so on (Landauer et al., 1998).

the network represents a fine-grained concept or word sense. An edge between two nodes represents a lexical semantic relation such as hypernymy and troponymy. WordNet-based measures consider two terms to be close if they occur close to each other in the network (connected by only a few arcs), if their definitions share many terms (Banerjee and Pedersen, 2003; Patwardhan and Pedersen, 2006), or if they share a lot of information (Lin, 1998; Resnik, 1999). The length of each arc/link (distance between nodes) can be assumed a unit length, or can be computed from corpus statistics. Within WordNet, the *is-a* hierarchy is much more well-developed than that of other lexical semantic relations. So, not surprisingly, the best WordNet-based measures are those that rely only on the *is-a* hierarchy. Therefore, they are good at measuring semantic similarity (e.g., *doctor–physician*), but not semantic relatedness (e.g., *doctor–scalpel*). Further, the measures can only be used in languages that have a (sufficiently developed) WordNet. WordNet sense information has been criticized to be too fine grained (Agirre and Lopez de Lacalle Lekuona, 2003; Navigli, 2006). See Hirst and Budanitsky (2005) for a comprehensive survey of WordNet-based measures.

2.2 Corpus-based measures

Strictly corpus-based measures of distributional similarity rely on the hypothesis that words that occur in similar context tend to be semantically close (Firth, 1957; Harris, 1940). The set of contexts of each target word u is represented by its distributional profile (DP)—the set of words that tend to co-occur with u within a certain distance, along with numeric scores signifying this co-occurrence tendency with u. Then measures such as cosine or α-skew divergence are used to determine how close the DPs of the two target words are. See Section 3 for more details and related work. These measures are very appealing because they rely simply on raw text, but, as described earlier, when used to rank word pairs in order of semantic distance, or to correct real-word spelling errors, they perform poorly, compared to the WordNet-based measures. See Weeds et al. (2004), Mohammad (2008), and Curran (2004) for detailed surveys of distributional measures.

As Mohammad and Hirst (2006) point out, the DP of a word u conflates information about the potentially many senses of u. For example, consider the following. The noun *bank* has two senses "river bank" and "financial institution". Assume that *bank*, when used in the "financial institution" sense, co-occurred with the noun *money* 100 times in a corpus. Similarly, assume that *bank*, when used in the "river bank" sense, co-occurred with the noun *boat* 80 times. So the DP of *bank* will have co-occurrence information with *money* as well as *boat*:

DPW(*bank*):
money,100; *boat*,80; *bond*,70; *fish*,77; ...

Assume that the DP of the word *ATM* is:

DPW(*ATM*):
money,120; *boat*,0; *bond*,90; *fish*,0; ...

Thus the distributional distance of *bank* with *ATM* will be some sort of an average of the semantic distance between the "financial institution" and "ATM" senses and the semantic distance between the "river bank" and "ATM" senses. However, in various natural language tasks, we need the semantic distance between the intended senses of *bank* and *ATM*, which often also tends to be the semantic distance between their closest senses.

2.3 Hybrid measures

Both Mohammad and Hirst (2006) and Patwardhan and Pedersen (2006) proposed measures that are not only distributional in nature but also rely on a lexical resource to exploit the manually encoded information therein as well as to overcome the sense-conflation problem (described in section 2.2). Since we essentially combine the Mohammad and Hirst method with a "pure" word-based distributional measure to create our hybrid approach, we briefly describe their method here.

Mohammad and Hirst (2006) generate separate distributional profiles for the different senses of a word, without using any sense-annotated data. They use the categories in a Roget-style thesaurus (*Macquaries* (Bernard, 1986)) as coarse senses or concepts. There are about 1000 categories in a thesaurus, and each category has on average 120 closely related words. A word may be found in more than one category if it has multiple meaning. They use a simple unsupervised algorithm to determine the vector of words that tend to co-occur with each concept and the corresponding strength of association (a measure of how strong the tendency to co-occur is). The target word u will be assigned one DPC for each of the concepts that

list u. Below are example DPCs of the two concepts pertaining to *bank*:[4]

DPC("fin. inst."):
money,1000; *boat*,32; *bond*,705; *fish*,0; ...
DPC("river bank"):
money,5; *boat*,863; *bond*,0; *fish*,948; ...

The distance between two words u, v is determined by calculating the closeness of each of the DPCs of u to each of DPCs of v, and the closest DPC-pair distance is chosen.

Mohammad and Hirst (2006) show that their approach performs better than other strictly corpus-based approaches that they experimented with. However, all those experiments were on word-pairs that were listed in the thesaurus. Their approach is not applicable otherwise. In Sections 3 and 4 we show how cosine–log-likelihood-ratio (or any comparable distributional measure) can be combined with the Mohammad and Hirst DPCs to form a hybrid approach that is not limited to the vocabulary of a lexical resource.

Erk and Padó (2008) proposed a way of representing a word sense in context by biasing the target word's DP according to the context surrounding a target (specific) occurrence of the target word. They use dependency relations and selectional preferences of the target word and combine multiple DPs of words appearing in the context of the target occurrence, in a manner so as to give more weight to words co-occurring with both the target word and the target occurrence's context words. The advantage of this approach is that it does not rely on a thesaurus or WordNet. Its disadvantage is that it relies on dependency relations and selectional preferences information, and that the context information it uses in order to determine the word sense is quite limited (only the words surrounding a single occurrence of the and hence the representation of that sense might not be sufficiently accurate. Their approach effectively assumes that each occurrence of a word has a unique sense.

3 Distributional Measures with Soft Semantic Constraints

Traditional distributional profiles of words (DPW) give word–word co-occurrence frequencies. For example, DPW(u) gives the number of times the target word u co-occurs with with all other words:[5]

$\mathrm{DPW}(u)$:
w_1,f(u,w_1); w_2,f(u,w_2); w_3,f(u,w_3); ...

where f stands for co-occurrence frequency (and can be generalized to stand for any strength of association (SoA) measure such as the log-likelihood ratio). Mohammad and Hirst create concept–word co-occurrence vectors, "distributional profiles of concepts" (DPCs), from non-annotated corpus. For example, DPC(c) gives the number of times the concept (thesaurus category) c co-occurs with all the words in a corpus.

$\mathrm{DPC}(c)$:
w_1,f(c,w_1); w_2,f(c,w_2); w_3,f(c,w_3); ...

A target word u that appears under thesaurus concepts c_1, ..., c_n would be assigned to DPC(c_1), ..., DPC(c_n). Therefore, if a target word v also appears under some same concept c, the DPCs of u and v would be indistinguishable.

We propose the creation of distributional profiles of word senses (DPWS(u_c)) that approximate the SoA of the target word u, when used in sense c, with each of the words in the corpus:

$\mathrm{DPWS}(u_c)$:
w_1,f(u_c,w_1); w_2,f(u_c,w_2); w_3,f(u_c,w_3); ...

In order to get exact counts, one needs sense-annotated data. However, such data is expensive to create, and is scarce. Therefore, we propose estimating these counts from the DPW and DPC counts:

$$f(u_c, w_i) = p(c|w_i) \times f(u, w_i) \qquad (1)$$

where the conditional probability $p(c|w_i)$ is calculated from the co-occurrence frequencies in DPCs; and the co-occurrence count $f(u, w_i)$ is calculated from DPWs. If the target word is not in the thesaurus's vocabulary, then we assume uniform distribution over all concepts, and in practice use a single sense, and take the conditional probability to be 1. Since the method takes sense-proportional co-occurrence counts, we will refer to this method as the **hybrid-sense-proportional-counts method** (or, **hybrid-prop** for short).

[4]The relatively large co-occurrence frequency values for DPCs as compared to DPWs is because a concept can be refered to by many words (on average 100).

[5]The dimensions of the DP co-occurrence vector can be defined arbitrarily, and do not have to correspond to the words in the vocabulary. The most notable alternative representation is the Latent Semantic Analysis and its variants (Landauer et al., 1998; Finkelstein et al., 2002; Budiu et al., 2006).

For example, below is the DPWS of *bank* in the "financial institution" sense, calculated from its DPW and DPCs:

DPW(*bank*):
money,100; *boat*,80; *bond*,70; *fish*,77; ...

DPC("fin. inst."):
money,1000; *boat*,32; *bond*,705; *fish*,0; ...
DPC("river bank"):
money,5; *boat*,863; *bond*,0; *fish*,948; ...

DPWS($bank_{\text{"fin.inst."}}$):
money,$(\frac{1000}{1000+5} \times 100)$; *boat*,$(\frac{32}{32+863} \times 80)$;
bond,$(\frac{705}{705+0} \times 70)$; *fish*,$(\frac{0}{0+948} \times 77)$; ...

Once the DPWS are calculated, any counts-based SoA and distance measures can be applied. For example, in this work we use log-likelihood ratio (Dunning, 1993) to determine the SoA between a word sense and co-occurring words, and cosine to determine the distance between two DPWS's log likelihood vectors (McDonald, 2000). We also contrast this measure with cosine of conditional probabilities vectors. Given two target words, we determine the distance between each of their DPWS pairings and the closest DPWS-pair distance is chosen.

3.1 The hybrid-sense-filtered-counts method

Since the DPCs are created in an unsupervised manner, they are expected to be somewhat noisy. Therefore, we also experimented with a variant of the method proposed above, that simply makes use of whether the conditional probability $p(c|w_i)$ is greater than 0 or not:

$$f(u_c, w_i) = \begin{cases} f(u, w_i) & \text{If } p(c|w_i) > 0 \\ 0 & \text{Otherwise} \end{cases} \quad (2)$$

Since this method essentially filters out collocates that are likely not relevant to the target sense c of the target word u, we will refer to this method as the **hybrid-sense-filtered-counts method** (or, just **hybrid-filt** for short). Below is an example hybrid-filtered DPWS of *bank* in the "financial institution" sense:

DPWS($bank_{\text{"fin.inst."}}$:
money,100); *boat*,80; *bond*,70; ...

Note that the collocate *fish* is now filtered out, whereas *bank's* co-occurrence counts with *money, boat,* and *bond* are left as is (and not sense-proportionally attenuated).

4 Evaluation

We evaluated various methods on the task of ranking word pairs in order of semantic distance. These methods included our sense-biased methods as well as several baselines: the Mohammad and Hirst (2006) DPC-based methods, the traditional word-based distributional similarity methods, and several Latent Semantic Analysis (LSA)-based methods. We used three testsets and their corresponding human judgment gold standards: (1) the Rubenstein and Goodenough (1965) set of 65 noun pairs—denoted **RG-65**; (2) the WordSimilarity-353 (Finkelstein et al., 2002) set of 353 noun pairs (which include the RG-65 pairs) of which we discarded of one repeating pair—denoted **WS-353**; and (3) the Resnik and Diab (2000) set of 27 verb pairs—denoted **RD-00**.

4.1 Corpora and Pre-processing

We generated distributional profiles (DPWs and DPCs) from the *British National Corpus (BNC) (Burnard, 2000)*, which is a balanced corpus. We lowercased the characters, and stripped numbers, punctuation marks, and any SGML-like syntactic tags, but kept sentence boundary markers. The BNC contained 102,100,114 tokens of 546,299 types (vocabulary size) after tokenization. For the verb set, we also lemmatized this corpus.

We considered two words as co-occurring if they occurred in a window of ± 5 words from each other. We stoplisted words that co-occurred with more than 2000 word types.

4.2 Results

The Spearman rank correlations of the automatic rankings of the RG-65, WS353, and RD-00 testsets with the corresponding gold-standard human rankings is listed in Table 1.[6] The higher the Spearman rank correlation, the more accurate is the distance measure.

4.2.1 Results on the RG-65 testset

Baselines. We replicated the traditional word-based distributional distance measure using cosine of vectors (DPs) containing conditional probabilities (**word-cos-cp**). Its rank correlation of .53 is close to the correlation of .54 reported in Mohammad and Hirst (2006), hereafter MH06. We replicated the MH06 concept-based approach

[6] Certain experiments were not pursued as they were redundant in supporting our claims.

Method	RG-65	WS-353	RD-00
Baselines (replicated):			
Traditional distributional measures			
word-cos-cp	.53	.31	.46
word-cos-ll	.70	**.54**	.51
word-cos-pmi	.62	.43	.57
Mohammad and Hirst methods and variants			
concept-cos-cp	.62	.38	.41
concept*-cos-cp	.65	.33	.43
concept-cos-ll	.60	.37	.43
concept*-cos-ll	.64	.25	.27
concept*-cos-pmi	.40	.19	.28
Other (LSA and variants)			
LSA	.56	.47	.55
GLSA-cos-pmi	.18	n.p.	n.p.
GLSA-cos-ll	.47	n.p.	.29
New methods:			
hybrid-prop-cos-ll	.72	.49	.53
hybrid-prop*-cos-ll	.69	.46	.45
hybrid-filt-cos-ll	.73	**.54**	.38
hybrid-filt*-cos-ll	**.77**	**.54**	.39
hybrid-prop*-cos-pmi	.58	.43	**.71**
hybrid-filt*-cos-pmi	.61	.42	.64

Table 1: Spearman rank correlation on RG-65, WS-353, and RD-00 testsets, trained on BNC. '*' indicates the use of a smaller bootstrapped concept–word co-occurrence matrix. 'n.p.' indicates that the experiment was not pursued.

(**concept-cos-cp**), and its bootstrapped variant that uses a smaller concept–word co-occurrence matrix (**concept*-cos-cp**). The latter yielded a correlation score .65, close to the .69 reported in MH06.

We also experimented with cosine of PMI vectors (**word-cos-pmi**) which obtained a correlation of .62. Log likelihood ratios (**word-cos-ll**) gave best results among the baseline methods (.70), and so we it more often in the implementations of our hybrid method.

We conducted experiments with LSA and its GLSA variants (Budiu et al., 2006) as additional baselines. A limited vocabulary of the 33,000 most frequent words in the BNC and all test words was used in these experiments. (A larger vocabulary was computationally expensive and 33,000 is also the vocabulary size used by Budiu et al. (2006) in their LSA experiments.)

New Methods: The hybrid method variants proposed in this paper (**hybrid-prop-cos-ll** and **hybrid-filt-cos-ll**) were the best performers on the RG-65 test set. Particularly, they performed better than both the traditional word-distance measures (**word-cos-ll**), and our concept-based methods—variants of the MH06 method that are used with likelihood ratios (**concept-cos-ll, concept*-cos-ll**). The -pmi methods were all poorer performers than their -ll counterparts. The -pmi hybrid variants obtained higher scores than the concept-based ones, but almost the same scores as the word-based ones.

4.2.2 Results on WS-353 and RD-00 testsets

On WS-353, all our hybrid methods out-performed their concept counterparts, and were on par with their word-based counterparts. On RD-00, **word-cos-pmi** out-performed all other word-based methods, and the hybrid -pmi methods were best performers with scores of .64 and .71. Our word-cos-ll, hybrid-prop-cos-ll, and the two hybrid pmi results on RD-00 are better than any non-WordNet results reported by Resnik and Diab (2000), including their syntax-informed methods—the variants of Lin ("distrib", .43) and Dorr ("LCS", .39). In fact, our hybrid*-prop-cos-pmi and hybrid*-filt-cos-pmi results reach correlation levels of the WordNet-based methods reported there (.66–.68). Also, on WS-353, our hybrid sense-filtered variants and word-cos-ll obtained a correlation score higher than published results using WordNet-based measures (Jarmasz and Szpakowicz, 2003) (.33 to .35) and Wikipedia-based methods (Ponzetto and Strube, 2006) (.19 to .48); and very close to the results obtained by thesaurus-based (Jarmasz and Szpakowicz, 2003) (.55) and LSA-based methods (Finkelstein et al., 2002) (.56).

The lower correlation scores of all measures on the WS-353 test set are possibly due to it having politically biased word pairs (examples include: *Arafat–peace, Arafat–terror, Jerusalem–Palestinian*) for which BNC texts are likely to induce low correlation with the human raters of WS-353. This testset also has disproportionately many terms from the news domain.

The concept methods performed poorly on WS-353 partly because many of the target words do not exist in the thesaurus. For instance, there were 17 such word types that occurred in 20 WS-353 testset word pairs. When excluding these pairs, concept-cos-cp goes up from .38 to .45, and concept*-cos-pmi from .19 to .24. Interestingly, results of the hybrid methods show that they were largely unaffected by the out-of-vocabulary problem on the WS-353 dataset.

On the verbs dataset RD-00, while hybrid-prop-cos-ll fared slightly better than word-cos-ll, using the smaller matrix seemed to hurt performance of

hybrid*-prop-cos-ll compared to word-cos-ll. But results suggest that the -pmi methods might serve as a better measure than -ll for verbs, although this claim should be tested more rigorously.

Human judgments of semantic distance are less consistent on verb-pairs than on noun-pairs, as reflected in inter-rater agreement measures in Resnik and Diab (2000) and others). Thus, not surprisingly, the scores of almost all measures are lower for the verb data than the RG-65 noun data.

5 Discussion

The hybrid methods proposed in this paper obtained higher accuracies than all other methods on the RG-65 testset (all of whose words were in the published thesaurus), and on the RD-00 testset, and their performance was at least respectable on the WS-353 testset (many of whose words were not in the published thesaurus). This is in contrast to the concept-distance methods which suffer greatly when the target words are not in the lexical resource (here, the thesaurus) they rely on, even though these methods can make use of co-occurrence information of words not in the thesaurus with concepts from the thesaurus.

Amongst the two hybrid methods proposed, the **sense-filtered-counts** method performed better using the smaller bootstrapped concept–word co-occurrence matrix whereas the sense-proportional method performed better using the larger concept–word co-occurrence matrix. We believe this is because the bootstrapping method proposed in Mohammad and Hirst (2006) has the effect of resetting to 0 the small co-occurrence counts. The noise from these small co-occurrence counts affects the sense-filtered-counts method more adversely (since any non-zero value will cause the inclusion of the corresponding collocate's full co-occurrence count) and so the bootstrapped matrix is more suitable for this method.

The results also show that the cosine of log-likelihood ratios method mostly performs better than cosine of conditional probabilities and the pmi methods on the noun sets. This further supports the claim by Dunning (1993) that log-likelihood ratio is much less sensitive than pmi to low counts. Interestingly, on the verb set, the pmi methods, and especially hybrid*-prop-cos-pmi, did extremely well. Further investigation is needed in order to determine if pmi is indeed more suitable for verb semantic similarity, and why.

6 Conclusion

Traditional distributional similarity conflates co-occurrence information pertaining to the many senses of the target words. Mohammad and Hirst (2006) show how distributional measures can be used to compute distance between very coarse word senses or concepts (thesaurus categories), and even obtain better results than traditional distributional similarity. However, their method requires that the target words be listed in the thesaurus, which is often not the case for domain-specific terms and named entities. In this paper, we proposed hybrid methods (**hybrid-sense-filtered-counts** and **hybrid-sense-proportional-counts**) that combine word–word co-occurrence information (traditional distributional similarity) with word–concept co-occurrence information (Mohammad and Hirst, 2006), with soft constraints in such a manner that the method makes use of information encoded in the thesaurus when available, and degrades gracefully if the target word is not listed in the thesaurus. Our method generates word-sense-biased distributional profiles (DPs) from non-annotated corpus-based word-based DPs and coarser-grained aggregated thesaurus-based "concept DPs" (DPCs). We showed that the hybrid method correlates with human judgments of semantic distance in most cases better than any of the other methods we replicated.

We are now interested in improving semantic distance measures for verb–verb, adjective–adjective, and cross-part-of-speech pairs, by exploiting specific information pertaining to these parts of speech in lexical resources in addition to purely co-occurrence information.

Abstract

In this paper, we first compare several strategies to handle the newly proposed three-way *Recognizing Textual Entailment* (RTE) task. Then we define a new measurement for a pair of texts, called *Textual Relatedness*, which is a weaker concept than semantic similarity or paraphrase. We show that an alignment model based on the predicate-argument structures using this measurement can help an RTE system to recognize the *Unknown* cases at the first stage, and contribute to the improvement of the overall performance in the RTE task. In addition, several heterogeneous lexical resources are tested, and different contributions from them are observed.

1 Introduction

Recognizing Textual Entailment (RTE) (Dagan et al., 2006) is a task to detect whether one *Hypothesis* (H) can be inferred (or entailed) by a *Text* (T). Being a challenging task, it has been shown that it is helpful to applications like question answering (Harabagiu and Hickl, 2006). The recent research on RTE extends the two-way annotation into three-way[1] [2], making it even more difficult, but more linguistic-motivated.

The straightforward strategy is to treat it as a three-way classification task, but the performance suffers a significant drop even when using the same classifier and the same feature model. In fact, it can also be dealt with as an extension to the traditional two-way classification, e.g., by identifying the *Entailment* (E) cases first and then further label the *Contradiction* (C) and *Unknown* (U) T-H pairs. Some other researchers also work on detecting negative cases, i.e. contradiction, instead of entailment (de Marneffe et al., 2008). However, according to our best knowledge, the detailed comparison between these strategies has not been fully explored, let alone the impact of the linguistic motivation behind the strategy selection. This paper will address this issue.

Take the following example from the RTE-4 test set (Giampiccolo et al., 2009) as an example,

T: *At least five people have been killed in a head-on train collision in north-eastern France, while others are still trapped in the wreckage. All the victims are adults.*

H: *A French train crash killed children.*

This is a pair of two contradicting texts, the mentioning of events (i.e. train crash) in both T and H are assumed to refer the same event[3]. In fact, the only contradicting part lies in the second sentence of T against H, that is, whether there are children among the victims. Therefore, this pair could also be classified as a *Known* (K) pair (=E∪C) against *Unknown* (U) pairs, instead of being classified as a *Non-entailment* (N) case (=C∪U) against E case in the traditional two-way annotation.

Furthermore, many state-of-the-art RTE approaches which are based on overlapping information or similarity functions between T and H, in fact over-cover the E cases, and sometimes, cover the C cases as well. Therefore, in this paper, we

Singapore, 6-7 August 2009.

would like to test whether applying this style of approaches to capture the K cases instead of E cases is more effective. While in lexical semantics, semantic relatedness is a weaker concept than semantic similarity, there is no counterpart at the sentence or text level. Therefore, in this paper, we propose a *Recognizing Textual Relatedness (RTR)* task as a subtask or the first step of RTE. By doing so, we choose *predicate-argument structure (PAS)* as the feature representation, which has already been shown quite useful in the previous RTE challenges (Wang and Neumann, 2007).

In order to obtain the PAS, we utilize a Semantic Role Labeling (SRL) system developed by Zhang et al. (2008). Although SRL has been shown to be effective for many tasks, e.g. information extraction, question answering, etc., it has not been successfully used for RTE, mainly due to the low coverage of the verb frame or semantic role resources or the low performance of the automatic SRL systems. The recent CoNLL shared tasks (Surdeanu et al., 2008; Hajič et al., 2009) have been focusing on semantic dependency parsing along with the traditional syntactic dependency parsing. The PAS from the system output is almost ready for use to build applications based on it. Therefore, another focus of this paper will be to apply SRL to the RTE task. In particular, it can improve the first stage binary classification (K vs. U), and the final result improves as well.

The rest of the paper will be organized as follows: Section 2 will give a brief literature review on both RTE and SRL; Section 3 describes the semantic parsing system, which includes a syntactic dependency parser and an SRL system; Section 4 presents an algorithm to align two PASs to recognize textual relatedness between T and H, using several lexical resources; The experiments will be described in Section 5, followed by discussions; and the final section will conclude the paper and point out directions to work on in the future.

2 Related Work

Although the term of *Textual Relatedness* has not been widely used by the community (as far as we know), many researchers have already incorporated modules to tackle it, which are usually implemented as an alignment module before the inference/learning module is applied. For example, Pado et al. (2009) mentioned two alignment modules, one is a phrase-based alignment system called MANLI (MacCartney et al., 2008), and the other is a stochastic aligner based on dependency graphs. Siblini and Kosseim (2009) performed the alignment on top of two ontologies. In this paper, we would like to follow this line of research but on another level of representation, i.e. the predicate-argument structures (PAS), together with different lexical semantic resources.

As for the whole RTE task, many people directly do the three-way classification with selective features (e.g. Agichtein et al. (2009)) or different inference rules to identify entailment and contradiction simultaneously (e.g. Clark and Harrison (2009)); while other researchers also extend their two-way classification system into three-way by performing a second-stage classification afterwards. An interesting task proposed by de Marneffe et al. (2008) suggested an alternative way to deal with the three-way classification, that is, to split out the contradiction cases first. However, it has been shown to be more difficult than the entailment recognition. Based on these previous works and our experimental observations, we propose an alternative two-stage binary classification approach, i.e. to identify the unknown cases from the known cases (entailment and contradiction) first. And the results show that due to the nature of these approaches based on overlapping information or similarity between T and H, this way of splitting is more reasonable.

However, RTE systems using semantic role labelers has not shown very promising results, although SRL has been successfully used in many other NLP tasks, e.g. information extraction, question answering, etc. According to our analysis of the data, there are mainly three reasons: a) the limited coverage of the verb frames or predicates; b) the undetermined relationships between two frames or predicates; and c) the unsatisfying performance of an automatic SRL system. For instance, Burchardt et al. (2007) attempted to use FrameNet (Baker et al., 1998) for the RTE-3 challenge, but did not show substantial improvement. With the recent CoNLL challenges, more and more robust and accurate SRL systems are ready for use, especially for the PAS identification. For the lexical semantics, we also discover that, if we relax the matching criteria (from similarity to relatedness), heterougeous resources can contribute to the coverage differently and then the effectiveness of PAS will be shown as well.

3 Semantic Parsing

In order to obtain the predicate-argument structures for the textual entailment corpus, we use the semantic role labeler described in (Zhang et al., 2008). The SRL system is trained on the Wall Street Journal sections of the Penn Treebank using PropBank and NomBank annotation of verbal and nominal predicates, and relations to their arguments, and produces as outputs the semantic dependencies. The head words of the arguments (including modifiers) are annotated as a direct dependent of the corresponding predicate words, labeled with the type of the semantic relation (Arg0, Arg1 ..., and various ArgMs). Note that for the application of SRL in RTE task, the PropBank and NomBank notation appears to be more accessible and robust than the the FrameNet notation (with much more detailed roles or frame elements bond to specific verb frames).

As input, the SRL system requires syntactic dependency analysis. We use the open source MST Parser (McDonald et al., 2005), trained also on the Wall Street Journal Sections of the Penn Treebank, using a projective decoder with second-order features. Then the SRL system goes through a pipeline of 4-stage processing: predicate identification (PI) identifies words that evokes a semantic predicate; argument identification (AI) identifies the arguments of the predicates; argument classification (AC) labels the argument with the semantic relations (roles); and predicate classification (PC) further differentiate different use of the predicate word. All components are built as maximal entropy based classifiers, with their parameters estimated by the open source TADM system[4], feature sets selected on the development set. Evaluation results from previous years' CoNLL shared tasks show that the system achieves state-of-the-art performance, especially for its out-domain applications.

4 Textual Relatedness

As we mentioned in the introduction, we break down the three-way classification into a two-stage binary classification. Furthermore, we treat the first stage as a subtask of the main task, which determines whether H is relevant to T. Similar to the probabilistic entailment score, we use a relatedness score to measure such relationship. Due to the nature of the entailment recognition that H should be fully entailed by T, we also make this relatedness relationship asymmetric. Roughly speaking, this *Relatedness* function $R(T, H)$ can be described as whether or how relevant H is to some part of T. The relevance can be realized as string similarity, semantic similarity, or being co-occurred in similar contexts.

Before we define the relatedness function formally, let us look at the representation again. After semantic parsing described in the previous section, we obtain a PAS for each sentence. On top of it, we define a *predicate-argument graph* (PAG), the nodes of which are predicates, arguments or sometimes both, and the edges of which are labeled semantic relations. Notice that each predicate can dominate zero, one, or more arguments, and each argument have one or more predicates which dominate it. Furthermore, the graph is not necessarily fully connected. Thus, the $R(T, H)$ function can be defined on the dependency representation as follows: if the PAG of H is semantically relevant to part of the PAG of T, H is semantically relevant to T.

In order to compare the two graphs, we further reduce the alignment complexity by breaking the graphs into sets of trees. Two types of decomposed trees are considered: one is to take each predicate as the root of a tree and arguments as child nodes, and the other is on the contrary, to take each argument as root and their governing predicates as child nodes. We name them as *Predicate Trees* (P-Trees) and *Argument Trees* (A-Trees) respectively. To obtain the P-Trees, we enumerate each predicate, find all the arguments which it directly dominates, and then construct a P-Tree. The algorithm to obtain A-Trees works in the similar way. Finally, we will have a set of P-Trees and a set of A-Trees for each PAG, both of which are simple trees with depth of one. Figure 1 shows an example of such procedures. Notice that we do not consider cross-sentential inference, instead, we simply take the union of tree sets from all the sentences. Figure 2 illustrates the PAG for both T and H after semantic parsing, and the resulting P-Trees and A-Trees after applying the decomposition algorithm.

Formally, we define the relatedness function for a T-H pair as the maximum value of the relatedness scores of all pairs of trees in T and H (P-trees and A-trees).

[4] http://tadm.sourceforge.net/

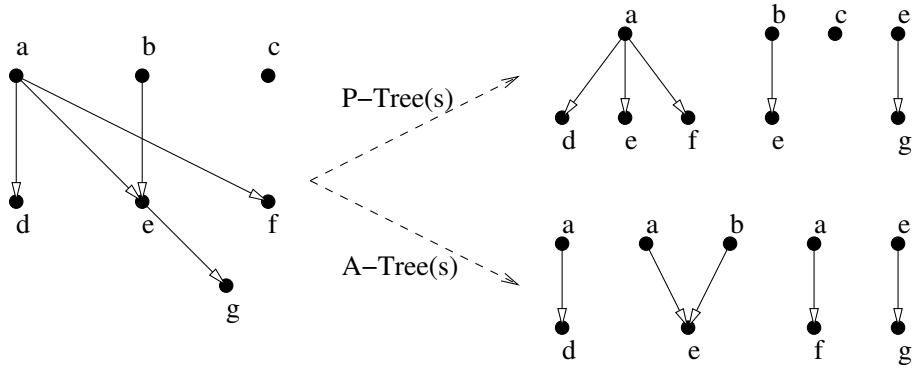

Figure 1: Decomposition of predicate-argument graphs (left) into P-Trees (right top) and A-Trees (right bottom)

$$R(T,H) = \max_{1\le i\le r, 1\le j\le s} \left\{ R(Tree_{T_i}, Tree_{H_j}) \right\}$$

In order to compare two P-Trees or A-Trees, we further define each predicate-argument pair contained in a tree as a semantic dependency triple. Each semantic dependency triple contains a predicate, an argument, and the semantic dependency label in between, in the form of $\langle Predicate, Dependency, Argument \rangle$. Then we define the relatedness function between two trees as the minimum value of the relatedness scores of all the triple pairs from the two trees.

$$R(Tree_T, Tree_H) = \min_{1\le i\le n, 1\le j\le m} \left\{ R(\langle P_T, D_{T_i}, A_{T_i}\rangle, \langle P_H, D_{H_j}, A_{H_j}\rangle) \right\}$$

For the relatedness function between two semantic dependency triples, we define the following two settings: the FULL match and the NOT-FULL match. Either match requires that the predicates are related at the first place. The former means both the dependencies and the arguments are related; while the latter only requires the dependencies to be related.

$$R(\langle P_T, D_T, A_T\rangle, \langle P_H, D_H, A_H\rangle) = \begin{cases} \text{Full} & R(P_T,P_H)=R(D_T,D_H)=R(A_T,A_H)=1 \\ \text{NotFull} & R(P_T,P_H)=R(D_T,D_H)=1 \\ \text{Other} & \text{Otherwise} \end{cases}$$

Now, the only missing components in our definition is the relatedness functions between predicates, arguments, and semantic dependencies. Fortunately, many people have done research on semantic relatedness in lexical semantics that we could use. Therefore, these functions can be realized by different string matching algorithms and/or lexical resources. Since the meaning of relevance is rather wide, apart from the string matching of the lemmas, we also incorporate various resources, from distributionally collected ones to hand-crafted ontologies. We choose VerbOcean (Chklovski and Pantel, 2004) to obtain the relatedness between predicates (after using WordNet (Fellbaum, 1998) to change all the nominal predicates into verbs) and use WordNet for the argument alignment. For the verb relations in VerbOcean, we consider all of them as related; and for WordNet, we not only use the synonyms, hyponyms, and hypernyms, but antonyms as well. Consequently, we simplify these basic relatedness functions into a binary decision. If the corresponding strings are matched or the relations mentioned above exist, the two predicates, arguments, or dependencies are related; otherwise, not.

In addition, the Normalized Google Distance (NGD) (Cilibrasi and Vitanyi, 2007) is applied to both cases[5]. As for the comparison between dependencies, we simply apply the string matching, except for modifier labels, which we treat them as the same[6]. In all, the main idea here is to incorporate both distributional semantics and ontological semantics in order to see whether their contributions are overlapping or complementary. In practice, we use empirical value 0.5 as the threshold. Below the threshold means they are related, oth-

[5]You may find the NGD values of all the content word pairs in RTE-3 and RTE-4 datasets at `http://www.coli.uni-sb.de/~rwang/resources/RTE3_RTE4_NGD.txt`.

[6]This is mainly because it is more difficult for the SRL system to differentiate modifier labels than the complements.

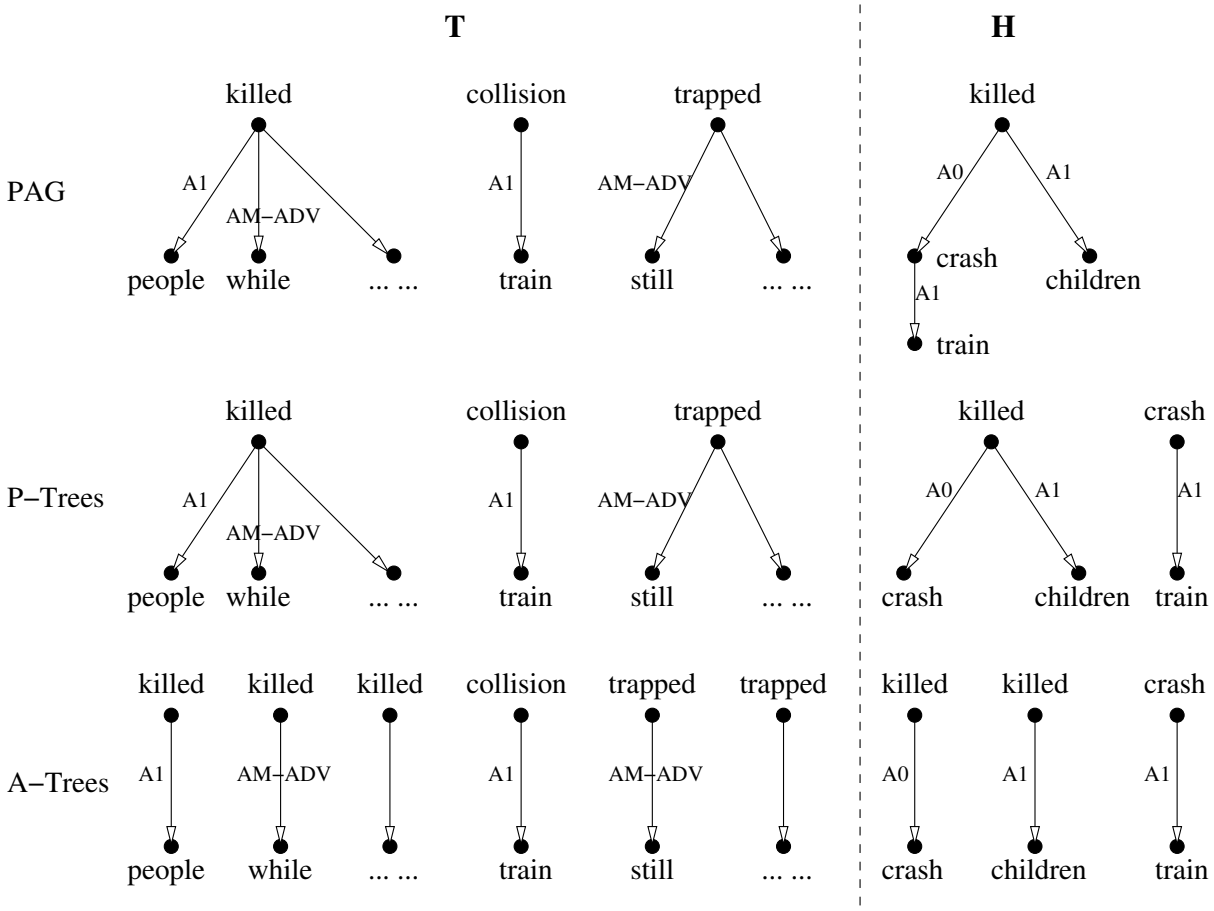

Figure 2: Predicate-argument graphs and corresponding P-Trees and A-trees of the T-H pair

erwise not. In order to achieve a better coverage, we use the OR operator to connect all the relatedness functions above, which means, if any of them holds, the two items are related.

Notice that, although we define only the relatedness between T and H, in principle, the graph representation can also be used for the entailment relationship. However, since it needs more fine-grained analysis and resources, we will leave it as the future work.

5 Experiments

In order to evaluate our method, we setup several experiments. The baseline system here is a simple Naive Bayes classifier with a feature set containing the Bag-of-Words (BoW) overlapping ratio between T and H, and also the syntactic dependency overlapping ratio. The feature model combines two baseline systems proposed by previous work, which gives out quite competitive performance. Since the main goal of this paper is to show the impact of the PAS-based alignment module, we will not compare our results with other RTE systems (In fact, the baseline system already outperforms the average accuracy score of the RTE-4 challenge).

The main data set used for testing here is the RTE-4 data set with three-way annotations (500 entailment T-H pairs (E), 150 contradiction pairs (C), and 350 unknown pairs (U)). The results on RTE-3 data set (combination of the development set and test set, in all, 822 E pairs, 161 C pairs, and 617 U pairs) is also shown, although the original annotation is two-way and the three-way annotation was done by different researchers after the challenge[7].

We will first show the performance of the baseline systems, followed by the results of our PAS-based alignment module and its impact on the whole task. After that, we will also give more detailed analysis of our alignment module, according to different lexical relatedness measurements.

[7]The annotation of the development set was done by students at Stanford, and the annotation of the test set was done as double annotation by NIST assessors, followed by adjudication of disagreements. Answers were kept consistent with the two-way decisions in the main task gold answer file.

5.1 Baselines

The baseline systems used here are based on overlapping ratio of words and syntactic dependencies between T and H. For the word overlapping ratio, we calculate the number of overlapping tokens between T and H and normalize it by dividing it by the number of tokens in H. The syntactic dependency overlapping ratio works similarly: we calculate the number of overlapping syntactic dependencies and divide it by the number of syntactic dependencies in H, i.e. the same as the number of tokens. Enlightened by the relatedness function, we also allow either FULL match (meaning both the dependencies and the parent tokens are matched), and NOTFULL match (meaning only the dependencies are matched). Here we only use string match between lemmas and syntactic dependencies. Table 1 presents the performance of the baseline system.

The results show that, even with the same classifier and the same feature model, with a proper two-stage strategy, it can already achieve better results than the three-way classification. Note that, the first strategy is not so successful, and that is the traditional two-way annotation of the RTE task. Our explanation here is that the BoW method (even with syntactic dependency features) is based on overlapping information shared by T and H, which essentially means the more information they share, the more relevant they are, instead of being more similar or the same. Therefore, for the "$ECU \rightarrow E/CU$" setting, methods based on overlapping information are not the best choice, while for "$ECU \rightarrow U/EC$", they are more appropriate.

In addition, the upper bound numbers show the accuracy when the first-stage classification is perfect, which give us an indication of how far we could go. The lower upper bound for the second strategy is mainly due to the low proportion of the C cases (15%) in the data set; while the other two both show large space for improvement.

5.2 The PAS-based Alignment Module

In this subsection, we present a separate evaluation of our PAS-based alignment module. As we mentioned before (cf. Section 4), there are several parameters to be tuned in our alignment algorithm: a) whether the relatedness function between P-Trees asks for the FULL match; b) whether the function for A-Trees asks for the FULL match; and c) whether both P-Trees and A-Trees being related are required or either of them holds is enough. Since they are all binary values, we use the 3-digit code to represent each setting, e.g. [FFO][8] means *either* P-Trees are FULL matched *or* A-Trees are FULL matched. The performances of different settings of the module are shown in the following Precision-Recall figure 3,

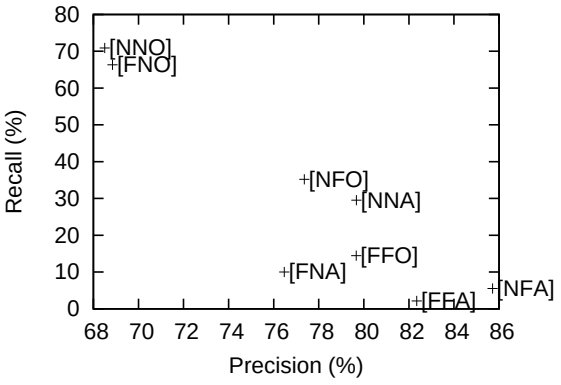

Figure 3: Precision and recall of different alignment settings

Since we will combine this module with the baseline system and it will be integrated as the first-stage classification, the F1 scores are not indicative for selecting the best setting. Intuitively, we may prefer higher precision than recall.

One limitation of our method we need to point out here is that, if some important predicates or arguments in H are not (correctly) identified by the SRL system, fewer P-Trees and A-Trees are required to be related to some part of T, thus, the relatedness of the whole pair could easily be satisfied, leading to false positive cases.

5.3 Impact on the Final Results

The best settings for RTE-3 data set is [NNA] and for RTE-4 data set is [NFO], which are both in the middle of the setting range shown in the previous figure 3.

As for the integration of the PAS-based alignment model with our BoW-based baseline, we only consider the third two-stage classification strategy in Table 1. Other strategies would also be interesting to try, however, the proposed alignment algorithm exploits relatedness between T and H, which might not be fine-grained enough to detect

[8] F stands for FULL, and O stands for OR. Other letters are, N stands for NOTFULL, and A stands for AND.

Strategies	Three-Way	Two-Stage		
	$E/C/U$	$E/CU \rightarrow E/C/U$	$C/EU \rightarrow C/E/U$	$U/EC \rightarrow U/E/C$
Accuray	53.20%	50.00%	53.50%	54.20%
Upper Bound	/	82.80%	68.70%	84.90%

Table 1: Performances of the Baselines

entailment or contradiction. New alignment algorithm has to be designed to explore other strategies. Thus, in this work, we believe that the alignment algorithm based on PAS (and other methods based on overlapping information between T and H) is suitable for the $U/EC \rightarrow U/E/C$ classification strategy.

Table 2 shows the final results.

The first observation is that the improvement of accuracy on the first stage of the classification can be preserved to the final results. And our PAS-based alignment module can help, though there is still large space for improvement. Compared with the significantly improved results on RTE-4, the improvement on RTE-3 is less obvious, mainly due to the relatively lower precision (70.33% vs. 79.67%) of the alignment module itself.

Also, we have to say that the improvement is not as big as we expected. There are several reasons for this. Besides the limitation of our approach mentioned in the previous section, the predicates and arguments themselves might be too sparse to convey all the information we need for the entailment detection. In addition, in some sense, the baseline is quite strong for this comparison, since the PAS-based alignment module relies on the overlapping words at the first place, there are quite a few pairs solved by both the main approach and the baseline. Then, it would be interesting to take a closer look at the lexical resources used in the main system, which is another additional knowledge it has, comparing with the baseline.

5.4 Impact of the Lexical Resources

We did an ablation test of the lexical resources used in our alignment module. Recall that we have applied three lexical resources, VerbOcean for the predicate relatedness function, WordNet for the argument relatedness function, and Normalized Google Distance for both. Table 3 shows the performances of the system without each of the resources,

The results clearly show that each lexical resource does contribute some improvement to the final performance of the system and it confirms the idea of combining lexical resources being acquired in different ways. For instance, at the beginning, we expected that the relationship between "*people*" and "*children*" could be captured by WordNet, but in fact not. Fortunately, the NGD has a quite low value of this pair of words (0.21), which suggests that they occur together quite often, or in other words, they are relevant.

One interesting future work on this aspect is to substitute the OR connector between these lexical resources with an AND operator. Thus, instead of using them to achieve a higher coverage, whether they could be filters for each other to increase the precision will also be interesting to know.

6 Conclusion and Future Work

In this paper, we address the motivation and issues of casting the three-way RTE problem into a two-stage binary classification task. We apply an SRL system to derive the predicate-argument structure of the input sentences, and propose ways of calculating semantic relatedness between the shallow semantic structures of T and H. The experiments show improvements in the first-stage classification, which accordingly contribute to the final results of the RTE task.

For future work, we would like to see whether the PAS can help the second-stage classification as well, e.g. the semantic dependency of negation (AM-NEG) could be helpful for the contraction recognition. Furthermore, since the PAS is usually a bag of unconnected graphs, we could find a way to joint them together, in order to consider both inter- and intra- sentential inferences based on it.

In addition, this approach has the potential to be integrated with other RTE modules. For instance, for the predicate alignment, we may consider to use DIRT rules (Lin and Pantel, 2001) or other paraphrase resources (Callison-Burch, 2008), and for the argument alignment, external named-entity recognizer and anaphora resolver would be very helpful. Even more, we also plan to compare/combine it with other methods which are not based on overlapping information between T and H.

Systems	Baseline1	Baseline2	SRL+Baseline2	The First Stage		
Data Sets	Three-Way	Two-Stage	Two-Stage	Baseline2	SRL+Baseline2	SRL
RTE-3 [NNA]	52.19%	52.50%	53.69%(2.87%↑)	59.50%	60.56%(1.78%↑)	70.33%
RTE-4 [NFO]	53.20%	54.20%	56.60%(6.39%↑)	67.10%	70.20%(4.62%↑)	79.67%

Table 2: Results on the Whole Datasets

Data Sets	SRL+Baseline	SRL+Baseline - VO	SRL+Baseline - NGD	SRL+Baseline - WN
RTE-3 [NNA]	53.69%	53.19%(0.93%↓)	53.50%(0.35%↓)	52.88%(1.51%↓)
RTE-4 [NFO]	56.60%	56.00%(1.06%↓)	56.10%(0.88%↓)	55.70%(1.59%↓)

Learning Term-weighting Functions for Similarity Measures

Wen-tau Yih
Microsoft Research
Redmond, WA, USA
scottyih@microsoft.com

Abstract

Measuring the similarity between two texts is a fundamental problem in many NLP and IR applications. Among the existing approaches, the cosine measure of the term vectors representing the original texts has been widely used, where the score of each term is often determined by a TFIDF formula. Despite its simplicity, the quality of such cosine similarity measure is usually domain dependent and decided by the choice of the term-weighting function. In this paper, we propose a novel framework that learns the term-weighting function. Given the labeled pairs of texts as training data, the learning procedure tunes the model parameters by minimizing the specified loss function of the similarity score. Compared to traditional TFIDF term-weighting schemes, our approach shows a significant improvement on tasks such as judging the quality of query suggestions and filtering irrelevant ads for online advertising.

1 Introduction

Measuring the semantic similarity between two texts is an important problem that has many useful applications in both NLP and IR communities. For example, Lin (1998) defined a similarity measure for automatic thesaurus creation from a corpus. Mihalcea et al. (2006) developed several corpus-based and knowledge-based word similarity measures and applied them to a paraphrase recognition task. In the domain of web search, different methods of measuring similarity between short text segments have recently been proposed for solving problems like query suggestion and alternation (Jones et al., 2006; Sahami and Heilman, 2006; Metzler et al., 2007; Yih and Meek, 2007).

Among these similarity measures proposed in various applications, the vector-based methods are arguably the most widely used. In this approach, the text being compared with is first represented by a term vector, where each term is associated with a weight that indicates its importance. The similarity function could be cosine (i.e., the inner product of two normalized unit term vectors, or equivalently a linear kernel), or other kernel functions such as the Gaussian kernel.

There are essentially two main factors that decide the quality of a vector-based similarity measure. One is the *vector operation* that takes as input the term vectors and computes the final similarity score (e.g., cosine). The other is how these term vectors are constructed, including the term selection process and how the weights are determined. For instance, a TFIDF scheme for measuring document similarity may follow the bag-of-words strategy to include all the words in the document when constructing the term vectors. The weight of each term is simply the product of its term frequency (i.e., the number of occurrences in the document) and inverse document frequency (i.e., the number of documents in a collection that contain this term).

Despite its simplicity and reasonable performance, such approach suffers from several weaknesses. For instance, the similarity measure is not domain-dependent and cannot be easily adjusted to better fit the final objective, such as being a metric value used for clustering or providing better ranking results. Researchers often need to experiment with variants of TFIDF formulas and different term selection strategies (e.g., removing stopwords or stemming) to achieve acceptable performance (Manning et al., 2008). In addition, when more information is available, such as the position of a term in the document or whether a term is part of an anchor text, incorporating it in the similarity measure in a principled manner may not be easy.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 793–802,
Singapore, 6-7 August 2009.

In this paper, we propose a general ***t***erm-***w***eighting l***ea***rning framewor***k***, TWEAK, that learns the term-weighting function for the vector-based similarity measures. Instead of using a fixed formula to decide the weight of each term, TWEAK uses a parametric function of features of each term, where the model parameters are learned from labeled data. Although the weight of each term conceptually represents its importance with respect to the document, tuning the model parameters to optimize for such objectives may not be the best strategy due to two reasons. While the label of whether a pair of texts is similar is not difficult to collect from human annotators[1], the label of whether a term in a document is important is often very ambiguous and hard to decide. Even if such annotation issue can be resolved, aligning the term weights with the *true* importance of each term may not necessarily lead to our real objective – deriving a better similarity measure for the target application. Therefore, our learning framework, TWEAK, assumes that we are given only the labels of the pairs of texts being compared, such as whether the two texts are considered similar by human subjects.

TWEAK is flexible in choosing various loss functions that are close to the true objectives, while still maintaining the simplicity of the vector-based similarity measures. For example, a system that implements the TFIDF cosine measure can easily replace the original term-weighting scores with the ones output by TWEAK without changing other portions of the algorithm. TWEAK is also novel compared to other existing learning methods for similarity measures. For instance, we do not learn the scores of all the terms in the vocabulary directly, which is one of the methods proposed by Bilenko and Mooney (2003). Because the vocabulary size is typically large in the text domain (e.g., all possible words in English), learning directly the term-weighting scores may suffer from the data sparsity issue and cannot generalize well in practice. Instead, we focus on learning the model parameters for features that each term may have, which results in a much smaller feature space. TWEAK also differs from the model combination approach proposed by Yih and Meek (2007), where the output scores of different similarity measures are combined via a learned linear function. In contrast, TWEAK effectively learns a new similarity measure by tuning the term-weighting function and can potentially be complementary to the model combination approach.

As will be demonstrated in our experiments, in applications such as judging the relevance of different query suggestions and determining whether a paid-search ad is related to the user query, TWEAK can incorporate various kinds of term–document information and learn a term-weighting function that significantly outperforms the traditional TFIDF scheme in several evaluation metrics, when using the same vector operation (i.e., cosine) and the same set of terms.

We organize the rest of the paper as follows. Sec. 2 first gives a high-level view of our term-weighting learning framework. We then formally define our model and present the loss functions that can be optimized for in Sec. 3. Experiments on target applications are presented in Sec. 4. Finally, we compare our approach with some related work in Sec. 5 and conclude the paper in Sec. 6.

2 Problem Statement

To simplify the description, assume that the texts we are comparing are two documents. A general architecture of vector-based similarity measures can be formally described as follows. Given two documents D_p and D_q, a similarity function maps them to a real-valued number, where a higher value indicates these two documents are semantically more related, considered by the measure.

Suppose a pre-defined vocabulary set $\mathcal{V} = \{t_1, t_2, \cdots, t_n\}$ consists of all possible terms (e.g., tokens, words) that may occur in the documents. Each document D_p is represented by a term vector of length n: $\mathbf{v}_p = (s_p^1, s_p^2, \cdots, s_p^n)$, where $s_p^i \in \mathbf{R}$ is the weight of term t_i, and is determined by the term-weighting function tw that depends on the term and the document (i.e., $s_p^i \equiv tw(t_i, D_p)$). The similarity between documents D_p and D_q is then computed by a vector operation function $f_{sim} : (\mathbf{v}_p, \mathbf{v}_q) \rightarrow \mathbf{R}$, illustrated in Fig. 1.

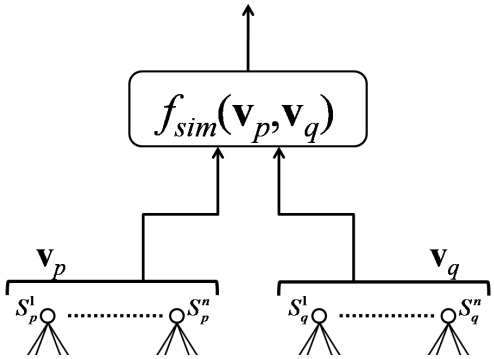
Determining the specific functions f_{sim} and tw effectively decides the final similarity measure. For example, the functions that construct the traditional TFIDF cosine similarity can be:

$$f_{sim}(\mathbf{v}_p, \mathbf{v}_q) \equiv \frac{\mathbf{v}_p \cdot \mathbf{v}_q}{||\mathbf{v}_p|| \cdot ||\mathbf{v}_q||} \quad (1)$$

$$tw(t_i, D_p) \equiv tf(t_i, D_p) \cdot \log\left(\frac{N}{df(t_i)}\right) \quad (2)$$

[1] As argued in (Sheng et al., 2008), low-cost labels may nowadays be provided by outsourcing systems such as Amazon's Mechanical Turk or online ESP games.

Figure 1: A general architecture of vector-based similarity measures



where N is the size of the document collection for deriving document frequencies, tf and df are the functions computing the term frequency and document frequency, respectively.

In contrast, TWEAK also takes a specified vector function f_{sim} but assumes a parametric term-weighting function $tw_{\mathbf{w}}$. Given the training data, it learns the model parameters $\mathbf{w}$ that optimize for the designated loss function.

3 Model

As a specific instantiation of our learning framework, the term-weighting function used in this paper is a linear combination of features extracted from the input term and document. In particular, the weight of term t_i with respect to document D_p is

$$s_p^i = tw_{\mathbf{w}}(t_i, D_p) \equiv \sum_j w_j \phi_j(t_i, D_p), \qquad (3)$$

where ϕ_j is the j-th feature function and w_j is the corresponding model parameter.

As for the vector operation function f_{sim}, we use the same cosine function (Eq. 1). Notice that we choose these functional forms for their simplicity and good empirical performance shown in preliminary experiments. However, other smooth functions can certainly be used.

The choice of loss function for training model parameters depends on the true objective in the target application. In this work, we consider two different learning settings: learning directly the *similarity metric* and learning the *preference ordering*, and compare several loss functions experimentally.

3.1 Learning Similarity Metric

In this setting, we assume that the learning algorithm is given a set of document pairs. Each of them is associated with a label that indicates whether these two documents are similar (e.g., a binary label where 1 means similar and 0 otherwise) or the degree of similarity (e.g., a real-valued label ranges from 0 to 1), considered by the human subjects. A training set of m examples can be denoted as $\{(y_1, (D_{p_1}, D_{q_1})), (y_2, (D_{p_2}, D_{q_2})), \cdots, (y_m, (D_{p_m}, D_{q_m}))\}$, where y_k is the label and (D_{p_k}, D_{q_k}) is the pair of documents to compare. Following the vector construction described in Eq. 3, let $\mathbf{v}_{p_1}, \mathbf{v}_{q_1}, \cdots, \mathbf{v}_{p_m}, \mathbf{v}_{q_m}$ be the corresponding term vectors of these documents.

We consider two commonly used loss functions, *sum-of-squares error* and *log loss*[2]:

$$L_{sse}(\mathbf{w}) = \frac{1}{2}\sum_k^m (y_k - f_{sim}(\mathbf{v}_{p_k}, \mathbf{v}_{q_k}))^2 \qquad (4)$$

$$L_{log}(\mathbf{w}) = \sum_k^m -y_k \log(f_{sim}(\mathbf{v}_{p_k}, \mathbf{v}_{q_k})) - (1 - y_k)\log(1 - f_{sim}(\mathbf{v}_{p_k}, \mathbf{v}_{q_k})) \qquad (5)$$

Eq. 4 and Eq. 5 can further be regularized by adding $\frac{\alpha}{2}||\mathbf{w}||^2$ in the loss function, which may improve the performance empirically and also constrain the range of the final term-weighting scores. Learning the model parameters for minimizing these loss functions can be done using standard gradient-based optimization methods. We choose the L-BFGS (Nocedal and Wright, 2006) method in our experiments for its guarantee to find a local minimum and fast convergence. The derivation of gradients is fairly straightforward, which we skip here.

Notice that other loss functions can also be used in this framework. Interested readers can refer to, say, (Bishop, 1995), for other loss functions and their theoretical justifications.

3.2 Learning Preference Ordering

In many applications where the similarity measure is applied, the goal is to obtain a *ranked* list of the candidate elements. For example, in the task of

[2] Although in theory the cosine function may return a negative value and make the log-loss uncomputable, this can be easily avoided in practice by selecting appropriate initial model parameters and by constraining the term-weighting scores to be non-negative.

filtering irrelevant ads, a good similarity measure is expected to rank appropriate ads higher than the irrelevant ones. A desired trade-off of false-positive (mistakenly filtered good ads) and false-negative (unfiltered bad ads) can be achieved by selecting a decision threshold. The exact value of the similarity measure, in this case, is not crucial. For these applications, it is more important if the model parameters can better predict the *pair-wise preference*. Learning preference ordering is also motivated by the observation that preference annotations are generally more reliable than categorical similarity labels (Carterette et al., 2008) and has been advocated recently by researchers (e.g., Burges et al. (2005)).

In the setting of learning preference ordering, we assume that each training example consists of *two* pairs of documents, associated with a label indicating which pair of documents is considered more preferable. A training set of m examples can be formally denoted as $\{(y_1, (x_{a_1}, x_{b_1})), (y_2, (x_{a_2}, x_{b_2})), \cdots, (y_m, (x_{a_m}, x_{b_m}))\}$, where $x_{a_k} = (D_{p_{a_k}}, D_{q_{a_k}})$ and $x_{b_k} = (D_{p_{b_k}}, D_{q_{b_k}})$ are two pairs of documents and $y_k \in \{0, 1\}$ indicates the pairwise order preference, where 1 means x_{a_k} should be ranked higher than x_{b_k} and 0 otherwise.

We use a loss function that is very similar to the one proposed by Dekel et al. (2004) for label ranking. Let Δ_k be the difference of the similarity scores of these two document pairs. Namely,

$$\Delta_k = f_{sim}(\mathbf{v}_{p_{a_k}}, \mathbf{v}_{q_{a_k}}) - f_{sim}(\mathbf{v}_{p_{b_k}}, \mathbf{v}_{q_{b_k}})$$

The loss function L, which can be shown to upper bound the pairwise accuracy (i.e., the 0-1 loss of the pairwise predictions), is:

$$L(\mathbf{w}) = \sum_{k=1}^{m} \log(1+\exp(-y_k \cdot \Delta_k - (1-y_k) \cdot (-\Delta_k))) \quad (6)$$

Similarly, Eq. 6 can be regularized by adding $\frac{\alpha}{2}||\mathbf{w}||^2$ in the loss function.

4 Experiments

We demonstrate how to apply our term-weighting learning framework, TWEAK, to measuring similarity for short text segments and to judging the relevance of an ad landing page given an query. In addition, we compare experimentally the performance of using different training settings, loss functions and features against the traditional TFIDF term-weighting scheme.

4.1 Similarity for Short Text Segments

Judging the similarity between two short text segments is a crucial problem for many search and online advertising applications. For instance, *query reformulation* or *query substitution* needs to measure the similarity between two queries. A product keyword recommendation system needs to determine whether the given product name and the suggested keyword is related.

Because the length of the text segment is typically short, ranging from a single word to a dozen words, naively applying methods based on word overlapping such as the Jaccard coefficient leads to poor results (Sahami and Heilman, 2006; Yih and Meek, 2007). To overcome this difficulty, Sahami and Heilman (2006) proposes a Web-kernel function, which first expands the short text segment by issuing it to a search engine as the query, and then collectes the snippets of the top results to construct a pseudo-document. TFIDF term vectors of the pseudo-documents are used to represent the original short text segments and the cosine score of these two vectors is used as the similarity measure.

In this section, we apply TWEAK to this problem by replacing the TFIDF term-weighting scheme with the learned term-weighting function, when constructing the vectors from the pseudo-documents. Our target application is *query suggestion* – automatically presenting queries that are related to the one issued by the user. In particular, we would like to use our similarity measure as a filter to determine whether queries suggested by various algorithms and heuristics are indeed closely related to the target query.

4.1.1 Task & Data

Our query suggestion dataset has been previously used in (Metzler et al., 2007; Yih and Meek, 2007) and is collected in the following way. From the search logs of a commercial search engine, a random sample of 363 thousand queries from the top 1 million most frequent queries in late 2005 were first taken as the query and suggestion candidates. Among them, 122 queries were chosen randomly as our target queries; each of them had up to 100 queries used as suggestions, generated by various query suggestion mechanisms.

Given these pairs of query and suggestions, human annotators judged the level of similarity using a 4-point scale – *Excellent*, *Good*, *Fair* and *Bad*,

where Excellent and Good suggestions are considered clearly related to the query intent, while the other two categories mean the suggestions are either too general or totally unrelated. In the end, 4,852 query/suggestion pairs that had effective annotations were collected. The distribution of the four labels is: Excellent - 5%, Good - 12%, Fair - 44% and Bad - 39%.

For the simplicity of both presentation and implementation, query/suggestion pairs labeled as Excellent or Good are treated as positive examples and the rest as negative ones. Notice that TWEAK is not restricted in using only binary labels. For instance, the pairwise preference learning setting only needs to know which pair of objects being compared is more preferred. The model and algorithm do not have to change regardless of whether the label reflects the degree of similarity (e.g, the original 4-scale labels) or binary categories. For the metric learning setting, an ordinal regression approach (e.g, (Herbrich et al., 2000)) can be applied for multi-category labels.

We used the same query expansion method as described in (Sahami and Heilman, 2006). Each query/suggestion was first issued to a commercial search engine. The result page with up to 200 snippets (i.e., titles and summaries) was used as the pseudo-document to create the term vector that represents the original query/suggestion. As described earlier in Eq. 3, the weight of each term is a linear function of a set of predefined features, which are described next.

4.1.2 Features

Because the pseudo-documents are constructed using the search result snippets instead of regular web documents, special formatting or link information provided by HTML is not very meaningful. Therefore, we focused on using features that are available for plain-text documents, including:

- **Bias**: 1 for all examples.
- **TF**: We used $\log(tf + 1)$ as the *term frequency* feature, where tf is the number of times the term occurs in the original pseudo-document.
- **DF**: We used $\log(df + 1)$ as the *document frequency* feature, where df is the number of documents in our collection that contain this term.
- **QF**: The search engine query log reflects the distribution of the words/phrases in which people are interested (Goodman and Carvalho, 2005; Yih et al., 2006). We took a log file with the most frequent 7.5 million queries and used $\log(qf + 1)$ as feature, where qf is the query frequency.
- **Cap**: A capitalized word may indicate being part of a proper noun or being more important. When the term is capitalized in at least one occurrence in the pseudo-document, the value of this feature is 1; otherwise, it is 0.
- **Loc & Len**: The beginning of a regular document often contains a summary with important words. In the pseudo-documents created using search snippets, words that occur in the beginning come from the top results, which are potentially more relevant to the original query/suggestion. We created two specific features using this location information. Let loc be the word position of the target term and len be the total number of words of this pseudo-document. The logarithmic value $\log(loc + 1)$ and the ratio loc/len were both used as features. In order for the learning procedure to adjust the scaling, the logarithmic value of the document length, $\log(len + 1)$, was also used.

4.1.3 Results

We conducted the experiments using 10-fold cross-validation. The whole query/suggestion pairs were first split into 10 subsets of roughly equal sizes. Pairs with the same target query were put in the same subset. In each round, one subset was used for testing. 95% of the remaining data was used for training the model and 5% was used as the development set. We trained six models with different values of the regularization hyperparameter $\alpha \in \{0.003, 0.01, 0.03, 0.1, 0.3, 1\}$ and determined which model to use based on its performance on the development set, although the result actually did not vary a lot as α changed.

We compared three learning configurations – metric learning with sum-of-squares error (Metric$_{sse}$) and log loss (Metric$_{log}$) and the pairwise preference learning (Preference). The learned term-weighting functions were used to compare with the Web-kernel similarity function, which implemented the TFIDF term-weighting scheme using Eq. 2.

Table 1: The AUC scores, mean averaged precision and precision at 3 of similarity measures using different term-weighting functions. The numbers with the † sign are statistically significantly better compared to the Web-kernel method.

Method	AUC	MAP	Prec@3
Web-kernel	0.732	0.540	0.556
Metric$_{sse}$	0.775†	0.590	0.553
Metric$_{log}$	0.781†	0.585	0.545
Preference	**0.782**†	**0.597**†	**0.570**

We evaluated these models using three different evaluation metrics: the AUC score, precision at k and MAP (mean averaged precision). The area under the ROC curve (AUC) is typically used to judge the overall quality of a ranking function. It has been shown equivalent to the averaged accuracy of the pairwise preference predictions of all possible element pairs in the sequence, and can be calculated by the the following Wilcoxon-Mann-Whitney statistic (Cortes and Mohri, 2004):

$$A(f;\mathbf{x},\mathbf{y}) = \sum_{i,j:y_i>y_j} \mathbf{I}_{f(x_i)>f(x_j)} + \frac{1}{2}\mathbf{I}_{f(x_i)=f(x_j)},$$

where f is the similarity measure, $\mathbf{x}$ is the sequence of compared elements and $\mathbf{y}$ is the labels.

Another metric that is commonly used in a ranking scenario is *precision at* k, which computes the accuracy of the top-ranked k elements and ignores the rest. We used $k = 3$ in our task, which means that for each target query, we selected three suggestions with the highest similarity scores and computed the averaged accuracy.

One issue of precision at k is that it does not provide an overall quality measure of the ranking function. Therefore, we also present MAP (mean averaged precision), which is a single number that summarizes the performance of the ranking function by considering both precision and recall, and has been shown reliable in evaluating various information retrieval tasks (Manning et al., 2008). Suppose there are m relevant elements in a sequence, where $r_1, r_2, \cdots, r_m$ are their locations. The averaged precision is then:

$$AP = \frac{1}{m}\sum_{j=1}^{m} \mathrm{Prec}(r_j),$$

where $\mathrm{Prec}(r_j)$ is the precision at r_j. We computed the averaged precision values of the 10 test sets in our cross-validation setting and report their mean value.

As shown in Table 1, all three learned term-weighting functions lead to better similarity measures compared to the TFIDF scheme in terms of the AUC and MAP scores, where the preference order learning setting performs the best. However, for the precision at 3 metric, only the preference learning setting has a higher score than the TFIDF scheme, but the difference is not statistically significant[3]. This is somewhat understandable since the design of our loss function focuses on the overall quality instead of only the performance of the top ranked elements.

4.2 Query/Page Similarity

Measuring whether a page is relevant to a given query is the main problem in information retrieval and has been studied extensively. Instead of retrieving web pages that are relevant to the query according to the similarity measure, our goal is to implement a paid-search ad filter for commercial search engines. In this scenario, textual ads with bid keywords that match the query can enter the auction and have a chance to be shown on the search result page. However, as the advertisers may bid on keywords that are not related to their advertisements, it is important for the system to filter irrelevant ads to ensure that users only receive useful information. For this purpose, we measure the similarity between the query and the ad landing page (i.e., the page pointed by the ad) and remove the ad when the score of its landing page is below a pre-selected threshold[4].

Given a pair of query and ad landing page, while the *query* term vector is constructed using the same query expansion technique described in Sec. 4.1, the *page* term vector can be created directly from the web page since it is a regular document that contains enough content. As usual, our goal is to produce a better similarity measure by learning the term-weighting functions for these two types of vectors jointly.

[3]We conducted a paired-t test on the 10 individual scores from the cross-validation results of each learned term-weighting function versus the Web-kernel method. The results are considered statistically significant when the p-value is lower than 0.05.

[4]One may argue that the filter should measure the similarity between the query and ad-text. However, an ad will not provide useful information to the user if the final destination page is not relevant to the query, even if its ad-text looks appealing.

4.2.1 Data

We first collected a random sample of queries and paid-search ads shown on a commercial search engine during 2008, as well as the ad landing pages. Judged by several human annotators, each page was labeled as relevant or not compared to the issued query. After removing some pairs where the query intent was not clear or the landing page was no longer available, we managed to collect 13,341 query/page pairs with reliable labels. Among them, 8,309 were considered relevant and 5,032 were labeled irrelevant.

4.2.2 Features

In this experiment, we tested the effect of using different features and experimented with three feature sets: *TF&DF*, *Plain-text* and *HTML*. *TF&DF* contains only $\log(tf+1)$, $\log(df+1)$ and the bias feature. The goal of using this feature set is to test whether we can learn a better term-weighting function given the *same* amount of information as the TFIDF scheme has. The second feature set, *Plain-text*, consists of all the features described in Sec. 4.1.2. As mentioned earlier, this set of features can be used for regular text documents that do not have special formatting information. Finally, feature set *HTML* is composed of all the features used in *Plain-text* plus features extracted from some special properties of web documents, including:

- **Hypertext**: The anchor text in an HTML document usually provides important information. If there is at least one occurrence of the term that appears in some anchor text, the value of this feature is 1; otherwise, it is 0.
- **URL**: A web document has a uniquely useful property – the name of the document, which is its URL. If the term is a substring of the URL, then the value of this feature is 1; otherwise, it is 0.
- **Title**: The value of this feature is 1 when the term is part of the title; otherwise, it is 0.
- **Meta**: Besides Title, several meta tags used in the HTML header explicitly show the important words selected by the page author. Specifically, whether the term is part of a meta-keyword is used as a binary feature. Whether the term is in the meta-description segment is also used.

Table 2: The AUC scores, true-positive rates at false-positive rates 0.1 and 0.2 of the ad filter based on different term-weighting functions. The difference between any pair of numbers of the same evaluation metric is statistically significant.

Method	AUC	$\text{TPR}_{\text{fnr}=0.1}$	$\text{TPR}_{\text{fnr}=0.2}$
TFIDF	0.794	0.527	0.658
TF&DF	0.806	0.430	0.639
Plain-text	0.832	0.503	0.704
HTML	**0.855**	**0.568**	**0.750**

Because the term vector that represents the query is created from the pseudo-document (i.e., a collection of search snippets), the values of these HTML-specific features are all 0 for the query term vector. This set of features are only useful for deciding the weights of the terms in a page term vector.

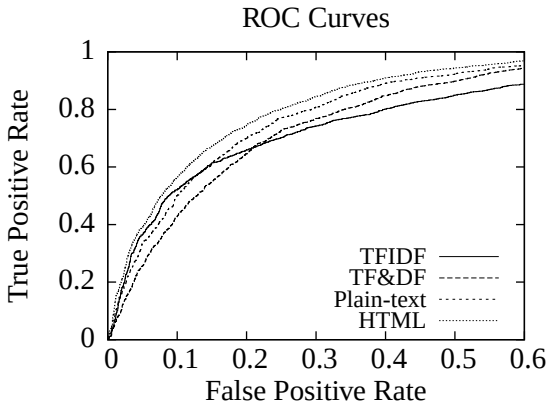
4.2.3 Results

We split our data into 10 subsets and conducted the experiments using the same 10-fold cross-validation setting described in Sec. 4.1.3, including how we used the development set to select the regularization hyper-parameter α. The pairs that have the same target query were again put in the same subsets. We used only the preference ordering learning setting for its good performance shown in the previous set of experiments. Models compared here were learned from the three different sets of features, as well as the same fixed TFIDF term-weighting formula (i.e., Eq. 2) used in Sec. 4.1. Table 2 reports the averaged results of the 10 testing sets in AUC, as well as the true-positive rates at two low false-positive rate points (FPR=0.1 and FPR=0.2). The difference between any pair of numbers of the same evaluation metric is statistically significant[5].

As we can see from the table, having more features does lead to a better term-weighting function. With all features (i.e., *HTML*), the model achieves the highest AUC score among all configurations. Features available in plain-text documents (i.e., *Plain-text*) other than term frequency and document frequency can still improve the performance significantly. When only the TF and DF features are available, the learned term-weighting function still outperforms the TFIDF scheme, al-

[5]We conduct paired-t tests as described in Sec. 4.1.3. All the p-values after Bonferroni correction are less than 0.01.

Figure 2: ROC Curves of the ad filters using different term-weighting functions



though the improvement gain is much smaller compared to the other two settings.

Notice that the behaviors of these models at different false-positive regions varies from the traditional TFIDF scheme. At a low false-positive point (e.g., FPR=10%), only the model that uses all features performs better than TFIDF. This phenomenon can be clearly observed from the ROC curves plotted in Fig. 2, where the models were trained using half of the data and applied to the other half to generate the similarity scores. If only the performance at a very low false-positive rate matters, TWEAK can still be easily adjusted by modifying the loss function using techniques such as training with utility (Domingos, 1999; Morik et al., 1999).

5 Related Work

Our term-weighting learning framework can be analogous to the "Siamese" architecture for learning jointly two neural networks that share the same set of model weights (Bromley et al., 1993). For instance, a term vector can be viewed as a very large single-layer neural network, where each term in the vocabulary is a node that takes as input the features and outputs the learned term-weighting score. Previous applications of this learning machine are typically problems in image processing or computer vision. For example, Chopra et al. (2005) designed an algorithm to learn a similarity metric for face verification, which is based on the difference between two vectors. In our earlier experiments (not reported in this paper) of using vector difference instead of cosine, we did not observe positive outcomes. We hypothesize that because the length of the term vector in our problem can be extremely large (i.e., the size of the vocabulary), a similarity measure based on vector difference can easily be affected by terms that do not occur in both documents, even when the co-occurred terms have very large weights.

Learning similarity measures for text has also been proposed by several researchers. For instance, Bilenko and Mooney (2003) applied SVMs to directly learn the weights of co-occurred words in two text records, which are then used for measuring similarity for duplicate detection. Although this approach worked moderately well in the database domain, it may not be suitable to handle general text similarity problems for two reasons. First, the vocabulary size is typically large, which results in a very high dimensional feature space for the learning problem. It is very likely that some rarely used and yet important terms occur in the testing documents but not in the training data. The weights of those terms may not be reliable or even be learned. Second, this learning approach can only learn the importance of the terms from the labels of whether two texts are considered similar, how to incorporate the basic information of these terms such as the position or query log frequency is not clear.

An alternative learning approach is to combine multiple similarity measures with learned coefficients (Yih and Meek, 2007), or to apply the technique of *kernel alignment* (Cristianini et al., 2002) to combining a set of kernel functions for tuning a more appropriate kernel based on labeled data. This type of approaches can be viewed as constructing an ensemble of different existing similarity measures without modifying the term weighting function, and may not generate mathematically equivalent similarity functions as derived by TWEAK. Although learning in this approach is usually very fast due to the model form and the small number of parameters to learn, its improvement is limited by the quality of the individual similarity measures. In spite of the fundamental difference between our approach and this combination method, it is worth noticing that these two approaches are in fact complementary to each other. Having a newly learned term-weighting function effectively provides a new similarity measure and therefore can be combined with other measures.

6 Conclusions

In this paper, we presented a novel term-weighting learning framework, TWEAK, for improving similarity measures based on term vectors. Given the labels of text pairs for training, our method learns the model parameters to calculate the score of each term, optimizing the desired loss function that is suitable for the target application. As we demonstrated in the experiments, TWEAK with different features and training settings significantly outperforms the traditional TFIDF term-weighting scheme.

TWEAK also enjoys several advantages compared to existing methods. From an engineering perspective, adopting the new term-weighting scores produced by our model is straightforward. If a similarity measure has been implemented, the algorithm need not be changed – only the term vectors need to be updated. From the learning perspective, additional information regarding each term with respect to the document can now be incorporated easily via feature functions. Weights (i.e., model parameters) of these features are learned in a principled way instead of being adjusted manually. Finally, TWEAK is potentially complementary to other methods for improving the similarity measure, such as model combination of various types of similarity measures (Yih and Meek, 2007) or different term vector construction methods such as Latent Semantic Analysis (Deerwester et al., 1990).

In the future, we plan to explore more vector operations other than the inner-product (i.e., cosine) as well as different functional forms of the term-weighting function (e.g. log-linear instead of linear). Designing new loss functions to better fit the true objectives in various target applications and studying the quality of a similarity measure based on both term-weighting learning and model combination are also on our agenda. In terms of applications, we would like to apply TWEAK in other problems such as paraphrase recognition and near-duplicate detection.

Abstract

Semantic similarity is a central concept that extends across numerous fields such as artificial intelligence, natural language processing, cognitive science and psychology. Accurate measurement of semantic similarity between words is essential for various tasks such as, document clustering, information retrieval, and synonym extraction. We propose a novel model of semantic similarity using the semantic relations that exist among words. Given two words, first, we represent the semantic relations that hold between those words using automatically extracted lexical pattern clusters. Next, the semantic similarity between the two words is computed using a Mahalanobis distance measure. We compare the proposed similarity measure against previously proposed semantic similarity measures on Miller-Charles benchmark dataset and WordSimilarity-353 collection. The proposed method outperforms all existing web-based semantic similarity measures, achieving a Pearson correlation coefficient of 0.867 on the Millet-Charles dataset.

1 Introduction

Similarity is a fundamental concept in theories of knowledge and behavior. Psychological experiments have shown that similarity acts as an organizing principle by which individuals classify objects, and make generalizations (Goldstone, 1994). For example, a biologist would classify a newly found animal specimen based upon the properties that it shares with existing categories of animals. We can then make additional inferences on the new specimen using the properties known for the existing category. As the similarity between two objects X and Y increases, so does the probability of correctly inferring that Y has the property T upon knowing that X has T (Tenenbaum, 1999). Accurate measurement of semantic similarity between lexical units such as words or phrases is important for numerous tasks in natural language processing such as word sense disambiguation (Resnik, 1995), synonym extraction (Lin, 1998a), and automatic thesauri generation (Curran, 2002). In information retrieval, similar or related words are used to expand user queries to improve recall (Sahami and Heilman, 2006).

Semantic similarity is a context dependent and dynamic phenomenon. New words are constantly being created and existing words are assigned with new senses on the Web. To decide whether two words are semantically similar, it is important to know the semantic relations that hold between the words. For example, the words *horse* and *cow* can be considered semantically similar because both horses and cows are useful animals in agriculture. Similarly, a *horse* and a *car* can be considered semantically similar because cars, and historically horses, are used for transportation. Semantic relations such as ***X* and *Y* are used in agriculture**, or ***X* and *Y* are used for transportation**, exist between two words *X* and *Y* in these examples. We use bold-italics, ***X***, to denote the slot of a word *X* in a lexical pattern.

We propose a *relational model* to compute the semantic similarity between two words. First, using snippets retrieved from a web search engine, we present an automatic lexical pattern extraction algorithm to represent the semantic relations that exist between two words. For example, given two words *ostrich* and *bird*, we extract ***X* is a *Y***, ***X* is a large *Y***, and ***X* is a flightless *Y*** from the Web. Using a set of semantically related words as training data, we evaluate the confidence of a lexical

*Research Fellow of the Japan Society for the Promotion of Science (JSPS)

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 803–812,
Singapore, 6-7 August 2009.

pattern as an indicator of semantic similarity. For example, the pattern ***X** is a **Y*** is a better indicator of semantic similarity between *X* and *Y* than the pattern ***X** and **Y***. Consequently, we would like to emphasize the former pattern by assigning it a higher confidence score. It is noteworthy that all lexical patterns are not independent – multiple lexical patterns can express the same semantic relation. For example, the pattern ***X** is a large **Y*** subsumes the more general pattern ***X** is a **Y*** and they both indicate a hypernymic relationship between *X* and *Y*. By clustering the semantically related patterns into groups, we can both overcome the data sparseness problem, and reduce the number of parameters during training. To identify semantically related patterns, we use a sequential pattern clustering algorithm that is based on the distributional hypothesis (Harris, 1954). We represent two words by a feature vector defined over the clusters of patterns. Finally, the semantic similarity is computed as the Mahalanobis distance between points corresponding to the feature vectors. By using Mahalanobis distance instead of Euclidean distance, we can account for the inter-dependence between semantic relations.

2 Related Work

Geometric models, such as multi-dimensional scaling has been used in psychological experiments analyzing the properties of similarity (Krumhansl, 1978). These models represent objects as points in some coordinate space such that the observed dissimilarities between objects correspond to the metric distances between the respective points. Geometric models assume that objects can be adequately represented as points in some coordinate space and that dissimilarity behaves like a metric distance function satisfying minimality, symmetry, and triangle inequality assumptions. However, both dimensional and metric assumptions are open to question.

Tversky (1977) proposed the *contrast model* of similarity to overcome the problems in geometric models. The contrast model relies on featural representation of objects, and it is used to compute the similarity between the representations of two objects. Similarity is defined as an increasing function of common features (i.e. features in common to the two objects), and as a decreasing function of distinctive features (i.e. features that apply to one object but not the other). The attributes of objects are primal to contrast model and it does not explicitly incorporate the relations between objects when measuring similarity.

Hahn et al. (2003) define similarity between two representations as the complexity required to transform one representation into the other. Their model of similarity is based on the *Representational Distortion* theory, which aims to provide a theoretical framework of similarity judgments. Their experiments using pattern sequences and geometric shapes show an inverse correlation between the number of transformations required to convert one pattern (or shape) to another, and the perceived similarity ratings by human subjects. How to represent an object, which transformations are allowed on a representation, and how to measure the complexity of a transformation, are all important decisions in the transformational model of similarity. Although distance measures such as edit distance have been used to find approximate matches in a dictionary, it is not obvious how to compute semantic similarity between words using representational distortion theory.

Given a taxonomy of concepts, a straightforward method to calculate similarity between two words (or concepts) is to find the length of the shortest path connecting the two words in the taxonomy (Rada et al., 1989). If a word is polysemous (i.e. has more than one sense) then multiple paths might exist between the two words. In such cases, only the shortest path between any two senses of the words is considered for calculating similarity. A problem that is frequently acknowledged with this approach is that it relies on the notion that all links in the taxonomy represent a uniform distance. As a solution to this problem, Schickel-Zuber and Faltings (2007) propose ontology structure based similarity (OSS) between two concepts in an ontology, which is an asymmetric distance function.

Resnik (1995) proposed a similarity measure using information content. He defined the similarity between two concepts C_1 and C_2 in the taxonomy as the maximum of the information content of all concepts C that subsume both C_1 and C_2. Then the similarity between two words is defined as the maximum of the similarity between any concepts that the words belong to. He used WordNet as the taxonomy; information content is calculated using the Brown corpus.

Li et al., (2003) combined structural seman-

tic information from a lexical taxonomy, and information content from a corpus, in a nonlinear model. They proposed a similarity measure that uses shortest path length, depth and local density in a taxonomy. Their experiments reported a Pearson correlation coefficient of 0.8914 on the Miller-Charles benchmark dataset (Miller and Charles, 1998). Lin (1998b) defined the similarity between two concepts as the information that is in common to both concepts and the information contained in each individual concept.

Cilibrasi and Vitanyi (2007) proposed a distance metric between words using page-counts retrieved from a web search engine. The proposed metric is named *Normalized Google Distance* (NGD) and is defined as the normalized information distance (Li et al., 2004) between two strings. They evaluate NGD in a word classification task. Unfortunately NGD only uses page-counts of words and ignores the context in which the words appear. Therefore, it produces inaccurate similarity scores when one or both words between which similarity is computed are polysemous.

Sahami and Heilman (2006) measured semantic similarity between two queries using snippets returned for those queries by a search engine. For each query, they collect snippets from a search engine and represent each snippet as a TF-IDF-weighted term vector. Each vector is L_2 normalized and the centroid of the set of vectors is computed. Semantic similarity between two queries is then defined as the inner product between the corresponding centroid vectors. They did not compare their similarity measure with taxonomy-based similarity measures.

Chen et al., (2006) propose a web-based double-checking model to compute the semantic similarity between words. For two words X and Y, they collect snippets for each word from a web search engine. Then they count the number of occurrences of X in the snippets for Y, and Y in the snippets for X. The two values are combined nonlinearly to compute the similarity between X and Y. This method heavily depends on the search engine's ranking algorithm. Although two words X and Y may be very similar, there is no reason to believe that one can find Y in the snippets for X, or vice versa. This observation is confirmed by the experimental results in their paper which reports 0 similarity scores for many pairs of words in the Miller-Charles dataset.

In our previous work (Bollegala et al., 2007), we proposed a semantic similarity measure using page counts and snippets retrieved from a Web search engine. To compute the similarity between two words X and Y, we queried a web search engine using the query *X AND Y* and extract lexical patterns that combine X and Y from snippets. A feature vector is formed using frequencies of 200 lexical patterns in snippets and four co-occurrence measures: Dice coefficient, overlap coefficient, Jaccard coefficient and pointwise mutual information. We trained a two-class support vector machine using automatically selected synonymous and non-synonymous word pairs from WordNet. This method reports a Pearson correlation coefficient of 0.837 with Miller-Charles ratings. However, it does not consider the relatedness between patterns.

Gabrilovich and Markovitch (2007) represent words using weighted vectors of Wikipedia-based concepts, and define the similarity between words as the cosine of the angle between the corresponding vectors. Their method can be used to compute similarity between words as well as between texts. Although Wikipedia is growing in popularity, not all concepts found on the Web have articles in Wikipedia. Specially, novel or not very popular concepts are not adequately covered by Wikipedia. Moreover, their method requires the concepts to be independent. For non-independent, hierarchical taxonomies such as open directory project (ODP)[1], their method produces suboptimal results.

3 Relational Model of Similarity

We propose a model to compute the semantic similarity between two words a and b using the set of semantic relations $R(a, b)$ that hold between a and b. We call the proposed model the *relational model* of semantic similarity and it is defined by the following equation,

$$\mathrm{sim}(a, b) = \Xi(R(a, b)). \quad (1)$$

Here, $\mathrm{sim}(a, b)$ is the semantic similarity between the two words a and b, and Ξ is a weighting function defined over the set of semantic relations $R(a, b)$. Given that a particular set of semantic relations are known to hold between two words, the function Ξ expresses our confidence on those words being semantically similar.

[1] http://www.dmoz.org

A semantic relation can be expressed in a number of ways. For example, given a taxonomy of words such as the WordNet, semantic relations (i.e. hypernymy, meronymy, synonymy etc.) between words can be directly looked up in the taxonomy. Alternatively, the labels of the edges in the path connecting two words can be used as semantic relations. However, in this paper we do not assume the availability of manually created resources such as dictionaries or taxonomies. We represent semantic relations using automatically extracted lexical patterns. Lexical patterns have been successfully used to represent various semantic relations between words such as hypernymy (Hearst, 1992), and meronymy (Berland and Charniak, 1999). Following these previous approaches, we represent $R(a, b)$ as a set of lexical patterns. Moreover, we denote the frequency of a lexical pattern r for a word pair (a, b) by $f(r, a, b)$.

So far we have not defined the functional form of Ξ. A straightforward approach is to use a linearly weighted combination of relations as shown below,

$$\Xi(R(a,b)) = \sum_{r_i \in R(a,b)} w_i \times f(r_i, a, b). \quad (2)$$

Here, w_i is the weight associated with the lexical pattern r_i and can be determined using training data. However, this formulation has two fundamental drawbacks. First, the number of weight parameters w_i is equal to the number of lexical patterns. Typically two words can co-occur in numerous patterns. Consequently, we end up with a large number of parameters in the model. Complex models with a large number of parameters are difficult to train because they tend to overfit to the training data. Second, the linear combination given in Equation 2 assumes the lexical patterns to be mutually independent. However, in practice this is not true. For example, both patterns *X is a Y* and *Y such as X* indicate a hypernymic relation between *X* and *Y*.

To overcome the above mentioned limitations, we first cluster the lexical patterns to identify the semantically related patterns. Our clustering algorithm is detailed in section 3.2. Next, we define Ξ using the formed clusters as follows,

$$\Xi(R(a,b)) = \mathbf{x}_{ab}^T \Lambda \sigma. \quad (3)$$

Here, $\mathbf{x}_{ab}$ is a feature vector representing the words a and b. Each formed cluster contributes a feature in vector $\mathbf{x}_{ab}$ as described later in Section 5. The vector σ is a prototypical vector representing synonymous word pairs. We compute σ as the centroid of feature vectors representing synonymous word pairs. Λ is the inter-cluster correlation matrix. The (i, j)-th element of matrix Λ denotes the correlation between the two clusters c_i and c_j. Matrix Λ is expected to capture the dependence between semantic relations. Intuitively, if two clusters i and j are highly correlated, then the (i, j)-th element of Λ will be closer to 1. Equation 3 computes the similarity between a word pair (a, b) and a set of synonymous word pairs. Intuitively, if the relations that exist between a and b are typical relations that hold between synonymous word pairs, then Equation 3 returns a high similarity score for a and b.

The proposed relational model of semantic similarity differs from feature models of similarity, such as the contrast model (Tversky, 1977), in that it is defined over the set of semantic relations that exist between two words instead of the set of features for each word. Specifically, in contrast model, the similarity $S(a, b)$ between two objects a and b is defined in terms of the features common to a and b, $A \cap B$, the features that are distinctive to a, $A - B$, and the features that are distinctive to b, $B - A$. The contrast model is formalized in the following equation,

$$S(a,b) = \theta f(A \cap B) - \alpha f(A - B) - \beta f(B - A). \quad (4)$$

Here, the function f measures the salience of a particular set of features, and non-negative parameters α, β, and θ determine the relative weights assigned to the different components. However, in the relational model of similarity we do not focus on features of individual words but on relations between two words.

Modeling similarity as a phenomenon of relations between objects rather than features of individual objects is central to computational models of analogy-making such as the structure mapping theory (SMT) (Falkenhainer et al., 1989). SMT claims that an analogy is a mapping of knowledge from one domain (base) into another (target) which conveys that a system of relations known to hold in the base also holds in the target. The target objects do not have to resemble their corresponding base objects. During the mapping process, features of individual objects are dropped and only relations are mapped. The proposed relational model of similarity uses this relational view

Ostrich, a large, flightless bird that lives in the dry grasslands of Africa.

Figure 1: A snippet returned for the query *"ostrich * * * * * bird"*.

of similarity to compute semantic similarity between words.

3.1 Extracting Lexical Patterns

To compute semantic similarity between two words using the relational model (Equation 3), we must first extract the numerous lexical patterns from contexts in which those two words appear. For this purpose, we propose a pattern extraction algorithm using snippets retrieved from a web search engine. The proposed method requires no language-dependent preprocessing such as part-of-speech tagging or dependency parsing, which can be both time consuming at Web scale, and likely to produce incorrect results because of the fragmented and ill-formed snippets.

Given two words a and b, we query a web search engine using the wildcard query *"a * * * * * b"* and download snippets. The "*" operator matches one word or none in a web page. Therefore, our wildcard query retrieves snippets in which a and b appear within a window of seven words. We attempt to approximate the local context of two words using wildcard queries. For example, Figure 1 shows a snippet retrieved for the query *"ostrich * * * * * bird"*.

For a snippet S, retrieved for a word pair (a, b), first, we replace the two words a and b, respectively, with two variables *X* and *Y*. We replace all numeric values by D, a marker for digits. Next, we generate all subsequences of words from S that satisfy all of the following conditions.

(i). A subsequence must contain exactly one occurrence of each *X* and *Y*

(ii). The maximum length of a subsequence is L words.

(iii). A subsequence is allowed to have gaps. However, we do not allow gaps of more than g number of words. Moreover, the total length of all gaps in a subsequence should not exceed G words.

(iv). We expand all negation contractions in a context. For example, *didn't* is expanded to *did not*. We do not skip the word *not* when generating subsequences. For example, this condition ensures that from the snippet *X is not a Y*, we do not produce the subsequence *X is a Y*.

Finally, we count the frequency of all generated subsequences and only use subsequences that occur more than N times as lexical patterns.

The parameters *L, g, G* and *N* are set experimentally, as explained later in Section 6. It is noteworthy that the proposed pattern extraction algorithm considers all the words in a snippet, and is *not* limited to extracting patterns only from the mid-fix (i.e., the portion of text in a snippet that appears between the queried words). Moreover, the consideration of gaps enables us to capture relations between distant words in a snippet. We use a modified version of the *prefixspan* algorithm (Pei et al., 2004) to generate subsequences from a text snippet. Specifically, we use the constraints (ii)-(iv) to prune the search space of candidate subsequences. For example, if a subsequence has reached the maximum length L, or contains the maximum number of gaps G, then we will not extend it further. By pruning the search space, we can speed up the pattern generation process. However, none of these modifications affect the accuracy of the proposed semantic similarity measure because the modified version of the prefixspan algorithm still generates the exact set of patterns that we would obtain if we used the original prefixspan algorithm (i.e. without pruning) and subsequently remove patterns that violate the above mentioned constraints. For example, some patterns extracted form the snippet shown in Figure 1 are: ***X**, a large **Y***, ***X** a flightless **Y***, and ***X**, large **Y** lives*.

3.2 Clustering Lexical Patterns

A semantic relation can be expressed using more than one pattern. By grouping the semantically related patterns, we can both reduce the model complexity in Equation 2, and consider the dependence among semantic relations in Equation 3. We use the distributional hypothesis (Harris, 1954) to find semantically related lexical patterns. The distributional hypothesis states that words that occur in the same context have similar meanings. If two lexical patterns are similarly distributed over a set of word pairs, then from the distributional hypothesis it follows that the two patterns must be similar.

We represent a pattern p by a vector $\mathbf{p}$ in which

the i-th element is the frequency $f(a_i, b_i, p)$ of p in a word pair (a_i, b_i). Given a set P of patterns and a similarity threshold θ, Algorithm 1 returns clusters of similar patterns. First, the function $SORT$ sorts the patterns in the descending order of their total occurrences in all word pairs. The total occurrences of a pattern p is defined as $\mu(p)$, and is given by,

$$\mu(p) = \sum_{(a,b) \in W} f(a, b, p). \quad (5)$$

Here, W is the set of word pairs. Then the outer for-loop (starting at line 3), repeatedly takes a pattern $\mathbf{p_i}$ from the ordered set P, and in the inner for-loop (starting at line 6), finds the cluster, c^* ($\in C$) that is most similar to $\mathbf{p_i}$. Similarity between $\mathbf{p_i}$ and the cluster centroid $\mathbf{c_j}$ is computed using cosine similarity. The centroid vector $\mathbf{c}_j$ of cluster c_j is defined as the vector sum of all pattern vectors for patterns in that cluster (i.e. $\mathbf{c}_j = \sum_{p \in c_j} \mathbf{p}$). If the maximum similarity exceeds the threshold θ, we append $\mathbf{p_i}$ to $\mathbf{c}^*$ (line 14). Here, the operator $\oplus$ denotes vector addition. Otherwise, we form a new cluster $\{\mathbf{p_i}\}$ and append it to C, the set of clusters. After all patterns are clustered, we compute the (i, j) element of the inter-cluster correlation matrix Λ (Equation 3) as the inner-product between the centroid vectors $\mathbf{c_i}$ and $\mathbf{c_j}$ of the corresponding clusters i and j. The parameter θ ($\in [0, 1]$) determines the *purity* of the formed clusters and is set experimentally in Section 5. Algorithm 1 scales linearly with the number of patterns. Moreover, sorting the patterns by their total word pair frequency prior to clustering ensures that the final set of clusters contains the most common relations in the dataset.

Algorithm 1 Sequential pattern clustering algorithm.

Input: patterns $P = \{\mathbf{p_1}, \ldots, \mathbf{p_n}\}$, threshold θ

11:         end if
12:     end for
13:     if max ≥ θ then
14:         c* ← c* ⊕ p_i
15:     else
16:         C ← C ∪ {p_i}
17:     end if
18: end for
19: return C
```

4 Evaluation Procedure

Evaluating a semantic similarity measure is difficult because the notion of semantic similarity is subjective. Miller-Charles (1998) dataset has been frequently used to benchmark semantic similarity measures. Miller-Charles dataset contains 30 word pairs rated by a group of 38 human subjects. The word pairs are rated on a scale from 0 (no similarity) to 4 (perfect synonymy). Because of the omission of two word pairs in earlier versions of WordNet, most researchers had used only 28 pairs for evaluations. The degree of correlation between the human ratings in the benchmark dataset and the similarity scores produced by an automatic semantic similarity measure, can be considered as a measurement of how well the semantic similarity measure captures the notion of semantic similarity held by humans. In addition to Miller-Charles dataset we also evaluate on the WordSimilarity-353 (Finkelstein et al., 2002) dataset. In contrast to Miller-Charles dataset which has only 30 word pairs, WordSimilarity-353 dataset contains 353 word pairs. Each pair has 13-16 human judgments, which were averaged for each pair to produce a single relatedness score. Following the previous work, we use both Miller-Charles dataset and WordSimilarity-353 dataset to evaluate the proposed semantic similarity measure.

5 Computing Semantic Similarity

To extract lexical patterns that express numerous semantic relations, we first select synonymous words from WordNet synsets. A synset is a set of synonymous words assigned for a particular sense of a word in WordNet. We randomly select 2000 synsets of nouns from WordNet. From each synset, a pair of synonymous words is selected. For polysemous nouns, we selected synonyms from the dominant sense. To perform a fair evaluation, we do not select any words that appear in the Miller-Charles dataset or the WordSimilarity-353

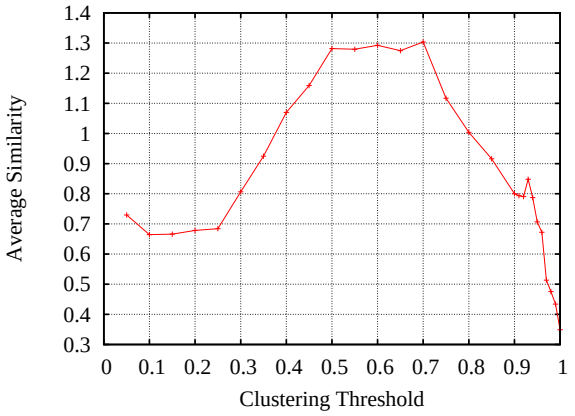

Figure 2: Average similarity vs. clustering threshold θ

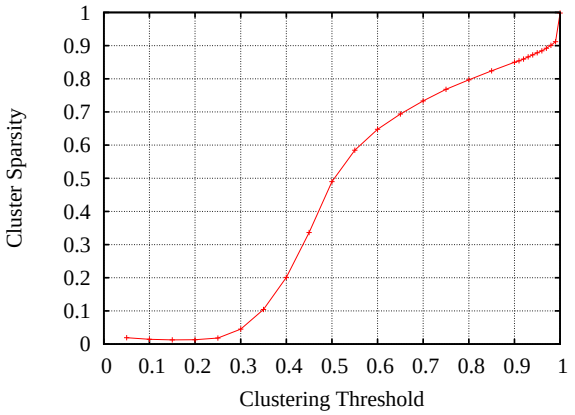

Figure 3: Sparsity vs. clustering threshold θ

dataset, which are used later for evaluation purposes. As we describe later, the clustering threshold θ is tuned using this set of 2000 word pairs selected from the WordNet.

We use the YahooBOSS API[2] and download 1000 snippets for each of those word pairs. Experimentally, we set the values for the parameters in the pattern extraction algorithm (Section 3.1): $L = 5$, $g = 2$, $G = 4$, and extract $5,238,637$ unique patterns. However, only $1,680,914$ of those patterns occur more than twice. Low frequency patterns often contain misspellings and are not suitable for training. Therefore, we selected patterns that occur at least 10 times in the snippet collection. Moreover, we remove very long patterns (ca. over 20 characters). The final set contains $140,691$ unique lexical patterns. The remainder of the experiments described in the paper use those patterns.

[2]http://developer.yahoo.com/search/boss/

We use the clustering Algorithm 1 to cluster the extracted patterns. The only parameter in Algorithm 1, the clustering threshold θ, is set as follows. We vary the value of theta θ from 0 to 1, and use Algorithm 1 to cluster the extracted set of patterns. We use the resultant set of clusters to represent a word pair by a feature vector. We compute a feature from each cluster as follows. First, we assign a weight w_{ij} to a pattern p_i that is in a cluster c_j as follows,

$$w_{ij} = \frac{\mu(p_i)}{\sum_{q \in c_j} \mu(q)}. \quad (6)$$

Here, $\mu(q)$ is the total frequency of a pattern, and it is given by Equation 5. Because we perform a hard clustering on patterns, a pattern can belong to only one cluster (i.e. $w_{ij} = 0$ for $p_i \notin c_j$). Finally, we compute the value of the j-th feature in the feature vector for word pair (a, b) as follows,

$$\sum_{p_i \in c_j} w_{ij} f(a, b, p_i). \quad (7)$$

For each set of clusters, we compute the element Λ_{ij} of the corresponding inter-cluster correlation matrix Λ by the cosine similarity between the centroid vectors for clusters c_i and c_j. The prototype vector σ in Equation 3 is computed as the vector sum of individual feature vectors for the synonymous word pairs selected from the WordNet as described above. We then use Equation 3 to compute the average of similarity scores for synonymous word pairs we selected from WordNet.

We select the θ that maximizes the average similarity score between those synonymous word pairs. Formally, the optimal value of θ, $\hat{\theta}$ is given by the following Equation,

$$\hat{\theta} = \text{argmax}_{\theta \in [0,1]} \left(\frac{1}{|W|} \sum_{(a,b) \in W} \text{sim}(a, b) \right). \quad (8)$$

Here, W is the set of synonymous word pairs (a, b), $|W|$ is the total number of synonymous word pairs (i.e. 2000 in our experiments), and $\text{sim}(a, b)$ is given by Equation 3. Because the averages are taken over 2000 word pairs this procedure gives a reliable estimate for θ. Moreover, this method does not require negative training instances such as, non-synonymous word pairs, which are difficult to create manually. Average similarity scores for various θ values are shown in Figure 2. From Figure 2, we see that initially average similarity increases when θ is increased.

This is because clustering of semantically related patterns reduces the sparseness in feature vectors. Average similarity is stable within a range of θ values between 0.5 and 0.7. However, increasing θ beyond 0.7 results in a rapid drop of average similarity. To explain this behavior consider Figure 3 where we plot the sparsity of the set of clusters (i.e. the ratio between singletons to total clusters) against threshold θ. As seen from Figure 3, high θ values result in a high percentage of singletons because only highly similar patterns will form clusters. Consequently, feature vectors for different word pairs do not have many features in common. The maximum average similarity score of 1.303 is obtained with $\theta = 0.7$, corresponding to $17,015$ total clusters out of which $12,476$ are singletons with exactly one pattern (sparsity = 0.733). For the remainder of the experiments in this paper we set θ to this optimal value and use the corresponding set of clusters to compute semantic similarity by Equation 3. Similarity scores computed using Equation 3 can be greater than 1 (see Figure 2) because of the terms corresponding to the non-diagonal elements in Λ. We do not normalize the similarity scores to $[0, 1]$ range in our experiments because the evaluation metrics we use are insensitive to linear transformations of similarity scores.

6 Experiments

Table 1 compares the proposed method against Miller-Charles ratings (MC), and previously proposed web-based semantic similarity measures: Jaccard, Dice, Overlap, PMI (Bollegala et al., 2007), Normalized Google Distance (NGD) (Cilibrasi and Vitanyi, 2007), Sahami and Heilman (SH) (2006), co-occurrence double checking model (CODC) (Chen et al., 2006), and support vector machine-based (SVM) approach (Bollegala et al., 2007). The bottom row of Table 1 shows the Pearson correlation coefficient of similarity scores produced by each algorithm with MC. All similarity scores, except for the human-ratings in Miller-Charles dataset, are normalized to $[0, 1]$ range for the ease of comparison. It is noteworthy that the Pearson correlation coefficient is invariant under a linear transformation. All similarity scores shown in Table 1 except for the proposed method are taken from the original published papers.

The highest correlation is reported by the proposed semantic similarity measure. The improvement of the proposed method is statistically significant (confidence interval $[0.73, 0.93]$) against all the similarity measures compared in Table 1 except against the SVM approach. From Table 1 we see that measures that use contextual information from snippets (e.g. SH, CODC, SVM, and proposed) outperform the ones that use only co-occurrence statistics (e.g. Jaccard, overlap, Dice, PMI, and NGD) such as page-counts. This is because similarity measures that use contextual information are better equipped to compute the similarity between polysemous words. Although both SVM and proposed methods use lexical patterns, unlike the proposed method, the SVM method does not consider the relatedness between patterns. The superior performance of the proposed method is attributable to its consideration of relatedness of patterns.

Table 2 summarizes the previously proposed WordNet-based semantic similarity measures. Despite the fact that the proposed method does not use manually compiled resources such as WordNet for computing similarity, its performance is comparable to similarity measures that use WordNet. We believe that the proposed method will be useful to compute the semantic similarity between named-entities for which manually created resources are either incomplete or do not exist.

We evaluate the proposed method using the WordSimilarity-353 dataset. Experimental results are presented in Table 3. Following previous work, we use Spearman rank correlation coefficient, which does not require ratings to be linearly dependent, for the evaluations on this dataset. Likewise with the Miller-Charles ratings, we measure the correlation between the similarity scores produced by the proposed method for word pairs in the WordSimilarity-353 dataset and the human ratings. A higher Spearman correlation coefficient (value=0.504, confidence interval $[0.422, 0.578]$) indicates a better agreement with the human notion of semantic similarity. From Table 3 we can see that the proposed method outperforms a wide variety of semantic similarity measures developed using numerous resources including lexical resources such as WordNet and knowledge sources such as Wikipedia (i.e. WikiRelate!). In contrast to the Miller-Charles dataset which only contains common English words selected from the WordNet, the WordSimilarity-353 dataset contains word pairs where one or both words are named entities (e.g. (*Maradona*, *foot-*

ball) and (*Jerusalem*, *Israel*)). Because the proposed method use snippets retrieved from a web search engine, it is capable of extracting expressive lexical patterns that can explicitly state the relationship between two entities.

If we must compare n objects using a feature model of similarity, then we only need to define features for each of those n objects. However, in the proposed relational model we must define relations between all pairs of objects. In the case where all n objects are different, this requires us to define relations for $n(n-1)/2$ object pairs. Defining relations for all pairs can be computationally costly for large n values. Efficiently comparing n objects using a relational model is an interesting future research direction of the current work.

7 Conclusion

We proposed a relational model to measure the semantic similarity between two words. First, to represent the numerous semantic relations that exist between two words, we extract lexical patterns from snippets retrieved from a web search engine. Second, we cluster the extracted patterns to identify the semantically related patterns. Third, using the pattern clusters we define a feature vector to represent two words and compute the semantic similarity by taking into account the inter-cluster correlation. The proposed method outperformed all existing web-based semantic similarity measures on two benchmark datasets.

Abstract

This paper introduces a new parser evaluation corpus containing around 700 sentences annotated with unbounded dependencies, from seven different grammatical constructions. We run a series of off-the-shelf parsers on the corpus to evaluate how well state-of-the-art parsing technology is able to recover such dependencies. The overall results range from 25% accuracy to 59%. These low scores call into question the validity of using Parseval scores as a general measure of parsing capability. We discuss the importance of parsers being able to recover unbounded dependencies, given their relatively low frequency in corpora. We also analyse the various errors made on these constructions by one of the more successful parsers.

1 Introduction

Statistical parsers are now obtaining Parseval scores of over 90% on the WSJ section of the Penn Treebank (Bod, 2003; Petrov and Klein, 2007; Huang, 2008; Carreras et al., 2008). McClosky et al. (2006) report an F-score of 92.1% using self-training applied to the reranker of Charniak and Johnson (2005). Such scores, in isolation, may suggest that statistical parsing is close to becoming a solved problem, and that further incremental improvements will lead to parsers becoming as accurate as POS taggers.

A single score in isolation can be misleading, however, for a number of reasons. First, the single score is an aggregate over a highly skewed distribution of all constituent types; evaluations which look at individual constituent or dependency types show that the accuracies on some, semantically important, constructions, such as coordination and PP-attachment, are much lower (Collins, 1999). Second, it is well known that the accuracy of parsers trained on the Penn Treebank degrades when they are applied to different genres and domains (Gildea, 2001). Finally, some researchers have argued that the Parseval metrics (Black et al., 1991) are too forgiving with respect to certain errors and that an evaluation based on syntactic dependencies, for which scores are typically lower, is a better test of parser performance (Lin, 1995; Carroll et al., 1998).

In this paper we focus on the first issue, that the performance of parsers on some constructions is much lower than the overall score. The constructions that we focus on are various unbounded dependency constructions. These are interesting for parser evaluation for the following reasons: one, they provide a strong test of the parser's knowledge of the grammar of the language, since many instances of unbounded dependencies are difficult to recover using shallow techniques in which the grammar is only superficially represented; and two, recovering these dependencies is necessary to completely represent the underlying predicate-argument structure of a sentence, useful for applications such as Question Answering and Information Extraction.

To give an example of the sorts of constructions we are considering, and the (in)ability of parsers to recover the corresponding unbounded dependencies, none of the parsers that we have tested were able to recover the dependencies shown in bold from the following sentences:

We have also developed techniques for recognizing and locating underground nuclear tests through the **waves** *in the ground which they* **generate**.

By Monday , they hope to have a sheaf of **documents** *both sides can* **trust**.

By means of charts showing wave-travel times and depths in the ocean at various locations , it is possible to estimate the **rate** *of approach and probable* **time** *of arrival at Hawaii* **of** *a tsunami getting under way at any spot in the Pacific .*

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 813–821,
Singapore, 6-7 August 2009.

The contributions of this paper are as follows. First, we present the first set of results for the recovery of a variety of unbounded dependencies, for a range of existing parsers. Second, we describe the creation of a publicly available unbounded dependency test suite, and give statistics summarising properties of these dependencies in naturally occurring text. Third, we demonstrate that performing the evaluation is surprisingly difficult, because of different conventions across the parsers as to how the underlying grammar is represented. Fourth, we show that current parsing technology is very poor at representing some important elements of the argument structure of sentences, and argue for a more focused construction-based parser evaluation as a complement to existing grammatical relation-based evaluations. We also perform an error-analysis for one of the more successful parsers.

There has been some prior work on evaluating parsers on long-range dependencies, but no work we are aware of that has the scope and focus of this paper. Clark et al. (2004) evaluated a CCG parser on a small corpus of object extraction cases. Johnson (2002) began the body of work on inserting traces into the output of Penn Treebank (PTB) parsers, followed by Levy and Manning (2004), among others. This PTB work focused heavily on the representation in the Treebank, evaluating against patterns in the trace annotation. In this paper we have tried to be more "formalism-independent" and construction focused.

2 Unbounded Dependency Corpus

2.1 The constructions

An unbounded dependency construction contains a word or phrase which appears to have been moved, while being interpreted in the position of the resulting "gap". An unlimited number of clause boundaries may intervene between the moved element and the gap (hence "unbounded").

The seven constructions in our corpus were chosen for being relatively frequent in text, compared to other unbounded dependency types, and relatively easy to identify. An example of each construction, along with its associated dependencies, is shown in Table 1. Here we give a brief description of each construction.

Object extraction from a relative clause is characterised by a relative pronoun (a *wh*-word or *that*) introducing a clause from which an argument in object position has apparently been extracted: *the paper which I wrote*. Our corpus includes cases where the extracted word is (semantically) the object of a preposition in the verb phrase: *the agency that I applied to*.

Object extraction from a reduced relative clause is essentially the same, except that there is no overt relative pronoun: *the paper I wrote; the agency I applied to*. We did not include participial reduced relatives such as *the paper written by the professor*.

Subject extraction from a relative clause is characterised by the apparent extraction of an argument from subject position: *the instrument that measures depth*. A relative pronoun is obligatory in this construction. Our corpus includes passive subjects: *the instrument which was used by the professor*.

Free relatives contain relative pronouns without antecedents: *I heard what she said*, where *what* does not refer to any other noun in the sentence. Free relatives can usually be paraphrased by noun phrases such as *the thing she said* (a standard diagnostic for distinguishing them from embedded interrogatives like *I wonder what she said*). The majority of sentences in our corpus are object free relatives, but we also included some adverbial free relatives: *She told us how to do it*.

Object *wh*-questions are questions in which the *wh*-word is the semantic object of the verb: *What did you eat?*. Objects of prepositions are included: *What city does she live in?*. Also included are a few cases where the *wh*-word is arguably adverbial, but is selected for by the verb: *Where is the park located?*.

Right node raising (RNR) is characterised by coordinated phrases from which a shared element apparently moves to the right: *Mary saw and Susan bought the book*. This construction is unique within our corpus in that the "raised" element can have a wide variety of grammatical functions. Examples include: noun phrase object of verb, noun phrase object of preposition (*material about or messages from the communicator*), a combination of the two (*applied for and won approval*), prepositional phrase modifier (*president and chief executive of the company*), infinitival modifier (*the will and the capacity to prevent the event*), and modified noun (*a good or a bad decision*).

Subject extraction from an embedded clause is characterised by a semantic subject which is ap-

parently extracted across two clause boundaries, as shown in the following bracketing (where $*$ marks the origin of the extracted element): *the responsibility which [the government said [$*$ lay with the voters]]*. Our corpus includes sentences where the embedded clause is a so-called small clause, i.e. one with a null copula verb: *the plan that she considered foolish*, where *plan* is the semantic subject of *foolish.*

2.2 The data

The corpus consists of approximately 100 sentences for each of the seven constructions; 80 of these were reserved for each construction for testing, giving a test set of 560 sentences in total, and the remainder were used for initial experimentation (for example to ensure that default settings for the various parsers were appropriate for this data). We did not annotate the full sentences, since we are only interested in the unbounded dependencies and full annotation of such a corpus would be extremely time-consuming.

With the exception of the question construction, all sentences were taken from the PTB, with roughly half from the WSJ sections (excluding 2-21 which provided the training data for many

of the parsers in our set) and half from Brown (roughly balanced across the different sections). The questions were taken from the question data in Rimell and Clark (2008), which was obtained from various years of the TREC QA track. We chose to use the PTB as the main source because the use of traces in the PTB annotation provides a starting point for the identification of unbounded dependencies.

Sentences were selected for the corpus by a combination of automatic and manual processes. A regular expression applied to PTB trees, searching for appropriate traces for a particular construction, was first used to extract a set of candidate sentences. All candidates were manually reviewed and, if selected, annotated with one or more grammatical relations representing the relevant unbounded dependencies in the sentence. Some of the annotation in the treebank makes identification of some constructions straightforward; for example right node raising is explicitly represented as RNR. Indeed it may have been possible to fully automate this process with use of the `tgrep` search tool. However, in order to obtain reliable statistics regarding frequency of occurrence, and to ensure a high-quality resource, we used fairly broad regular expressions to identify the original set followed by manual review.

We chose to represent the dependencies as grammatical relations (GRs) since this format seemed best suited to represent the kind of semantic relationship we are interested in. GRs are head-based dependencies that have been suggested as a more appropriate representation for general parser evaluation than phrase-structure trees (Carroll et al., 1998). Table 1 gives examples of how GRs are used to represent the relevant dependencies. The particular GR scheme we used was based on the Stanford scheme (de Marneffe et al., 2006); however, the specific GR scheme is not too crucial since the whole sentence is not being represented in the corpus, only the unbounded dependencies.

3 Experiments

The five parsers described in Section 3.2 were used to parse the test sentences in the corpus, and the percentage of dependencies in the test set recovered by each parser for each construction was calculated. The details of how the parsers were run and how the parser output was matched against the gold standard are given in Section 3.3. This is essentially a recall evaluation, and so is open to abuse; for example, a program which returns all the possible word pairs in a sentence, together with all possible labels, would score 100%. However, this is easily guarded against: we simply assume that each parser is being run in a "standard" mode, and that each parser has already been evaluated on a full corpus of GRs in order to measure precision and recall across all dependency types. (Calculating precision for the unbounded dependency evaluation would be difficult since that would require us to know how many *incorrect* unbounded dependencies were returned by each parser.)

Construction	WSJ	Brown	Overall
Obj rel clause	2.3	1.1	1.4
Obj reduced rel	2.7	2.8	2.8
Sbj rel clause	10.1	5.7	7.4
Free rel	2.6	0.9	1.3
RNR	2.2	0.9	1.2
Sbj embedded	2.0	0.3	0.4

Table 2: Frequency of constructions in the PTB (percentage of sentences).

3.1 Statistics relating to the constructions

Table 2 shows the percentage of sentences in the PTB, from those sections that were examined, which contain an example of each type of unbounded dependency. Perhaps not surprisingly, root subject extractions from relative clauses are by far the most common, with the remaining constructions occurring in roughly between 1 and 2% of sentences. Note that, although examples of each individual construction are relatively rare, the combined total is over 10% (assuming that each construction occurs independently). Section 6 contains a discussion regarding the frequency of occurrence of these events and the consequences of this for parser performance.

Table 3 shows the average and maximum distance between head and dependent for each construction, as measured by the difference between word indices. This is a fairly crude measure of distance but gives some indication of how "long-range" the dependencies are for each construction. The cases of object extraction from a relative clause and subject extraction from an embedded clause provide the longest dependencies, on average. The following sentence gives an example of how far apart the head and dependent can be in a

Construction	Avg Dist	Max Dist
Obj rel clause	6.8	21
Obj reduced rel	3.4	8
Sbj rel clause	4.4	18
Free rel	3.4	16
Obj wh-question	4.8	9
RNR	4.8	23
Sbj embedded	7.0	21

Table 3: Distance between head and dependent.

subject embedded construction:

the same **stump** *which had impaled the car of many a guest in the past thirty years and which he refused to have* **removed**.

3.2 The parsers

The parsers that we chose to evaluate are the C&C CCG parser (Clark and Curran, 2007), the Enju HPSG parser (Miyao and Tsujii, 2005), the RASP parser (Briscoe et al., 2006), the Stanford parser (Klein and Manning, 2003), and the DCU post-processor of PTB parsers (Cahill et al., 2004), based on LFG and applied to the output of the Charniak and Johnson reranking parser. Of course we were unable to evaluate every publicly available parser, but we believe these are representative of current wide-coverage robust parsing technology.[1]

The C&C parser is based on CCGbank (Hockenmaier and Steedman, 2007), a CCG version of the Penn Treebank. It is ideally suited for this evaluation because CCG was designed to capture the unbounded dependencies being considered. The Enju parser was designed with a similar motivation to C&C, and is also based on an automatically extracted grammar derived from the PTB, but the grammar formalism is HPSG rather than CCG. Both parsers produce head-word dependencies reflecting the underlying predicate-argument structure of a sentence, and so in theory should be straightforward to evaluate.

The RASP parser is based on a manually constructed POS tag-sequence grammar, with a statistical parse selection component and a robust partial-parsing technique which allows it to return output for sentences which do not obtain a full spanning analysis according to the grammar. RASP has not been designed to capture many of the dependencies in our corpus; for example, the tag-sequence grammar has no explicit representation of verb subcategorisation, and so may not know that there is a missing object in the case of extraction from a relative clause (though it does recover some of these dependencies). However, RASP is a popular parser used in a number of applications, and it returns dependencies in a suitable format for evaluation, and so we considered it to be an appropriate and useful member of our parser set.

The Stanford parser is representative of a large number of PTB parsers, exemplified by Collins (1997) and Charniak (2000). The Parseval scores reported for the Stanford parser are not the highest in the literature, but are competitive enough for our purposes. The advantage of the Stanford parser is that it returns dependencies in a suitable format for our evaluation. The dependencies are obtained by a set of manually defined rules operating over the phrase-structure trees returned by the parser (de Marneffe et al., 2006). Like RASP, the Stanford parser has not been designed to capture unbounded dependencies; in particular it does not make use of any of the trace information in the PTB. However, we wanted to include a "standard" PTB parser in our set to see which of the unbounded dependency constructions it is able to deal with.

Finally, there is a body of work on inserting trace information into the output of PTB parsers (Johnson, 2002; Levy and Manning, 2004), which is the annotation used in the PTB for representing unbounded dependencies. The work which deals with the PTB representation directly, such as Johnson (2002), is difficult for us to evaluate because it does not produce explicit dependencies. However, the DCU post-processor is ideal because it does produce dependencies in a GR format. It has also obtained competitive scores on general GR evaluation corpora (Cahill et al., 2004).

3.3 Parser evaluation

The parsers were run essentially out-of-the-box when parsing the test sentences. The one exception was C&C, which required some minor adjusting of parameters, as described in the parser documentation, to obtain close to full coverage on the data. In addition, the C&C parser comes with a

[1] One obvious omission is any form of dependency parser (McDonald et al., 2005; Nivre and Scholz, 2004). However, the dependencies returned by these parsers are local, and it would be non-trivial to infer from a series of links whether a long-range dependency had been correctly represented. Also, dependency parsers are not significantly better at recovering head-based dependencies than constituent parsers based on the PTB (McDonald et al., 2005).

	Obj RC	Obj Red	Sbj RC	Free	Obj Q	RNR	Sbj Embed	Total
C&C	**59.3**	62.6	80.0	72.6	(**81.2**) 27.5	**49.4**	22.4	(**59.7**) 53.6
Enju	47.3	**65.9**	**82.1**	**76.2**	32.5	47.1	**32.9**	**54.4**
DCU	23.1	41.8	56.8	46.4	27.5	40.8	5.9	35.7
Rasp	16.5	1.1	53.7	17.9	27.5	34.5	15.3	25.3
Stanford	22.0	1.1	74.7	64.3	**41.2**	45.4	10.6	38.1

Table 4: Parser accuracy on the unbounded dependency corpus; the highest score for each construction is in bold; the figures in brackets for C&C derive from the use of a separate question model.

specially designed question model, and so we applied both this and the standard model to the object *wh*-question cases.

The parser output was evaluated against each dependency in the corpus. Due to the various GR schemes used by the parsers, an exact match on the dependency label could not always be expected. We considered a correctly recovered dependency to be one where the gold-standard head and dependent were correctly identified, and the label was an "acceptable match" to the gold-standard label. To be an acceptable match, the label had to indicate the grammatical function of the extracted element at least to the level of distinguishing active subjects, passive subjects, objects, and adjuncts. For example, we allowed an `obj` (object) relation as a close enough match for `dobj` (direct object) in the corpus, even though `obj` does not distinguish different kinds of objects, but we did not allow generic "relative pronoun" relations that are underspecified for the grammatical role of the extracted element.

The differences in GR schemes were such that we ended up performing a time-consuming largely manual evaluation. We list here some of the key differences that made the evaluation difficult.

In some cases, the parser's set of labels was less fine-grained than the gold standard. For example, RASP represents the direct objects of both verbs and prepositions as `dobj` (direct object), whereas the gold-standard uses `pobj` for the preposition case. We counted the RASP output as correctly matching the gold standard.

In other cases, the label on the dependency containing the gold-standard head and dependent was too underspecified to be acceptable by itself. For example, where the gold-standard relation was `dobj(placed,buckets)`, DCU produced `relmod(buckets,placed)` with a generic "relative modifier" label. However, the correct label could be recovered from elsewhere in the parser output, specifically a combination of `relpro(buckets,which)` and `obj(placed,which)`. In this case we counted the DCU output as correctly matching the gold standard.

In some constructions the Stanford scheme, upon which the gold-standard was based, makes different choices about heads than other schemes. For example, in the the phrase *Honolulu, which is the center of the warning system*, the corpus contains a subject dependency with *center* as the head: `nsubj(center,Honolulu)`. Other schemes, however, treat the auxiliary verb *is* as the head of the dependency, rather than the predicate nominal *center*. As long as the difference in head selection was due solely to the idiosyncracies of the GR schemes involved, we counted the relation as correct.

Finally, the different GR schemes treat coordination differently. In the corpus, coordinated elements are always represented with two dependencies. Thus the phrase *they may half* **see** *and half* **imagine** *the old* **splendor** has two gold-standard dependencies: `dobj(see,splendor)` and `dobj(imagine,splendor)`. If a parser produced only the former dependency, but appeared to have the coordination correct, then we awarded two marks, even though the second dependency was not explicitly represented.

4 Results

Accuracies for the various parsers are shown in Table 4, with the highest score for each construction in bold. Enju and C&C are the top performers, operating at roughly the same level of accuracy across most of the constructions. Use of the C&C question model made a huge difference for the *wh*-object construction (81.2% vs. 27.5%), showing that adaptation techniques specific to a particular

construction can be successful (Rimell and Clark, 2008).

In order to learn more from these results, in Section 5 we analyse the various errors made by the C&C parser on each construction. The conclusions that we arrive at for the C&C parser we would also expect to apply to Enju, on the whole, since the design of the two parsers is so similar. In fact, some of the recommendations for improvement on this corpus, such as the need for a better parsing model to make better attachment decisions, are parser independent.

The poor performance of RASP on this corpus is clearly related to a lack of subcategorisation information, since this is crucial for recovering extracted arguments. For Stanford, incorporating the trace information from the PTB into the statistical model in some way is likely to help. The C&C and Enju parsers do this through their respective grammar formalisms. Our informal impression of the DCU post-processor is that it has much of the machinery available to recover the dependencies that the Enju and C&C parsers do, but for some reason which is unclear to us it performs much worse.

5 Analysis of the C&C Parser

We categorised the errors made by the C&C parser on the development data for each construction. We chose the C&C parser for the analysis because it was one of the top performers and we have more knowledge of its workings than those of Enju.

The C&C parser first uses a supertagger to assign a small number of CCG lexical categories (essentially subcategorisation frames) to each word in the sentence. These categories are then combined using a set of combinatory rules to build a CCG derivation. The parser uses a log-linear probability model to select the highest-scoring derivation (Clark and Curran, 2007). In general, errors in dependency recovery may occur if the correct lexical category is not assigned by the supertagger for one or more of the words in a sentence, or if an incorrect derivation is chosen by the parsing model.

For unbounded dependency recovery, one source of errors (labeled **type 1** in Table 5) is the wrong lexical category being assigned to the word (normally a verb or preposition) governing the extraction site. In *these testaments that I would submit here*, if *submit* is assigned a category for an intransitive rather than transitive verb, the verb-object relation will not be recovered.

	1a	1b	1c	1d	2	3	Errs	Tot
ObjRC			6		5	2	13	20
ObjRed	2		1	1	1	3	8	23

Free	1					1	2	22
ObjQ			2	2			4	25
RNR			2	1	7	3	13	28
SbjEmb	3	2	1			4	10	13
Subtotal	6	2	12	4				
Total	24				21	14	59	174

Table 5: Error analysis for C&C. *Errs* is the total number of errors for a construction, *Tot* is the number of dependencies of that type in the development data.

There are a number of reasons why the wrong category may be assigned. First, the lexicon may not contain enough information about possible categories for the word (**1a**), or the necessary category may not exist in the parser's grammar at all (**1b**). Even if the grammar contains the correct category and the lexicon makes it available, the parsing model may not choose it (**1c**). Finally, a POS-tagging error on the word may mislead the parser into assigning the wrong category (**1d**).[2]

A second source of errors (**type 2**) is attachment decisions that the parser makes independently of the unbounded dependency. In *Morgan ... carried in several buckets of water from the spring which he poured into the copper boiler*, the parser assigns the correct categories for the relative pronoun and verb, but chooses *spring* rather than *buckets* as the head of the relativized NP (i.e. the object of *pour*). Most attachment errors involve prepositional phrases (PPs) and coordination, which have long been known to be areas where parsers need improvement.

Finally, errors in unbounded dependency recovery may be due to complex errors in the surrounding parse context (**type 3**). We will not comment more on these cases since they do not tell us much about unbounded dependencies in particular.

Table 5 shows the distribution of error types across constructions for the C&C parser. Subject relative clauses, for example, did not have any errors of type 1, because a verb with an extracted

[2]We considered an error to be type 1 only when the category error occurred on the word governing the extraction site, except in the subject embedded sentences, where we also included the embedding verb, since the category of this verb is key to dependency recovery.

subject does not require a special lexical category. Most of the errors here are of type 2. For example, in *a series of pipes and a pressure-measuring chamber which record the rise and fall of the water surface*, the parser attaches the relative clause to *chamber* but not to *series*.

Subject embedded sentences show a different pattern. Many of the errors can be attributed to problems with the lexicon and grammar (1a and 1b). For example, in *shadows that they imagined were Apaches*, the word *imagined* never appears in the training data with the correct category, and so the required entry is missing from the lexicon.

Object extraction from a relative clause had a higher number of errors involving the parsing model (1c). In *the first carefree, dreamless sleep that she had known*, the transitive category is available for *known*, but not selected by the model.

The majority of the errors made by the parser are due to insufficient grammar coverage or weakness in the parsing model due to sparsity of head dependency data, the same fundamental problems that have dogged automatic parsing since its inception. Hence one view of statistical parsing is that it has allowed us to solve the easy problems, but we are still no closer to a general solution for the recovery of the "difficult" dependencies. One possibility is to create more training data targeting these constructions – effectively "active learning by construction" – in the way that Rimell and Clark (2008) were able to build a question parser. We leave this idea for future work.

6 Discussion

Unbounded dependencies are rare events, out in the Zipfian "long tail". They will always constitute a fraction of a percent of the overall total of head-dependencies in any corpus, a proportion too small to make a significant impact on global measures of parser accuracy, when expressive parsers are compared to those that merely approximate human grammar using finite-state or context-free covers. This will remain the case even when such measures are based on dependencies, rather than on parse trees.

Nevertheless, unbounded dependencies remain highly significant in a much more important sense. They support the constructions that are central to those applications of parsing technology for which precision is as important as recall, such as open-domain question-answering. As low-power approximate parsing methods improve (as they must if they are ever to be usable at all for such tasks), we predict that the impact of the constructions we examine here will become evident. No matter how infrequent object questions like "What do frogs eat?" are, if they are answered as if they were subject questions ("Herons"), users will rightly reject any excuse in terms of the overall statistical distribution of related bags of words.

Whether such improvements in parsers come from the availability of more human-labeled data, or from a breakthrough in unsupervised machine learning, we predict an imminent "Uncanny Valley" in parsing applications, due to the inability of parsers to recover certain semantically important dependencies, of the kind familiar from humanoid robotics and photorealistic animation. In such applications, the closer the superficial resemblance to human behavior gets, the more disturbing subtle departures become, and the more they induce mistrust and revulsion in the user.

7 Conclusion

In this paper we have demonstrated that current parsing technology is poor at recovering some of the unbounded dependencies which are crucial for fully representing the underlying predicate-argument structure of a sentence. We have also argued that correct recovery of such dependencies will become more important as parsing technology improves, despite the relatively low frequency of occurrence of the corresponding grammatical constructions. We also see this more focused parser evaluation methodology — in this case construction-focused — as a way of improving parsing technology, as an alternative to the exclusive focus on incremental improvements in overall accuracy measures such as Parseval.

Abstract

We connect two scenarios in structured learning: **adapting** a parser trained on one corpus to another annotation style, and **projecting** syntactic annotations from one language to another. We propose **quasi-synchronous grammar** (QG) features for these structured learning tasks. That is, we score a aligned pair of source and target trees based on local features of the trees and the alignment. Our quasi-synchronous model assigns positive probability to any alignment of any trees, in contrast to a synchronous grammar, which would insist on some form of structural parallelism.

In monolingual dependency parser adaptation, we achieve high accuracy in translating among multiple annotation styles for the same sentence. On the more difficult problem of cross-lingual parser projection, we learn a dependency parser for a target language by using bilingual text, an English parser, and automatic word alignments. Our experiments show that unsupervised QG projection improves on parses trained using only high-precision projected annotations and far outperforms, by more than 35% absolute dependency accuracy, learning an unsupervised parser from raw target-language text alone. When a few target-language parse trees are available, projection gives a boost equivalent to doubling the number of target-language trees.

1 Introduction

1.1 Parser Adaptation

Consider the problem of learning a dependency parser, which must produce a directed tree whose vertices are the words of a given sentence. There are many differing conventions for representing syntactic relations in dependency trees. Say that we wish to output parses in the Prague style and so have annotated a small **target corpus**—e.g., 100 sentences—with those conventions. A parser trained on those hundred sentences will achieve mediocre dependency accuracy (the proportion of words that attach to their correct parent).

But what if we also had a large number of trees in the CoNLL style (the **source corpus**)? Ideally they should help train our parser. But unfortunately, a parser that learned to produce perfect CoNLL-style trees would, for example, get both links "wrong" when its coordination constructions were evaluated against a Prague-style gold standard (Figure 1).

If it were just a matter of this one construction, the obvious solution would be to write a few rules by hand to transform the large source training corpus into the target style. Suppose, however, that there were many more ways that our corpora differed. Then we would like to *learn a statistical model to transform one style of tree into another.*

We may not possess hand-annotated training data for this tree-to-tree transformation task. That would require the two corpora to annotate some of the *same* sentences in different styles.

But fortunately, we can automatically obtain a noisy form of the necessary paired-tree training data. A parser trained on the source corpus can parse the sentences in our target corpus, yielding trees (or more generally, probability distributions over trees) in the source style. We will then learn a tree transformation model relating these noisy source trees to our known trees in the target style.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 822–831,
Singapore, 6-7 August 2009.

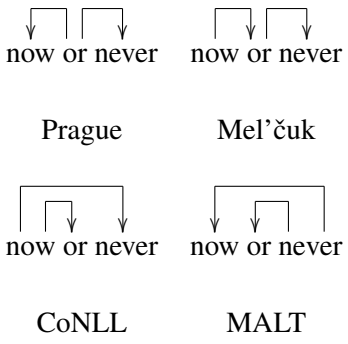

Figure 1: Four of the five logically possible schemes for annotating coordination show up in human-produced dependency treebanks. (The other possibility is a reverse Mel'čuk scheme.) These treebanks also differ on other conventions.

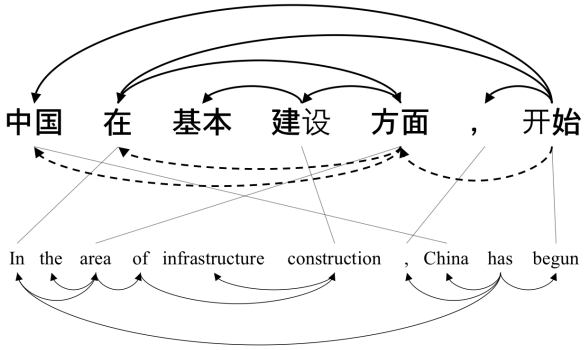

Figure 2: With the English tree and alignment provided by a parser and aligner at test time, the Chinese parser finds the correct dependencies (see §6). A monolingual parser's incorrect edges are shown with dashed lines.

This model should enable us to convert the original large source corpus to target style, giving us additional training data in the target style.

1.2 Parser Projection

For many target languages, however, we do not have the luxury of a large parsed "source corpus" in the language, even one in a different style or domain as above. Thus, we may seek other forms of data to augment our small target corpus. One option would be to leverage unannotated text (McClosky et al., 2006; Smith and Eisner, 2007). But we can also try to transfer syntactic information from a parsed source corpus *in another language*. This is an extreme case of out-of-domain data. This leads to the second task of this paper: *learning a statistical model to transform a syntactic analysis of a sentence in one language into an analysis of its translation*.

Tree transformations are often modeled with *synchronous* grammars. Suppose we are given a sentence w' in the "source" language and its translation w into the "target" language. Their syntactic parses t' and t are presumably not independent, but will tend to have some parallel or at least correlated structure. So we could *jointly* model the parses t', t and the alignment a between them, with a model of the form $p(t, a, t' \mid w, w')$.

Such a joint model captures how t, a, t' mutually constrain each other, so that even partial knowledge of some of these three variables can help us to recover the others when training or decoding on bilingual text. This idea underlies a number of recent papers on syntax-based alignment (using t and t' to better recover a), grammar induction from bitext (using a to better recover t and t'), parser projection (using t' and a to better recover t), as well as full joint parsing (Smith and Smith, 2004; Burkett and Klein, 2008).

In this paper, we condition on the 1-best source tree t'. As for the alignment a, our models either condition on the 1-best alignment or integrate the alignment out. Our models are thus of the form $p(t \mid w, w', t', a)$ or, in the generative case, $p(w, t, a \mid w', t')$. We intend to consider other formulations in future work.

So far, this is very similar to the monolingual parser adaptation scenario, but there are a few key differences. Since the source and target sentences in the bitext are in different languages, there is no longer a trivial alignment between the words of the source and target trees. Given word alignments, we could simply try to project dependency links in the source tree onto the target text. A link-by-link projection, however, could result in invalid trees on the target side, with cycles or disconnected words. Instead, our models learn the necessary transformations that align and transform a source tree into a target tree by means of quasi-synchronous grammar (QG) features.

Figure 2 shows an example of bitext helping disambiguation when a parser is trained with only a small number of Chinese trees. With the help of the English tree and alignment, the parser is able to recover the correct Chinese dependencies using QG features. Incorrect edges from the monolingual parser are shown with dashed lines. (The bilingual parser corrects additional errors in the second half of this sentence, which has been removed to improve legibility.) The parser is able to recover the long-distance dependency from the first Chinese word (*China*) to the last (*begun*), while skipping over the intervening noun

phrase that confused the undertrained monolingual parser. Although, due to the auxiliary verb, "China" and "begun" are *siblings* in English and not in direct dependency, the QG features still leverage this indirect projection.

1.3 Plan of the Paper

We start by describing the features we use to augment conditional and generative parsers when scoring pairs of trees (§2). Then we discuss in turn monolingual (§3) and cross-lingual (§4) parser adaptation. Finally, we present experiments on cross-lingual parser projection in conditions when no target language trees are available for training (§5) and when some trees are available (§6).

2 Form of the Model

What should our model of source and target trees look like? In our view, traditional approaches based on synchronous grammar are problematic both computationally and linguistically. Full inference takes $O(n^6)$ time or worse (depending on the grammar formalism). Yet synchronous models only consider a limited hypothesis space: e.g., parses must be projective, and alignments must decompose according to the recursive parse structure. (For example, two nodes can be aligned only if their respective parents are also aligned.) The synchronous model's probability mass function is also restricted to decompose in this way, so it makes certain conditional independence assumptions; put another way, it can evaluate only certain properties of the triple (t, a, t').

We instead model (t, a, t') as an *arbitrary graph* that includes dependency links among the words of each sentence as well as arbitrary alignment links between the words of the two sentences. This permits non-synchronous and many-to-many alignments. The only hard constraint we impose is that the dependency links within each sentence must constitute a valid monolingual parse—a directed projective spanning tree.[1]

Given the two sentences w, w', our probability distribution over possible graphs considers local features of the parses, the alignment, and both jointly. Thus, we learn what local syntactic configurations tend to occur in each language and how they correspond across languages. As a result, we might learn that parses are "mostly synchronous," but that there are some systematic cross-linguistic divergences and some instances of sloppy (non-parallel or inexact) translation. Our model is thus a form of quasi-synchronous grammar (QG) (Smith and Eisner, 2006a). In that paper, QG was applied to word alignment and has since found applications in question answering (Wang et al., 2007), paraphrase detection (Das and Smith, 2009), and machine translation (Gimpel and Smith, 2009).

All the models in this paper are conditioned on the source tree t'. Conditionally-trained models of adaptation and projection also condition on the target string w and its alignment a to w' and thus have the form $p(t \mid w, w', t', a)$; the unsupervised, generative projection models in §5 have the form $p(w, t, a \mid w', t')$.

The score s of a given tuple of trees, words, and alignment can thus be written as a dot product of weights $\mathbf{w}$ with features $\mathbf{f}$ and $\mathbf{g}$:

$$s(t, t', a, w, w') = \sum_i w_i f_i(t, w) + \sum_j w_j g_j(t, t', a, w, w')$$

The features $\mathbf{f}$ look only at target words and dependencies. In the conditional models of §3 and §6, these features are those of an edge-factored dependency parser (McDonald et al., 2005). In the generative models of §5, $\mathbf{f}$ has the form of a dependency model with valence (Klein and Manning, 2004). All models, for instance, have a feature template that considers the parts of speech of a potential parent-child relation.

In order to benefit from the source language, we also need to include bilingual features $\mathbf{g}$. When scoring a candidate target dependency link from word $x \rightarrow y$, these features consider the relationship of their corresponding source words x' and y'. (The correspondences are determined by the alignment a.) For instance, the source tree t' may contain the link $x' \rightarrow y'$, which would cause a feature for *monotonic* projection to fire for the $x \rightarrow y$ edge. If, on the other hand, $y' \rightarrow x' \in t'$, a *head-swapping* feature fires. If $x' = y'$, i.e. x and y align to the same word, the *same-word* feature fires. Similar features fire when x' and y' are in grandparent-grandchild, sibling, c-command, or none-of-the above relationships, or when y aligns to NULL. These alignment classes are called *configurations* (Smith and Eisner, 2006a, and following). When training is conditioned on the target words (see §3 and §6 below), we conjoin these

[1] Non-projective parsing would also be possible.

configuration features with the part of speech and coarse part of speech of one or both of the source and target words, i.e. the feature template has from one to four tags.

In conditional training, the exponentiated scores s are normalized by a constant: $Z = \sum_t \exp[s(t, t', a, w, w')]$. For the generative model, the locally normalized generative process is explained in §5.3.4.

Previous researchers have written fix-up rules to massage the projected links after the fact and learned a parser from the resulting trees (Hwa et al., 2005). Instead, our models learn the necessary transformations that align and transform a source tree into a target tree. Other researchers have tackled the interesting task of learning parsers from unparsed bitext alone (Kuhn, 2004; Snyder et al., 2009); our methods take advantage of investments in high-resource languages such as English. In work most closely related to this paper, Ganchev et al. (2009) constrain the posterior distribution over target-language dependencies to align to source dependencies some "reasonable" proportion of the time ($\approx 70\%$, cf. Table 2 in this paper). This approach performs well but cannot directly learn regular cross-language non-isomorphisms; for instance, some fixup rules for auxiliary verbs need to be introduced. Finally, Huang et al. (2009) use features, somewhat like QG configurations, on the shift-reduce actions in a monolingual, target-language parser.

3 Adaptation

As discussed in §1, the adaptation scenario is a special case of parser projection where the word alignments are one-to-one and observed. To test our handling of QG features, we performed experiments in which training saw the correct parse trees in both source and target domains, and the mapping between them was simple and regular. We also performed experiments where the source trees were replaced by the noisy output of a trained parser, making the mapping more complex and harder to learn.

We used the subset of the Penn Treebank from the CoNLL 2007 shared task and converted it to dependency representation while varying two parameters: (1) CoNLL vs. Prague coordination style (Figure 1), and (2) preposition the head vs. the child of its nominal object.

We trained an edge-factored dependency parser (McDonald et al., 2005) on "source" domain data that followed one set of dependency conventions. We then trained an edge-factored parser with QG features on a small amount of "target" domain data. The source parser outputs were produced for all target data, both training and test, so that features for the target parser could refer to them.

In this task, we know what the gold-standard source language parses are for any given text, since we can produce them from the original Penn Treebank. We can thus measure the contribution of adaptation loss alone, and the combined loss of imperfect source-domain parsing with adaptation (Table 1). When no target domain trees are available, we simply have the performance of the source domain parser on this out-of-domain data. Training a target-domain parser on as few as 10 sentences shows substantial improvements in accuracy. In the "gold" conditions, where the target parser starts with perfect source trees, accuracy approaches 100%; in the realistic "parse" conditions, where the target-domain parser gets noisy source-domain parses, the improvements are quite significant but approach a lower ceiling imposed by the performance of the source parser.[2]

The adaptation problem in this section is a simple proof of concept of the QG approach; however, more complex and realistic adaptation problems exist. Monolingual adaptation is perhaps most obviously useful when the source parser is a black-box or rule-based system or is trained on unavailable data. One might still want to use such a parser in some new context, which might require new data or a new annotation standard.

We are also interested in scenarios where we want to avoid expensive retraining on large reannotated treebanks. We would like a linguist to be able to annotate a few trees according to a hypothesized theory and then quickly use QG adaptation to get a parser for that theory. One example would be adapting a constituency parser to produce dependency parses. We have concentrated here on adapting between two dependency parse styles, in order to line up with the cross-lingual tasks to which we now turn.

[2] In the diagonal cells, source and target styles match, so training the QG parser amounts to a "stacking" technique (Martins et al., 2008). The small training size and overregularization of the QG parser mildly hurts in-domain parsing performance.

	% Dependency Accuracy on Target

Table 1: Adapting a parser to a new annotation style. We learn to parse in a "target" style (wide column label) given some number (narrow column label) of supervised target-style training sentences. As a font of additional features, *all training and test sentences* have already been augmented with parses in some "source" style (row label): either gold-standard parses (an oracle experiment) or else the output of a parser trained on 18k source trees (more realistic). If we have 0 training sentences, we simply output the source-style parse. But with 10 or 100 target-style training sentences, each off-diagonal block learns to adapt, mostly closing the gap with the diagonal block in the same column. In the diagonal blocks, source and target styles match, and the QG parser degrades performance when acting as a "stacked" parser.

4 Cross-Lingual Projection: Background

As in the adaptation scenario above, many syntactic structures can be transferred from one language to another. In this section, we evaluate the extent of this direct projection on a small hand-annotated corpus. In §5, we will use a QG generative model to learn dependency parsers from bitext when there are no annotations in the target language. Finally, in §6,we show how QG features can augment a target-language parser trained on a small set of labeled trees.

For syntactic annotation projection to work at all, we must hypothesize, or observe, that at least some syntactic structures are preserved in translation. Hwa et al. (2005) have called this intuition the **Direct Correspondence Assumption** (DCA, with slight notational changes):

> Given a pair of sentences w and w' that are translations of each other with syntactic structure t and t', if nodes x' and y' of t' are aligned with nodes x and y of t, respectively, and if syntactic relationship $R(x', y')$ holds in t', then $R(x, y)$ holds in t.

The validity of this assumption clearly depends on the node-to-node alignment of the two trees. We again work in a dependency framework, where syntactic nodes are simply lexical items. This allows us to use existing work on word alignment.

Hwa et al. (2005) tested the DCA under idealized conditions by obtaining hand-corrected dependency parse trees of a few hundred sentences of Spanish-English and Chinese-English bitext. They also used human-produced word alignments.

Corpus	Prec.[%]	Rec.[%]
Spanish	64.3	28.4
(no punc.)	72.0	30.8
Chinese	65.1	11.1
(no punc.)	68.2	11.5

Table 2: Precision and recall of direct dependency projection via one-to-one links alone.

Since their word alignments could be many-to-many, they gave a heuristic Direct Projection Algorithm (DPA) for resolving them into component dependency relations. It should be noted that this process introduced empty words into the projected target language tree and left words that are unaligned to English detached from the tree; as a result, they measured performance in dependency F-score rather than accuracy. With manual English parses and word alignments, this DPA achieved 36.8% F-score in Spanish and 38.1% in Chinese. With Collins-model English parses and GIZA++ word alignments, F-score was 33.9% for Spanish and 26.3% for Chinese. Compare this to the Spanish attach-left baseline of 31.0% and the Chinese attach-right baselines of 35.9%. These discouragingly low numbers led them to write language-specific transformation rules to fix up the projected trees. After these rules were applied to the projections of automatic English parses, F-score was 65.7% for English and 52.4% for Chinese.

While these F-scores were low, it is useful to look at a subset of the alignment: dependencies projected across one-to-one alignments before the heuristic fix-ups had a much higher precision, if lower recall, than Hwa et al.'s final results. Us-

ing Hwa et al.'s data, we calculated that the precision of projection to Spanish and Chinese via these one-to-one links was $\approx 65\%$ (Table 2). There is clearly more information in these direct links than one would think from the F-scores. To exploit this information, however, we need to overcome the problems of (1) learning from partial trees, when not all target words are attached, and (2) learning in the presence of the still considerable noise in the projected one-to-one dependencies—e.g., at least 28% error for Spanish non-punctuation dependencies.

What does this noise consist of? Some errors reflect fairly arbitrary annotation conventions in treebanks, e.g. should the auxiliary verb govern the main verb or vice versa. (Examples like this suggest that the projection problem contains the adaptation problem above.) Other errors arise from divergences in the complements required of certain head words. In the German-English translation pair, with co-indexed words aligned,

$$[\text{an } [\text{den Libanon}_1]]\ \text{denken}_2 \ \leftrightarrow\ \text{remember}_2\ \text{Lebanon}_1$$

we would prefer that the preposition *an* attach to *denken*, even though the preposition's object *Libanon* aligns to a direct child of *remember*. In other words, we would like the grandparent-parent-child chain of *denken* $\rightarrow$ *an* $\rightarrow$ *Libanon* to align to the parent-child pair of *remember* $\rightarrow$ *Lebanon*. Finally, naturally occurring bitexts contain some number of free or erroneous translations. Machine translation researchers often seek to strike these examples from their training corpora; "free" translations are not usually welcome from an MT system.

5 Unsupervised Cross-Lingual Projection

First, we consider the problem of parser projection when there are zero target-language trees available. As in much other work on unsupervised parsing, we try to learn a generative model that can predict target-language sentences. Our novel contribution is to *condition the probabilities of the generative actions* on the dependency parse of a source-language translation. Thus, our generative model is a quasi-synchronous grammar, exactly as in (Smith and Eisner, 2006a).[3]

When training on target sentences w, therefore, we tune the model parameters to maximize not $\sum_t p(t, w)$ as in ordinary EM, but rather $\sum_t p(t, w, a \mid t', w')$. We hope that this *conditional EM* training will drive the model to posit appropriate syntactic relationships in the latent variable t, because—thanks to the structure of the QG model—that is the easiest way for it to exploit the extra information in t', w' to help predict w.[4] At test time, t', w' are not made available, so we just use the trained model to find $\text{argmax}_t\, p(t \mid w)$, backing off from the conditioning on t', w' and summing over a.

Below, we present the specific generative model (§5.1) and some details of training (§5.2). We will then compare three approaches (§5.3):

§**5.3.2** a straight EM baseline (which does not condition on t', w' at all)

§**5.3.3** a "hard" projection baseline (which naively projects t', w' to derive direct supervision in the target language)

§**5.3.4** our conditional EM approach above (which makes t', w' available to the learner for "soft" indirect supervision via QG)

5.1 Generative Models

Our base models of target-language syntax are generative dependency models that have achieved state-of-the art results in unsupervised dependency structure induction. The simplest version, called Dependency Model with Valence (DMV), has been used in isolation and in combination with other models (Klein and Manning, 2004; Smith and Eisner, 2006b). The DMV generates the right children, and then independently the left children, for each node in the dependency tree. Nodes correspond to words, which are represented by their part-of-speech tags. At each step of generation, the DMV stochastically chooses whether to stop generating, conditioned on the currently generating head; whether it is generating to the right or left; and whether it has yet generated any children on that side. If it chooses to continue, it then

[3] Our task here is new; they used it for alignment.

[4] The contrastive estimation of Smith and Eisner (2005) also used a form of conditional EM, with similar motivation. They suggested that EM grammar induction, which learns to predict w, unfortunately learns mostly to predict lexical topic or other properties of the training sentences that do not strongly require syntactic latent variables. To focus EM on modeling the *syntactic* relationships, they conditioned the prediction of w on almost complete knowledge of the lexical items. Similarly, we condition on a source translation of w. Furthermore, our QG model structure makes it easy for EM to learn to exploit the (explicitly represented) syntactic properties of that translation when predicting w.

stochastically generates the tag of a new child, conditioned on the head. The parameters of the model are thus of the form

$$p(stop \mid head, dir, adj) \quad (1)$$

$$p(child \mid head, dir) \quad (2)$$

where $head$ and $child$ are part-of-speech tags, $dir \in \{\text{left}, \text{right}\}$, and $adj, stop \in \{\text{true}, \text{false}\}$. ROOT is stipulated to generate a single right child.

Bilingual configurations that condition on t', w' (§2) are incorporated into the generative process as in Smith and Eisner (2006a). When the model is generating a new child for word x, aligned to x', it first chooses a configuration and then chooses a source word y' in that configuration. The child y is then generated, conditioned on its parent x, most recent sibling a, and its source analogue y'.

5.2 Details of EM Training

As in previous work on grammar induction, we learn the DMV from part-of-speech-tagged target-language text. We use expectation maximization (EM) to maximize the likelihood of the data. Since the likelihood function is nonconvex in the unsupervised case, our choice of initial parameters can have a significant effect on the outcome. Although we could also try many random starting points, the initializer in Klein and Manning (2004) performs quite well.

The base dependency parser generates the right dependents of a head separately from the left dependents, which allows $O(n^3)$ dynamic programming for an n-word target sentence. Since the QG annotates nonterminals of the grammar with single nodes of t', and we consider two nodes of t' when evaluating the above dependency configurations, QG parsing runs in $O(n^3m^2)$ for an m-word source sentence. If, however, we restrict candidate senses for a target child c to come from links in an IBM Model 4 Viterbi alignment, we achieve $O(n^3k^2)$, where k is the maximum number of possible words aligned to a given target language word. In practice, $k \ll m$, and parsing is not appreciably slower than in the monolingual setting.

If all configurations were equiprobable, the source sentence would provide no information to the target. In our QG experiments, therefore, we started with a bias towards direct parent–child links and a very small probability for breakages of locality. The values of other configuration parameters seem, experimentally, less important for insuring accurate learning.

5.3 Experiments

Our experiments compare learning on target language text to learning on parallel text. In the latter case, we compare learning from high-precision one-to-one alignments alone, to learning from all alignments using a QG.

5.3.1 Corpora

Our development and test data were drawn from the German TIGER and Spanish Cast3LB treebanks as converted to projective dependencies for the CoNLL 2007 Shared Task (Brants et al., 2002; Civit Torruella and Martí Antonín, 2002).[5]

Our training data were subsets of the 2006 Statistical Machine Translation Workshop Shared Task, in particular from the German-English and Spanish-English Europarl parallel corpora (Koehn, 2002). The Shared Task provided pre-built automatic GIZA++ word alignments, which we used to facilitate replicability. Since these word alignments do not contain posterior probabilities or null links, nor do they distinguish which links are in the IBM Model intersection, we treated all links as equally likely when learning the QG. Target language words unaligned to any source language words were the only nodes allowed to align to NULL in QG derivations.

We parsed the English side of the bitext with the projective dependency parser described by McDonald et al. (2005) trained on the Penn Treebank §§2–20. Much previous work on unsupervised grammar induction has used gold-standard part-of-speech tags (Smith and Eisner, 2006b; Klein and Manning, 2004; Klein and Manning, 2002). While there are no gold-standard tags for the Europarl bitext, we did train a conditional Markov

[5] We made one change to the annotation conventions in German: in the dependencies provided, words in a noun phrase governed by a preposition were all attached to that preposition. This meant that in the phrase *das Kind* ("the child") in, say, subject position, *das* was the child of *Kind*; but, in *für das Kind* ("for the child"), *das* was the child of *für*. This seems to be a strange choice in converting from the TIGER constituency format, which does in fact annotate NPs inside PPs; we have standardized prepositions to govern only the head of the noun phrase. We did *not* change any other annotation conventions to make them more like English. In the Spanish treebank, for instance, control verbs are the children of their verbal complements: in *quiero decir* ("I want to say"="I mean"), *quiero* is the child of *decir*. In German coordinations, the coordinands all attach to the first, but in English, they all attach to the last. These particular divergences in annotation style hurt all of our models equally (since none of them have access to labeled trees). These annotation divergences are one motivation for experiments below that include some target trees.

Baselines	Dependency accuracy [%] German	Spanish
Modify prev.	18.2	28.5
Modify next	27.5	21.4
EM	30.2	25.6
Hard proj.	66.2	59.1
Hard proj. w/EM	58.6	53.0
QG w/EM	**68.5**	**64.8**

Table 3: Test accuracy with unsupervised training methods

model tagger on a few thousand tagged sentences. This is the only supervised data we used in the target. We created versions of each training corpus with the first thousand, ten thousand, and hundred thousand sentence pairs, each a prefix of the next. Since the target-language-only baseline converged much more slowly, we used a version of the corpora with sentences 15 target words or fewer.

5.3.2 Fully Unsupervised EM

Using the target side of the bitext as training data, we initialized our model parameters as described in §5.2 and ran EM. We checked convergence on a development set and measured unlabeled dependency accuracy on held-out test data. We compare performance to simple attach-right and attach left baselines (Table 3). For mostly head-final German, the "modify next" baseline is better; for mostly head-initial Spanish, "modify previous" wins. Even after several hundred iterations, performance was slightly, but not significantly better than the baseline for German. EM training did not beat the baseline for Spanish.[6]

5.3.3 Hard Projection, Semi-Supervised EM

The simplest approach to using the high-precision one-to-one word alignments is labeled "hard projection" in the table. We filtered the training corpus to find sentences where enough links were projected to completely determine a target language tree. Of course, we needed to filter more than 1000 sentences of bitext to output 1000 training sentences in this way. We simply perform supervised training with this subset, which is still quite noisy (§4), and performance quickly plateaus. Still, this method substantially improves over the baselines and unsupervised EM.

Restricting ourselves to fully projected trees seems a waste of information. We can also simply take all one-to-one projected links, impute expected counts for the remaining dependencies with EM, and update our models. This approach ("hard projection with EM"), however, performed worse than using only the fully projected trees. In fact, only the first iteration of EM with this method made any improvement; afterwards, EM degraded accuracy further from the numbers in Table 3.

5.3.4 Soft Projection: QG & Conditional EM

The quasi-synchronous model used all of the alignments in re-estimating its parameters and performed significantly better than hard projection. Unlike EM on the target language alone, the QG's performance does not depend on a clever initializer for initial model weights—all parameters of the generative model except for the QG configuration features were initialized to zero. Setting the prior to prefer direct correspondence provides the necessary bias to initialize learning.

Error analysis showed that certain types of dependencies eluded the QG's ability to learn from bitext. The Spanish treebank treats some verbal complements as the heads of main verbs and auxiliary verbs as the children of participles; the QG, following the English, learned the opposite dependency direction. Spanish treebank conventions for punctuation were also a common source of errors. In both German and Spanish, coordinations (a common bugbear for dependency grammars) were often mishandled: both treebanks attach the later coordinands and any conjunctions to the first coordinand; the reverse is true in English. Finally, in both German and Spanish, preposition attachments often led to errors, which is not surprising given the unlexicalized target-language grammars. Rather than trying to adjudicate which dependencies are "mere" annotation conventions, it would be useful to test learned dependency models on some extrinsic task such as relation extraction or machine translation.

6 Supervised Cross-Lingual Projection

Finally, we consider the problem of parser projection when some target language trees are available. As in the adaptation case (§3), we train a conditional model (*not* a generative DMV) of the target

[6] While these results are worse than those obtained previously for this model, the experiments in Klein and Manning (2004) and only used sentences of 10 words or fewer, without punctuation, and with gold-standard tags. Punctuation in particular seems to trip up the initializer: since a sentence-final periods appear in most sentences, EM often decides to make it the head.

tree given the target sentence, using the monolingual and bilingual QG features, including configurations conjoined with tags, outlined above (§2).

For these experiments, we used the LDC's English-Chinese Parallel Treebank (ECTB). Since manual word alignments also exist for a part of this corpus, we were able to measure the loss in accuracy (if any) from the use of an automatic English parser and word aligner. The source-language English dependency parser was trained on the Wall Street Journal, where it achieved 91% dependency accuracy on development data. However, it was only 80.3% accurate when applied to our task, the English side of the ECTB.[7]

After parsing the source side of the bitext, we train a parser on the annotated target side, using QG features described above (§2). Both the monolingual target-language parser and the projected parsers are trained to optimize conditional likelihood of the target trees t' with ten iterations of stochastic gradient ascent.

In Figure 3, we plot the performance of the target-language parser on held-out bitext. Although projection performance is, not surprisingly, better if we know the true source trees at training and test time, even with the 1-best output of the source parser, QG features help produce a parser as accurate asq one trained on twice the amount of monolingual data. In ablation experiments, we included bilingual features only for directly projected links, with no features for head-swapping, grandparents, etc. When using 1-best English parses, parsers trained only with direct-projection and monolingual features performed worse; when using gold English parses, parsers with direct-projection-only features performed better when trained with more Chinese trees.

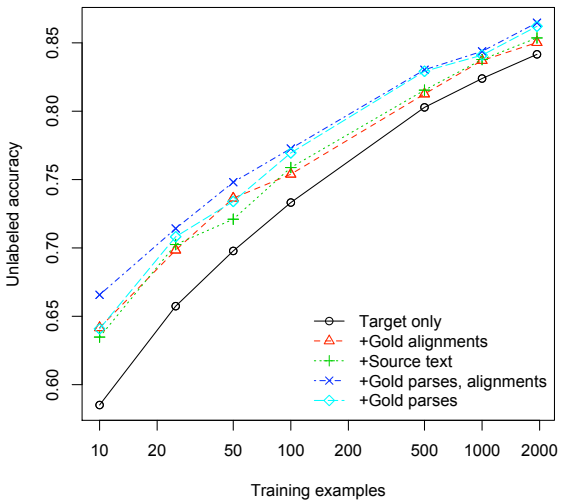

Figure 3: Parser projection with target trees. Using the true or 1-best parse trees in the source language is equivalent to having twice as much data in the target language. Note that the penalty for using automatic alignments instead of gold alignments is negligible; in fact, using *Source text* alone is often higher than +*Gold alignments*. Using gold source trees, however, significantly outperforms using 1-best source trees.

7 Discussion

The two related problems of parser adaptation and projection are often approached in different ways. Many adaptation methods operate by simple augmentations of the target feature space, as we have done here (Daume III, 2007). Parser projection, on the other hand, often uses a multi-stage pipeline (Hwa et al., 2005). The methods presented here move parser projection much closer in efficiency and simplicity to monolingual parsing.

We showed that augmenting a target parser with quasi-synchronous features can lead to significant improvements—first in experiments with adapting to different dependency representations in English, and then in cross-language parser projection. As with many domain adaptation problems, it is quite helpful to have some annotated target data, especially when annotation styles vary (Dredze et al., 2007). Our experiments show that unsupervised QG projection improves on parsers trained using only high-precision projected annotations and far outperforms, by more than 35% absolute dependency accuracy, unsupervised EM. When a small number of target-language parse trees is available, projection gives a boost equivalent to doubling the number of target trees.

The loss in performance from conditioning only on noisy 1-best source parses points to some natural avenues for improvement. We are exploring methods that incorporate a packed parse forest on the source side and similar representations of uncertainty about alignments. Building on our recent belief propagation work (Smith and Eisner, 2008), we can jointly infer two dependency trees and their alignment, under a joint distribution $p(t, a, t' \mid w, w')$ that evaluates the full graph of dependency and alignment edges.

[7] It would be useful to explore whether the techniques of §3 above could be used to improve English accuracy by domain adaptation. In theory a model with QG features trained to perform well on Chinese should not suffer from an inaccurate, but consistent, English parser, but the results in Figure 3 indicate a significant benefit to be had from better English parsing or from joint Chinese-English inference.

Abstract

We investigate the effectiveness of self-training PCFG grammars with latent annotations (PCFG-LA) for parsing languages with different amounts of labeled training data. Compared to Charniak's lexicalized parser, the PCFG-LA parser was more effectively adapted to a language for which parsing has been less well developed (i.e., Chinese) and benefited more from self-training. We show for the first time that self-training is able to significantly improve the performance of the PCFG-LA parser, a single generative parser, on both small and large amounts of labeled training data. Our approach achieves state-of-the-art parsing accuracies for a single parser on both English (91.5%) and Chinese (85.2%).

1 Introduction

There is an extensive research literature on building high quality parsers for English (Collins, 1999; Charniak, 2000; Charniak and Johnson, 2005; Petrov et al., 2006), however, models for parsing other languages are less well developed. Take Chinese for example; there have been several attempts to develop accurate parsers for Chinese (Bikel and Chiang, 2000; Levy and Manning, 2003; Petrov and Klein, 2007), but the state-of-the-art performance, around 83% F measure on Penn Chinese Treebank (achieved by the Berkeley parser (Petrov and Klein, 2007)) falls far short of performance on English (∼90-92%). As pointed out in (Levy and Manning, 2003), there are many linguistic differences between Chinese and English, as well as structural differences between their corresponding treebanks, and some of these make it a harder task to parse Chinese. Additionally, the fact that the available treebanked Chinese materials are more limited than for English also increases the challenge of building high quality Chinese parsers. Many of these differences would also tend to apply to other less well investigated languages.

In this paper, we focus on English and Chinese because the former is a language for which extensive parsing research has been conducted while the latter is a language that has been less extensively studied. We adapt and improve the Berkeley parser, which learns PCFG grammars with latent annotations, and show through comparative studies that this parser significantly outperforms Charniak's parser, which was initially developed for English and subsequently ported to Chinese. We focus on answering two questions: how well does a parser perform across languages and how much does it benefit from self-training?

The first question is of special interest when choosing a parser that is designed for one language and adapting it to another less studied language. We improve the PCFG-LA parser by adding a language-independent method for handling rare words and adapt it to another language, Chinese, by creating a method to better model Chinese unknown words. Our results show that the PCFG-LA parser performs significantly better than Charniak's parser on Chinese, and is also somewhat more accurate on English, although both parsers have high accuracy.

The second question is important because labeled training data is often quite limited, especially for less well investigated languages, while unlabeled data is ubiquitous. Early investigations on self-training for parsing have had mixed results. Charniak (1997) reported no improvements from self-training a PCFG parser on the standard WSJ training set. Steedman et al. (2003) reported some degradation using a lexicalized tree adjoining grammar parser and minor improvement using Collins lexicalized PCFG parser; however, this gain was obtained only when the parser

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 832–841,
Singapore, 6-7 August 2009.

was trained on a small labeled set. Reichart and Rappoport (2007) obtained significant gains using Collins lexicalized parser with a different self-training protocol, but again they only looked at small labeled sets. McClosky et al. (2006) effectively utilized unlabeled data to improve parsing accuracy on the standard WSJ training set, but they used a two-stage parser comprised of Charniak's lexicalized probabilistic parser with n-best parsing and a discriminative reranking parser (Charniak and Johnson, 2005), and thus it would be better categorized as "co-training" (McClosky et al., 2008). It is worth noting that their attempts at self-training Charniak's lexicalized parser directly resulted in no improvement. There are other successful semi-supervised training approaches for dependency parsing, such as (Koo et al., 2008; Wang et al., 2008), and it would be interesting to investigate how they could be applied to constituency parsing.

We show in this paper, for the first time, that self-training is able to significantly improve the performance of the PCFG-LA parser, a single generative parser, on both small and large amounts of labeled training data, for both English and Chinese. With self-training, a fraction of the WSJ or CTB6 treebank training data is sufficient to train a PCFG-LA parser that is able to achieve or even beat the accuracies obtained using a single parser trained on the entire treebank without self-training. We conjecture based on our comparison of the PCFG-LA parser to Charniak's parser that the addition of self-training data helps the former parser learn more fine-grained latent annotations without over-fitting.

The rest of this paper is organized as follows. We describe the PCFG-LA parser and several enhancements in Section 2, and discuss self-training in Section 3. We then outline the experimental setup in Section 4, describe the results in Section 5, and present a detailed analysis in Section 6. The last section draws conclusions and describes future work.

2 Parsing Model

The Berkeley parser (Petrov et al., 2006; Petrov and Klein, 2007) is an efficient and effective parser that introduces latent annotations (Matsuzaki et al., 2005) to refine syntactic categories to learn better PCFG grammars. In the example parse tree in Figure 1(a), each syntactic category is split into multiple latent subcategories, and accordingly the original parse tree is decomposed into many parse trees with latent annotations. Figure 1(b) depicts one of such trees. The grammar and lexical rules are split accordingly, e.g., NP→PRP is split into different NP-i→PRP-j rules. The expansion probabilities of these split rules are the parameters of a PCFG-LA grammar.

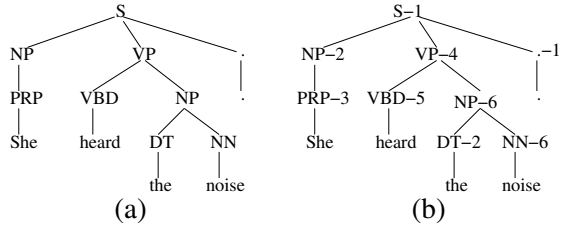

Figure 1: (a) original treebank tree, (b) after latent annotation.

The objective of training is to learn a grammar with latent annotations that maximizes the likelihood of the training trees, i.e., the sum of the likelihood of all parse trees with latent annotations. Since the latent annotations are not available in the treebank, a variant of the EM algorithm is utilized to learn the rule probabilities for them. The Berkeley parser employs a hierarchical split-merge method that gradually increases the number of latent annotations and adaptively allocates them to different treebank categories to best model the training data. In this paper, we call a grammar trained after n split-merge steps an n-th *order* grammar. The order of a grammar is a step (not continuous) function of the number of latent annotations because the split-merge algorithm first splits each latent annotation into two and then merges some of the splits back based on their ability to increase training likelihood.

For this paper, we implemented[1] our own version of Berkeley parser. Updates include better handling of rare words across languages, as well as unknown Chinese words. The parser is able to process difficult sentences robustly using adaptive beam expansion. The training algorithm was updated to support a wide range of self-training experiments (e.g., posterior-weighted unlabeled data, introducing self-training in later iterations) and to make use of multiple processors to parallelize EM training. The parallelization is crucial

[1] A major motivation for this implementation was to support some algorithms we are developing. Most of our enhancements will be merged with a future release of the Berkeley parser.

for training a model with large volumes of data in a reasonable amount of time[2].

We next describe the language-independent method to handle rare words, which is important for training better PCFG-LA grammars especially when the training data is limited in size, and our unknown Chinese word handling method, highlighting the importance of utilizing language-specific features to enhance parsing performance. As we will see later, both of these methods significantly improve parsing performance.

2.1 Rare Word Handling

Whereas rule expansions are frequently observed in the treebank, word-tag co-occurrences are sparser and more likely to suffer from over-fitting. Although the lexicon smoothing method in the Berkeley parser is able to make the word emission probabilities of different latent states of a POS tag more alike, the EM training algorithm still strongly discriminates among word identities. Suppose word tag pairs $\langle w_1, t\rangle$ and $\langle w_2, t\rangle$ both appear the same number of times in the training data. In a PCFG grammar without latent annotations, the probabilities of emitting these two words given tag t would be the same, i.e., $p(w_1|t) = p(w_2|t)$. After introducing latent annotation x to tag t, the emission probabilities of these two words given a latent state t_x may no longer be the same because $p(w_1|t_x)$ and $p(w_2|t_x)$ are two independent parameters that the EM algorithm optimizes on. It is beneficial to learn subcategories of POS tags to model different types of words, especially for frequent words; however, it is not desirable to strongly discriminate among rare words because it could distract the model from learning about common phenomena.

To handle this problem, the probability of a latent state t_x generating a rare word w is forced to be proportional to the emission probability of word w given the surface tag t. This is achieved by mapping all words with frequency less than threshold[3] λ to the *unk* symbol, and for each latent state t_x of a POS tag t, accumulating the word tag statistics of these rare words to $c_r(t_x, \textit{unk}) = \sum_{w:c(w)<\lambda} c(t_x, w)$, and then redistributing them among the rare words to estimate their emission probabilities:

$$c(t_x, w) = c_r(t_x, unk) \cdot \frac{c(t, w)}{c_r(t, unk)}$$
$$p(w|t_x) = c(t_x, w) / \sum\nolimits_w c(t_x, w)$$

2.2 Chinese Unknown Word Handling

The Berkeley parser utilizes statistics associated with rare words (e.g., suffix, capitalization) to estimate the emission probabilities of unknown words at decoding time. This is adequate for for English, however, only a limited number of classes of unknown words, such as digits and dates, are handled for Chinese. In this paper, we develop a character-based unknown word model inspired by (Huang et al., 2007) that reflects the fact that characters in any position (prefix, infix, or suffix) can be predictive of the part-of-speech (POS) type for Chinese words. In our model, the word emission probability, $p(w|t_x)$, of an unknown word w given the latent state t_x of POS tag t is estimated by the geometric average of the emission probability of the characters c_k in the word:

$$P(w|t_x) = \sqrt[n]{\prod\nolimits_{c_k \in w, P(c_k|t) \neq 0} P(c_k|t)}$$

where $n = |\{c_k \in w | P(c_k|t) \neq 0\}|$. Characters not seen in the training data are ignored in the computation of the geometric average. We back off to use the rare word statistics regardless of word identity when the above equation cannot be used to compute the emission probability.

3 Parser Self-Training

Our hypothesis is that combining automatically labeled parses with treebank trees will help the EM training of the PCFG-LA parser to make more informed decisions about latent annotations and thus generate more effective grammars. In this section, we discuss how self-training is applied to train a PCFG-LA parser.

There are several ways to automatically label the data. A fairly standard method is to parse the unlabeled sentences with a parser trained on labeled training data, and then combine the resulting parses with the treebank training data to retrain the parser. This is the approach we chose for self-training. An alternative approach is to run EM directly on the labeled treebank trees and the unlabeled sentences, without explicit parse trees for the unlabeled sentences. However, because the

[2]The parallel version is able to train our largest grammar on a 8-core machine within a week, while the non-parallel version is not able to finish even after 3 weeks.

[3]The value of λ is tuned on the development set.

brackets would need to be determined for the unlabeled sentences together with the latent annotations, this would increase the running time from linear in the number of expansion rules to cubic in the length of the sentence.

Another important decision is how to weight the gold standard and automatically labeled data when training a new parser model. Errors in the automatically labeled data could limit the accuracy of the self-trained model, especially when there is a much greater quantity of automatically labeled data than the gold standard training data. To balance the gold standard and automatically labeled data, one could duplicate the treebank data to match the size of the automatically labeled data; however, the training of the PCFG-LA parser would result in redundant applications of EM computations over the same data, increasing the cost of training. Instead we weight the posterior probabilities computed for the gold and automatically labeled data, so that they contribute equally to the resulting grammar. Our preliminary experiments show that balanced weighting is effective, especially for Chinese (about 0.4% absolute improvement) where the automatic parse trees have a relatively lower accuracy.

The training procedure of the PCFG-LA parser gradually introduces more latent annotations during each split-merge stage, and the self-labeled data can be introduced at any of these stages. Introduction of the self-labeled data in later stages, after some important annotations are learned from the treebank, could result in more effective learning. We have found that a middle stage introduction (after 3 split-merge iterations) of the automatically labeled data has an effect similar to balancing the weights of the gold and automatically labeled trees, possibly due to the fact that both methods place greater trust in the former than the latter. In this study, we introduce the automatically labeled data at the outset and weight it equally with the gold treebank training data in order to focus our experiments to support a deeper analysis.

4 Experimental Setup

For the English experiments, sections from the WSJ Penn Treebank are used as labeled training data: section 2-19 for training, section 22 for development, and section 23 as the test set. We also used 210k[4] sentences of unlabeled news articles in the BLLIP corpus for English self-training.

For the Chinese experiments, the Penn Chinese Treebank 6.0 (CTB6) (Xue et al., 2005) is used as labeled data. CTB6 includes both news articles and transcripts of broadcast news. We partitioned the news articles into train/development/test sets following Huang et al. (2007). The broadcast news section is added to the training data because it shares many of the characteristics of newswire text (e.g., fully punctuated, contains nonverbal expressions such as numbers and symbols). In addition, 210k sentences of unlabeled Chinese news articles are used for self-training. Since the Chinese parsers in our experiments require word-segmented sentences as input, the unlabeled sentences need to be word-segmented first. As shown in (Harper and Huang, 2009), the accuracy of automatic word segmentation has a great impact on Chinese parsing performance. We chose to use the Stanford segmenter (Chang et al., 2008) in our experiments because it is consistent with the treebank segmentation and provides the best performance among the segmenters that were tested. To minimize the discrepancy between the self-training data and the treebank data, we normalize both CTB6 and the self-training data using UW Decatur (Zhang and Kahn, 2008) text normalization.

Table 1 summarizes the data set sizes used in our experiments. We used slightly modified versions of the treebanks; empty nodes and nonterminal-yield unary rules[5], e.g., NP→VP, are deleted using tsurgeon (Levy and Andrew, 2006).

	Train	**Dev**	**Test**	**Unlabeled**
English	39.8k (950.0k)	1.7k (40.1k)	2.4k (56.7k)	210k (5,082.1k)
Chinese	24.4k (678.8k)	1.9k (51.2k)	2.0k (52.9k)	210k (6,254.9k)

Table 1: The number of sentences (and words in parentheses) in our experiments.

We trained parsers on 20%, 40%, 60%, 80%, and 100% of the treebank training data to evaluate

[4]This amount was constrained based on both CPU and memory. We plan to investigate cloud computing to exploit more unlabeled data.

[5]As nonterminal-yield unary rules are less likely to be posited by a statistical parser, it is common for parsers trained on the standard Chinese treebank to have substantially higher precision than recall. This gap between bracket recall and precision is alleviated without loss of parse accuracy by deleting the nonterminal-yield unary rules. This modification similarly benefits both parsers we study here.

the effect of the amount of labeled training data on parsing performance. We also compare how self-training impacts the models trained with different amounts of gold-standard training data. This allows us to simulate scenarios where the language has limited human-labeled resources.

We compare models trained only on the gold labeled training data with those that utilize additional unlabeled data. Self-training (PCFG-LA or Charniak) proceeds in two steps. In the first step, the parser is first trained on the allocated labeled training data (e.g., 40%) and is then used to parse the unlabeled data. In the second step, a new parser is trained on the weighted combination[6] of the allocated labeled training data and the additional automatically labeled data. The development set is used in each step to select the grammar order with the best accuracy for the PCFG-LA parser and to tune the smoothing parameters for Charniak's parser.

5 Results

In this section, we first present the effect of unknown and rare word handling for the PCFG-LA parser, and then compare and discuss the performance of the PCFG-LA parser and Charniak's parser across languages with different amounts of labeled training, either with or without self-training.

5.1 Rare and Unknown Word Handling

Table 2 reports the effect of unknown and rare word handing for the PCFG-LA parser trained on 100%[7] of the labeled training data. The rare word handling improves the English parser by 0.68% and the Chinese parser by 0.56% over the Berkeley parser. The Chinese unknown word handling method alone improves the Chinese parser by 0.47%. The rare and unknown handling methods together improve the Chinese parser by 0.92%. All the improvements are statistically significant[8].

We found that the rare word handling method becomes more effective as the number of latent annotations increases, especially when there is not a sufficient amount of labeled training data. Sharing statistics of the rare words during training results in more robust grammars with better parsing performance. The unknown word handling method also gives greater improvements on grammars trained on smaller amounts of training data, suggesting that it is quite helpful for modeling unseen words at decoding time. However, it tends to be less effective when the number of latent annotations increases, probably because the probability estimation of unseen words based on surface tags is less reliable for finer-gained latent annotations.

	English	Chinese
PCFG-LA	89.95	83.23
+R	90.63	83.79
+U	N/A	83.70
+R+U	N/A	84.15

Table 2: Effects of rare word handling (+R) and Chinese unknown handling (+U) on the test set.

5.2 Labeled Data Only

When comparing the two parsers on both languages in Figure 2 with treebank training, it is clear that they perform much better on English than Chinese. While this is probably due in part to the years of research on English, Chinese still appears to be more challenging than English. The comparison between the two parsing approaches provides two interesting conclusions.

First, the PCFG-LA parser always performs significantly better than Charniak's parser on Chinese, although both model English well. Admittedly Charniak's parser has not been optimized[9] on Chinese, but neither has the PCFG-LA parser[10]. The lexicalized model in Charniak's parser was first optimized for English and required sophisticated smoothing to deal with sparseness; however, the lexicalized model developed for Chinese works less well. In contrast, the PCFG-LA parser learns the latent annotations from the data, without any specification of what precisely should be modeled and how it should be modeled. This flexibility may help it better model new languages.

Second, while both parsers benefit from increased amounts of gold standard training data, the PCFG-LA parser gains more. The PCFG-LA parser is initially poorer than Charniak's parser

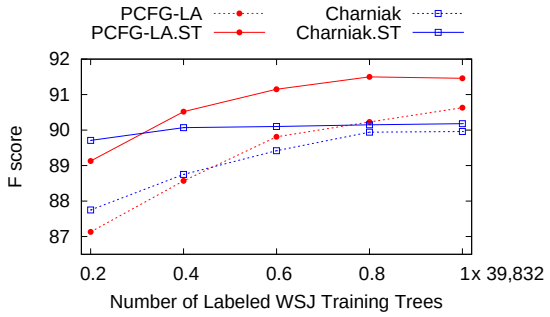
[6] We balance the size of manually and automatically labeled data by posterior weighting for the PCFG-LA parsers and by duplication for Charniak's parser.

[7] Greater improvements are obtained using smaller amounts of labeled training data.

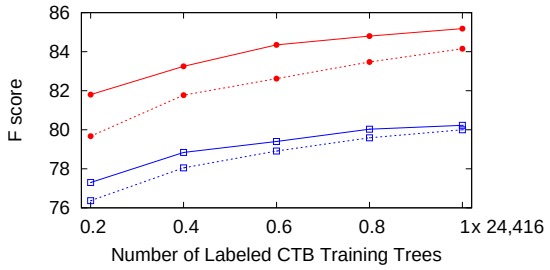
[8] We use Bikel's randomized parsing evaluation comparator to determine the significance ($p < 0.05$) of difference between two parsers' output.

[9] The Chinese port includes modification of the head table, implementation of a Chinese punctuation model, etc.

[10] The PCFG-LA parser without the unknown word handling method still outperforms Charniak's parser on Chinese.



(a) English



(b) Chinese

Figure 2: The performance of the PCFG-LA parser and Charniak's parser evaluated on the test set, trained with different amounts of labeled training data, with and without self-training (ST).

when trained on 20% WSJ training data, probably because the training data is too small for it to learn fine-grained annotations without over-fitting. As more labeled training data becomes available, the performance of the PCFG-LA parser improves quickly and finally outperforms Charniak's parser significantly. Moreover, performance of the PCFG-LA parser continues to grow when more labeled training data is available, while the performance of Charniak's parser levels out at around 80% of the labeled data. The PCFG-LA parser improves by 3.5% when moving from 20% to 100% training data, compared to a 2.21% gain for Charniak's parser. Similarly for Chinese, the PCFG-LA parser also gains more (4.48% vs 3.63%).

5.3 Labeled + Self-Labeled

The PCFG-LA parser is also able to benefit more from self-training than Charniak's parser. On the WSJ data set, Charniak's parser benefits from self-training initially when there is little labeled training data, but the improvement levels out quickly as more labeled training trees become available. In contrast, the PCFG-LA parser benefits consistently from self-training[11], even when using 100% of the labeled training set. Similar trends are also found for Chinese.

It should be noted that the PCFG-LA parser trained on a fraction of the treebank training data plus a large amount of self-labeled training data, which comes with little or no cost, performs comparably or even better than grammars trained with additional labeled training data. For example, the self-trained PCFG-LA parser with 60% labeled data is able to outperform the grammar trained with 100% labeled training data alone for both English and Chinese. With self-training, even 40% labeled WSJ training data is sufficient to train a PCFG-LA parser that is comparable to the model trained on the entire WSJ training data alone. This is of significant importance, especially for languages with limited human-labeled resources.

One might conjecture that the PCFG-LA parser benefits more from self-training than Charniak's parser because its self-labeled data has higher accuracy. However, this is not true. As shown in Figure 2 (a), the PCFG-LA parser trained with 40% of the WSJ training set alone has a much lower performance (88.57% vs 89.96%) than Charniak's parser trained on the full WSJ training set. With the same amount of self-training data (labeled by each parser), the resulting PCFG-LA parser obtains a much higher F score than the self-trained Charniak's parser (90.52% vs 90.18%). Similar patterns can also be found for Chinese.

	English	Chinese
PCFG-LA	90.63	84.15
+ Self-training	91.46	85.18

Table 3: Final results on the test set.

Table 3 reports the final results on the test set when trained on the entire WSJ or CTB6 training set. For English, self-training contributes 0.83% absolute improvement to the PCFG-LA parser, which is comparable to the improvement obtained from using semi-supervised training with the two-stage parser in (McClosky et al., 2006). Note that their improvement is achieved with the addition of 2,000k unlabeled sentences using the combination of a generative parser and a discriminative reranker, compared to using only 210k unlabeled sentences with a single generative parser in our approach. For Chinese, self-training results in a

[11] One may notice that the self-trained PCFG-LA parser with 100% labeled WSJ data has a slightly lower test accuracy than the self-trained PCFG-LA parser with 80% labeled WSJ data. This is due to the variance in parser performance when initialized with different seeds and the fact that the development set is used to pick the best model for evaluation.

state-of-the-art parsing model with 85.18% accuracy (1.03% absolute improvement) on a representative test set. Both improvements are statistically significant.

6 Analysis

In this section, we perform a series of analyses, focusing on English (refer to Figure 3), to investigate why the PCFG-LA parser benefits more from additional data, most particularly automatically labeled data, when compared to Charniak's parser. Similar analyses have been done for Chinese with similar results (refer to Figure 4).

Charniak's parser is a lexicalized PCFG parser that models lexicalized dependencies explicitly observable in the training data and relies on smoothing to avoid over-fitting. Although it is able to benefit from more training data because of broader lexicon and rule coverage and more robust estimation of parameters, its ability to benefit from the additional data is limited in the sense that it is not able to generate additional predictive features that are supported by this data. As shown in figure 3(a), the parsing accuracy of Charniak's parser on the test set improves as the amount of labeled training data increases; however, the training accuracy[12] degrades as more data is added. Note that the training accuracy[13] of Charniak's parser also

[12]The parser is tested on the treebank labeled set that the parser is trained on.

[13]The self-training data is combined with the labeled treebank trees in a weighted manner; otherwise, the training accuracy would be even lower.

decreases after the addition of self-training data. This is expected for models like Charniak's parser with fixed model parameters; it is harder to model more data with greater diversity. The addition of self-labeled data helps on the test set initially but it provides little gain when the labeled training data becomes relatively large.

In contrast, the PCFG-LA grammar is able to model the training data with different granularities. Fewer latent annotations are employed when the training set is small. As the size of the training data increases, it is able to allocate more latent annotations to better model the data. As shown in Figure 3 (b), for a fixed amount (20%) of labeled training data, the accuracy of the model on training data continues to improve as the number of latent annotation increases. Although it is important to limit the number of latent annotations to avoid over-fitting, the ability to model training data accurately given sufficient latent annotations is desirable when more training data is available. When trained on the labeled data (20%) alone, the 5-th order grammar achieves its optimal generalization performance (based on the development set) and begins to degrade afterwords. With the addition of self-training data, the 5-th order grammar achieves an even greater accuracy on the test set and its performance continues to increase[14] when moving to the 6-th or even 7-th order grammar.

Figure 3 (c) plots the training and test curves of the English PCFG-LA parser with varying amounts of labeled training data, with and without self-training. This figure differs substantially from Figure 3 (a). First, as mentioned earlier, the PCFG-LA parser benefits much more from self-training than Charniak's parser with moderate to large amounts of labeled training data. Second, in contrast to Charniak's parser for which training accuracy degrades consistently as the amount of labeled training data increases, the training accuracy of the PCFG-LA parser sometimes improves when trained on more labeled training data (e.g., the best model (at order 6) trained on 40%[15] labeled training data alone has a higher training accuracy than the best model (at order 5) trained on 20% labeled training data). Third, the addition of self-labeled data supports more accurate PCFG-LA grammars with higher orders than those trained without self-training, as evidenced by scores on both the training and test data. This suggests that the self-trained grammars are able to utilize more latent annotations to learn deeper dependencies.

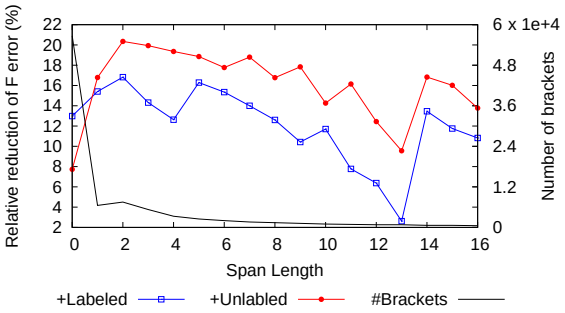

Figure 5: The relative reduction of bracketing errors for different span lengths, evaluated on the test set. The baseline model is the PCFG-LA parser trained on 20% of the WSJ training data. The +Unlabeled curve corresponds to the parser trained with the additional automatically labeled data and the +Labeled curve corresponds to the parser trained with additional 20% labeled training data. The counts of the brackets are computed on the gold reference. Span length '0' is designated for the effect on preterminal POS tags to differentiate it from the non-terminal brackets spanning only one word.

Figure 5 compares the effect of additional treebank labeled and automatically labeled data on the relative reduction of bracketing errors for different span lengths. It is clear from the figure that the improvement in parsing accuracy from self-training is the result of better bracketing across all span lengths[16]. However, even though the automatically labeled training data provides more improvement than the additional treebank labeled data in terms of parsing accuracy, this data is less effective at improving tagging accuracy than the additional treebank labeled training data.

So, how could self-training improve rule estimation when training the PCFG-LA parser with more latent annotations? One possibility is that the automatically labeled data smooths the parameter

[14] Although the 20% self-trained grammar has a higher test accuracy at the 7-th round than the 6-th round, the development accuracy was better at the 6-th round, and thus we report the test accuracy of the 6-th round grammar in Figure 3 (c).

[15] For models trained with greater amounts of labeled training data, although their training accuracy becomes lower (due to greater diversity) for the grammars (all at order 6) selected by the development set, their 7-th order grammars (not reported in the figure) actually have both higher training and test accuracies than the 6-th order grammar trained on less training data.

[16] There is a slight degradation in bracketing accuracy for some spans longer than 16 words, but the effect is negligible due to their low counts.

estimates in the EM algorithm, enabling effective training of models with more parameters to learn deeper dependencies. Let $p(a \rightarrow b|e,t)$ be the posterior probability of expanding subcategories a to b given the event e, which is a rule expansion on a treebank parse tree t. T_l and T_u are the sets of gold and automatically labeled parse trees, respectively. The update of the rule expansion probability $p(a \rightarrow b)$ in self-training (with weighting parameter α) can be expressed as:

$$\frac{\sum_{t \in T_l} \sum_{e \in t} p(a \rightarrow b|e,t) + \alpha \sum_{t \in T_u} \sum_{e \in t} p(a \rightarrow b|e,t)}{\sum_{b} (\sum_{t \in T_l} \sum_{e \in t} p(a \rightarrow b|e,t) + \alpha \sum_{t \in T_u} \sum_{e \in t} p(a \rightarrow b|e,t))}$$

Since the unlabeled data is parsed by a lower order grammar (with fewer latent annotations), the expected counts from the automatically labeled data can be thought of as counts from a lower-order grammar[17] that smooth the higher-order (with more latent annotations) grammar.

We observe that many of the rule parameters of the grammar trained on WSJ training data alone have zero probabilities (rules with extremely low probabilities are also filtered to zero), as was also pointed out in (Petrov et al., 2006). On the one hand, this is what we want because the grammar should learn to avoid impossible rule expansions. On the other hand, this might also be a sign of over-fitting of the labeled training data. As shown in Figure 3 (b), the grammar obtained with the addition of automatically labeled data contains many more non-zero rules, and its performance continues to improve with more latent annotations. Similar patterns also appear when using self-training for other amounts of labeled training data. As is partially reflected by the zero probability rules, the addition of the automatically labeled data enables the exploration of a broader parameter space with less danger of over-fitting the data. Also note that the benefit of the automatically labeled data is less clear in the early training stages (i.e., when there are fewer latent annotations), as can be seen in Figure 3 (b). This is probably because there is a small number of free parameters and the treebank data is sufficiently large for robust parameter estimation.

[17] We also trained models using only the automatically labeled data without combining it with human-labeled training data, but they were no more accurate than those trained on the human-labeled training data alone without self-training.

7 Conclusion

In this paper, we showed that PCFG-LA parsers can be more effectively applied to languages where parsing is less well developed and that they are able to benefit more from self-training than lexicalized generative parsers. We show for the first time that self-training is able to significantly improve the performance of a PCFG-LA parser, a single generative parser, on both small and large amounts of labeled training data.

We conjecture based on our analysis that the EM training algorithm is able to exploit the information available in both gold and automatically labeled data with more complex grammars while being less affected by over-fitting. Better results would be expected by combining the PCFG-LA parser with discriminative reranking approaches (Charniak and Johnson, 2005; Huang, 2008) for self training. Self-training should also benefit other discriminatively trained parsers with latent annotations (Petrov and Klein, 2008), although training would be much slower compared to using generative models, as in our case.

In future work, we plan to scale up the training process with more unlabeled training data (e.g., gigaword) and investigate automatic selection of materials that are most suitable for self-training. We also plan to investigate domain adaptation and apply the model to other languages with modest treebank resources. Finally, it is also important to explore other ways to exploit the use of unlabeled data.

Abstract

Applying statistical parsers developed for English to languages with freer word-order has turned out to be harder than expected. This paper investigates the adequacy of different statistical parsing models for dealing with a (relatively) free word-order language. We show that the recently proposed *Relational-Realizational (RR)* model consistently outperforms state-of-the-art *Head-Driven (HD)* models on the Hebrew Treebank. Our analysis reveals a weakness of HD models: their intrinsic focus on configurational information. We conclude that the form-function separation ingrained in RR models makes them better suited for parsing nonconfigurational phenomena.

1 Introduction

Parsing technology has come a long way since Charniak (1996) demonstrated that a simple treebank PCFG performs better than any other parser (with $F_1 75$ accuracy) on parsing the WSJ Penn treebank (Marcus et al., 1993). Treebank Grammars (Scha, 1990; Charniak, 1996) trained on large corpora nowadays present the best available means to parse natural language text.

The performance curve for parsing the WSJ was a steep one at first, as the incorporation of notions such as *head*, *distance*, *subcategorization* (Charniak, 1997; Collins, 1999) brought about a dramatic increase in parsing accuracy to the level of $F_1 88$. Discriminative approaches, Data-Oriented Parsing ('all-subtrees') approaches, and self-training techniques brought further improvements, and recent results are starting to level off at around $F_1 92.1$ (McClosky et al., 2008).

As the interest of the NLP community grows to encompass more languages, we observe efforts towards adapting an English parser for parsing other languages (e.g., (Collins et al., 1999)), or towards designing a language-independent framework based on principles underlying the models for parsing English (Bikel, 2002). The performance curve for parsing other languages with these models looks rather different. A case in point is Modern Standard Arabic. Since the initial effort of (Bikel, 2002) to parse the Arabic treebank (Maamouri et al., 2004), which yielded $F_1 75$ accuracy, four years and successive revisions have led to no more than $F_1 79$ (Maamouri et al., 2008).

This pattern from Arabic is not peculiar. The level of state-of-the-art results for other languages still lags behind those for English, even after putting considerable effort into the adaptation.[1] Given that these languages are inherently different from English and from one another, it appears that we cannot avoid a question concerning the *adequacy* of the models used to parse them. That is, given the properties of a language, which modeling strategy would be appropriate for parsing it?

Until recently, there has been practically no computationally affordable alternative to the *Head-Driven (HD)* approach in the development of phrase-structure based statistical parsing models. Recently, we proposed the *Relational-Realizational (RR)* approach that rests upon different premises (Tsarfaty and Sima'an, 2008). The question of how the RR model fares against the HD models that have so far been predominantly used has never been tackled. Yet, it is precisely such a comparison that can shed new light on the question of adequacy we posed above.

Empirically quantifying the effects of different modeling choices has been addressed for English by, e.g., (Johnson, 1998; Klein and Manning, 2003), and for German by, e.g., (Dubey, 2004;

[1] Consider, e.g., "The PaGe shared task on parsing German" (Kubler, 2008), reporting $F_1 75, F_1 79, F_1 83$ for the participating parsers.

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 842–851,
Singapore, 6-7 August 2009.

Rafferty and Manning, 2008). This paper provides an empirical systematic comparison of conceptually different modeling strategies with respect to parsing Hebrew. This comparison is intended to provide a first answer to the question of parser adequacy in the face of word-order freedom.

Our two empirical results are unequivocal. Firstly, RR models significantly outperform HD models (about 2 points absolute improvement in F_1) in parsing the Modern Hebrew treebank. In particular, RR models show better performance in identifying the constituents for which syntactic positions are relatively free. Secondly, we show a novel variation of the HD model, incorporating the *Relational* notions of the RR model, on the hypothesis that this might bridge the gap. The RR model remains superior.

Our post-experimental analysis shows that HD modeling is inherently problematic for parsing a language with freer word-order because of the hard-wiring of notions such as *left*, *right* and *distance from the head*. RR models, taking a principled approach towards capturing variable form-function correspondence patterns, are better suited for parsing *nonconfigurational* phenomena.

2 The Data

This section describes some properties of Modern Hebrew (henceforth, Hebrew) that make it significantly different from English. These properties affect the syntactic representations found in the Hebrew Treebank and the kind of syntactic phenomena a parser for Hebrew has to cope with.

Modern Hebrew is a Semitic language with a canonical SVO word-order pattern,[2] yet it allows considerable freedom in the placement of syntactic constituents in a clause. For example, linguistic elements of any kind may be fronted, triggering an inversion familiar from Germanic languages as in (1b) (*Triggered Inversion (TI)* in (Shlonsky, 1997)). Under some information structuring conditions, *Verb Initial (VI)* constructions are also allowed, as in (1c) (Melnik, 2002). All sentences in (1) thus mean "Dani gave the present to Dina", despite their different word-ordering.

(1) a. *dani natan et hamatana ledina*
Dani gave ACC the-present to-Dina

b. *et hamatana natan dani ledina*
ACC the-present gave Dani to-Dina

[2]SVO is an abbreviation for the Subject-Verb-Object type in the *basic word-order* typology of (Greenberg, 1963).

Word Order	Frequency	Relative Frequency
SV	1612	41%
VS	1144	29%
No S	624	16%
No V	550	14%

Table 1: **Modern Hebrew Predicative Clause-Types** in 3930 Predicative Matrix Clauses in the Training Set of the Modern Hebrew Treebank.

c. *natan dani et hamatana ledina*
gave Dani ACC the-present to-Dina

A corpus study we conducted on a fragment of the Modern Hebrew treebank reveals that although there is a significant number of subjects preceding verbs in simple (matrix) clauses (41%), there are also a fair number of sentences for which this order is reversed (29%), and there is evidence for other configurations, such as empty realization of subjects (16%) and non-verbal realization of predicates (14%).

In the face of such lack of consistency in its configurational position, the grammatical function *Object* in Hebrew is indicated by *Differential Object Marking (DOM)* (Aissen, 2003). NP objects in Hebrew are marked for *accusativity* (using the marker *et*) if they are also marked for *definiteness* (indicated by the prefix *ha*). So, in contrast with (2a)-(2b), the indefinite object renders (2c) ungrammatical, and the missing accusativity renders (2d) awkward. The fact that marking NP objects involves the joint contribution of multiple surface elements (*et, ha*) contributing features to the NP constituent is referred to as *extended exponence* (Matthews, 1993, p. 182).

(2) a. *dani natan matana ledina*
Dani gave present to-Dina
"Dani gave a present to Dina"

b. *dani natan et hamatana ledina*
Dani gave ACC the-present to-Dina
"Dani gave the present to Dina"

c. **dani natan et matana ledina*
Dani gave ACC present to-Dina

d. *??dani natan hamatana ledina*
Dani gave the-present to-Dina

These data pose a challenge to generative parsing models, as they would be required to generate alternative word-order patterns while maintaining a coherent pattern of object marking, encom-

passing the contribution of multiple surface exponents. The question this paper addresses is therefore what kind of modeling approach would be adequate for modeling the interplay between *syntax* and *morphology* in marking grammatical relations in Hebrew, as reflected by the sentence-pair (3). They both mean, roughly, "Dani gave the present to Dina yesterday; their word-order vary, but the pattern of object marking is retained.

(3) a. *dani natan etmol et hamatana ledina*
Dani gave yesterday ACC the-present to-Dina

b. *et hamatana natan etmol dani ledina*
ACC the-present gave yesterday dani to-dina

3 The Models

The different models we experiment with are all trained on syntactic structures annotated in the Modern Hebrew Treebank (Sima'an et al., 2001). The native representation of clause-level categories in the Treebank employs flat structures. This choice was made due to the lack of empirical evidence in Hebrew for grouping freely positioned syntactic elements to form a constituent.[3] In order to compensate for the ambiguity in the *interpretation* of flat structures, additional information such as morphological marking and grammatical function labels is added to the phrase-structure trees.

3.1 The *State-Splits* Approach

The simplest way to encode grammatical functions information on top of the phrase-structure representation in the treebank is by decorating non-terminal nodes with morphological or functional features, similarly to the rich representation format of syntactic categories in GPSG. This is the approach taken by the annotators of the Hebrew treebank in which information about morphological marking appears at multiple levels of constituency (Guthmann et al., 2009), and functional features (such as *subject*, *object*, etc.) decorate phrase-level constituent labels (Sima'an et al., 2001). The S-level representation of our example sentences (3a)–(3b) then would be as we depict in figure 1, which can be read off as feature-rich PCFG productions. We refer to this approach as the *State-Splits (SP)* approach, which serves as the baseline for the rest of our investigation.

3.2 The *Head-Driven* Approach

Following the linguistic wisdom that the internal organization of syntactic constituents revolves around their *heads*, *Head-Driven (HD)* models have been proposed by (Magerman, 1995; Charniak, 1997; Collins, 1999). In a generative HD model, the head daughter is generated first, conditioned on properties of the mother node. Then, sisters of the head daughter are generated conditioned on the head, typically by *left* and *right* generation processes. Overall, HD processes have the modeling advantage that they capture structurally-marked positions that characterize the *argument structure* of the sentence. The simplest possible process uses unigram probabilities, but (Klein and Manning, 2003) show that using *vertical* and *horizontal* Markovization improves parsing accuracy.[4]

An unlexicalized generative HD model will generate our two example sentences as we illustrate in figure 2. The generation of the context-free events in figure 1 is then broken down to seven different context-free parameters each, encoding head-parent and head-sister structural relationships — the latter mediated with a structurally-marked *delta* function (Δ_i). The rich morphological representation of phrase-level NP objects (+*def/acc*), for instance, is conditioned on the *head* sister, its *direction*, and the *distance from the head* (check, e.g., nodes $\Delta_{L_1}, \Delta_{R_2}$).

3.3 The *Relational-Realizational* Approach

The *Relational-Realizational (RR)* parsing model of (Tsarfaty and Sima'an, 2008) similarly decomposes the generation of the context-free events in figure 1 into multiple independent parameters, but does so in a conceptually different way. Instead of decomposing a context-free event to *head* and *sisters*, the RR model is best viewed as a generative grammar that decomposes it to *form* and *function*.

The RR grammar first generates a set of grammatical functions depicting the *Relational Network (RN)* (Perlmutter, 1982) of the clause. This

[3] Such clauses are defined formally as *exocentric* in formal theories of syntax, and are used to describe syntactic structures in, e.g., Tagalog, Hungarian and Warlpiri (Bresnan, 2001, page 110). This flat representation format is characteristic of treebanks for other languages with relatively-free word-order as well, such as German (cf. (Kubler, 2008)).

[4] The success of Head-Driven models (Charniak, 1997; Collins, 2003) was initially attributed to the fact that they were fully lexicalized, but (Klein and Manning, 2003) show that an unlexicalized model combining Head-Driven Markovian processes with linguistically motivated state-splits can approach the performance of fully lexicalized models.

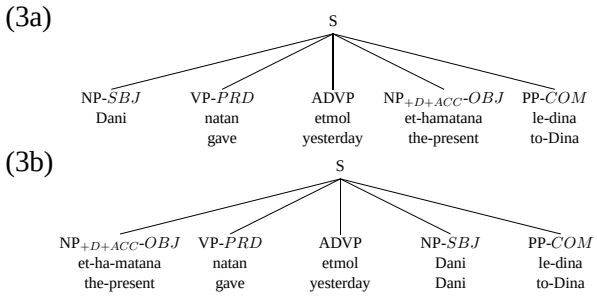

Figure 1: The *State-Splits* Approach for Ex. (3)

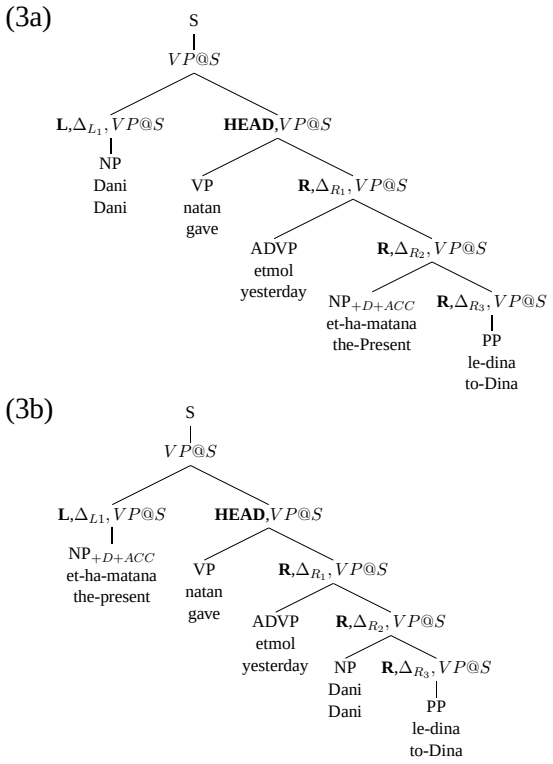

Figure 2: The *Head-Driven* Approach for Ex. (3)

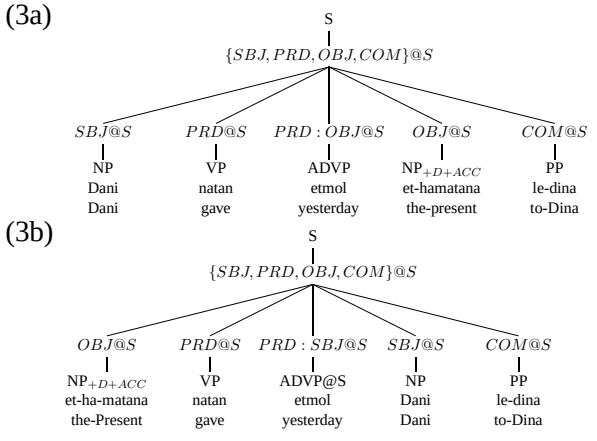

Figure 3: The *Relational-Realizational* Approach

RN provides an abstract set-theoretic representation of the *argument structure* of the clause.[5] This is called the *projection* phase. Then an ordering of the grammatical relations is generated, including reserved contextual slots for adjunction and/or punctuation marks. This is called the *configuration* phase. Finally, each of the grammatical function labels and adjunction slots gets realized as a morphosyntactic representation (a category label plus dominated morphological features) of the respective daughter constituent. This is called the *realization* phase.[6]

Figure 3 shows the generation of sentences (3a)–(3b) following the *projection*, *configuration* and *realization* phases corresponding to the top-down context-free layers of the tree. In both cases, the same relational network is generated, capturing the fact that they have the same argument structure. Then the different orderings of the grammatical elements are generated, reserving an adjunction slot for sentential modification (labeled by short context). Interestingly, the HD/RR models for our sentences are of comparable size (seven parameters) but the parameter types encode radically different notions. Illustrative of the difference is the realization of a morphologically marked NP object. In the RR model this is conditioned on a grammatical relation (check, for instance, node OBJ@S) and in the HD model it is conditioned on linear ordering or configurational notions such as *left*, *right* and *distance*.

4 Experiments

Goal We set out to compare the performance of the different modeling approaches for parsing Modern Hebrew. Considerable effort was devoted to making the models strictly comparable, in terms of preparing the data, defining statistical events, and unifying the rules determining cross-cutting linguistic notions (e.g., *heads* and *predicates*, *grammatical functions* and *subcat sets*). We spell out some of the setup considerations below.

Data We use the Modern Hebrew treebank (MHTB) (Sima'an et al., 2001) consisting of 6501 sentences from news-wire texts, morphologically analyzed and syntactically annotated as phrase-

[5] Unlike in HD models or dependency grammars, the *head* predicative element has no distinguished status here.

[6] Realization of adjunction slots (but not of function labels) may generate multiple sisters adjoining at a single position.

Table 3: PCFG Parameter Classes for All Models

structure trees. In our version of the MHTB, *definiteness* and *accusativity* features are percolated from the PoS-tags level to phrase-level categories, extending the procedure of (Guthmann et al., 2009). For all models, we applied non-terminal state-splits distinguishing finite from non-finite verb forms and possessive from non-possessive noun phrases. We head-annotated the treebank, and based on the 'subject', 'object', 'complement' and 'conjunction' labels in the MHTB we devised an automatic procedure to annotate all the grammatical functions indicated in table 2.[7]

Procedure For all models, we learn a PCFG by reading off the parameters described in table 3, in accordance with the trees depicted in figures 1–3.[8] For all models, we use relative frequency estimates. For lexical parameters, we use a simple smoothing procedure assigning probability to unknown words using the per-tag distribution of rare words ("rare" threshold set to < 2). The input to our parser consists of morphologically segmented surface forms, and the parser has to assign the syntactic as well as morphological analysis to the surface segments.[9] We use the standard development/training/test split as in (Tsarfaty and Sima'an, 2008). Since our goal is a detailed comparison and fine-grained analysis of the results we concentrate on the development set. We use a general-purpose CKY parser (Schmid, 2004) to exhaustively parse the sentences, and we strip off all model-specific information prior to evaluation.

Evaluation We use standard *Parseval* measures calculated for the original, flat, canonical representation of the parse trees.[10] We report *Precision/Recall* for the coarse-grained non-terminal categories. In addition to overall Parseval scores we report the accuracy results *Per Syntactic Category*. We further report model size in terms of the number of parameters. As is well known in Machine Learning, models with more parameters require more data to learn, and are more vulnerable to sparseness. In our evaluation we thus follow the rule of thumb that (all else being equal) for models of equal size the better performing model is preferred, and for models with equal performance, the smaller one is preferred.

5 Results and Analysis

5.1 Overall Results

Table 4 shows the parsing results for the **State-Split (SP) PCFG**, the **Head-Driven (HD) PCFG** and the **Relational-Realizational (RR) PCFG** models on parsing the Modern Hebrew Treebank, with *definiteness* and *accusativity* marked on PoS-tags as well as phrase-level categories. For all models, we experiment with grandparent encoding. For non-HD models, we also examine the utility of a head-category split.[11]

[7] The enhanced corpus will be available at `www.science.uva.nl/~rtsarfat/resources.htm`.

[8] Our training procedure is strictly equivalent to the transform-detransform methodology of (Johnson, 1998), but we implement a tree-traverse procedure as in (Bikel, 2002) collecting all parameters per event at once.

[9] This setup is more difficult than, e.g., the Arabic parsing setup of (Bikel, 2002), as they assume gold-standard pos-tags as input. Yet it is easier than the setup of (Tsarfaty, 2006; Goldberg and Tsarfaty, 2008) which uses unsegmented surface forms as input. The decision to use segmented and untagged forms was made to retain a realistic scenario. Morphological analysis is known to be ambiguous, and we do not assume that morphological features are known up front. Morphological segmentation is also ambiguous, but for our purposes it is unavoidable. When comparing different models on an individual sentence they may propose segmentation to sequences of different lengths, for which accuracy results cannot be faithfully compared. See (Tsarfaty, 2006) for discussion.

[10] The flat canonical representation also allows for a fair comparison that is not biased by the differing branching factors of the different models.

[11] In HD models, a head-tag is already assumed in the conditioning context for sister nodes (Klein and Manning, 2003).

Table 5: **Per-Category Evaluation of Parsing Performance for Different Models:** Prec/Rec Per Category Calculated for All Sentences.

For all models, grandparent encoding is helpful. For HD models, a higher Markovian order improves performance. This shows that even in Hebrew there are linear-precedence tendencies that help steer the disambiguation in the right direction, which is in line with our observation that word-order patterns in Modern Hebrew are not completely free (cf. table 1).

The best SP model performs equally or better than all HD models. This might be due to the smaller size of SP grammars, resulting in more robust estimates. But it is remarkable that, given the feature-rich representation, such a simple treebank grammar provides better disambiguation capacity than linguistically articulated HD models. We attribute this to the fact that parent-daughter relations have a stronger association with grammatical functions than relations between neighbouring nodes. For Hebrew, such adjacency relations may be arbitrary due to word-order variability.

Overall, RR models show the best performance for the set of all models with parent encoding, and for the set of all models without. Our best RR model shows 6.6%/8.4% Prec/Rec error reduction from the best SP model. The Recall improvement shows that the RR model is much better in generalizing, recovering successfully more of the constituents found in the gold representation. The best RR model also outperforms HD models with 8.7%/6.7% Prec/Rec error reduction from the best HD model. The resulting precision improvement of the RR relative to HD is larger than the improvement relative to SP, and the Recall improvement pattern is reversed. So it seems that the HD model generalizes better than the SP model, but also gets generalizations wrong more often than the SP model.

The RR model combines the generalization advantage of breaking down context-free events while it maintains the coherence advantage of learning flat trees (cf. (Johnson, 1998)). The best RR model obtains the best performance among all models: $F_1 76.41$. To put this result in context, for the setting in which the Arabic parser of (Maamouri et al., 2008) obtains $F_1 78.1$, — i.e., with gold standard feature-rich tags — the best RR model obtains $F_1 83.3$ accuracy which is the best parsing result reported for a Semitic language so far. RR models also have the advantage of resulting in more compact grammars, which makes learning and parsing with them much more computationally efficient.

5.2 Per-Category Break-Down Analysis

To understand better the merits of the different models we conducted a break-down analysis of performance-per-category for the best performing models of each kind. The break-down results are shown in table 5. We divided the table into three sets of categories: those for which the RR model gave the best performance, those for which the SP model gave the best performance, and those for which there is no clear trend.

The most striking outcome is that the RR model identifies at higher accuracy precisely those syntactic elements that are freely positioned with re-

In our SP or RR models, head-information is used as yet another feature-value pair rather than an object with a distinguished status during generation.

spect to the head: NPs, PPs, ADVPs and SBARs. Adjectives, in contrast, have clear ordering constraints — they always appear after the noun. S level elements, when embedded, always appear immediately after a conjunction or a relativizer. In particular, NPs and PPs realize arguments and adjuncts that may occupy different positions relative to the head. The RR model is better than the other models in identifying those elements partly because morphological information helps to disambiguate syntactically relevant chunks and make correct attachment decisions about them.

Remarkably, predicative (verb-less) phrases (PREDP), which are characteristic of Semitic languages, are hard to parse, but here too the RR does slightly better than the other two, as it allows for variability in the means to realize a (verbal or verb-less) predicate. Both RR and HD models outperform SP for VPs, which is due to the specific nature of VPs in the MHTB – they exist *only* for complement phrases with strict linear ordering.

6 Distances, Functions and Subcategorization Frames

Markovian processes to the *left* and to the *right* of the head provide a first approximation of the predicate's *argument structure*, as they capture trends in the co-occurrences of constituents reflected in their pattern of *positioning* and *adjacency*. But as our results so far show, such an approximation is empirically less rewarding for a language in which grammatical relations are not tightly correlated with structural notions.[12]

Collins (2003) attempted a more abstract formulation of argument-structure by articulating left and right *subcat-sets*. Each set represents those arguments that are expected to occur at each side of the head. Argument sisters ("complements") are generated if and only if they are required, and their generation 'cancels' the requirement in the set. Adjuncts ("modifiers") may be freely generated at any position.

At first glance, such a dissociation of configurational positions and subcategorization sets seems to be more adequate for parsing Hebrew, because it allows for some variability in the order of generation. But here too, since the model uses sets of

[12]Conditioning based on *adjacency* and *distance* is also common inside *dependency parsing* models, and we conjecture that this is one of the reasons for their difficulty in coping with freer word-order languages, a difficulty pointed out in (Nivre et al., 2007).

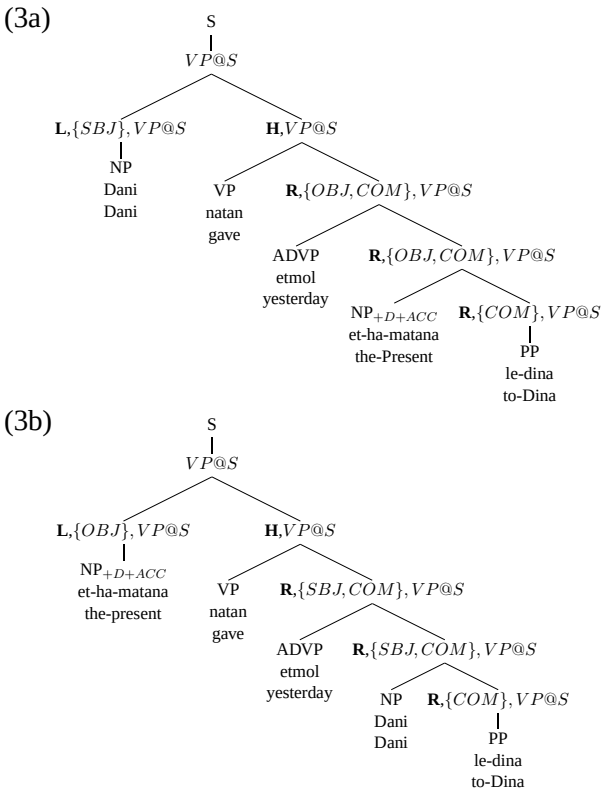

Figure 4: The *Relational Head-Driven* Approach

constituent labels, it disambiguates the grammatical functions of an NP solely based on the direction of the head, which is adequate for English but not for Hebrew. In order to relax this association further, we propose to replace constituent labels in the subcat-sets with grammatical relations identical to the functional elements in the relational network of the RR. This provides means to mediate the cancellation of constituents in the sets with their functions and correlate it with morphology.

To get an idea of the implications of such a modeling strategy, let us consider our example sentences in such a Relational-HD model as depicted in figure 4. Both representations share the event of generating the verbal head. Sisters are generated conditioned on the head and the functional elements remaining to be "cancelled". Each of the two trees consists of an event realizing an "object", one for an NP to the right of the head, and the other for an NP to its left. In both cases, an object constituent will be generated jointly with the morphological features associated with it. Evidently, when using sets of grammatical relations instead of constituent-labels, correlation of morphology and grammatical functions is more straight-forward to maintain.

Model	**SP-PCFG**	**HD-PCFG**	**HD-PCFG**	**HD-PCFG**	**HD-PCFG**	**RR-PCFG**
Type of Distance Δ *or Subcategorization*	Phrase-Level State-Splits	Intervening Verb/Punc	Left and Right #Constituents	Left and Right Constituent Labels	Left and Right Function Labels	Subcat Sets Configuration
Precision/Recall (#Params)	70.95/70.32 (13884)	72.39 / 71.97 (11650)	72.70 / 74.46 (18058)	72.42 / 74.29 (16334)	72.84/74.62 (16460)	76.32/76.51 (13618)

Table 6: **Incorporating Distance and Grammatical Functions into Head-Driven Parsing Models** Reporting Precison/Recall (#Parameters) for Sentences Length < 40.

6.1 Results and Analysis

Table 6 reports the results of experimenting with HD models with different instantiations of a *distance* function, starting from the standard notion of (Collins, 2003) and ending with our proposed, relational, function sets. For all HD models, we retain the *head*, *left* and *right* generation cycle and only change the conditioning context (Δ_i) for sister generation.

As a baseline, we show the results of adding grammatical function information as state-splits on top of an SP-PCFG.[13] This SP model presents much lower performance than the RR model although they are almost of the same size and they start off with the same information. This result shows that sophisticated modeling can blunt the claws of the sparseness problem. One may obtain the same number of parameters for two different models, but correlate them with more profound linguistic notions in one model than in the other. In our case, there is more statistical evidence in the data for, e.g., case marking patterns, than for association of grammatical relations with structurally-marked positions.

For all HD variations, the RR model continues to outperform HD models. The function-set variation performs slightly (but not significantly) better than the category-set. What seems to be still standing in the way of getting useful disambiguation cues for HD models is the fact that the *left* and *right* direction of realization is hardwired in their representation. This breaks down a coherent distribution over morphosyntactic representations realizing grammatical relations to arbitrary position-dependent fragments, which results in larger grammars and inferior performance.[14]

[13]The startegy of adding grammatical functions as state-splits is used in, e.g., German (Rafferty and Manning, 2008).

[14]Due to the difference in the size of the grammars, one could argue that smoothing will bridge the gap between the HD and RR modeling strategies. However, the better size/accuracy trade-off shown here for RR models suggests that they provide a good bias/variance balancing point, especially for feature-rich models characterizing morphologically rich languages. A promising strategy then would be to smooth or split-and-merge (Petrov et al., 2006)) RR-based models rather than to add an elaborate smoothing component to configurationally-based HD models.

7 A Typological Detour

Hebrew, Arabic and other Semitic Languages are known to be substantially different from English in that English is strongly *configurational*. In configurational languages word-order is fixed, and information about the grammatical functions of constituents (e.g., *subject* or *object*) is often correlated with structurally-marked positions inside highly-nested constituency structures. *Nonconfigurational* languages (Hale, 1983), in contrast, allow for freedom in their word-ordering and information about grammatical relations between constituents is often marked by means of *morphology*.

Configurationality is hardly a clear-cut notion. The difference in the configurationality level of different languages is often conceived as depicted in figure 7. In *linguistic typology*, the branch of linguistics that studies the differences between languages (Song, 2001), the division of labor between linear ordering and morphological marking in the realization of grammatical relations is often viewed as a continuum. Common wisdom has it that the lower a language is on the configurationality scale, the more morphological marking we expect to be used (Bresnan, 2001, page 6).

For a statistical parser to cope with nonconfigurational phenomena as observed in, for instance, Hebrew or German, it should allow for flexibility in the *form* of realization of the grammatical *functions* within the phrase-structure representation of trees. Recent morphological theories employ *Form-Function* separation as a widely-accepted practice for enhancing the adequacy of models describing variability in the realization of grammatical *properties*. Our results suggest that the adequacy of syntactic processing models is related to such typological insights as well, and is enhanced by adopting a similar form-function separation for expressing grammatical *relations*.

configurational ———————— *nonconfigurational*
Chinese>English>{German,Hebrew}>Warlpiri

Figure 5: **The Configurationality Scale**

The HD assumptions take the function of a constituent to be transparently related to its formal position, which entails word-order rigidity. Such transparent relations between configurational positions and grammatical functions are assumed by other kinds of parsing frameworks such as the 'all-subtrees' approach of Data-Oriented Parsing, and the distinction between left and right application in CCG-based parsers.

The RR modeling strategy stipulates a strict separation between *form* — parametrizing explicitly basic word-order (Greenberg, 1963) and morphological realization (Greenberg, 1954) — and function — parametrizing relational networks borrowed from (Perlmutter, 1982) — which makes it possible to statistically learn complex form-function mapping reflected in the data. This is an adequate means to capture, e.g., morphosyntactic interactions, which characterize the *less-configurational* languages on the scale.

8 Conclusion

In our comparison of the HD and RR modeling approaches, the RR approach is shown to be empirically superior and typologically more adequate for parsing a language exhibiting word-order variation interleaved with extended morphology. HD models are less accurate and more vulnerable to sparseness as they assume transparent mappings between form and function, based on *left* and *right* decompositions hard-wired in the HD representation. RR models, in contrast, employ *form* and *function* separation which allows the statistical model to learn complex correspondance patterns reflected in the data. In the future we plan to investigate how the different models fare against one another in parsing different languages. In particular we wish to examine whether parsing different languages should be pursued by different models, or whether the RR strategy can effectively cope with different languages types. Finally, we wish to explore the implications of RR modeling for applications that consider the form of expression in multiple languages, for instance *Statistical Machine Translation (SMT)*.

Abstract

Sets of lexical items sharing a significant aspect of their meaning (*concepts*) are fundamental in linguistics and NLP. Manual concept compilation is labor intensive, error prone and subjective. We present a web-based concept extension algorithm. Given a set of terms specifying a concept in some language, we translate them to a wide range of intermediate languages, disambiguate the translations using web counts, and discover additional concept terms using symmetric patterns. We then translate the discovered terms back into the original language, score them, and extend the original concept by adding back-translations having high scores. We evaluate our method in 3 source languages and 45 intermediate languages, using both human judgments and WordNet. In all cases, our cross-lingual algorithm significantly improves high quality concept extension.

1 Introduction

A *concept* (or lexical category) is a set of lexical items sharing a significant aspect of their meanings (e.g., types of food, tool names, etc). Concepts are fundamental in linguistics and NLP, in thesauri, dictionaries, and various applications such as textual entailment and question answering.

Great efforts have been invested in manual preparation of concept resources such as WordNet (WN). However, manual preparation is labor intensive, which means it is both costly and slow to update. Applications needing data on some very specific domain or on a recent news-related event may find such resources lacking. In addition, manual preparation is error-prone and susceptible to subjective concept membership decisions, frequently resulting in concepts whose terms do not belong to the same level of granularity[1]. As a result, there is a need to find methods for automatic improvement of concept coverage and quality.

The web is a huge up-to-date corpus covering many domains, so using it for concept extension has the potential to address the above problems. The majority of web pages are written in a few salient languages, hence most of the web-based information retrieval studies are done on these languages. However, due to the substantial growth of the multilingual web[2], languages in which concept terms are expressed in the most precise manner frequently do not match the language where information is needed. Moreover, representations of the same concept in different languages may complement each other.

In order to benefit from such cross-lingual information, concept acquisition systems should be able to gather concept terms from many available languages and convert them to the desired language. In this paper we present such an algorithm. Given a set of words specifying a concept in some source language, we translate them to a range of intermediate languages and disambiguate the translations using web counts. Then we discover additional concept terms using symmetric patterns and translate the discovered terms back into the original language. Finally we score the back-translations using their intermediate languages' properties, and extend the original concept by adding back-translations having high scores. The only language-specific resource required by the algorithm are multilingual dictionaries, and its processing times are very modest.

We performed thorough evaluation for 24 concepts in 3 source languages (Hebrew, English and Russian) and 45 intermediate languages. Concept definitions were taken from existing WordNet subtrees, and the obtained new terms were manually

scored by human judges. In all cases we have significantly extended the original concept set with high precision. We have also performed a fully automatic evaluation with 150 concepts, showing that the algorithm can re-discover WN concepts with high precision and recall when given only partial lists as input.

Section 2 discusses related work, Section 3 details the algorithm, Section 4 describes the evaluation protocol and Section 5 presents our results.

2 Related work

One of the main goals of this paper is the extension or automated creation of lexical databases such as WN. Due to the importance of WN for NLP tasks, substantial research was done on direct or indirect automated extension of the English WN (e.g., (Snow et al., 2006)) or WN in other languages (e.g., (Vintar and Fišer, 2008)). The majority of this research was done on extending the tree structure (finding new synsets (Snow et al., 2006) or enriching WN with new relationships (Cuadros and Rigau, 2008)) rather than improving the quality of existing concept/synset nodes. Other related studies develop concept acquisition frameworks for on-demand tasks where concepts are defined by user-provided seeds or patterns (Etzioni et al., 2005; Davidov et al., 2007), or for fully unsupervised database creation where concepts are discovered from scratch (Banko et al., 2007; Davidov and Rappoport, 2006).

Some papers directly target specific applications, and build lexical resources as a side effect. Named Entity Recognition can be viewed as an instance of the concept acquisition problem where the desired concepts contain words that are names of entities of a particular kind, as done in (Freitag, 2004) using co-clustering and in (Etzioni et al., 2005) using predefined pattern types.

The two main algorithmic approaches to the problem are pattern-based concept discovery and clustering of context feature vectors. The latter approach represents word contexts as vectors in some space and uses similarity measures and automatic clustering in that space (Deerwester et al., 1990). Pereira et al.(1993), Curran and Moens (2002) and Lin (1998) use syntactic features in the vector definition. Pantel and Lin (2002) improves on the latter by clustering by committee. Caraballo (1999) uses conjunction and appositive annotations in the vector representation. While great effort has been made for improving the computational complexity of these methods (Gorman and Curran, 2006), they still remain data and computation intensive.

The second major algorithmic approach is to use lexico-syntactic patterns. Patterns have been shown to produce more accurate results than feature vectors, at a lower computational cost on large corpora (Pantel et al., 2004). In concept acquisition, pattern-based methods were shown to outperform LSA by a large margin (Widdows and Dorow, 2002). Since (Hearst, 1992), who used a manually prepared set of initial lexical patterns in order to acquire relationships, numerous pattern-based methods have been proposed for the discovery of concepts from seeds (Pantel et al., 2004; Davidov et al., 2007; Pasca et al., 2006). Most of these studies were done for English, while some show the applicability of their methods to other languages, including Greek, Czech, Slovene and French.

Most of these papers attempt to discover concepts from data available in some specific language. Recently several studies have proposed to utilize a second language or several specified languages in order to extract or extend concepts (Vintar and Fišer, 2008; van der Plas and Tiedemann, 2006) or paraphrases (Bosma and Callison-Burch, 2007). However, these methods usually require the availability of parallel corpora, which limits their usefulness. Most of these methods utilize distributional measures, hence they do not possess the advantages of the pattern-based framework.

Unlike in the majority of recent studies, where the framework is designed with specific languages in mind, in our task, in order to take advantage of information from diverse languages, the algorithm should be able to deal well with a wide variety of possible intermediate languages without any manual adaptations. Relying solely on multilingual dictionaries and the web, our algorithm should be able to discover language-specific patterns and concept terms. While some of the proposed frameworks could potentially be language-independent, little research has been done to confirm this. There are a few obstacles that may hinder applying common pattern-based methods to other languages. Many studies utilize parsing or POS tagging, which frequently depend on the availability and quality of language-specific tools. Some studies specify seed patterns in advance, and

it is not clear whether translated patterns can work well on different languages. Also, the absence of clear word segmentation in some languages (e.g., Chinese) can make many methods inapplicable.

A few recently proposed concept acquisition methods require only a handful of seed words and no pattern pre-specification (Davidov et al., 2007; Pasca and Van Durme, 2008). While these studies avoid some of the obstacles above, it still remains open whether such methods are indeed language-independent. In the translation to intermediate languages part of our framework, we adapt the algorithms in (Davidov and Rappoport, 2006; Davidov et al., 2007) to suit diverse languages (including ones without explicit word segmentation). We also develop a method for efficient automated disambiguation and translation of terms to and from any available intermediate language.

Our study is related to cross-language information retrieval (CLIR/CLEF) frameworks. Both deal with information extracted from a set of languages. However, the majority of CLIR studies pursue different targets. One of the main CLIR goals is the retrieval of *documents* based on explicit queries, when the document language is not the query language (Volk and Buitelaar, 2002). These frameworks usually develop language-specific tools and algorithms including parsers and taggers in order to integrate multilingual *queries* and *documents* (Jagarlamudi and Kumaran, 2007). Our goal is to develop a *language-independent* method using cross-lingual information, for the extension and improvement of *concepts* rather than the retrieval of documents. Besides, unlike in many CLIR frameworks, intermediate languages are not specified in advance and the language of requested data is the same as the language of request, while available information may be found in many different intermediate languages.

3 The Algorithm

Our algorithm is comprised of the following stages: (1) given a set of words in a *source* language as a specification for some concept, we automatically translate them to a diverse set of *intermediate* languages, using multilingual dictionaries; (2) the translations are disambiguated using web counts; (3) for each language, we retrieve a set of web snippets where these translations co-appear and apply a pattern-based concept extension algorithm for discovering additional terms; (4) we translate the discovered terms back to the source language, and disambiguate them; (5) we score the back-translated terms using data on their behavior in the intermediate languages, and merge the sets obtained from different languages into a single one, retaining terms whose score passes a certain threshold. Stages 1-3 of the algorithm have been described in (Davidov and Rappoport, 2009), where the goal was to translate a concept given in one language to other languages. The framework presented here includes the new stages 4-5, and its goal and evaluation methods are completely different.

3.1 Concept specification and translation

We start from a set of words denoting a concept in a given source language. Thus we may use words like *(apple, banana, ...)* as the definition of the concept of fruit or *(bear, wolf, fox, ...)* as the definition of wild animals. In order to reduce noise, we limit the length (in words) of multiword expressions considered as terms. To calculate this limit for a language, we randomly take 100 terms from the appropriate dictionary and set a limit as $Lim_{mwe} = round(avg(length(w)))$ where $length(w)$ is the number of words in term w. For languages like Chinese without inherent word segmentation, $length(w)$ is the number of characters in w. While for many languages $Lim_{mwe} = 1$, some languages like Vietnamese usually require two or more words to express terms.

3.2 Disambiguation of translated terms

One of the problems in utilization of multilingual information is ambiguity of translation. First, in order to apply the concept acquisition algorithm, at least some of the given concept terms must be automatically translated to each intermediate language. In order to avoid reliance on parallel corpora, which do not exist or are extremely small for most of our language pairs, we use bilingual dictionaries. Such dictionaries usually provide many translations, one or more for each sense, so this translation is inherently fuzzy. Second, once we acquire translated term lists for each intermediate language, we need to translate them back to the source language and such back-translations are also fuzzy. In both cases, we need to select the appropriate translation for each term.

While our desire would be to work with as many languages as possible, in practice, some or even

most of the concept terms may be absent from the appropriate dictionary. Such concept terms are ignored.

One way to deal with ambiguity is by applying distributional methods, usually requiring a large single-language corpus or, more frequently, parallel corpora. However, such corpora are not readily available for many languages and domains. Extracting such statistical information on-demand is also computationally demanding, limiting its usability. Hence, we take a simple but effective query-based approach. This approach, while being powerful as we show in the evaluation, only relies on a few web queries and does not rely on any language-specific resources or data.

We use the conjecture that terms of the same concept tend to co-appear more frequently than ones belonging to different concepts[3]. Thus, we select a translation of a term co-appearing most frequently with some translation of a different term of the same concept. We estimate how well translations of different terms are connected to each other. Let $C = \{C_i\}$ be the given seed words for some concept. Let $Tr(C_i, n)$ be the n-th available translation of word C_i and $Cnt(s)$ denote the web count of string s obtained by a search engine. We select a translation $Tr(C_i)$ according to:

$$F(w_1, w_2) = \frac{Cnt(\text{“}w_1 * w_2\text{”}) \times Cnt(\text{“}w_2 * w_1\text{”})}{Cnt(w_1) \times Cnt(w_2)}$$

$$Tr(C_i) = \underset{s_i}{argmax} \left(\max_{\substack{s_j \\ j \neq i}} (F(Tr(C_i, s_i), Tr(C_j, s_j))) \right)$$

We utilize the $Yahoo!$ “x * y”,“x * * y” wildcards that allow to count only co-appearances where x and y are separated by a single word or word pair. As a result, we obtain a set of disambiguated term translations. This method is used both in order to translate from the source language to each intermediate language and to back-translate the newly discovered concept terms from the intermediate to the source language.

The number of queries in this stage depends on the ambiguity of the concept terms' translations. In order to decrease the amount of queries, if there are more than three possible senses we sort them by frequency[4] and take three senses with medium frequency. This allows us to skip the most ambiguous and rare senses without any significant effect on performance. Also, if the number of combinations is still too high (>30), we randomly sample at most 30 of the possible combinations.

3.3 Pattern-based extension of concept terms in intermediate languages

We first mine the web for contexts containing the translations. Then we extract from the retrieved snippets contexts where translated terms co-appear, and detect patterns where they co-appear symmetrically. Then we use the detected patterns to discover additional concept terms. In order to define word boundaries, for each language we manually specify boundary characters such as punctuation/space symbols. This data, along with dictionaries, is the only language-specific data in our framework.

Web mining for translation contexts. In order to get language-specific data, we need to restrict web mining each time to the processed intermediate language. This restriction is straightforward if the alphabet or term translations are language-specific or if the search API supports restriction to this language[5]. In case where there are no such natural restrictions, we attempt to detect and add to our queries a few language-specific frequent words. Using our dictionaries, we find 1–3 of the 15 most frequent words in a desired language that are unique to that language, and we ‘and’ them with the queries to ensure proper language selection. This works well for almost all languages (Esperanto being a notable exception).

For each pair A, B of disambiguated term translations, we construct and execute the following two queries: {“A * B”, “B * A”}[6]. When we have 3 or more terms we also add {A B C D}-like conjunction queries which include 3-5 words. For languages with $Lim_{mwe} > 1$, we also construct queries with several “*” wildcards between terms. For each query we collect snippets containing text fragments of web pages. Such snippets frequently include the search terms. Since $Yahoo!$ $Boss$ allows retrieval of up to the 1000 first results (50 in each query), we collect several thousands snippets. For most of the intermediate languages, only a few dozen queries (40 on the average) are required to obtain sufficient data, and queries can be parallelized. Thus the relevant data can be downloaded

[3] Our results here support this conjecture.

[4] Frequency is estimated by web count for a given word.

[5] Yahoo! allows restriction for 42 languages.

[6] These are Yahoo! queries where enclosing words in “” means searching for an exact phrase and “*” means a wildcard for exactly one arbitrary word.

in seconds. This makes our approach practical for on-demand retrieval or concept verification tasks.

Meta-patterns. Following (Davidov et al., 2007), we seek symmetric patterns to retrieve concept terms. We use two meta-pattern types. First, a *Two-Slot* pattern type constructed as follows:

$$[Prefix]\ C_1\ [Infix]\ C_2\ [Postfix]$$

C_i are slots for concept terms. We allow up to Lim_{mwe} space-separated[7] words to be in a single slot. Infix may contain punctuation, spaces, and up to $Lim_{mwe} \times 4$ words. Prefix and Postfix are limited to contain punctuation characters and/or Lim_{mwe} words.

Terms of the same concept frequently co-appear in lists. To utilize this, we introduce two additional *List* pattern types[8]:

$$[Prefix]\ C_1\ [Infix]\ (C_i\ [Infix])+ \quad (1)$$
$$[Infix]\ (C_i\ [Infix])+\ C_n\ [Postfix] \quad (2)$$

Following (Widdows and Dorow, 2002), we define a pattern graph. Nodes correspond to terms and patterns to edges. If term pair (w_1, w_2) appears in pattern P, we add nodes N_{w_1}, N_{w_2} to the graph and a directed edge $E_P(N_{w_1}, N_{w_2})$ between them.

Symmetric patterns. We consider only symmetric patterns. We define a symmetric pattern as a pattern where some concept terms C_i, C_j appear both in left-to-right and right-to-left order. For example, if we consider the terms $\{apple, pineapple\}$ we select a List pattern "$(one\ C_i,)+\ and\ C_n$." if we find both "one *apple*, one *pineapple*, one guava and orange." and "one watermelon, one *pineapple* and *apple*.". If no such patterns are found, we turn to a weaker definition, considering as symmetric those patterns where the same terms appear in the corpus in at least two different slots. Thus, we select a pattern "for C_1 and C_2" if we see both "for *apple* and guava," and "for orange and *apple*,".

Retrieving concept terms. We collect terms in two stages. First, we obtain "high-quality" core terms and then we retrieve potentially more noisy ones. At the first stage we collect all terms[9] that are bidirectionally connected to at least two different original translations, and call them *core* concept terms C_{core}. We also add the original ones as core terms. Then we detect the rest of the terms C_{rest} that are connected to the core stronger than to the remaining words, as follows:
$G_{in}(c)=\{w \in C_{core} | E(N_w, N_c) \vee E(N_c, N_w)\}$
$G_{out}(c)=\{w \notin C_{core} | E(N_w, N_c) \vee E(N_c, N_w)\}$
$C_{rest}=\{c | |G_{in}(c)| > |G_{out}(c)|\}$

For the sake of simplicity, we do not attempt to discover more patterns/instances iteratively by requerying the web. If we have enough data, we use windowing to improve result quality. If we obtain more than 400 snippets for some concept, we divide the data into equal parts, each containing up to 400 snippets. We apply our algorithm independently to each part and select only the words that appear in more than one part.

3.4 Back-translation and disambiguation

At the concept acquisition phase of our framework we obtained sets of terms for each intermediate language, each set representing a concept. In order to be useful for the enhancement of the original concept, these terms are now back-translated to the source language. We disambiguate each back-translated term using the process described in Section 3.2. Having sets of back-translated terms for each intermediate language, our goal is to combine these into a single set.

3.5 Scoring and merging the back translations

We do this merging using the following scoring strategy, assigning for each proposed term t' in concept C the score $S(t', C)$, and selecting terms with $S(t', C) > H$ where H is a predefined threshold.

Our scoring is based on the two following considerations. First, we assume that terms extracted from more languages tend to be less noisy and language-dependent. Second, we would like to favor languages with less resources for a given concept, since noise empirically appears to be less prominent in such languages[10].

For language L and concept $C = \{t_1 \dots t_k\}$ we get a disambiguated set of translations $\{Tr(t_1, L) \dots Tr(t_k, L)\}$. We define relative lan-

[7] As before, for languages without space-based word separation Lim_{mwe} limits the number of characters instead.

[8] $(E)+$ means one or more instances of E.

[9] We do not consider as terms the 50 most frequent words.

[10] Preliminary experimentation, as well as the evaluation results presented in this paper, support both of these considerations.

guage frequency by

$$LFreq(L,C) = \frac{\sum_{t_i \in C}(Freq(Tr(t_i,L)))}{\sum_{L',t_i \in C}(Freq(Tr(t_i,L'))}$$

where $Freq(Tr(t_i,L))$ is a frequency of term's t_i translation to language L estimated by the number of web hits. Thus languages in which translated concept terms appear more times will get higher relative frequency, potentially indicating a greater concept translation ambiguity. Now, for each new term t' discovered through $LNum(t')$ different languages $L_1 \ldots L_{LNum(t')}$ we calculate a term score [11] $S(t',C)$:

$$S(t',C) = LNum(t') \cdot \left(1 - \sum_i LFreq(L_i,C)\right)$$

For each discovered term t', $S(t',C) \in [0, LNum(t')]$, while discovery of t' in less frequent languages will cause the score to be closer to $LNum(t')$. So terms appearing in a greater number of infrequent languages will get higher scores.

After the calculation of score for each proposed term, we retain terms whose scores are above the predefined threshold H. In our experiments we have used $H = 3$, usually meaning that acquisition of a term through 3-4 uncommon intermediate languages should be enough to accept it. The same score measure can also be used to filter out "bad" terms in an already existing concept.

4 Experimental Setup

We describe here the languages, concepts and dictionaries we used in our experiments.

4.1 Languages and concepts

One of the main goals in this research is to take advantage of concept data in every possible language. As intermediate languages, we used 45 languages including major west European languages like French or German, Slavic languages like Russian, Semitic languages as Hebrew and Arabic, and diverse Asian languages such as Chinese and Persian. To configure parameters we have used a set of 10 concepts in Russian as a development set. These concepts were not used in evaluation.

We examined a wide variety of concepts and for each of them we used all languages with available translations. Table 1 shows the resulting top 10 most utilized languages in our experiments.

[11] In this expression i runs only on languages with term t' hence the summation is not 1.

English	**Russian**	**Hebrew**
German(68%)	English(70%)	English(66%)
French(60%)	German(62%)	German(65%)
Italian(60%)	French(62%)	Italian(61%)
Portuguese(57%)	Spanish(58%)	French(59%)
Spanish(55%)	Italian(56%)	Spanish(57%)
Turkish(51%)	Portuguese(54%)	Portuguese(57%)
Russian(50%)	Korean(50%)	Korean(48%)
Korean(46%)	Turkish(49%)	Russian(43%)
Chinese(45%)	Chinese(47%)	Turkish(43%)
Czech(42%)	Polish (44%)	Czech(40%)

Table 1: The ten most utilized intermediate languages in our experiments. In parentheses we show the percentage of new terms that these languages helped discover.

We have used the English, Hebrew (Ordan and Winter, 2008) and Russian (Gelfenbeynand et al., 2003) WordNets as sources for concepts and for the automatic evaluation. Our concept set selection was based on English WN subtrees. To perform comparable experiments with Russian and Hebrew, we have selected the same subtrees in the Hebrew and Russian WN. Concept definitions given to human judges for evaluation were based on the corresponding WN glosses. For automated evaluation we selected 150 synsets/subtrees containing at least 10 single word terms (existing in all three tested languages).

For manual evaluation we used a subset of 24 of these concepts. In this subset we tried to select generic concepts manually, such that no domain expert knowledge was required to check their correctness. Ten of these concepts were identical to ones used in (Widdows and Dorow, 2002; Davidov and Rappoport, 2006), which allowed us to compare our results to recent work in case of English. Table 2 shows these 10 concepts along with the sample terms. While the number of tested concepts is not very large, it provides a good indication for the quality of our approach.

Concept	Sample terms
Musical instruments	guitar, flute, piano
Vehicles/transport	train, bus, car
Academic subjects	physics, chemistry, psychology
Body parts	hand, leg, shoulder
Food	egg, butter, bread
Clothes	pants, skirt, jacket
Tools	hammer, screwdriver, wrench
Places	park, castle, garden
Crimes	murder, theft, fraud
Diseases	rubella, measles, jaundice

Table 2: Ten of the selected concepts with sample terms.

4.2 Multilingual dictionaries

We developed tools for automatic access to a number of dictionaries. We used Wikipedia cross-language links as our main source ($> 60\%$) for offline translation. These links include translation of Wikipedia terms into dozens of languages. The main advantage of using Wikipedia is its wide coverage of concepts and languages. However, one problem it has is that it frequently encodes too specific senses and misses common ones (*bear* is translated as *family Ursidae*, missing its common "wild animal" sense). To overcome these difficulties, we also used Wiktionary and complemented these offline resources with automated queries to several (25) online dictionaries. We start with Wikipedia definitions, then Wiktionary, and then, if not found, we turn to online dictionaries.

5 Evaluation and Results

Potential applications of our framework include both the extension of existing lexical databases and the construction of new databases from a small set of seeds for each concept. Consequently, in our evaluation we aim to check both the ability to extend nearly complete concepts and the ability to discover most of the concept given a few seeds. Since in our current framework we extend a small subset of concepts rather than the whole database, we could not utilize application-based evaluation strategies such as performance in WSD tasks (Cuadros and Rigau, 2008).

5.1 Human judgment evaluation

In order to check how well we can extend existing concepts, we count and verify the quality of new concept terms discovered by the algorithm given complete concepts from WN. Performing an automatic evaluation of such new terms is a challenging task, since there are no exhaustive term lists available. Thus, in order to check how well newly added terms fit the concept definition, we have to use human judges.

We provided four human subjects with 24 lists of newly discovered terms, together with original concept definitions (written as descriptive natural language sentences) and asked them to rank (1-10, 10 being best) how well each of these terms fits the given definition. We have instructed judges to accept common misspellings and reject words that are too general/narrow for the provided definition.

We mixed the discovered terms with equal amounts of terms from three control sets: (1) terms from the original WN concept; (2) randomly selected WN terms; (3) terms obtained by applying the single-language concept acquisition algorithm described in Section 3.3 in the source language. Kappa inter-annotator agreement scores were above 0.6 for all tests below.

5.1.1 WordNet concept extension

The middle column of Table 3 shows the judge scores and average amount of added terms for each source language. In this case the algorithm was provided with complete term lists as concept definitions, and was requested to extend these lists. We can see that while the scores for original WN terms are not perfect (7/10), single-language and cross-lingual concept extension achieve nearly the same scores. However, the latter discovers many more new concept terms without reducing quality. The difference becomes more substantial for Hebrew, which is a resource-poor source language, heavily affecting the performance of single-language concept extension methods.

The low ranks for WN reflect the ambiguity of definition of some of its classification subtrees. Thus, for the 'body part' concept defined in WordNet as "any part of an organism such as an organ or extremity" (which is not supposed to require domain-specific knowledge to identify) low scores were given (correctly) by judges to generic terms such as tissue, system, apparatus and process (process defined in WN as "a natural prolongation or projection from a part of an organism"), positioned in WN as direct hyponyms of body parts. Low scores were also given to very specific terms like "saddle" (posterior part of the back of a domestic fowl) or very ambiguous terms like "small" (the slender part of the back).

5.1.2 Seed-based concept extension

The rightmost column of Table 3 shows similar information to the middle column, but when only the three most frequent terms from the original WN concept were given as concept definitions. We can see that even given three words as seeds, the cross-lingual framework allows to discover many new terms. Surprisingly, terms extracted by the cross-lingual framework achieve significantly higher scores not only in comparison to the single-language algorithm but also in comparison to existing WN terms. Thus while the "native" WN concept and single-language concept extension re-

sults get a score of 7/10, terms obtained by the cross-lingual framework obtain an average score of nearly 9/10.

This suggests that our cross-lingual framework can lead to better (from a human judgment point of view) assignment of terms to concepts, even in comparison to manual annotation.

	Input	
	all terms	3 terms
English		
WordNet	7.2	7.2
Random	1.8	1.8
SingleLanguage	7.0(10)	7.8(18)
Crosslingual	6.9(19)	8.8(26)
Russian		
WordNet	7.8	7.8
Random	1.9	1.9
SingleLanguage	7.4(10)	8.1(16)
Crosslingual	7.6(21)	9.0(29)
Hebrew		
WordNet	7.0	7.0
Random	1.3	1.3
SingleLanguage	6.5(4)	7.5(6)
Crosslingual	6.8(18)	8.9(24)

Table 3: Human judgment scores for concept extension in three languages (1 . . . 10, 10 is best). The WordNet, Random and SingleLanguage rows provide corresponding baselines. Average count of newly added terms are shown in parentheses. Average original WN concept size in this set was 36 for English, 32 for Russian and 27 for Hebrew.

5.2 WordNet-based evaluation

While human judgment evaluation provides a good indication for the quality of our framework, it has severe limitations. Thus terms in many concepts require domain expertise to be properly labeled. We have complemented human judgment evaluation with automated WN-based evaluation with a greater (150) number of concepts. For each of the 150 concepts, we have applied our framework on a subset of the available terms, and estimated precision and recall of the resulting term list in comparison to the original WN term list. The evaluation protocol and metrics were very similar to (Davidov and Rappoport, 2006; Widdows and Dorow, 2002) which allowed us to do indirect comparison to previous work.

Table 4 shows precision and recall for this task comparing single-language concept extension and the cross-lingual framework. We can see that in all cases, utilization of the latter greatly improves recall. It also significantly outperforms the single-language pattern-based method introduced by (Davidov and Rappoport, 2006), which achieves average precision of 79.3 on a similar set in English (in comparison to 86.7 in this study). We can also see a decrease in precision when the algorithm is provided with 50% of the concept terms as input and had to discover the remaining 50%. However, careful examination of the results shows that this decrease is due to discovery of additional correct terms not present in WordNet.

	Input					
	50% terms			3 terms		
	P	R	F	P	R	F
English						
SingleLanguage	89.2	75.9	82.0	80.6	15.2	25.6
CrossLingual	86.5	91.1	88.7	86.7	60.2	71.1
Russian						
SingleLanguage	91.3	69.0	78.6	82.1	18.3	29.9
CrossLingual	84.9	86.2	85.5	85.3	62.1	71.9
Hebrew						
SingleLanguage	93.8	38.6	54.7	90.2	5.7	10.7
CrossLingual	86.5	82.4	84.4	93.9	55.6	69.8

Table 4: WordNet-based precision (P) and recall (R) for concept extension.

5.3 Contribution of each language

Each of the 45 languages we used influences the score of at least 5% of the discovered terms. However, it is not apparent if all languages are indeed beneficial or if only a handful of languages can be used. In order to check this point we have performed partial automated tests as described in Section 5.2, removing one language at a time. We also tried to remove random subsets of 2-3 languages, comparing them to removal of one of them. We saw that in each case removal of more languages caused a consistent (while sometimes minor) decrease both in precision and recall metrics. Thus, each language contributes to the system.

6 Discussion

We proposed a framework which given a set of terms defining a concept in some language, utilizes multilingual information available on the web in order to extend this list. This method allows to take advantage of web data in many languages, requiring only multilingual dictionaries. Our method was able to discover a substantially greater number of terms than state-of-the-art single language pattern-based concept extension methods, while retaining high precision.

We also showed that concepts obtained by this method tend to be more coherent in comparison to corresponding concepts in WN, a manually prepared resource. Due to its relative language-independence and modest data requirements, this framework allows gathering required

concept information from the web even if it is scattered among different and relatively uncommon or resource-poor languages.

Abstract

Bilingual dictionaries are vital resources in many areas of natural language processing. Numerous methods of machine translation require bilingual dictionaries with large coverage, but less-frequent language pairs rarely have any digitalized resources. Since the need for these resources is increasing, but the human resources are scarce for less represented languages, efficient automatized methods are needed. This paper introduces a fully automated, robust pivot language based bilingual dictionary generation method that uses the WordNet of the pivot language to build a new bilingual dictionary. We propose the usage of WordNet in order to increase accuracy; we also introduce a bidirectional selection method with a flexible threshold to maximize recall. Our evaluations showed 79% accuracy and 51% weighted recall, outperforming representative pivot language based methods. A dictionary generated with this method will still need manual post-editing, but the improved recall and precision decrease the work of human correctors.

1 Introduction

In recent decades automatic and semi-automatic machine translation systems gradually managed to take over costly human tasks. This much welcomed change can be attributed not only to major developments in techniques regarding translation methods, but also to important translation resources, such as monolingual or bilingual dictionaries and corpora, thesauri, and so on. However, while widely used language pairs can fully take advantage of state-of-the-art developments in machine translation, certain low-frequency, or less common language pairs lack some or even most of the above mentioned translation resources. In that case, the key to a highly accurate machine translation system switches from the choice and adaptation of the translation method to the problem of available translation resources between the chosen languages.

One possible solution is bilingual corpus acquisition for statistical machine translation (SMT). However, for highly accurate SMT systems large bilingual corpora are required, which are rarely available for less represented languages. Rule or sentence pattern based systems are an attractive alternative, for these systems the need for a bilingual dictionary is essential.

Our paper targets bilingual dictionary generation, a resource which can be used within the frameworks of a rule or pattern based machine translation system. Our goal is to provide a low-cost, robust and accurate dictionary generation method. Low cost and robustness are essential in order to be re-implementable with any arbitrary language pair. We also believe that besides high precision, high recall is also crucial in order to facilitate post-editing which has to be performed by human correctors. For improved precision, we propose the usage of WordNet, while for good recall we introduce a bidirectional selection method with local thresholds.

Our paper is structured as follows: first we overview the most significant related works, after which we analyze the problems of current dictionary generation methods. We present the details of our proposal, exemplified with the Japanese-Hungarian language pair. We evaluate the generated dictionary, performing also a comparative evaluation with two other pivot-language based methods. Finally we present our conclusions.

2 Related works

2.1 Bilingual dictionary generation

Various corpus based, statistical methods with very good recall and precision were developed starting from the 1980's, most notably using the

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 862–870,
Singapore, 6-7 August 2009.

Dice-coefficient (Kay & Röscheisen, 1993), *correspondence-tables* (Brown, 1997), or *mutual information* (Brown et al., 1998).

As an answer to the corpus-based method's biggest disadvantage, namely the need for a large bilingual corpus, in the 1990's Tanaka and Umemura (1994) presented a new approach. As a resource, they only use dictionaries to and from a pivot language to generate a new dictionary. These so-called pivot language based methods rely on the idea that the lookup of a word in an uncommon language through a third, intermediated language can be automated. Tanaka and Umemura's method uses bidirectional source-pivot and pivot-target dictionaries (harmonized dictionaries). Correct translation pairs are selected by means of inverse consultation, a method that relies on counting the number of pivot language definitions of the source word, through which the target language definitions can be identified (Tanaka and Umemura, 1994).

Sjöbergh (2005) also presented an approach to pivot language based dictionary generation. When generating his English pivoted Swedish-Japanese dictionary, each Japanese-to-English description is compared with each Swedish-to-English description. Scoring is based on word overlap, weighted with inverse document frequency; the best matches being selected as translation pairs.

These two approaches described above are the best performing ones that are general enough to be applicable with other language pairs as well. In our research we used these two methods as baselines for comparative evaluation.

There are numerous refinements of the above methods, but for various reasons they cannot be implemented with any arbitrary language pair. Shirai and Yamamoto (2001) used English to design a Korean-Japanese dictionary, but because the usage of language-specific information, they conclude that their method *'can be considered to be applicable to cases of generating among languages similar to Japanese or Korean through English'*. In other cases, only a small portion of the lexical inventory of the language is chosen to be translated: Paik et al. (2001) proposed a method with multiple pivots (English and Kanji/Hanzi characters) to translate Sino-Korean entries. Bond and Ogura describe a Japanese-Malay dictionary that uses a novel technique in its improved matching through normalization of the pivot language, by means of semantic classes, but only for nouns (2007). Besides English, they also use Chinese as a second pivot.

2.2 Lexical database in lexical acquisition

Large lexical databases are vital for many areas in natural language processing (NLP), where large amount of structured linguistic data is needed. The appearance of WordNet (Miller et al., 1990) had a big impact in NLP, since not only did it provide one of the first wide-range collections of linguistic data in electronic format, but it also offered a relatively simple structure that can be implemented with other languages as well. In the last decades since the first, English WordNet, numerous languages adopted the WordNet structure, thus creating a potential large multilingual network. The Japanese language is one of the most recent ones added to the WordNet family (Isahara et al. 2008), but the Hungarian WordNet is still under development (Prószéky et al. 2001; Miháltz and Prószéky 2004).

Multilingual projects, such as EuroWordNet (Vossen 1998; Peters et al. 1998), Balkanet (Stamou et al. 2002) or Multilingual Central Repository (Agirre et al. 2007) aim to solve numerous problems in natural language processing. EuroWordNet was specifically designed for word disambiguation purposes in cross-language information retrieval (Vossen 1998). The internal structure of the multilingual WordNets itself can be a good starting point for bilingual dictionary generation. In case of EuroWordNet, besides the internal design of the initial WordNet for each language, an Inter-Lingual-Index interlinks word meaning across languages is implemented (Peters et al. 1998). However, there are two limitations: first of all, the size of each individual language database is relatively small (Vossen 1998), covering only the most frequent words in each language, thus not being sufficient for creating a dictionary with a large coverage. Secondly, these multilingual databases cover only a handful of languages, with Hungarian or Japanese not being part of them. Adding a new language would require the existence of a WordNet of that language.

3 Problems of current pivot language based methods

3.1 Selection method shortcomings

Previous pivot language based methods generate and score a number of translation candidates, and the candidate's scores that exceed a certain predefined global threshold are selected as viable translation pairs. However, the scores highly de-

pend on the entry itself or the number of translations in the pivot language, therefore there is a variance in what that score represents. For this reason, a large number of good entries are entirely left out from the dictionary, because all of their translation candidates scored low, while faulty translation candidates are selected, because they exceed the global threshold. Due to this effect the recall value drops significantly.

3.2 Dictionaries not enough as resource

Regardless of the language pair, in most cases the meanings of the corresponding words are not identical; they only overlap to a certain extent. Therefore, the pivot language based dictionary generation problem can be defined as the identification of the common elements or the extent of the relevant overlapping in the source-to-pivot and target-to-pivot definitions.

Current methods perform a strictly lexical overlap of the source-pivot and target-pivot entries. Even if the meanings of the source and target head words are transferred to the pivot language, this is rarely done with the same set of words or definitions. Thus, due to the different word-usage or paraphrases, even semantically identical or very similar head words can have different definitions in different dictionaries. As a result, performing only lexical overlap, current methods cannot identify the differences between totally different definitions resulted by unrelated concepts, and differences in only nuances resulted by lexicographers describing the same concept, but with different words.

4 Proposed method

4.1 Specifics of our proposal

For higher precision, instead of the familiar lexical overlap of the current methods we calculate the semantically expanded lexical overlap of the source-to-pivot and target-to-pivot translations. In order to do that, we use semantic information extracted from the WordNet of the pivot language.

To improve recall, we introduce *bidirectional selection.* As we stated above, the global threshold eliminates a large number of good translation pairs, resulting in a low recall. As a solution, we can group the translations that share the same source or target entry, and set *local thresholds* for each head word. For example, for a source language head word *entry_source* there could be multiple target language candidates: $entry\_target_1, \ldots, entry\_target_n$. If the top scoring $entry\_target_k$ candidates are selected, we ensure that at least one translation will be available for *entry_source*, maintaining a high recall. Since we can group the entries in the source language and target language as well, we perform this selection twice, once in each direction. Local thresholds depend on the top scoring *entry_target*, being set to $maxscore \cdot c$. Constant c varies between 0 and 1, allowing a small window not only for the maximum, but high scoring candidates as well. It is language and selection method dependent (see §5.1 for details).

4.2 Translation resources

As an example of a less-common language pair, we have chosen Japanese and Hungarian. For translation candidate generation, we have chosen two freely available dictionaries with English as the pivot language. The Japanese-English dictionary had 197282, while the Hungarian-English contained 189331 1-to-1 entry pairs. The Japanese-English dictionary had part-of-speech (POS) information as well, but to ensure robustness, our method does not use this information.

To select from the translation candidates, we mainly use *WordNet* (Miller et. al., 1990). From WordNet we consider four types of information: *sense categorization, synonymy*, *antonymy* and *semantic categories* provided by the tree structure of nouns and verbs.

4.3 Dictionary generation method

Our proposed method consists of two steps. In step 1 we generate a number of translation pair candidates, while in step 2 we score and select from them based on semantic information extracted from WordNet.

Step 1: translation candidate generation

Using the source-pivot and pivot-target dictionaries, we connect the source and target entries that share at least one common translation in the pivot language. We consider each source-target pair a *translation candidate*. With our Japanese-English and English-Hungarian dictionaries we accumulated 436966 Japanese-Hungarian translation candidates.

Step 2: translation pair selection

We examine the translation candidates one by one, looking up the source-pivot and target-pivot dictionaries, comparing the translations in the pivot language. There are six types of translations that we label *A-F* and explain below. First,

we perform a strictly lexical match based only on the dictionaries. Next, using information extracted from WordNet we attempt to identify the correct translation pairs.

(a) Lexically unambiguous translation pairs

Some of the translation candidates have exactly the same translations into in the pivot language; we consider these pairs as being correct by default. Also among the translation candidates we identified a number of source entries that had only one target translation; and a number of target entries that had only one source translation. Being the sole candidates for the given entries, we consider these pairs too as being correct. 37391 Japanese-Hungarian translation pairs were retrieved with this method (*type A* pairs).

(b) Using sense description

For most polysemous words WordNet has detailed descriptions with synonyms for each sense. We use these synonyms of WordNet's sense descriptions to disambiguate the meanings of the common translations. For a given source-target translation candidate (s,t) we look up the source-pivot and target-pivot translations ($s \rightarrow I = \{s \rightarrow i_1, \ldots, s \rightarrow i_n\}$ and $t \rightarrow I = \{t \rightarrow i_1, \ldots, t \rightarrow i_m\}$). We select the elements that are common in the two definitions ($I' = (s \rightarrow I) \cap (t \rightarrow I)$) and we look up their respective senses from WordNet ($sns(I')$). We identify the words' senses comparing each synonym in the WordNet's synonym description with each word from the dictionary definition. As a result, for each common word we arrive at a certain set of senses from the source-pivot definitions ($sns((s \rightarrow I')$) and a certain set of senses from the target-pivot definitions ($sns((t \rightarrow I')$). We mark $score_B(s,t)$ the maximum ratio of the identical and total number of identified senses (Jaccard coefficient). The higher the $score_B(s,t)$ is, the more probable is candidate (s,t) a valid translation.

$$score_B(s,t) = \max_{i' \in (s \rightarrow I) \cap (t \rightarrow I)} \frac{|sns(s \rightarrow i') \cap sns(t \rightarrow i')|}{|sns(s \rightarrow i') \cup sns(t \rightarrow i')|} \quad (1)$$

For example, *正解 (seikai: correct, right, correct interpretation)* and *helyes (correct, proper, right, appropriate)* have two common translations ($I' = \{right, correct\}$), thus $score_B(s,t)$ can be performed with these two words. The adjective *right* has 13 senses according to WordNet, among them 4 were identified from the Japanese to English definition ($sns(right) = \{\#1, \#3, \#5, \#10\}$, all identified through *correct*) and 5 from the Hungarian to English definition ($sns(right) = \{\#1, \#3, \#5, \#6, \#10\}$, through *correct* or *proper*). As a result, 4 senses are common, and 1 is different. Thus the adjective *right*'s score is 0.8 ($score_B(s,t)[right](正解, helyes)$). The adjective *correct* has 4 senses, all of them are recognized by both definitions through *right*, therefore the score through *correct* is 1 ($score_B(s,t)[correct](正解, helyes)$). The maximum of the above scores is the final score: $score_B(s,t)(正解, helyes) = 1$.

All translation candidates are verified based on all four POS available from WordNet. Since synonymy information is available for nouns (N), verbs (V), adjectives (A) and adverbs (R), four separate scores are calculated for each POS.

Scores that pass a global threshold are considered correct. 33971 Japanese-Hungarian candidates (*type B* translations) were selected, with these two languages the global threshold was set to 0.1. Even this low value ensures that at least one of ten meanings is shared by the two entries of the pair, thus being suitable as translation pair.

(c) Using synonymy, antonymy and semantic categories

We expand the source-to-pivot and target-to-pivot definitions with information from WordNet (synonymy, antonymy and semantic category, respectively). Thus the similarity of the two expanded pivot language descriptions gives a better indication on the suitability of the translation candidate. Using the three relations, the common versus total number of translations (Jaccard coefficient) will define the appropriateness of the translation candidate.

$$score_{C,D,E}(s,t) = \frac{|ext(s \rightarrow i) \cap ext(t \rightarrow i)|}{|ext(s \rightarrow i) \cup ext(t \rightarrow i)|} \quad (2)$$

Since the same word or concept's translations into the pivot language also share the same semantic value, the extension with synonyms ($ext(l \rightarrow i) = (l \rightarrow i) \cup syn(l \rightarrow i)$, where $l = \{s,t\}$) the extended translation should share more common elements.

In case of antonymy, we expand the initial definitions with the *antonyms of the antonyms* ($ext(l \rightarrow i) = (l \rightarrow i) \cup ant(ant(l \rightarrow i))$, where $l = \{s,t\}$). This extension is different from the synonymy extension, in most cases the resulting set of words being considerably larger.

Along with synonymy, antonymy is also available for nouns, verbs, adjectives and adverbs, four separate scores are calculated for each POS.

Semantic categories are provided by the tree structure (hypernymy/hyponymy) of nouns and verbs of WordNet. We transpose each entry from the pivot translations to its semantic categories ($ext(l \rightarrow i) = \Sigma semcat(l \rightarrow i)$, where $l = \{s,t\}$). We assume that the correct translation pairs share a high percentage of semantic categories. Accordingly, the translations of semantically similar or identical entries should share a high number of common semantic categories.

The scores based on these relations highly depend on the number of pivot language translations; therefore we use the bidirectional selection method with local thresholds for each source and target head word. Local thresholds are set based on the best scoring candidate for a given entry. The thresholds were *maxscore*·0.9 for synonymy and antonymy; and *maxscore*·0.8 for the semantic categories (see §5.1 for details).

Using synonymy, 196775 candidate pairs (*type C*), with antonymy 99614 pairs (*type D*); while with semantic categories 195480 pairs (*type E*) were selected.

(d) Combined semantic information

The three separate lists of type C, D and E selection methods resulted in slightly different results, proving that they cannot be used as standalone selection methods (see §5.2 for details).

Because of the multiple POS labelling of numerous words in WordNet, many translation pairs can be selected up to four times based on separate POS information (noun, verb, adjective, adverb), all within one single semantic information based methods. Since we use a bidirectional selection method, experiments showed that translation pairs that were selected during both directions, in most cases were the correct translations. Similarly, translation pairs selected during only one direction were less accurate. In other words, translation pairs whose target language translation was selected as a good translation for the source language entry; and whose source language translation was also selected as a good translation for the target language entry, should be awarded with a higher score. In the same way, entries selected only during one direction should receive a penalty. For every translation candidate we select the maximum score from the several POS (noun, verb, adjective and adverb for synonymy and antonymy relations; noun and verb for semantic category) based scores, multiplied by a multiplication factor (*mfactor*). The multiplication factor varies between 0 and 1, awarding the candidates that were selected both times during the double directional selection; and punishing when selection was made only in a single direction. The product gives the combined score ($score_F$), c_1, c_2 and c_3 are constants. In case of Japanese and Hungarian, these method scored best with the constants set to 1, 0.5 and 0.8, respectively. The combined score also highly depends on the word entry, therefore local thresholds are used in this selection method as well, which were empirically set to *maxscore·0.85* (see §5.1 for details).

$$score_F(s,t) = \prod_{rel} \begin{pmatrix} (c_1 + \max(score_{rel}(s,t))) \cdot \\ (c_2 + c_3 \cdot mfactor_{rel}(s,t)) \end{pmatrix} \qquad (3)$$

As an example, for the Japanese entry 購入 *(kōnyū: buy, purchase)* there are 10 possible Hungarian translations; using the above methods 5 of them (#1, #7, #8, #9, #10) are selected as correct ones. Among these, only 1 of them (#1) is a correct translation, the rest have similar or totally different meanings. However, with the combined scores the faulty translations were eliminated and a new, correct, but previously average scoring translation (#2) was selected (Table 1).

#	translation candidate	$score_F$	$score_C$				$score_D$				$score_E$	
			N	V	A	R	N	V	A	R	N	V
1	vétel *(purchase)*	**2.012**	0.193	0.096	0	0	0	**0.500**	0	0	0.154	**0.500**
2	üzlet *(business transaction)*	**1.387**	0.026	0.030	0	0	0	0.250	0	0	0.020	0.077
3	hozam *(output, yield)*	1.348	0.095	0.071	0	0	0	0	0	0	0.231	0.062
4	emelőrúd *(lever, purchase)*	1.200	0.052	0.079	0	0	0	0	0	0	0.111	0.067
5	előny *(advantage, virtue)*	1.078	0.021	0.020	0	0	0	0	0	0	0.054	0.056
6	támasz *(purchase, support)*	1.053	0.014	0.015	0	0	0	0	0	0	0.037	0.031
7	vásárlás *(shopping)*	0.818	0.153	**0.285**	0	0	0	0	0	0	0.273	0.200
8	szerzemény *(attainment)*	0.771	0.071	**0.285**	0	0	0	0	0	0	0.136	0.200
9	könnyítés *(facilitation)*	0.771	0.064	**0.285**	0	0	0	0	0	0	0.136	0.200
10	emelőszerkezet *(lever)*	0.459	**0.285**	**0.285**	0	0	0	0	0	0	**0.429**	0.200

Table 1: Translation candidate scoring for 購入: *buy, purchase* (above thresholds in bold)

161202 translation pairs were retrieved with this method (*type F*).

During pre-evaluation *type A* and *type B* translations received a score of above 75%, while *type C*, *type D* and *type E* scored low (see §5.2 for details). However, *type F* translations scored close to 80%, therefore from the six translation methods presented above we chose only three (*type A*, *B* and *F*) to construct the dictionary, while the remaining three methods (*type C*, *D* and *E*) are used only indirectly for *type F* selection.

With the described selection methods 187761 translation pairs, with 48973 Japanese and 44664 Hungarian unique entries was generated.

5 Threshold settings and pre-evaluation

5.1 Local threshold settings

As development set we considered all translation candidates whose Hungarian entry starts with "zs" (IPA: ʒ). We assume that the behaviour of this subset of words reflects the behaviour of the entire vocabulary. 133 unique entries totalling 515 translation candidates comprise this development set. After this, we manually scored the 515 translation candidates as *correct* (the translation conveys the same meaning, or the meanings are slightly different, but in a certain context the translation is possible) or *wrong* (the translation pair's two entries convey a different meaning). The scoring was performed by one of the authors who is a native Hungarian and fluent in Japanese. 273 entries were marked as *correct*. Next, we experimented with a number of thresholds to determine which ones provide with the best F-scores (Table 2). The F-scores were determined as follows: for example using synonymy information (type C) in case of threshold=0.85%, 343 of the 515 translation pairs were above the threshold. Among these, 221 were marked as correct by our manual evaluator, thus the precision being 221/343·100=64.43 and the recall being 221/273·100=80.95. F-score is the harmonic mean of precision and recall (71.75 in this case).

selection type	**threshold value** (%)				
	0.75	**0.80**	**0.85**	**0.90**	**0.95**
C	70.27	70.86	71.75	**72.81**	66.95
D	69.92	70.30	70.32	**70.69**	66.66
E	73.71	**74.90**	72.52	71.62	65.09
F	78.78	79.07	**79.34**	78.50	76.94

Table 2: Selection type F-scores with varying thresholds (best threshold values in bold)

5.2 Selection method evaluation

As a pre-evaluation of the above selection methods, we randomly selected 200 1-to-1 source-target entries resulted by each method. The same evaluator scored the translation pairs as *correct* (the translation conveys the same meaning, or the meanings are slightly different, but in a certain context the translation is possible), *undecided* (the translation pair's semantic value is similar, but a translation based on them would be faulty) or *wrong* (the translation pair's two entries convey a different meaning).

selection type	**evaluation score** (%)		
	correct	*undecided*	*wrong*
A	75.5	6.5	18
B	83	7	10
C	68	5.5	26.5
D	60	9	31
E	71	5.5	23.5
F	79	5	16

Table 3: Selection type evaluation

The results showed that *type A* and *type B* selections scored higher than all order-based selections, with *type C*, *type D* and *type E* selections failing to deliver the desired accuracy (Table 3).

6 Evaluation

We performed three types of evaluation:
(1) frequency-weighted recall evaluation
(2) 1-to-1 entry precision evaluation
(3) 1-to-multiple entry evaluation

For comparative purposes we also performed each type of evaluation for two other pivot language based methods whose characteristics permit to be implementable with virtually any language pair. In order to do so, we constructed two other Hungarian-Japanese dictionaries using the methods proposed by Tanaka & Umemura and Sjöbergh, using the same source dictionaries.

6.1 Recall evaluation

It is well known that one of the most challenging aspects of dictionary generation is word ambiguity. It is relatively easy to automatically generate the translations of low-frequency keywords, because they tend to be less ambiguous. On the contrary, the ambiguity of the high frequency words is much higher than their low-frequency counterparts, and as a result conventional methods fail to translate a considerable number of them. However, this discrepancy is not reflected in the traditional recall evaluation, since each

word has an equal weight, regardless of its frequency of use. As a result, we performed a frequency weighted recall evaluation. We used a Japanese frequency dictionary (F_D) generated from the Japanese EDR corpus (Isahara, 2007) to weight each Japanese entry. Setting the standard to the frequency dictionary (its recall value being 100), we automatically search for each entry (w) from the frequency dictionary, looking whether or not it is included in the bilingual dictionary (W_D). If it is recalled, we weight it with its frequency from the frequency dictionary.

$$recall_w = \frac{\sum_{w \in W_D} frequency(w)}{\sum_{w \in F_D} frequency(w)} \cdot 100 \quad (4)$$

method	recall
our method	51.68
Sjöbergh method	37.03
Tanaka method	30.76
initial candidates	51.68
Japanese-English(*)	73.23

Table 4: Recall evaluation results (* marks a manually created dictionary)

The frequency weighted recall value results show that our method's dictionary (51.68) outscores every other automatically generated method's dictionary (37.03, 30.76) with a significant advantage. Moreover, it maintains the score of the initial translation candidates, therefore managing to maximize the recall value, owing to the bidirectional selection method with local thresholds. However, the recall value of a manually created Japanese-English dictionary is higher than any automatically generated dictionary's value (Table 4).

6.2 1-to-1 precision evaluation

With 1-to-1 precision evaluation we determine the translation accuracy of our method, compared with the two baseline methods. 200 random pairs were selected from each of the three Hungarian-Japanese dictionaries, scoring them manually the same way as with selection type evaluation (*correct*, *undecided*, *wrong*) (Table 5). The manual scoring was performed by one of the authors, who is a native Hungarian and fluent in Japanese. Since no independent evaluator was available for these two languages, after a random identification code being assigned to each of the 600 selected translation pairs (200 from each dictionary), they were mixed. Therefore the evaluator did not know the origin of the translation pairs, only after manual scoring the total score for each dictionary was available, after regrouping based on the initial identification codes. The process was repeated 10 times, 2000 pairs were manually checked from each dictionary.

code	Japanese entry	Hungarian entry	classification
k9g6 n5d8	報告 (hōkoku: information, report)	hír (report, information, news)	*correct*
j8h0 k1x5	初 (ubu: innocent, naive)	zöld (green, verdant)	*undecided*
a5b6 n8i3	エントリ (entori: entry <a contest>)	bejárat (entry, entrance)	*wrong*

Table 5: 1-to-1 precision evaluation examples

method	evaluation score (%)		
	correct	*undecided*	*wrong*
our method	79.15%	6.15%	14.70%
Sjöbergh method	54.05%	9.80%	36.15%
Tanaka method	62.50%	7.95%	29.55%

Table 6: 1-to-1 precision evaluation results

To rank the methods we only consider the *correct* translations. Our method performed best with an average of 79.15%, outscoring Tanaka method's 62.50% and Sjöbergh method's 54.05% (Table 6). The maximum deviance of the *correct* translations during the 10 repetitions was less than 3% from the average.

6.3 1-to-multiple evaluation

While with 1-to-1 precision evaluation we estimated the accuracy of the translation pairs, with 1-to-multiple we calculate the true reliability of the dictionary, with the initial translation candidates set as recall benchmark. When looking up the meanings or translations of a certain head word, the user, whether he's a human or a machine, expects all translations to be accurate. Therefore we evaluated 200 randomly selected Japanese entries from the initial translation candidates, together with all of their Hungarian translations, scoring them as *correct* (all translations are correct), *acceptable* (the good translations are predominant, but there are up to 2 erroneous translations), *wrong* (the number or wrong translations exceeds 2) or *missing* (the translation is missing) (Table 7).

The same type of mixed, manual evaluation was performed by the same author on samples of 200 entries from each Japanese-Hungarian dictionary. This evaluation was also repeated 10 times.

To rank the methods, we only consider the *correct* translations. Our method scored best with

71.45%, outperforming Sjöbergh method's 61.65% and Tanaka method's 46.95% (Table 8).

code	Japanese entry	Hungarian translations	classification
j4h8 m9x 5	圧縮 (asshuku: compression, squeeze)	összenyomás (compression, crush, squeeze: *correct*) összeszorítás (compression, confinement: *correct*) zsugorítás (shrinkage: *correct*)	*correct*
h9j9l 3v1	底面 (teimen: base)	alap (base, bottom, foundation: *correct*) alapzat (base, bed, bottom: *correct*) lúg (alkali, base: *undecided*) támpont (base: *correct*)	*acceptable*
l0k6 m3n 7	鳴らす (narasu: to sound, to ring, to beat)	bekerít (to encircle, to enclose, to ring: *wrong*) cseng (to clang, to clank, to ring, to tinkle: *correct*) hangzik (to ring, to sound: *correct*) horkan (to snort: *wrong*) üt (to bang, to knock, to ring: *wrong*)	*wrong*

Table 7: 1-to-multiple entry evaluation examples

method	evaluation score (%)			
	correct	*acceptable*	*wrong*	*missing*
our method	71.45	13.85	14.70	0
Sjöbergh method	61.65	11.30	15.00	12.05
Tanaka method	46.95	3.35	9.10	40.60

Table 8: 1-to-many evaluation results

7 Discussion

Based on the recall evaluations, the traditional methods showed their major weakness by losing substantially from the initial recall values, scored by the initial translation candidates. Our method maintains the same value with the translation candidates, but we cannot say that the recall is perfect. When compared with a manually created dictionary, our method also lost significantly.

Precision evaluation also showed an improvement compared with the traditional methods, our method outscoring the other two methods with the 1-to-1 precision evaluation. 1-to-multiple evaluation was also the highest, proving that WordNet based methods outperform dictionary based methods. Discussing the weaknesses of our system, we have to divide the problems into two categories: recall problems deal with the difficulty in connecting the target and source entries through the pivot language, while precision problems discuss the reasons why erroneous pairs are produced.

7.1 Recall problems

We managed to maximize the recall of our initial translation candidates, but in many cases certain translation pairs still could not be generated because the link from the source language to the target language through the pivot language simply doesn't exist. The main reasons are: the entry is missing from at least one of the dictionaries; translations in the pivot language are expressions or explanations; or there is no direct translation or link between the source and target entries. The entries that could not be recalled are mostly expressions, rare entries, words specific to a language (ex: *tatami: floor-mat,* or *gulyás: goulash*).

Moreover, a number of head words don't have any synonym, antonym and/or hypernymy/hyponymy information in WordNet, and as a result these words could not participate in the type B, C, D, E and F scoring.

7.2 Precision problems

We identified two types of precision problems. The most obvious reasons for erroneous translations are the polysemous nature of words and the meaning-range differences across languages. With words whose senses are clear and mostly preserved even through the pivot language, most of the correct senses were identified and correctly translated. Nouns, adjectives and adverbs had a relatively high degree of accuracy. However, verbs proved to be the most difficult POS to handle. Because semantically they are more flexible than other POS categories, and the meaning range is also highly flexible across languages, the identification of the correct translation is increasingly difficult. For this reason, the number of faulty translations and the number of meanings that are not translated was relatively high.

One other source of erroneous translations is the quality of the initial dictionaries. Even the unambiguous *type A* translations fail to produce the desired accuracy, although they are the unique candidate for a given word entry. The main reason for this is the deficiency of the initial dictionaries, which contain a great number of irrelevant or low usage translations, shadowing the main, important senses of some words. In other cases the resource dictionaries don't contain translations of all meanings; homonyms are

present as pivot entries with different meanings, sometimes creating unique, but faulty links.

8 Conclusions

We proposed a new pivot language based method to create bilingual dictionaries that can be used as translation resource for machine translation. In contrast to conventional methods that use dictionaries only, our method uses WordNet as a main resource of the pivot language to select the suitable translation pairs. As a result, we eliminate most of the weaknesses caused by the structural differences of dictionaries, while profiting from the semantic relations provided by WordNet. We believe that because of the nature of our method it can be re-implemented with most language pairs.

In addition, owing to features such as the bidirectional selection method with local thresholds we managed to maximize recall, while maintaining a precision which is better than any other compared method's score. During exemplification, we generated a mid-large sized Japanese-Hungarian dictionary with relatively good recall and promising precision.

The dictionary is freely available online (http://mj-nlp.homeip.net/mjszotar), being also downloadable at request.

Abstract

We present a novel approach for multilingual document clustering using only comparable corpora to achieve cross-lingual semantic interoperability. The method models document collections as weighted graph, and supervisory information is given as sets of must-linked constraints for documents in different languages. Recursive k-nearest neighbor similarity propagation is used to exploit the prior knowledge and merge two language spaces. Spectral method is applied to find the best cuts of the graph. Experimental results show that using limited supervisory information, our method achieves promising clustering results. Furthermore, since the method does not need any language dependent information in the process, our algorithm can be applied to languages in various alphabetical systems.

1 Introduction

Document clustering is unsupervised classification of text collections into distinct groups of similar documents. It has been used in many information retrieval tasks, including data organization (Siersdorfer and Sizov, 2004), language modeling (Liu and Croft, 2004), and improving performances of text categorization system (Aggarwal et al., 1999). Advance in internet technology has made the task of managing multilingual documents an intriguing research area. The growth of internet leads to the necessity of organizing documents in various languages. There exist thousands of languages, not to mention countless minor ones. Creating document clustering model for each language is simply unfeasible. We need methods to deal with text collections in diverse languages simultaneously.

Multilingual document clustering (MLDC) involves partitioning documents, written in more than one languages, into sets of clusters. Similar documents, even if they are written in different languages, should be grouped together into one cluster. The major challenge of MLDC is achieving cross-lingual semantic interoperability. Most monolingual techniques will not work since documents in different languages are mapped into different spaces. Spectral method such as Latent Semantic Analysis has been commonly applied for MLDC task. However, current techniques strongly rely on the presence of common words between different languages. This method would only work if the languages are highly related, i.e., languages that share the same root. Therefore, we need another method to improve the robustness of MLDC model.

In this paper, we focus on the problem of bridging multilingual space for document clustering. We are given text documents in different languages and asked to group them into clusters such that documents that belong to the same topic are grouped together. Traditional monolingual approach is impracticable since it is unable to predict how similar two multilingual documents are. They have two different spaces which make conventional cosine similarity irrelevant. We try to solve this problem utilizing prior knowledge in the form of must-linked constraints, gathered from comparable corpora. Propagation method is used to guide the language-space merging process. Experimental results show that the approach gives encouraging clustering results.

This paper is organized as follows. In section 2, we review related work. In section 3, we propose our algorithm for multilingual document clustering. The experimental results are shown in section 4. Section 5 concludes with a summary.

2 Related Work

Chen and Lin (2000) proposed methods to cluster multilingual documents using translation technology, relying on cross-lingual dictionary and machine-translation system. Multilingual ontology, such as Eurovoc, is also popular for MLDC (Pouliquen et al., 2004). However, such resources are scarce and expensive to build. Several other drawbacks of using this technique include dictionary limitation and word ambiguity.

More recently, parallel texts have been used to connect document collections from different languages (Wei et al., 2008). This is done by collapsing columns in a term by document matrix that are translations of each other. Nevertheless, building parallel texts is also expensive and requires a lot of works, hence shifting the paradigm of multilingual works to comparable corpora.

Comparable corpora are collections of texts in different languages regarding similar topics produced at the same time. The key difference between comparable corpora and parallel texts is that documents in comparable corpora are not necessarily translations of each other. They are easier to be acquired, and do not need exhaustive works to be prepared. News agencies often give information in many different languages and can be good sources for comparable corpora. Terms in comparable corpora, being about the same topic, up to some point explain the same concepts in different languages. Pairing comparable corpora with spectral method such as Latent Semantic Analysis has become prevalent, e.g. (Gliozzo and Strapparava, 2005). They rely on the presence of common words and proper nouns among various languages to build a language-independent space. The performance of such method is highly dependent on the languages being used. Here, we present another approach to exploit knowledge in comparable corpora; using propagation method to aid spreading similarity between collections of documents in different languages.

Spectral clustering is the task of finding good clusters by using information contained in the eigenvectors of a matrix derived from the data. It has been successfully applied in many applications including information retrieval (Deerwester et al., 2003) and computer vision (Meila and Shi, 2000). An in-depth analysis of spectral algorithm for clustering problems is given in (Ng et al., 2002). Zhang and Mao (2008) used a related technique called Modularity Eigenmap to extract community structure features from the document network to solve hypertext classification problem.

Semi-supervised clustering enhances clustering task by incorporating prior knowledge to aid clustering process. It allows user to guide the clustering process by giving some feedback to the model. In traditional clustering algorithm, only unlabeled data is used to find assignments of data points to clusters. In semi-supervised clustering, prior knowledge is given to improve performance of the system. The supervision is usually given as pair of must-linked constraints and cannot link constraints, first introduced in (Wagstaff and Cardie, 2000). Kamvar et al. (2003) proposed spectral learning algorithm that can take supervisory information in the form of pairwise constraints or labeled data. Their algorithm is intended to be used in monolingual context, while our algorithm is designed to work in multilingual context.

3 Multilingual Spectral Clustering

There have been several works on multilingual document clustering as mention previously in Section 2. Our key contribution here is the propagation method to make spectral clustering algorithm works for multilingual problems. The clustering model exploits the supervisory information by detecting k nearest neighbors of the newly-linked documents, and propagates document similarity to these neighbors. The model can be applied to any multilingual text collections regardless of the languages. Overall algorithm is given in Section 3.1 and the method to merge multilingual spaces by similarity propagation is given in Section 3.2.

3.1 Spectral Clustering Algorithm

Spectral clustering tries to find good clusters by using top eigenvectors of normalized data affinity matrix. The document set is being modeled as undirected graph $G(V, E, W)$, where V, E, and W denote the graph vertex set, edge set, and transition probability matrix, respectively. In graph G, $v \in V$ represents a document, and weight $w_{ij} \in W$ represents transition probability between document v_i to v_j. The transition probabilities can be interpreted as edge flows in Markov random walk over graph vertices (documents in collections).

Algorithm to perform spectral clustering is given in Algorithm 1. Let A be affinity matrix

where element A_{ij} is cosine similarity between document v_i and v_j (Algorithm 1, line 1). It is straightforward that documents belonging to different languages will have similarity zero. Rare exception occurs when they have common words because the languages are related one another. As a consequence, the similarity matrix will have many zeros. Our model amplifies prior knowledge in the form of comparable corpora by performing document similarity propagation, presented in Section 3.2 (Algorithm 1, line 4; Algorithm 2, explained in Section 3.2). After propagation, the affinity matrix is post-processed (Algorithm 1, line 6, explained in Section 3.2) before being transformed into transition probability matrix.

The transformation can be done using any normalization for spectral methods. Define $N = D^{-1}A$, as in (Meila and Shi, 2001), where D is the diagonal matrix whose elements $D_{ij} = \sum_j A_{ij}$ (Algorithm 1, line 7). Alternatively, we can define $N = D^{-1/2}AD^{-1/2}$ (Ng et al., 2002), or $N = (A + d_{max}I - D)/d_{max}$ (Fiedler, 1975), where d_{max} is the maximum rowsum of A. For our experiment, we use the first normalization method, though other methods can be applied as well.

Meila and Shi (2001) show that probability transition matrix N with t strong clusters will have t piecewise constant eigenvectors. They also suggest using these t eigenvectors in clustering process. We use the information contains in t largest eigenvectors of N (Algorithm 1, line 8-11) and perform K-means clustering algorithm to find the data clusters (Algorithm 1, line 12).

Algorithm 1 Multilingual Spectral Clustering

Input: Term by document matrix M, pairwise constraints

Output: Document clusters

1: Create graph affinity matrix $A \in \mathbb{R}^{n \times n}$ where each element A_{ij} represents the similarity between document v_i and v_j.
2: **for all** pairwise constraints in comparable corpora **do**
3: $A_{ij} \leftarrow 1, A_{ji} \leftarrow 1$.
4: Recursive Propagation $(A, S, \beta, k, v_i, v_j)$.
5: **end for**
6: Post-process matrix A so that every value in A is greater than δ and less than 1.
7: Form a diagonal matrix D, where $D_{ii} = \sum_j A_{ij}$. Normalize $N = D^{-1}A$.
8: Find $x_1, x_2 \cdots, x_t$, the t largest eigenvectors of N.
9: Form matrix $X = [x_1, x_2, \cdots, x_t] \in \mathbb{R}^{n \times t}$.
10: Normalize row X to be unit length.
11: Project each document into eigen-space spanned by the above t eigenvectors (by treating each row of X as a point in $\mathbb{R}^t$, row i represents document v_i).
12: Apply K-means algorithm in this space to find document clusters.

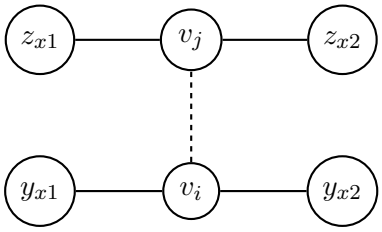
3.2 Propagating Prior Knowledge

We use information obtained from comparable corpora to merge multilingual language spaces. Suppose we have text collections in L different languages. We combine this collections with comparable corpora, also in L languages, that act as our supervisory information. Comparable corpora are used to gather prior knowledge by making must-linked constraints for documents in different languages that belong to the same topic in the corpora, propagating similarity to other documents while doing so.

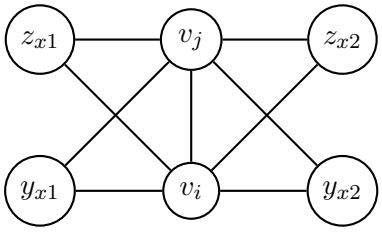
Initially, our affinity matrix A represents cosine similarity between all pairs of documents. A_{ij} is set to zero if j is not the top k nearest neighbors of i and likewise. Next, set A_{ij} and A_{ji} to 1 if document i and document j are different in language and belong to the same topic in our comparable corpora. This will incorporate the must-linked constraint to our model. We can also give supervisory information for pairs of document in the same language, but this is optional. We also do not use cannot-linked constraints since the main goal is to merge multilingual spaces. In our experiment we show that using only must-linked constraints with propagation is enough to achieve encouraging clustering results.

The supervisory information acquired from comparable corpora only connects two nodes in our graph. Therefore, the number of edges between documents in different languages is about as many as the number of must-linked constraints given. We argue that we need more edges between pairs of documents in different languages to get better results.

We try to build more edges by propagating similarity to other documents that are most similar to the newly-linked documents. Figure 1 gives an illustration of edge-creation process when two multilingual documents (nodes) are connected. Sup-



(a) Connect two nodes



(b) Effect on neighbor nodes

Figure 1: Pairing two multilingual documents affect their neighbors. v_i and v_j are documents in two different languages. y_x and z_x are neighbors of v_i and v_j respectively.

pose that we have six documents in two different languages. Initially, documents are only connected with other documents that belong to the same language. The supervisory information tells us that two multilingual documents v_i and v_j should be connected (Figure 1(a)). We then build an edge between these two documents. Furthermore, we also use this information to build edges between v_i and neighbors of v_j and likewise (Figure 1(b)).

This follows from the hypothesis that bringing together two documents should also bring other documents that are similar to those two closer in our clustering space. Klein et al. (2002) stated that a good clustering algorithm, besides satisfying known constraints, should also be able to satisfy the implications of those constraints. Here, we allow not only instance-level inductive implications, but utilize it to get higher-level inductive implications. In other words, we alter similarity space so that it can detect other clusters by changing the topology of the original space.

The process is analogous to shortening the distance between sets of documents in Euclidean space. In vector space model, two documents that are close to each other have high similarity, and thus will belong to the same cluster. Pairing two documents can be seen as setting the distance in this space to 0, thus raising their similarity to 1. While doing so, each document would also draw sets of documents connected to it closer to the centre of the merge, which is equivalent to increasing their similarities.

Suppose we have document v_i and v_j, and y and z are sets of their respective k nearest neighbors, where $|y| = |z| = k$. The propagation method is a recursive algorithm with base S, the number of desired level of propagation. Recursive k-nearest neighbor makes decision to give high similarity between multilingual documents not only determined by their similarity to the newly-linked documents, but also their similarity to the k nearest neighbors of the respective document. Several documents are affected by a single supervisory information. This will prove useful when only limited amount of supervisory information given. It uses document similarity matrix A, as defined in the previous section.

1. For $y_x \in y$ we propagate $\beta A_{v_i y_x}$ to $A_{v_j y_x}$. Set $A_{y_x v_j} = A_{v_j y_x}$ (Algorithm 2, line 5-6). In other words, we propagate the similarity between document v_i and y nearest neighbors of v_i to document v_j.

2. Similarly, for $z_x \in z$ we propagate $\beta A_{v_j z_x}$ to $A_{v_i z_x}$. Set $A_{z_x v_i} = A_{v_i z_x}$ (Algorithm 2, line 10-11). In other words, we propagate the similarity between document v_j and z nearest neighbors of v_j to document v_i.

3. Propagate higher order similarity to k nearest neighbors of y and z, discounting the similarity quadratically, until required level of propagation S is reached (Algorithm 2, line 7 and 12).

The coefficient β represents the degree of enforcement that the documents similar to a document in one language, will also have high similarity with other document in other language that is paired up with its ancestor. On the other hand, k represents the number of documents that are affected by pairing up two multilingual documents. After propagation, similarity of documents that falls below some threshold δ is set to zero (Algorithm 1, line 6). This post-processing step is performed to nullify insignificant similarity values propagated to a document. Additionally, if there exists similarity of documents that is higher than one, it is set to one.

Algorithm 2 Recursive Propagation

Input: Affinity matrix A, level of propagation S, β, number of nearest neighbors k, document v_i and v_j

Output: Propagated affinity matrix

if $S = 0$ **then**
  return
else
  for all $y_x \in k$-NN document v_i **do**
    $A_{v_j y_x} \leftarrow A_{v_j y_x} + \beta A_{v_i y_x}$

    Recursive Propagation $(A, S-1, \beta^2, k, y_x, v_j)$
  end for
  for all $z_x \in k$-NN document v_j **do**
    Set $A_{v_i z_x} \leftarrow A_{v_i z_x} + \beta A_{v_j z_x}$
    Set $A_{z_x v_i} \leftarrow A_{v_i z_x}$
    Recursive Propagation $(A, S-1, \beta^2, k, v_i, z_x)$
  end for
end if

4 Performance Evaluation

The goals of empirical evaluation include (1) testing whether the propagation method can merge multilingual space and produce acceptable clustering results; (2) comparing the performance to spectral clustering method without propagation.

4.1 Data Description

We tested our model using Reuters Corpus Volume 2 (RCV2), a multilingual corpus containing news in thirteen different languages. For our experiment, three different languages: English, French, and Spanish; in six different topics: science, sports, disasters accidents, religion, health, and economy are used. We discarded documents with multiple category labels.

We do not apply any language specific preprocessing method to the raw text data. Monolingual TFIDF is used for feature weighting. All document vectors are then converted into unit vector by dividing by its length. Table 1 shows the average length of documents in our corpus.

4.2 Evaluation Metric

For our experiment, we used Rand Index (RI) which is a common evaluation technique for clustering task where the true class of unlabeled data is known. Rand Index measures the percentage of decisions that are correct, or simply the accuracy of the model. Rand Index is defined as:

$$RI = \frac{TP + TN}{TP + FP + TN + FN}$$

Rand Index penalizes false positive and false negative decisions during clustering. It takes into account decision that assign two similar documents to one cluster (TP), two dissimilar documents to different clusters (TN), two similar documents to different clusters (FN), and two dissimilar documents to one cluster (FP). We do not include links created by supervisory information when calculating true positive decisions and only consider the number of free decisions made.

We also used F_α-measure, the weighted harmonic mean of precision (P) and recall (R). F_α-measure is defined as:

$$F_\alpha = \frac{(\alpha^2 + 1)PR}{\alpha^2 P + R}$$
$$P = \frac{TP}{TP + FP}$$
$$R = \frac{TP}{TP + FN}$$

Last, we used purity to evaluate the accuracy of assignments. Purity is defined as:

$$Purity = \frac{1}{N} \sum_t \max_j |\omega_t \cap c_j|$$

where N is the number of documents, t is the number of clusters, j is the number of classes, ω_t and c_j are sets of documents in cluster t and class j respectively.

	English	French	Spanish	Total

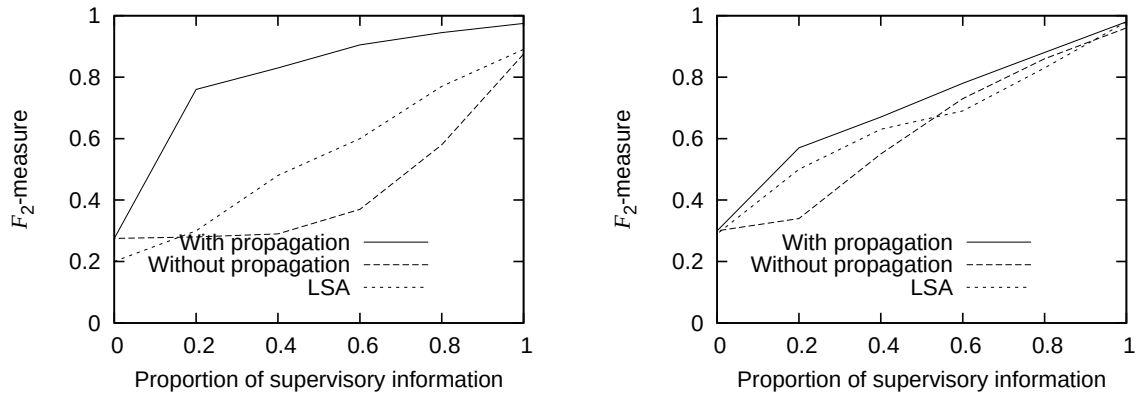
4.3 Experimental Results

To prove the effectiveness of our clustering algorithm, we performed the following experiments on our data set. We first tested our algorithm on four topics, science, sports, religion, and economy. We then tested our algorithm using all six topics to get an understanding of the performance of our model in larger collections with more topics. We used subset of our data as supervisory information and built must-linked constraints from it. The proportion of supervisory information provided to the system is given in x-axis (Figure 2 - Figure 4.3). 0.2 here means 20% of documents in each language are taken to be used as prior knowledge. Since the number of documents in each language for our experiment is the same, we have the same numbers of documents in subset of English collection, subset of French collection, and subset of Spanish collection. We also ensure there are same numbers of documents for a particular topic in all three languages. We can build must-linked constraints as follows. For each document in the subset of English collection, we create must-linked constraints with one randomly selected document from the subset of French collection and one randomly selected document from the subset of Spanish collection that belong to the same topic with it. We then create must-linked constraint between the respective French and Spanish documents. The constraints given to the algorithm are chosen so that there are several links that connect every topic in every language. Note that the class label in-



(a) F_2-measure for 6 topics

(b) F_2-measure for 4 topics

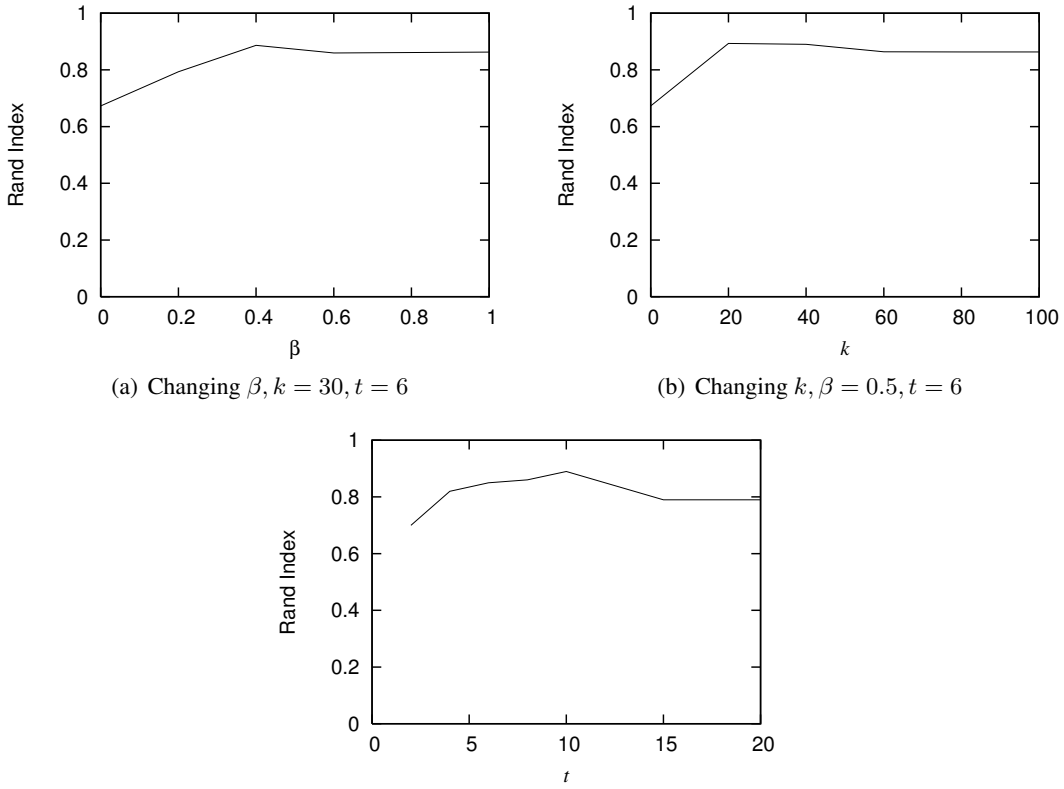
Figure 4: F_2-measure on the RCV2 task with (a) 1800 documents, 6 topics; and (b) 1200 documents, 4 topics as the proportion of supervisory information increases. $k = 30, \delta = 0.03, \beta = 0.5, t =$ number of topics, and $S = 2$.

formation is only used to build must-linked constraints between documents, and we do not assign the documents to a particular cluster.

Figure 2 shows the Rand Index as proportion of supervisory information increases. Figure 3 and Figure 4.3 give purity and F_2-measure for the algorithm respectively. To show the importance of the propagation in multilingual space, we give comparison with spectral clustering model without propagation. Three lines in Figure 2 to Figure 4.3 indicate: (1) results with propagation (solid line); (2) results without propagation (long-dashed line); and (3) results using Latent Semantic Analysis(LSA)-based method by exploiting common words between languages (short-dashed line). For each figure, 6 plots are taken starting from 0 in 0.2-point-increments. We conducted the experiments three times for each proportion of supervisory information and use the average values. As we can see from Figure 2, Figure 3, and Figure 4.3, the propagation method can significantly improve the performance of spectral clustering algorithm. For 1800 documents in 6 topics, we manage to achieve RI $= 0.91$, purity $= 0.84$, and F_2-measure $= 0.76$ with only 20% of documents (360 documents) used as supervisory information. Spectral clustering algorithm without propagation can only achieve $0.69, 0.30, 0.28$ for RI, purity, and F_2-measure respectively. The propagation method is highly effective when only small amount of supervisory information given to the algorithm. Obviously, the more supervisory information given, the better the performance is. As the number of supervisory information increases, the difference of the model performance with and without propagation becomes smaller. This is because there are already enough links between multilingual documents, so we do not necessarily build more links through similarity propagation anymore. However, even when there are already many links, our model with propagation still outperforms the model without propagation.

We compare the performance of our algorithm to LSA-based multilingual document clustering model. We performed LSA to the multilingual term by document matrix. We do not use parallel texts and only rely on common words across languages as well as must-linked constraints to build multilingual space. The results show that exploiting common words between languages alone is not enough to build a good multilingual semantic space, justifying the usage of supervisory information in multilingual document clustering task. When supervisory information is introduced, our method achieves better results than LSA-based method. In general, the LSA-based method performs better than the model without propagation.

We assess the sensitivity of our algorithm to parameter β, the penalty for similarity propagation. We assess the sensitivity of our algorithm to parameter β, the penalty for similarity propagation. We tested our algorithm using various β, starting from 0 to 1 in 0.2-point-increments, while other parameters being held constant. Figure 5(a) shows that changing β to some extent affects the performance of the algorithm. However, after some value of reasonable β is found, increasing β does not have significant impact on the per-



(a) Changing $\beta, k = 30, t = 6$

(b) Changing $k, \beta = 0.5, t = 6$

(c) Changing $t, \beta = 0.5, k = 30$

Figure 5: Rand Index on the RCV2 task with 1800 documents and 6 topics as (a) β increases; (b) k increases; and (c) t increases. $\delta = 0.03, S = 2$, and 20% of documents are used as supervisory information.

formance of the algorithm. We also tested our algorithm using various k, starting from 0 to 100 in 20-point-increments. Figure 5(b) reveals that the performances of the model with different k are comparable, as long as k is not too small. However, using too large k will slightly decrease the performance of the model. Too many propagations make several dissimilar documents receive high similarity value that cannot be nullified by the post-processing step. Last, we experimented using various t ranging from 2 to 20. Figure 5(c) shows that the method performs best when $t = 10$, and for reasonable value of t the method achieves comparable performance.

5 Conclusion

We present here a multilingual spectral clustering model that is able to work irrespective of the languages being used. The key component of our model is the propagation algorithm to merge multilingual spaces. We tested our algorithm on Reuters RCV2 Corpus and compared the performance with spectral clustering model without propagation. Experimental results reveal that using limited supervisory information, the algorithm achieves encouraging clustering results.

Abstract

Topic models are a useful tool for analyzing large text collections, but have previously been applied in only monolingual, or at most bilingual, contexts. Meanwhile, massive collections of interlinked documents in dozens of languages, such as Wikipedia, are now widely available, calling for tools that can characterize content in many languages. We introduce a polylingual topic model that discovers topics aligned across multiple languages. We explore the model's characteristics using two large corpora, each with over ten different languages, and demonstrate its usefulness in supporting machine translation and tracking topic trends across languages.

1 Introduction

Statistical topic models have emerged as an increasingly useful analysis tool for large text collections. Topic models have been used for analyzing topic trends in research literature (Mann et al., 2006; Hall et al., 2008), inferring captions for images (Blei and Jordan, 2003), social network analysis in email (McCallum et al., 2005), and expanding queries with topically related words in information retrieval (Wei and Croft, 2006). Much of this work, however, has occurred in monolingual contexts. In an increasingly connected world, the ability to access documents in many languages has become both a strategic asset and a personally enriching experience. In this paper, we present the polylingual topic model (PLTM). We demonstrate its utility and explore its characteristics using two polylingual corpora: proceedings of the European parliament (in eleven languages) and a collection of Wikipedia articles (in twelve languages).

There are many potential applications for polylingual topic models. Although research literature is typically written in English, bibliographic databases often contain substantial quantities of work in other languages. To perform topic-based bibliometric analysis on these collections, it is necessary to have topic models that are aligned across languages. Such analysis could be significant in tracking international research trends, where language barriers slow the transfer of ideas.

Previous work on bilingual topic modeling has focused on machine translation applications, which rely on sentence-aligned parallel translations. However, the growth of the internet, and in particular Wikipedia, has made vast corpora of *topically* comparable texts—documents that are topically similar but are not direct translations of one another—considerably more abundant than ever before. We argue that topic modeling is both a useful and appropriate tool for leveraging correspondences between semantically comparable documents in multiple different languages.

In this paper, we use two polylingual corpora to answer various critical questions related to polylingual topic models. We employ a set of direct translations, the EuroParl corpus, to evaluate whether PLTM can accurately infer topics when documents genuinely contain the same content. We also explore how the characteristics of different languages affect topic model performance. The second corpus, Wikipedia articles in twelve languages, contains sets of documents that are not translations of one another, but are very likely to be about similar concepts. We use this corpus to explore the ability of the model both to infer similarities between vocabularies in different languages, and to detect differences in topic emphasis between languages. The internet makes it possible for people all over the world to access documents from different cultures, but readers will not be fluent in this wide variety of languages. By linking topics across languages, polylingual topic models can increase cross-cultural understanding by providing readers with the ability to characterize

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 880–889,
Singapore, 6-7 August 2009.

the contents of collections in unfamiliar languages and identify trends in topic prevalence.

2 Related Work

Bilingual topic models for parallel texts with word-to-word alignments have been studied previously using the HM-bitam model (Zhao and Xing, 2007). Tam, Lane and Schultz (Tam et al., 2007) also show improvements in machine translation using bilingual topic models. Both of these translation-focused topic models infer word-to-word alignments as part of their inference procedures, which would become exponentially more complex if additional languages were added. We take a simpler approach that is more suitable for topically similar document tuples (where documents are not direct translations of one another) in more than two languages. A recent extended abstract, developed concurrently by Ni et al. (Ni et al., 2009), discusses a multilingual topic model similar to the one presented here. However, they evaluate their model on only two languages (English and Chinese), and do not use the model to detect differences between languages. They also provide little analysis of the differences between polylingual and single-language topic models. Outside of the field of topic modeling, Kawaba et al. (Kawaba et al., 2008) use a Wikipedia-based model to perform sentiment analysis of blog posts. They find, for example, that English blog posts about the Nintendo Wii often relate to a hack, which cannot be mentioned in Japanese posts due to Japanese intellectual property law. Similarly, posts about whaling often use (positive) nationalist language in Japanese and (negative) environmentalist language in English.

3 Polylingual Topic Model

The polylingual topic model (PLTM) is an extension of latent Dirichlet allocation (LDA) (Blei et al., 2003) for modeling polylingual document tuples. Each tuple is a set of documents that are loosely equivalent to each other, but written in different languages, e.g., corresponding Wikipedia articles in French, English and German. PLTM assumes that the documents in a tuple share the same tuple-specific distribution over topics. This is unlike LDA, in which each document is assumed to have its own document-specific distribution over topics. Additionally, PLTM assumes that each "topic" consists of a *set* of discrete distributions

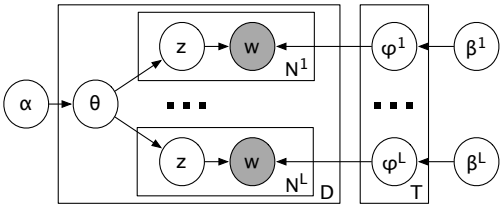

Figure 1: Graphical model for PLTM.

over words—one for each language $l = 1, \ldots, L$. In other words, rather than using a single set of topics $\Phi = \{\boldsymbol{\phi}_1, \ldots, \boldsymbol{\phi}_T\}$, as in LDA, there are L sets of language-specific topics, $\Phi^1, \ldots, \Phi^L$, each of which is drawn from a language-specific symmetric Dirichlet with concentration parameter β^l.

3.1 Generative Process

A new document tuple $\boldsymbol{w} = (\boldsymbol{w}^1, \ldots, \boldsymbol{w}^L)$ is generated by first drawing a tuple-specific topic distribution from an asymmetric Dirichlet prior with concentration parameter α and base measure $\boldsymbol{m}$:

$$\boldsymbol{\theta} \sim \text{Dir}\,(\boldsymbol{\theta}, \alpha \boldsymbol{m}). \tag{1}$$

Then, for each language l, a latent topic assignment is drawn for each token in that language:

$$\boldsymbol{z}^l \sim P(\boldsymbol{z}^l \,|\, \boldsymbol{\theta}) = \textstyle\prod_n \theta_{z_n^l}. \tag{2}$$

Finally, the observed tokens are themselves drawn using the language-specific topic parameters:

$$\boldsymbol{w}^l \sim P(\boldsymbol{w}^l \,|\, \boldsymbol{z}^l, \Phi^l) = \textstyle\prod_n \phi^l_{w_n^l | z_n^l}. \tag{3}$$

The graphical model is shown in figure 1.

3.2 Inference

Given a corpus of training and test document tuples—$\mathcal{W}$ and $\mathcal{W}'$, respectively—two possible inference tasks of interest are: computing the probability of the test tuples given the training tuples and inferring latent topic assignments for test documents. These tasks can either be accomplished by averaging over samples of $\Phi^1, \ldots, \Phi^L$ and $\alpha\boldsymbol{m}$ from $P(\Phi^1, \ldots, \Phi^L, \alpha\boldsymbol{m} \,|\, \mathcal{W}', \beta)$ or by evaluating a point estimate. We take the latter approach, and use the MAP estimate for $\alpha\boldsymbol{m}$ and the predictive distributions over words for $\Phi^1, \ldots, \Phi^L$. The probability of held-out document tuples $\mathcal{W}'$ given training tuples $\mathcal{W}$ is then approximated by $P(\mathcal{W}' \,|\, \Phi^1, \ldots, \Phi^L, \alpha\boldsymbol{m})$.

Topic assignments for a test document tuple $\boldsymbol{w} = (\boldsymbol{w}^1, \ldots, \boldsymbol{w}^L)$ can be inferred using Gibbs

sampling. Gibbs sampling involves sequentially resampling each z_n^l from its conditional posterior:

$$P(z_n^l = t \mid \boldsymbol{w}, \boldsymbol{z}_{\setminus l,n}, \Phi^1, \ldots, \Phi^L, \alpha\boldsymbol{m}) \propto \phi^l_{w_n^l|t} \frac{(N_t)_{\setminus l,n} + \alpha m_t}{\sum_t N_t - 1 + \alpha}, \quad (4)$$

where $\boldsymbol{z}_{\setminus l,n}$ is the current set of topic assignments for all other tokens in the tuple, while $(N_t)_{\setminus l,n}$ is the number of occurrences of topic t in the tuple, excluding z_n^l, the variable being resampled.

4 Results on Parallel Text

Our first set of experiments focuses on document tuples that are known to consist of direct translations. In this case, we can be confident that the topic distribution is genuinely shared across all languages. Although direct translations in multiple languages are relatively rare (in contrast with comparable documents), we use direct translations to explore the characteristics of the model.

4.1 Data Set

The EuroParl corpus consists of parallel texts in eleven western European languages: Danish, German, Greek, English, Spanish, Finnish, French, Italian, Dutch, Portuguese and Swedish. These texts consist of roughly a decade of proceedings of the European parliament. For our purposes we use alignments at the speech level rather than the sentence level, as in many translation tasks using this corpus. We also remove the twenty-five most frequent word types for efficiency reasons. The remaining collection consists of over 121 million words. Details by language are shown in Table 1.

Table 1: Average document length, # documents, and unique word types per 10,000 tokens in the EuroParl corpus.

Figure 2: EuroParl topics (T=400)

The concentration parameter α for the prior over document-specific topic distributions is initialized to $0.01\,T$, while the base measure $\boldsymbol{m}$ is initialized to the uniform distribution. Hyperparameters $\alpha\boldsymbol{m}$ are re-estimated every 10 Gibbs iterations.

4.2 Analysis of Trained Models

Figure 2 shows the most probable words in all languages for four example topics, from PLTM with 400 topics. The first topic contains words relating to the European Central Bank. This topic provides an illustration of the variation in technical terminology captured by PLTM, including the wide array of acronyms used by different languages. The second topic, concerning children, demonstrates the variability of everyday terminology: although the four Romance languages are closely

related, they use etymologically unrelated words for children. (Interestingly, all languages except Greek and Finnish use closely related words for "youth" or "young" in a separate topic.) The third topic demonstrates differences in inflectional variation. English and the Romance languages use only singular and plural versions of "objective." The other Germanic languages include compound words, while Greek and Finnish are dominated by inflected variants of the same lexical item. The final topic demonstrates that PLTM effectively clusters "syntactic" words, as well as more semantically specific nouns, adjectives and verbs.

Although the topics in figure 2 seem highly focused, it is interesting to ask whether the model is genuinely learning mixtures of topics or simply assigning entire document tuples to single topics. To answer this question, we compute the posterior probability of each topic in each tuple under the trained model. If the model assigns all tokens in a tuple to a single topic, the maximum posterior topic probability for that tuple will be near to 1.0. If the model assigns topics uniformly, the maximum topic probability will be near $1/T$. We compute histograms of these maximum topic probabilities for $T \in \{50, 100, 200, 400, 800\}$. For clarity, rather than overlaying five histograms, figure 3 shows the histograms converted into smooth curves using a kernel density estimator.[1] Although there is a small bump around 1.0 (for extremely short documents, e.g., "Applause"), values are generally closer to, but greater than, $1/T$.

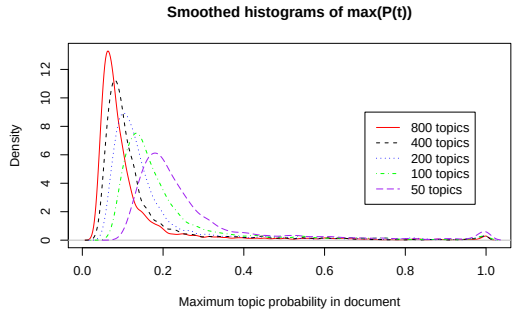

Figure 3: Smoothed histograms of the probability of the most probable topic in a document tuple.

Although the posterior distribution over topics for each tuple is not concentrated on one topic, it is worth checking that this is not simply because the model is assigning a single topic to the tokens in each of the languages. Although the model does not distinguish between topic assignment variables within a given document tuple (so it is technically incorrect to speak of different posterior distributions over topics for different documents in a given tuple), we can nevertheless divide topic assignment variables between languages and use them to estimate a Dirichlet-multinomial posterior distribution for each language in each tuple. For each tuple we can then calculate the Jensen-Shannon divergence (the average of the KL divergences between each distribution and a mean distribution) between these distributions. Figure 4 shows the density of these divergences for different numbers of topics. As with the previous figure, there are a small number of documents that contain only one topic in all languages, and thus have zero divergence. These tend to be very short, formulaic parliamentary responses, however. The vast majority of divergences are relatively low (1.0 indicates no overlap in topics between languages in a given document tuple) indicating that, for each tuple, the model is not simply assigning all tokens in a particular language to a single topic. As the number of topics increases, greater variability in topic distributions causes divergence to increase.

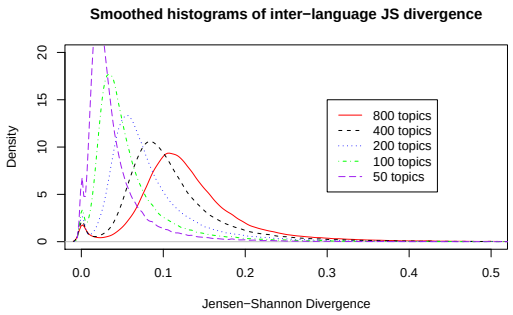

Figure 4: Smoothed histograms of the Jensen-Shannon divergences between the posterior probability of topics between languages.

4.3 Language Model Evaluation

A topic model specifies a probability distribution over documents, or in the case of PLTM, document tuples. Given a set of training document tuples, PLTM can be used to obtain posterior estimates of $\Phi^1, \ldots, \Phi^L$ and $\alpha\boldsymbol{m}$. The probability of previously unseen held-out document tuples given these estimates can then be computed. The higher the probability of the held-out document tuples, the better the generalization ability of the model.

[1] We use the R `density` function.

Analytically calculating the probability of a set of held-out document tuples given $\Phi^1, \ldots, \Phi^L$ and $\alpha\boldsymbol{m}$ is intractable, due to the summation over an exponential number of topic assignments for these held-out documents. However, recently developed methods provide efficient, accurate estimates of this probability. We use the "left-to-right" method of (Wallach et al., 2009). We perform five estimation runs for each document and then calculate standard errors using a bootstrap method.

Table 2 shows the log probability of held-out data in nats per word for PLTM and LDA, both trained with 200 topics. There is substantial variation between languages. Additionally, the predictive ability of PLTM is consistently slightly worse than that of (monolingual) LDA. It is important to note, however, that these results do not imply that LDA should be preferred over PLTM—that choice depends upon the needs of the modeler. Rather, these results are intended as a quantitative analysis of the difference between the two models.

Table 2: Held-out log probability in nats/word. (Smaller magnitude implies better language modeling performance.) PLTM does slightly worse than monolingual LDA models, but the variation between languages is much larger.

Lang	PLTM	sd	LDA	sd
DA	-8.11	0.00067	-8.02	0.00066
DE	-8.17	0.00057	-8.08	0.00072
EL	-8.44	0.00079	-8.36	0.00087
EN	-7.51	0.00064	-7.42	0.00069
ES	-7.98	0.00073	-7.87	0.00070
FI	-9.25	0.00089	-9.21	0.00065
FR	-8.26	0.00072	-8.19	0.00058
IT	-8.11	0.00071	-8.02	0.00058
NL	-7.84	0.00067	-7.75	0.00099
PT	-7.87	0.00085	-7.80	0.00060
SV	-8.25	0.00091	-8.16	0.00086

As the number of topics is increased, the word counts per topic become very sparse in monolingual LDA models, proportional to the size of the vocabulary. Figure 5 shows the proportion of all tokens in English and Finnish assigned to each topic under LDA and PLTM with 800 topics. More than 350 topics in the Finnish LDA model have zero tokens assigned to them, and almost all tokens are assigned to the largest 200 topics. English has a larger tail, with non-zero counts in all but 16 topics. In contrast, PLTM assigns a significant number of tokens to almost all 800 topics, in very similar proportions in both languages. PLTM topics therefore have a higher granularity – i.e., they are more specific. This result is important: informally, we have found that increasing the granularity of topics correlates strongly with user perceptions of the utility of a topic model.

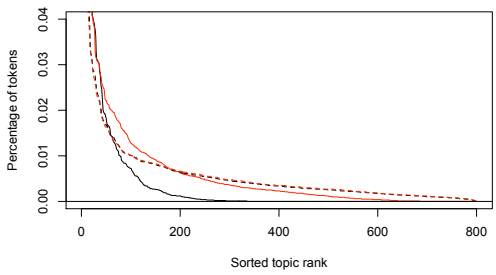

Figure 5: Topics sorted by number of words assigned. Finnish is in black, English is in red; LDA is solid, PLTM is dashed. LDA in Finnish essentially learns a 200 topic model when given 800 topics, while PLTM uses all 800 topics.

4.4 Partly Comparable Corpora

An important application for polylingual topic modeling is to use small numbers of comparable document tuples to link topics in larger collections of distinct, non-comparable documents in multiple languages. For example, a journal might publish papers in English, French, German and Italian. No paper is exactly comparable to any other paper, but they are all roughly topically similar. If we wish to perform topic-based bibliometric analysis, it is vital to be able to track the same topics across all languages. One simple way to achieve this topic alignment is to add a small set of comparable document tuples that provide sufficient "glue" to bind the topics together. Continuing with the example above, one might extract a set of connected Wikipedia articles related to the focus of the journal and then train PLTM on a joint corpus consisting of journal papers and Wikipedia articles.

In order to simulate this scenario we create a set of variations of the EuroParl corpus by treating some documents as if they have no parallel/comparable texts – i.e., we put each of these documents in a single-document tuple. To do this, we divide the corpus $\mathcal{W}$ into two sets of document tuples: a "glue" set $\mathcal{G}$ and a "separate" set $\mathcal{S}$ such that $|\mathcal{G}| \,/\, |\mathcal{W}| = p$. In other words, the proportion of tuples in the corpus that are treated as "glue" (i.e., placed in $\mathcal{G}$) is p. For every tuple in $\mathcal{S}$, we assign each document in that tuple to a new single-document tuple. By doing this, every document in $\mathcal{S}$ has its own distribution over topics, independent of any other documents. Ideally, the "glue" doc-

uments in $\mathcal{G}$ will be sufficient to align the topics across languages, and will cause comparable documents in $\mathcal{S}$ to have similar distributions over topics even though they are modeled independently.

Table 3: The effect of the proportion p of "glue" tuples on mean Jensen-Shannon divergence in estimated topic distributions for pairs of documents in $\mathcal{S}$ that were originally part of a document tuple. Lower divergence means the topic distributions distributions are more similar to each other.

p	Mean JS	# of pairs	Std. Err.
0.01	0.83755	487670	0.00018
0.05	0.79144	467288	0.00021
0.1	0.70228	443753	0.00026
0.25	0.38480	369608	0.00029
0.5	0.29712	246380	0.00030

Table 4: Topics are meaningful within languages but diverge between languages when only 1% of tuples are treated as "glue" tuples. With 25% "glue" tuples, topics are aligned.

lang	Topics at $p = 0.01$
DE	rußland russland russischen tschetschenien sicherheit
EN	china rights human country s burma
FR	russie tchétchénie union avec russe région
IT	ho presidente mi perché relazione votato

lang	Topics at $p = 0.25$
DE	rußland russland russischen tschetschenien ukraine
EN	russia russian chechnya cooperation region belarus
FR	russie tchétchénie avec russe russes situation
IT	russia unione cooperazione cecenia regione russa

We train PLTM with 100 topics on corpora with $p \in \{0.01, 0.05, 0.1, 0.25, 0.5\}$. We use 1000 iterations of Gibbs sampling with $\beta = 0.01$. Hyperparameters $\alpha\boldsymbol{m}$ are re-estimated every 10 iterations. We calculate the Jensen-Shannon divergence between the topic distributions for each pair of individual documents in $\mathcal{S}$ that were originally part of the same tuple prior to separation. The lower the divergence, the more similar the distributions are to each other. From the results in figure 4, we know that leaving all document tuples intact should result in a mean JS divergence of less than 0.1. Table 3 shows mean JS divergences for each value of p. As expected, JS divergence is greater than that obtained when all tuples are left intact. Divergence drops significantly when the proportion of "glue" tuples increases from 0.01 to 0.25. Example topics for $p = 0.01$ and $p = 0.25$ are shown in table 4. At $p = 0.01$ (1% "glue" documents), German and French both include words relating to Russia, while the English and Italian word distributions appear locally consistent but unrelated to Russia. At $p = 0.25$, the top words for all four languages are related to Russia.

These results demonstrate that PLTM is appropriate for aligning topics in corpora that have only a small subset of comparable documents. One area for future work is to explore whether initialization techniques or better representations of topic co-occurrence might result in alignment of topics with a smaller proportion of comparable texts.

4.5 Machine Translation

Although the PLTM is clearly not a substitute for a machine translation system—it has no way to represent syntax or even multi-word phrases—it is clear from the examples in figure 2 that the sets of high probability words in different languages for a given topic are likely to include translations. We therefore evaluate the ability of the PLTM to generate bilingual lexica, similar to other work in unsupervised translation modeling (Haghighi et al., 2008). In the early statistical translation model work at IBM, these representations were called "cepts," short for concepts (Brown et al., 1993).

We evaluate sets of high-probability words in each topic and multilingual "synsets" by comparing them to entries in human-constructed bilingual dictionaries, as done by Haghighi et al. (2008). Unlike previous work (Koehn and Knight, 2002), we evaluate all words, not just nouns. We collected bilingual lexica mapping English words to German, Greek, Spanish, French, Italian, Dutch and Swedish. Each lexicon is a set of pairs consisting of an English word and a translated word, $\{w_e, w_\ell\}$. We do not consider multi-word terms. We expect that simple analysis of topic assignments for sequential words would yield such collocations, but we leave this for future work.

For every topic t we select a small number K of the most probable words in English (e) and in each "translation" language (ℓ): $\mathcal{W}_{te}$ and $\mathcal{W}_{t\ell}$, respectively. We then add the Cartesian product of these sets for every topic to a set of candidate translations $\mathcal{C}$. We report the number of elements of $\mathcal{C}$ that appear in the reference lexica. Results for $K = 1$, that is, considering only the single most probable word for each language, are shown in figure 6. Precision at this level is relatively high, above 50% for Spanish, French and Italian with $T = 400$ and 800. Many of the candidate pairs that were not in the bilingual lexica were valid translations (e.g. EN "comitology" and IT

"comitalogia") that simply were not in the lexica. We also do not count morphological variants: the model finds EN "rules" and DE "vorschriften," but the lexicon contains only "rule" and "vorschrift." Results remain strong as we increase K. With $K = 3, T = 800$, 1349 of the 7200 candidate pairs for Spanish appeared in the lexicon.

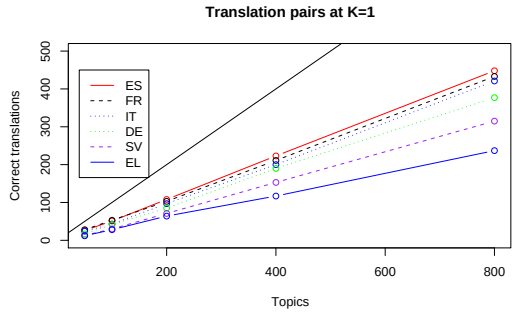

Figure 6: Are the single most probable words for a given topic in different languages translations of each other? The number of such pairs that appear in bilingual lexica is shown on the y-axis. For $T = 800$, the top English and Spanish words in 448 topics were exact translations of one another.

4.6 Finding Translations

In addition to enhancing lexicons by aligning topic-specific vocabulary, PLTM may also be useful for adapting machine translation systems to new domains by finding translations or near translations in an unstructured corpus. These aligned document pairs could then be fed into standard machine translation systems as training data. To evaluate this scenario, we train PLTM on a set of document tuples from EuroParl, infer topic distributions for a set of held-out documents, and then measure our ability to align documents in one language with their translations in another language.

It is not necessarily clear that PLTM will be effective at identifying translations. In finding a low-dimensional semantic representation, topic models deliberately smooth over much of the variation present in language. We are therefore interested in determining whether the information in the document-specific topic distributions is sufficient to identify semantically identical documents.

We begin by dividing the data into a training set of 69,550 document tuples and a test set of 17,435 document tuples. In order to make the task more difficult, we train a relatively coarse-grained PLTM with 50 topics on the training set. We then use this model to infer topic distributions for each

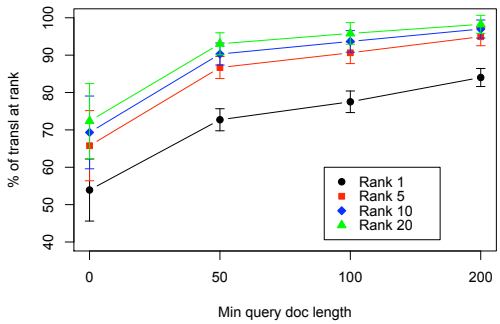

Figure 7: Percent of query language documents for which the target language translation is ranked at or above 1, 5, 10 or 20 by JS divergence, averaged over all language pairs.

of the 11 documents in each of the held-out document tuples using a method similar to that used to calculate held-out probabilities (Wallach et al., 2009). Finally, for each pair of languages ("query" and "target") we calculate the difference between the topic distribution for each held-out document in the query language and the topic distribution for each held-out document in the target language. We use both Jensen-Shannon divergence and cosine distance. For each document in the query language we rank all documents in the target language and record the rank of the actual translation.

Results averaged over all query/target language pairs are shown in figure 7 for Jensen-Shannon divergence. Cosine-based rankings are significantly worse. It is important to note that the length of documents matters. As noted before, many of the documents in the EuroParl collection consist of short, formulaic sentences. Restricting the query/target pairs to only those with query and target documents that are both longer than 50 words results in significant improvement and reduced variance: the average proportion of query documents for which the true translation is ranked highest goes from 53.9% to 72.7%. Performance continues to improve with longer documents, most likely due to better topic inference. Results vary by language. Table 5 shows results for all target languages with English as a query language. Again, English generally performs better with Romance languages than Germanic languages.

5 Results on Comparable Texts

Directly parallel translations are rare in many languages and can be extremely expensive to produce. However, the growth of the web, and in particular Wikipedia, has made *comparable* text cor-

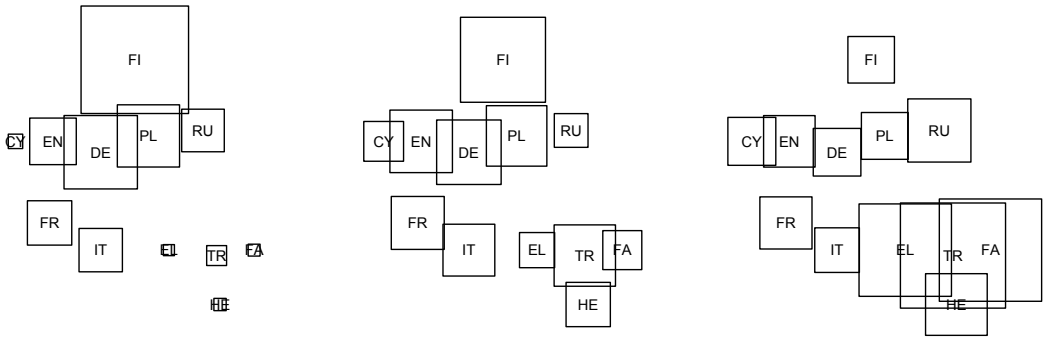

Figure 8: Squares represent the proportion of tokens in each language assigned to a topic. The left topic, *world ski km won*, centers around Nordic counties. The center topic, *actor role television actress*, is relatively uniform. The right topic, *ottoman empire khan byzantine*, is popular in all languages but especially in regions near Istanbul.

Table 5: Percent of English query documents for which the translation was in the top $n \in \{1, 5, 10, 20\}$ documents by JS divergence between topic distributions. To reduce the effect of short documents we consider only document pairs where the query and target documents are longer than 100 words.

Lang	1	5	10	20

SV	80.4	92.1	94.9	96.5

pora – documents that are topically similar but are not direct translations of one another – considerably more abundant than true parallel corpora.

In this section, we explore two questions relating to comparable text corpora and polylingual topic modeling. First, we explore whether comparable document tuples support the alignment of fine-grained topics, as demonstrated earlier using parallel documents. This property is useful for building machine translation systems as well as for human readers who are either learning new languages or analyzing texts in languages they do not know. Second, because comparable texts may not use exactly the same topics, it becomes crucially important to be able to characterize differences in topic prevalence at the document level (do different languages have different perspectives on the same article?) and at the language-wide level (which topics do particular languages focus on?).

5.1 Data Set

We downloaded XML copies of all Wikipedia articles in twelve different languages: Welsh, German, Greek, English, Farsi, Finnish, French, Hebrew, Italian, Polish, Russian and Turkish. These versions of Wikipedia were selected to provide a diverse range of language families, geographic areas, and quantities of text. We preprocessed the data by removing tables, references, images and info-boxes. We dropped all articles in non-English languages that did not link to an English article. In the English version of Wikipedia we dropped all articles that were not linked to by any other language in our set. For efficiency, we truncated each article to the nearest word after 1000 characters and dropped the 50 most common word types in each language. Even with these restrictions, the size of the corpus is 148.5 million words.

We present results for a PLTM with 400 topics. 1000 Gibbs sampling iterations took roughly four days on one CPU with current hardware.

5.2 Which Languages Have High Topic Divergence?

As with EuroParl, we can calculate the Jensen-Shannon divergence between pairs of documents within a comparable document tuple. We can then average over all such document-document divergences for each pair of languages to get an overall "disagreement" score between languages. Interestingly, we find that almost all languages in our corpus, including several pairs that have historically been in conflict, show average JS divergences of between approximately 0.08 and 0.12 for $T = 400$, consistent with our findings for EuroParl translations. Subtle differences of sentiment may be below the granularity of the model.

Figure 9: Wikipedia topics (T=400).

Overall, these scores indicate that although individual pages may show disagreement, Wikipedia is on average consistent between languages.

5.3 Are Topics Emphasized Differently Between Languages?

Although we find that if Wikipedia contains an article on a particular subject in some language, the article will tend to be topically similar to the articles about that subject in other languages, we also find that across the whole collection different languages emphasize topics to different extents. To demonstrate the wide variation in topics, we calculated the proportion of tokens in each language assigned to each topic. Figure 8 represents the estimated probabilities of topics given a specific language. Competitive cross-country skiing (left) accounts for a significant proportion of the text in Finnish, but barely exists in Welsh and the languages in the Southeastern region. Meanwhile, interest in actors and actresses (center) is consistent across all languages. Finally, historical topics, such as the Byzantine and Ottoman empires (right) are strong in all languages, but show geographical variation: interest centers around the empires.

6 Conclusions

We introduced a polylingual topic model (PLTM) that discovers topics aligned across multiple languages. We analyzed the characteristics of PLTM in comparison to monolingual LDA, and demonstrated that it is possible to discover aligned topics. We also demonstrated that relatively small numbers of topically comparable document tuples are sufficient to align topics between languages in non-comparable corpora. Additionally, PLTM can support the creation of bilingual lexica for low resource language pairs, providing candidate translations for more computationally intense alignment processes without the sentence-aligned translations typically used in such tasks. When applied to comparable document collections such as Wikipedia, PLTM supports data-driven analysis of differences and similarities across *all* languages for readers who understand *any one* language.

Abstract

We have designed, implemented and evaluated an end-to-end system spellchecking and autocorrection system that does not require *any* manually annotated training data. The World Wide Web is used as a large noisy corpus from which we infer knowledge about misspellings and word usage. This is used to build an error model and an n-gram language model. A small secondary set of news texts with artificially inserted misspellings are used to tune confidence classifiers. Because no manual annotation is required, our system can easily be instantiated for new languages. When evaluated on human typed data with real misspellings in English and German, our web-based systems outperform baselines which use candidate corrections based on hand-curated dictionaries. Our system achieves 3.8% total error rate in English. We show similar improvements in preliminary results on artificial data for Russian and Arabic.

1 Introduction

Spellchecking is the task of predicting which words in a document are misspelled. These predictions might be presented to a user by underlining the misspelled words. Correction is the task of substituting the well-spelled hypotheses for misspellings. Spellchecking and autocorrection are widely applicable for tasks such as word-processing and postprocessing Optical Character Recognition. We have designed, implemented and evaluated an end-to-end system that performs spellchecking and autocorrection.

The key novelty of our work is that the system was developed entirely without the use of manually annotated resources or any explicitly compiled dictionaries of well-spelled words. Our multi-stage system integrates knowledge from statistical error models and language models (LMs) with a statistical machine learning classifier. At each stage, data are required for training models and determining weights on the classifiers. The models and classifiers are all automatically trained from frequency counts derived from the Web and from news data. System performance has been validated on a set of human typed data. We have also shown that the system can be rapidly ported across languages with very little manual effort.

Most spelling systems today require some handcrafted language-specific resources, such as lexica, lists of misspellings, or rule bases. Systems using statistical models require large annotated corpora of spelling errors for training. Our statistical models require no annotated data. Instead, we rely on the Web as a large noisy corpus in the following ways. 1) We infer information about misspellings from term usage observed on the Web, and use this to build an error model. 2) The most frequently observed terms are taken as a noisy list of potential candidate corrections. 3) Token n-grams are used to build an LM, which we use to make context-appropriate corrections. Because our error model is based on scoring substrings, there is no fixed lexicon of well-spelled words to determine misspellings. Hence, both novel misspelled or well-spelled words are allowable. Moreover, in combination with an n-gram LM component, our system can detect and correct real-word substitutions, ie, word usage and grammatical errors.

Confidence classifiers determine the thresholds for spelling error detection and autocorrection, given error and LM scores. In order to train these classifiers, we require some textual content with some misspellings and corresponding well-spelled words. A small subset of the Web data from news pages are used because we assume they contain

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 890–899,
Singapore, 6-7 August 2009.

relatively few misspellings. We show that confidence classifiers can be adequately trained and tuned without real-world spelling errors, but rather with clean news data injected with artificial misspellings.

This paper will proceed as follows. In Section 2, we survey related prior research. Section 3 describes our approach, and how we use data at each stage of the spelling system. In experiments (Section 4), we first verify our system on data with artificial misspellings. Then we report performance on data with real typing errors in English and German. We also show preliminary results from porting our system to Russian and Arabic.

2 Related Work

Spellchecking and correction are among the oldest text processing problems, and many different solutions have been proposed (Kukich, 1992). Most approaches are based upon the use of one or more manually compiled resources. Like most areas of natural language processing, spelling systems have been increasingly empirical, a trend that our system continues.

The most direct approach is to model the causes of spelling errors directly, and encode them in an algorithm or an error model. Damerau-Levenshtein edit distance was introduced as a way to detect spelling errors (Damerau, 1964). Phonetic indexing algorithms such as Metaphone, used by GNU Aspell (Atkinson, 2009), repesent words by their approximate 'soundslike' pronunciation, and allow correction of words that appear orthographically dissimilar. Metaphone relies upon data files containing phonetic information. Linguistic intuition about the different causes of spelling errors can also be represented explicitly in the spelling system (Deorowicz and Ciura, 2005).

Almost every spelling system to date makes use of a lexicon: a list of terms which are treated as 'well-spelled'. Lexicons are used as a source of corrections, and also to filter words that should be ignored by the system. Using lexicons introduces the distinction between 'non-word' and 'real-word' errors, where the misspelled word is another word in the lexicon. This has led to the two sub-tasks being approached separately (Golding and Schabes, 1996). Lexicon-based approaches have trouble handling terms that do not appear in the lexicon, such as proper nouns, foreign terms, and neologisms, which can account for a large proportion of 'non-dictionary' terms (Ahmad and Kondrak, 2005).

A word's context provides useful evidence as to its correctness. Contextual information can be represented by rules (Mangu and Brill, 1997) or more commonly in an n-gram LM. Mays et al (1991) used a trigram LM and a lexicon, which was shown to be competitive despite only allowing for a single correction per sentence (Wilcox-O'Hearn et al., 2008). Cucerzan and Brill (2004) claim that an LM is much more important than the channel model when correcting Web search queries. In place of an error-free corpus, the Web has been successfully used to correct real-word errors using bigram features (Lapata and Keller, 2004). This work uses pre-defined confusion sets.

The largest step towards an automatically trainable spelling system was the statistical model for spelling errors (Brill and Moore, 2000). This replaces intuition or linguistic knowledge with a training corpus of misspelling errors, which was compiled by hand. This approach has also been extended to incorporate a pronunciation model (Toutanova and Moore, 2002).

There has been recent attention on using Web search query data as a source of training data, and as a target for spelling correction (Yang Zhang and Li, 2007; Cucerzan and Brill, 2004). While query data is a rich source of misspelling information in the form of query-revision pairs, it is not available for general use, and is not used in our approach.

The dependence upon manual resources has created a bottleneck in the development of spelling systems. There have been few language-independent, multi-lingual systems, or even systems for languages other than English. Language-independent systems have been evaluated on Persian (Barari and QasemiZadeh, 2005) and on Arabic and English (Hassan et al., 2008). To our knowledge, there are no previous evaluations of a language-independent system across many languages, for the full spelling correction task, and indeed, there are no pre-existing standard test sets for typed data with real errors and language context.

3 Approach

Our spelling system follows a noisy channel model of spelling errors (Kernighan et al., 1990). For an observed word w and a candidate correction s, we compute $P(s|w)$ as $P(w|s) \times P(s)$.

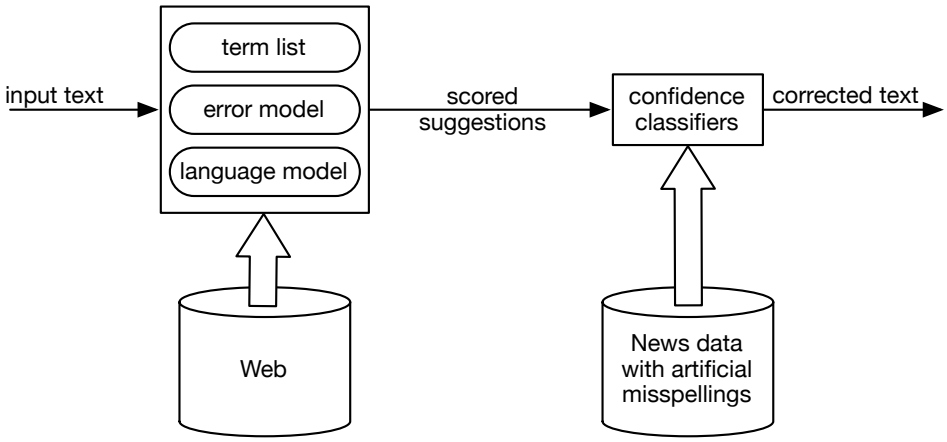

Figure 1: Spelling process, and knowledge sources used.

The text processing workflow and the data used in building the system are outlined in Figure 1 and detailed in this section. For each token in the input text, candidate suggestions are drawn from the term list (Section 3.1), and scored using an error model (Section 3.2). These candidates are evaluated in context using an LM (Section 3.3) and re-ranked. For each token, we use classifiers (Section 3.4) to determine our confidence in whether a word has been misspelled and if so, whether it should be autocorrected to the best-scoring suggestion available.

3.1 Term List

We require a list of terms to use as candidate corrections. Rather than attempt to build a lexicon of words that are well-spelled, we instead take the most frequent tokens observed on the Web. We used a large ($>$ 1 billion) sample of Web pages, tokenized them, and took the most frequently occurring ten million tokens, with very simple filters for non-words (too much punctuation, too short or long). This term list is so large that it should contain most well-spelled words, but also a large number of non-words or misspellings.

3.2 Error Model

We use a substring error model to estimate $P(w|s)$. To derive the error model, let R be a partitioning of s into adjacent substrings, and similarly let T be a partitioning of w, such that $|T| = |R|$. The partitions are thus in one-to-one alignment, and by allowing partitions to be empty, the alignment models insertions and deletions of substrings. Brill and Moore estimate $P(w|s)$ as follows:

$$P(w|s) \approx \max_{R,\, T \text{ s.t. } |T|=|R|} \prod_{i=1}^{|R|} P(T_i|R_i) \qquad (1)$$

Our system restricts partitionings that have substrings of length at most 2.

To train the error model, we require triples of (intended_word, observed_word, count), which are described below. We use maximum likelihood estimates of $P(T_i|R_i)$.

3.2.1 Using the Web to Infer Misspellings

To build the error model, we require as training data a set of (intended_word, observed_word, count) triples, which is compiled from the World Wide Web. Essentially the triples are built by starting with the term list, and a process that automatically discovers, from that list, putative pairs of spelled and misspelled words, along with their counts.

We believe the Web is ideal for compiling this set of triples because with a vast amount of user-generated content, we believe that the Web contains a representative sample of both well-spelled and misspelled text. The triples are not used directly for proposing corrections, and since we have a substring model, they do not need to be an exhaustive list of spelling mistakes.

The procedure for finding and updating counts for these triples also assumes that 1) misspellings tend to be orthographically similar to the intended word; Mays et al (1991) observed that 80% of

misspellings derived from single instances of insertion, deletion, or substitution; and 2) words are usually spelled as intended.

For the error model, we use a large corpus (up to 3.7×10^8 pages) of crawled public Web pages. An automatic language-identification system is used to identify and filter pages for the desired language. As we only require a small window of context, it would also be possible to use an n-gram collection such as the Google Web 1T dataset.

Finding Close Words. For each term in the term list (defined in Section 3.1), we find all other terms in the list that are "close" to it. We define closeness using Levenshtein-Damerau edit distance, with a conservative upper bound that increases with word length (one edit for words of up to four characters, two edits for up to twelve characters, and three for longer words). We compile the term list into a trie-based data structure which allows for efficient searching for all terms within a maximum edit distance. The computation is 'embarassingly parallel' and hence easily distributable. In practice, we find that this stage takes tens to hundreds of CPU-hours.

Filtering Triples. At this stage, for each term we have a cluster of orthographically similar terms, which we posit are potential misspellings. The set of pairs is reflexive and symmetric, e.g. it contains both (*recieve*, *receive*) and (*receive*, *recieve*). The pairs will also include e.g. (*deceive*, *receive*). On the assumption that words are spelled correctly more often than they are misspelled, we next filter the set such that the first term's frequency is at least 10 times that of the second term. This ratio was chosen as a conservative heuristic filter.

Using Language Context. Finally, we use the contexts in which a term occurs to gather directional weightings for misspellings. Consider a term w; from our source corpus, we collect the set of contexts $\{c_i\}$ in which w occurs. The definition of a context is relatively arbitrary; we chose to use a single word on each side, discarding contexts with fewer than a total of ten observed occurrences. For each context c_i, candidate "intended" terms are w and w's close terms (which are at least 10 times as frequent as w). The candidate which appears in context c_i the most number of times is deemed to be the term intended by the user in that context.

The resulting dataset consists of triples of the original observed term, one of the "intended" terms as determined by the above algorithm, and the number of times this term was intended. For a single term, it is possible (and common) to have multiple possible triples, due to the context-based assignment.

Inspecting the output of this training process shows some interesting patterns. Overall, the dataset is still noisy; there are many instances where an obviously misspelled word is not assigned a correction, or only some of its instances are. The dataset contains around 100 million triples, orders of magnitude larger than any manually compiled list of misspellings . The kinds of errors captured in the dataset include stereotypical spelling errors, such as *acomodation*, but also OCR-style errors. *computationaUy* was detected as a misspelling of *computationally* where the 'U' is an OCR error for 'll'; similarly, *Postmodem* was detected as a misspelling of *Postmodern* (an example of 'keming').

The data also includes examples of 'real-word' errors. For example, 13% of occurrences of *occidental* are considered misspellings of *accidental*; contrasting with 89% of occurrences of the non-word *accidential*. There are many examples of terms that would not be in a normal lexicon, including neologisms (*mulitplayer* for *multiplayer*), companies and products (*Playstaton* for *Playstation*), proper nouns (*Schwarznegger* for *Schwarzenegger*) and internet domain names (*mysapce.com* for *myspace.com*).

3.3 Language Model

We estimate $P(s)$ using n-gram LMs trained on data from the Web, using Stupid Backoff (Brants et al., 2007). We use both forward and backward context, when available. Contrary to Brill and Moore (2000), we observe that user edits often have both left and right context, when editing a document.

When combining the error model scores with the LM scores, we weight the latter by taking their λ'th power, that is

$$P(w|s) * P(s)^{\lambda} \quad (2)$$

The parameter λ reflects the relative degrees to which the LM and the error model should be trusted. The parameter λ also plays the additional role of correcting our error model's misestimation of the rate at which people make errors. For example, if errors are common then by increasing λ we

can reduce the value of $P(w|w) * P(w)^{\lambda}$ relative to $\sum_{s \neq w} P(s|w) * P(s)^{\lambda}$.

We train λ by optimizing the average inverse rank of the correct word on our training corpus, where the rank is calculated over all suggestions that we have for each token.

During initial experimentation, it was noticed that our system predicted many spurious autocorrections at the beginnings and ends of sentences (or in the case of sentence fragments, the end of the fragment). We hypothesized that we were weighting the LM scores too highly in such cases. We therefore conditioned λ on how much context was available, obtaining values $\lambda_{i,j}$ where i, j represent the amount of context available to the LM to the left and right of the current word. i and j are capped at n, the order of the LM.

While conditioning λ in this way might at first appear ad hoc, it has a natural interpretation in terms of our confidence in the LM. When there is no context to either side of a word, the LM simply uses unigram probabilities, and this is a less trustworthy signal than when more context is available.

To train $\lambda_{i,j}$ we partition our data into bins corresponding to pairs i, j and optimize each $\lambda_{i,j}$ independently.

Training a constant λ, a value of 5.77 was obtained. The conditioned weights $\lambda_{i,j}$ increased with the values of i and j, ranging from $\lambda_{0,0} = 0.82$ to $\lambda_{4,4} = 6.89$. This confirmed our hypothesis that the greater the available context the more confident our system should be in using the LM scores.

3.4 Confidence Classifiers for Checking and Correction

Spellchecking and autocorrection were implemented as a three stage process. These employ confidence classifiers whereby precision-recall tradeoffs could be tuned to desirable levels for both spellchecking and autocorrection.

First, all suggestions s for a word w are ranked according to their $P(s|w)$ scores. Second, a spellchecking classifier is used to predict whether w is misspelled. Third, if w is both predicted to be misspelled and s is non-empty, an autocorrection classifier is used to predict whether the top-ranked suggestion is correct.

The spellchecking classifier is implemented using two embedded classifiers, one of which is used when s is empty, and the other when it is non-empty. This design was chosen because the useful signals for predicting whether a word is misspelled might be quite different when there are no suggestions available, and because certain features are only applicable when there are suggestions.

Our experiments will compare two classifier types. Both rely on training data to determine threshold values and training weights.

A "simple" classifier which compares the value of $log(P(s|w)) - log(P(w|w))$, for the original word w and the top-ranked suggestion s, with a threshold value. If there are no suggestions other than w, then the $log(P(s|w))$ term is ignored.

A logistic regression classifier that uses five feature sets. The first set is a scores feature that combines the following scoring information (i) $log(P(s|w)) - log(P(w|w))$ for top-ranked suggestion s. (ii) LM score difference between the original word w and the top suggestion s. (iii) $log(P(s|w)) - log(P(w|w))$ for second top-ranked suggestion s. (iv) LM score difference between w and second top-ranked s. The other four feature sets encode information about case signatures, number of suggestions available, the token length, and the amount of left and right context.

Certain categories of tokens are blacklisted, and so never predicted to be misspelled. These are numbers, punctuation and symbols, and single-character tokens.

The training process has three stages. (1) The context score weighting is trained, as described in Section 3.3. (2) The spellchecking classifier is trained, and tuned on held-out development data. (3) The autocorrection classifier is trained on the instances with suggestions that the spellchecking classifier predicts to be misspelled, and it too is tuned on held-out development data.

In the experiments reported in this paper, we trained classifiers so as to maximize the F_1-score on the development data. We note that the desired behaviour of the spellchecking and autocorrection classifiers will differ depending upon the application, and that it is a strength of our system that these can be tuned independently.

3.4.1 Training Using Artificial Data

Training and tuning the confidence classifiers require supervised data, in the form of pairs of misspelled and well-spelled documents. And indeed we posit that relatively noiseless data are needed to train robust classifiers. Since these data are

Language	Sentences	
	Train	Test
English	116k	58k
German	87k	44k
Arabic	8k	4k
Russian	8k	4k

Table 1: Artificial data set sizes. The development set is approximately the same size as the training set.

not generally available, we instead use a clean corpus into which we artificially introduce misspellings. While this data is not ideal, we show that in practice it is sufficient, and removes the need for manually-annotated gold-standard data.

We chose data from news pages crawled from the Web as the original, well-spelled documents. We chose news pages as an easily identifiable source of text which we assume is almost entirely well-spelled. Any source of clean text could be used. For each language the news data were divided into three non-overlapping data sets: the training and development sets were used for training and tuning the confidence classifiers, and a test set was used to report evaluation results. The data set sizes, for the languages used in this paper, are summarized in Table 1.

Misspelled documents were created by artificially introducing misspelling errors into the well-spelled text. For all data sets, spelling errors were randomly inserted at an average rate of 2 per hundred characters, resulting in an average word misspelling rate of 9.2%. With equal likelihood, errors were either character deletions, transpositions, or insertions of randomly selected characters from within the same document.

4 Experiments

4.1 Typed Data with Real Errors

In the absence of user data from a real application, we attempted our initial evaluation with typed data via a data collection process. Typed data with real errors produced by humans were collected. We recruited subjects from our coworkers, and asked them to use an online tool customized for data collection. Subjects were asked to randomly select a Wikipedia article, copy and paste several text-only paragraphs into a form, and retype those paragraphs into a subsequent form field. The subjects were asked to pick an article about a favorite city or town. The subjects were asked to type at a normal pace avoiding the use of backspace or delete buttons. The data were tokenized, automatically segmented into sentences, and manually preprocessed to remove certain gross typing errors. For instance, if the typist omitted entire phrases/sentences by mistake, the sentence was removed. We collected data for English from 25 subjects, resulting in a test set of 11.6k tokens, and 495 sentences. There were 1251 misspelled tokens (10.8% misspelling rate.)

Data were collected for German Wikipedia articles. We asked 5 coworkers who were German native speakers to each select a German article about a favorite city or town, and use the same online tool to input their typing. For some typists who used English keyboards, they typed ASCII equivalents to non-ASCII characters in the articles. This was accounted for in the preprocessing of the articles to prevent misalignment. Our German test set contains 118 sentences, 2306 tokens with 288 misspelled tokens (12.5% misspelling rate.)

4.2 System Configurations

We compare several system configurations to investigate each component's contribution.

4.2.1 Baseline Systems Using Aspell

Systems 1 to 4 have been implemented as baselines. These use GNU Aspell, an open source spell checker (Atkinson, 2009), as a suggester component plugged into our system instead of our own Web-based suggester. Thus, with Aspell, the suggestions and error scores proposed by the system would all derive from Aspell's handcrafted custom dictionary and error model. (We report results using the best combination of Aspell's parameters that we found.)

System 1 uses Aspell tuned with the logistic regression classifier. System 2 adds a context-weighted LM, as per Section 3.3, and uses the "simple" classifier described in Section 3.4. System 3 replaces the simple classifier with the logistic regression classifier. System 4 is the same but does not perform blacklisting.

4.2.2 Systems Using Web-based Suggestions

The Web-based suggester proposes suggestions and error scores from among the ten million most frequent terms on the Web. It suggests the 20 terms with the highest values of $P(w|s) \times f(s)$ using the Web-derived error model.

Systems 5 to 8 correspond with Systems 1 to 4, but use the Web-based suggestions instead of Aspell.

4.3 Evaluation Metrics

In our evaluation, we aimed to select metrics that we hypothesize would correlate well with real performance in a word-processing application. In our intended system, misspelled words are autocorrected when confidence is high and misspelled words are flagged when a highly confident suggestion is absent. This could be cast as a simple classification or retrieval task (Reynaert, 2008), where traditional measures of precision, recall and F metrics are used. However we wanted to focus on metrics that reflect the quality of end-to-end behavior, that account for the combined effects of flagging and automatic correction. Essentially, there are three states: a word could be unchanged, flagged or corrected to a suggested word. Hence, we report on error rates that measure the errors that a user would encounter if the spellchecking/autocorrection were deployed in a word-processor. We have identified 5 types of errors that a system could produce:

1. E_1: A misspelled word is wrongly corrected.
2. E_2: A misspelled word is not corrected but is flagged.
3. E_3: A misspelled word is not corrected or flagged.
4. E_4: A well spelled word is wrongly corrected.
5. E_5: A well spelled word is wrongly flagged.

It can be argued that these errors have varying impact on user experience. For instance, a well spelled word that is wrongly corrected is more frustrating than a misspelled word that is not corrected but is flagged. However, in this paper, we treat each error equally.

E_1, E_2, E_3 and E_4 pertain to the correction task. Hence we can define Correction Error Rate (CER):

$$\text{CER} = \frac{E_1 + E_2 + E_3 + E_4}{T}$$

where T is the total number of tokens. E_3 and E_5 pertain to the nature of flagging. We define Flagging Error Rate (FER) and Total Error Rate (TER):

$$\text{FER} = \frac{E_3 + E_5}{T}$$

$$\text{TER} = \frac{E_1 + E_2 + E_3 + E_4 + E_5}{T}$$

For each system, we computed a No Good Suggestion Rate (NGS) which represents the proportion of misspelled words for which the suggestions list did not contain the correct word.

5 Results and Discussion

5.1 Experiments with Artificial Errors

System	TER	CER	FER	NGS
1. Aspell, no LM, LR	17.65	6.38	12.35	18.3
2. Aspell, LM, Sim	4.82	2.98	2.86	18.3
3. Aspell, LM, LR	4.83	2.87	2.84	18.3
4. Aspell, LM, LR (no blacklist)	22.23	2.79	19.89	16.3
5. WS, no LM, LR	9.06	7.64	6.09	10.1
6. WS, LM, Sim	2.62	2.26	1.43	10.1
7. WS, LM, LR	**2.55**	**2.21**	**1.29**	10.1
8. WS, LM, LR (no blacklist)	21.48	2.21	19.75	8.9

Table 2: Results for English news data on an independent test set with artificial spelling errors. Numbers are given in percentages. LM: Language Model, Sim: Simple, LR: Logistic Regression, WS: Web-based suggestions. NGS: No good suggestion rate.

Results on English news data with artificial spelling errors are displayed in Table 2. The systems which do not employ the LM scores perform substantially poorer that the ones with LM scores. The Aspell system yields a total error rate of 17.65% and our system with Web-based suggestions yields TER of 9.06%.

When comparing the simple scorer with the logistic regression classifier, the Aspell Systems 2 and 3 generate similar performances while the confidence classifier afforded some gains in our Web-based suggestions system, with total error reduced from 2.62% to 2.55%. The ability to tune each phase during development has so far proven more useful than the specific features or classifier used. Blacklisting is crucial as seen by our results for Systems 4 and 8. When the blacklisting mechanism is not used, performance steeply declines.

When comparing overall performance for the data between the Aspell systems and the Web-based suggestions systems, our Web-based suggestions fare better across the board for the news data with artificial misspellings. Performance

gains are evident for each error metric that was examined. Total error rate for our best system (System 7) reduces the error of the best Aspell system (System 3) by 45.7% (from 4.83% to 2.62%). In addition, our no good suggestion rate is only 10% compared to 18% in the Aspell system. Even where no LM scores are used, our Web-based suggestions system outperforms the Aspell system.

The above results suggest that the Web-based suggestions system performs at least as well as the Aspell system. However, it must be highlighted that results on the test set with artificial errors does not guarantee similar performance on real user data. The artificial errors were generated at a systematically uniform rate, and are not modeled after real human errors made in real word-processing applications. We attempt to consider the impact of real human errors on our systems in the next section.

5.2 Experiments with Human Errors

System	TER	CER	FER	NGS
English Aspell	4.58	**3.33**	2.86	23.0
English WS	**3.80**	3.41	**2.24**	17.2
German Aspell	14.09	10.23	5.94	44.4
German WS	**9.80**	**7.89**	**4.55**	32.3

Table 3: Results for Data with Real Errors in English and German.

Results for our system evaluated on data with real misspellings in English and in German are shown in Table 3. We used the systems that performed best on the artificial data (System 3 for Aspell, and System 7 for Web suggestions). The misspelling error rates of the test sets were 10.8% and 12.5% respectively, higher than those of the artificial data which were used during development. For English, the Web-based suggestions resulted in a 17% improvement (from 4.58% to 3.80%) in total error rate, but the correction error rate was slightly (2.4%) higher.

By contrast, in German our system improved total error by 30%, from 14.09% to 9.80%. Correction error rate was also much lower in our German system, comparing 7.89% with 10.23% for the Aspell system. The no good suggestion rates for the real misspelling data are also higher than that of the news data. Our suggestions are limited to an edit distance of 2 with the original, and it was found that in real human errors, the average edit distance of misspelled words is 1.38 but for our small data, the maximum edit distance is 4 in English and 7 in German. Nonetheless, our no good suggestion rates (17.2% and 32.3%) are much lower than those of the Aspell system (23% and 44%), highlighting the advantage of not using a hand-crafted lexicon.

Our results on real typed data were slightly worse than those for the news data. Several factors may account for this. (1) While the news data test set does not overlap with the classifier training set, the nature of the content is similar to the train and dev sets in that they are all news articles from a one week period. This differs substantially from Wikipedia article topics that were generally about the history and sights a city. (2) Second, the method for inserting character errors (random generation) was the same for the news data sets while the real typed test set differed from the artificial errors in the training set. Typed errors are less consistent and error rates differed across subjects. More in depth study is needed to understand the nature of real typed errors.

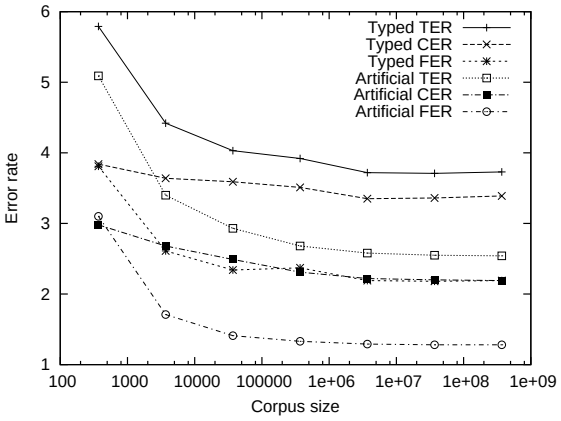

Figure 2: Effect of corpus size used to train the error model.

5.3 Effect of Web Corpus Size

To determine the effects of the corpus size on our automated training, we evaluated System 7 using error models trained on different corpus sizes. We used corpora containing $10^3, 10^4, \ldots, 10^9$ Web pages. We evaluated on the data set with real errors. On average, about 37% of the pages in our corpus were in English. So the number of pages we used ranged from about 370 to about 3.7×10^8. As shown in Figure 2, the gains are small after about 10^6 documents.

5.4 Correlation across data sets

We wanted to establish that performance improvement on the news data with artificial errors are likely to lead to improvement on typed data with real errors. The seventeen English systems reported in Table 3, Table 2 and Figure 2 were each evaluated on both English test sets. The rank correlation coefficient between total error rates on the two data sets was high ($\tau = 0.92$; $p < 5 \times 10^{-6}$). That is, if one system performs better than another on our artificial spelling errors, then the first system is very likely to also perform better on real typing errors.

5.5 Experiments with More Languages

System	TER	CER	FER	NGS
German Aspell	8.64	4.28	5.25	29.4
German WS	4.62	3.35	2.27	16.5
Arabic Aspell	11.67	4.66	8.51	25.3
Arabic WS	4.64	3.97	2.30	15.9
Russian Aspell	16.75	4.40	13.11	40.5
Russian WS	3.53	2.45	1.93	15.2

Table 4: Results for German, Russian, Arabic news data.

Our system can be trained on many languages with almost no manual effort. Results for German, Arabic and Russian news data are shown in Table 4. Performance improvements by the Web suggester over Aspell are greater for these languages than for English. Relative performance improvements in total error rates are 47% in German, 60% in Arabic and 79% in Russian. Differences in no good suggestion rates are also very pronounced between Aspell and the Web suggester.

It cannot be assumed that the Arabic and Russian systems would perform as well on real data. However the correlation between data sets reported in Section 5.4 lead us to hypothesize that a comparison between the Web suggester and Aspell on real data would be favourable.

6 Conclusions

We have implemented a spellchecking and autocorrection system and evaluated it on typed data. The main contribution of our work is that while this system incorporates several knowledge sources, an error model, LM and confidence classifiers, it does not require any manually annotated resources, and infers its linguistic knowledge entirely from the Web. Our approach begins with a very large term list that is noisy, containing both spelled and misspelled words, and derived automatically with no human checking for whether words are valid or not.

We believe this is the first published system to obviate the need for any hand labeled data. We have shown that system performance improves from a system that embeds handcrafted knowledge, yielding a 3.8% total error rate on human typed data that originally had a 10.8% error rate. News data with artificially inserted spellings were sufficient to train confidence classifiers to a satisfactory level. This was shown for both German and English. These innovations enable the rapid development of a spellchecking and correction system for any language for which tokenizers exist and string edit distances make sense. We have done so for Arabic and Russian.

In this paper, our results were obtained without any optimization of the parameters used in the process of gathering data from the Web. We wanted to minimize manual tweaking particularly if it were necessary for every language. Thus heuristics such as the number of terms in the term list, the criteria for filtering triples, and the edit distance for defining close words were crude, and could easily be improved upon. It may be beneficial to perform more tuning in future. Furthermore, future work will involve evaluating the performance of the system for these language on real typed data.

7 Acknowledgment

We would like to thank the anonymous reviewers for their useful feedback and suggestions. We also thank our colleagues who participated in the data collection.

Abstract

Models of language learning play a central role in a wide range of applications: from psycholinguistic theories of how people acquire new word knowledge, to information systems that can automatically match content to users' reading ability. We present a novel statistical approach that can infer the distribution of a word's likely acquisition age automatically from authentic texts collected from the Web. We then show that combining these acquisition age distributions for all words in a document provides an effective semantic component for predicting reading difficulty of new texts. We also compare our automatically inferred acquisition ages with norms from existing oral studies, revealing interesting historical trends as well as differences between oral and written word acquisition processes.

1 Introduction

Word acquisition refers to the temporal process by which children learn the meaning and understanding of new words. Some words are acquired at a very early age, some are acquired at early primary school grades, and some are acquired at high school or even later in life as the individual undergoes experiences related to that word. A related concept to acquisition age is document grade level readability which refers to the school grade level of the document's intended audience. It applies in situations where documents are written with the expressed intent of being understood by children in a certain school grade. For example, textbooks authored specifically for fourth graders are said to have readability grade level four.

We develop and evaluate a novel statistical model that draws a connection between document grade level readability and age acquisition distributions. Based on previous work in the area, we define a model for document readability using a logistic Rasch model and the quantiles of the acquisition age distributions. We then proceed to infer the age acquisition distributions for different words from document readability data collected by crawling the web.

We examine the inferred acquisition distributions from two perspectives. First, we analyze and contrast them with previous studies on oral word acquisition, revealing interesting historical trends as well as differences between oral and written word acquisition processes. Second, the inferred acquisition distributions serve as parameters for the readability model, which enables us to predict the readability level of novel documents.

To our knowledge, this is the first published study of a method to 'reverse-engineer' individual word acquisition statistics from graded texts. By obtaining such a fine-grained model of how language evolves over time, we obtain a new, rich source of semantic features for a document. The increasing amounts of content available from the Web and other sources also means that these flexible models of authentic usage can be easily adapted for different tasks and populations. Our work serves to complement the growing body of research using statistics and machine learning for language learning tasks, and has applications including predicting reading difficulty for Web pages and other non-traditional documents, reader-specific example and question generation for lexical practice in intelligent tutoring systems, and analysis tools for language learning research.

2 A Model for Document Readability and Word Acquisition

For a fixed word and a fixed population of individuals $\mathcal{T}$ the age of acquisition (AoA) distribution p_w represents the age at which word w was

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 900–909,
Singapore, 6-7 August 2009.

acquired by the population. Existing AoA norm studies almost universally summarize AoA ratings in terms of two parameters: mean and standard deviation, ignoring higher-level moments such as skew. For direct comparison with these studies we follow this convention and thus our goal is to estimate AoA for a word w in terms of mean μ_w and standard deviation σ_w parameters using the (truncated) normal distribution

$$p_w(t) \propto N(t\,;\mu_w,\sigma_w) = \frac{e^{-(t-\mu_w)^2/(2\sigma_w^2)}}{\sqrt{2\pi\sigma_w^2}} \quad (1)$$

where the proportionality constant ensures that the distribution is normalized over the range of ages under consideration e.g., $t \in [6, 18]$ for school grades. It is important to note that our model is not restricted by the assumption of (1) and can be readily extended to the Gamma family of distributions, if modeling asymmetric spread in the distribution is appropriate.

For a fixed vocabulary V of distinct words the age acquisition distributions for all words $w \in V$ are defined using $2|V|$ parameters

$$\{(\mu_w, \sigma_w) : w \in V\}. \quad (2)$$

These parameters, which are the main objects of interest, can in principle be estimated from data using standard statistical techniques. Unfortunately, data containing explicit acquisition ages is very difficult to obtain reliably. Explicit word acquisition data is based on interviewing adults regarding their age acquisition process during childhood and so may be unreliable and difficult to obtain for a large representative group of people.

On the other hand, it is possible to reliably collect large quantities of readability data defined as pairs of documents and ages of intended audience. As we demonstrate later in the paper, such data may be automatically obtained by crawling specialized resources on the Web. We demonstrate how to use such data to estimate the word acquisition parameters (2) and to use the estimates to predict future readability ages.

Traditionally, document readability has been defined in terms of the school grade level at which a large portion of the words have been acquired by most children (Chall and Dale, 1995). We propose the following interpretation of that definition, which is made appropriate for quantitative studies by taking into account the inherent randomness in the acquisition process.

Definition 1. *A document $d = (w_1, \ldots, w_m)$ is said to have $(1-\epsilon_1, 1-\epsilon_2)$-readability level t if by age t no less than $1-\epsilon_1$ percent of the words in d have been acquired each by no less than $1-\epsilon_2$ percent of the population.*

We denote by q_w the quantile function of the cdf corresponding to the acquisition distribution p_w. In other words, $q_w(r)$ represents the age at which r percent of the population $\mathcal{T}$ have acquired word w. Despite the fact that it does not have a closed form, it is a continuous and smooth function of the parameters μ_w, σ_w in (1) (assuming $\mathcal{T}$ is infinite) and can be tabulated before inference begins.

Following Definition 1 we define a logistic Rasch readability model:

$$\log \frac{P(d \text{ is } (s,r)\text{-readable at age } t)}{1 - P(d \text{ is } (s,r)\text{-readable at age } t)} = \theta(q_d(s,r) - t) \quad (3)$$

where $q_d(s,r)$ is the s quantile of $\{q_{w_i}(r) : i = 1, \ldots, m\}$. An equivalent formulation to (3) that makes the probability model more explicit is

$$P(d \text{ is } (s,r)\text{-readable at age } t) = \frac{\exp(\theta(q_d(s,r) - t))}{1 + \exp(\theta(q_d(s,r) - t))}. \quad (4)$$

In other words, the probability of a document d being (s,r)-readable increases exponentially with $q_d(s,r)$ which is the age at which s percent of the words in d have been acquired each by r percent of the population.

The parameter $r = 1 - \epsilon_2$ determines what it means for a word to be acquired and is typically considered to be a high value such as 0.8. The parameter $s = 1 - \epsilon_1$ determines how many of the document words need to be acquired for it to be readable. It can be set to a high value such as 0.9 if a very precise understanding is required for readability but can be reduced when a more modest definition of readability applies.

We note that due to the discreteness of the set $\{q_{w_i}(r) : i = 1, \ldots, m\}$, neither $q_d(s,r)$ nor the loglikelihood are differentiable in the parameters (2). This raises some practical difficulties with respect to the computational maximization of the likelihood and subsequent estimation of (2). However, for long documents containing a large number of words, $q_d(s,r)$ is approximately smooth which motivates a maximum likelihood procedure using gradient descent on a smoothed version of

$q_d(s)$. Alternative optimization techniques which do not require smoothness may also be used.

In the case of a normal distribution (1) we have that a word is acquired by r percent of the population at age $w = \mu + \Phi^{-1}(r)\sigma$, where Φ is the cumulative distribution function (cdf) of the normal distribution. To investigate the distribution of acquisition ages we assume that the μ, σ parameters corresponding to different words in a document are drawn from Gamma distributions $\mu \sim G(\alpha_1, \beta_1)$ and $\sigma \sim G(\alpha_2, \beta_2)$. The normal and Gamma distributions are chosen in part because they are flexible enough to model many situations and also admit good statistical estimation theory. Noting that $\Phi^{-1}(r)\sigma \sim G(\alpha_2, \Phi^{-1}(r)\beta_2)$, we can write the distribution of the acquisition ages as the following convolution

$$f_W(w) = \frac{w^{\alpha_1+\alpha_2-1}e^{-w/\beta_2}}{\Gamma(\alpha_1)\Gamma(\alpha_2)\beta_1^{\alpha_1}\beta_2^{\alpha_2}} * \int_0^1 \frac{t^{\alpha_1-1}e^{\frac{(\beta_1-\beta_2)tw}{\beta_1\beta_2}}}{(1-t)^{1-\alpha_2}}dt$$

which reverts to a Gamma when $\beta_1 = \beta_2$.

The distribution of the s-percentile of f_W, which amounts to (r, s)-readability of documents, can be analyzed by combining f_W above with a standard normal approximation of order statistics (e.g., (David and Nagaraja, 2003))

$$X_{\lfloor mp \rfloor} \sim N\left(F_W^{-1}(p), \frac{p(1-p)}{m[f_W(F_W^{-1}(p))]^2}\right)$$

where m is the document length and F_W is the cdf corresponding to f_W.

Figure 1 shows the relationship between document length and confidence interval (CI) width in readability prediction. It contrasts the CI widths for model based intervals and empirical intervals. In both cases, documents of lengths larger than 100 words provide CI widths shorter than 1 year. This finding is also noteworthy as it provides empirical support for the long-standing 'rule-of-thumb' that readability measures become unreliable for passages of less than 100 words (Fry, 1990).

3 Experimental Results

Our experimental study is divided into three parts. The first part examines the word acquisition distributions that were estimated based on readability data. The second part compares the estimated

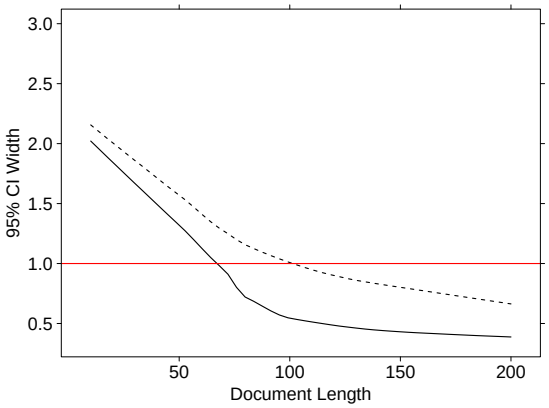

Figure 1: A comparison of model (dashed) vs. empirical (solid) 95% confidence interval widths as a function of document length ($r = 0.9$ and $s = 0.7$). CI widths were computed using 1000 Monte Carlo samples generated from the f_W model fit to the data and from the empirical distribution. Word distributions correspond to a 1577 word document written for a 7th grade audience taken from the Web 1-12 corpus.

(written) acquisition ages with oral acquisition ages obtained from interview studies reported in the literature. The third part focuses on using the estimated word acquisition distributions to predict document readability. These three experimental studies are described in the three subsections below.

In our experiments we used three readability datasets. The corpora were compiled by crawling web pages containing documents authored for audiences of specific grade levels. The Web 1-12 data contains 373 documents, with each document written for a particular school grade level in the range 1-12. The Weekly Reader (WR) dataset, was obtained by crawling the commercial website www.wrtoolkit.com after receiving special permission. That dataset contains a total of 1780 documents, with 4 readability levels ranging from 2 to 5 indicating the school grade levels of the intended audience. A total of 788 documents with readability between grades 2 and 5 and having length greater than 50 words were selected from 1780 documents. The Reading A-Z dataset, contains a set of 215 documents was obtained from Reading A-Z.com, spanning grade 1 through grade 6.

The grade levels in these three corpora, which correspond to US school grades, were either explicitly specified by the organization or authors

who created the text, or implicit in the classroom curriculum page where the document was acquired. The pages were drawn from a wide range of subject areas, including history, science, geography, and fiction.

To reduce the possibility of overfitting, we used a common feature selection technique of eliminating words appearing in less than 4 documents. In the experiments we used maximum likelihood to estimate the model parameters $\{(\mu_w, \sigma_w^2) : w \in V\}$ for the Rasch model (3). The maximum likelihood was obtained using a non-smooth coordinate descent procedure.

3.1 Estimation of Word Acquisition Distributions

Figure 2 displays the inferred age acquisition distributions and empirical word appearances of three words: `thought` (left), `multitude` (middle), and `assimilate` (right). In these plots, the empirical cdf of word appearances is indicated by a piecewise constant line while the probability density function of the estimated AoA distribution is indicated by a dashed line. The vertical line indicates the 0.8 quantile of the AoA distribution which corresponds to the grade by which 80% of the children have acquired the word.

The word `assimilation` appears in 2 documents having 12th grade readability. The high grade level of these documents results in a high estimated acquisition age and the paucity of observations leads to a large uncertainty in this estimate as seen by the variance of the acquisition age distribution. The word `thought` appears several times in multiple grades. It is first observed in the 1st grade and not again until the 4th grade resulting in an estimated acquisition age falling between the two. The variance of this acquisition distribution is relatively small due to the frequent use of this word. The empirical cdf shows that `multitude` is used in grades 6, 8, and 9. Relative to `thought` and `assimilation` the word `multitude` was used less and more frequently respectively, which leads to an acquisition age distribution with a larger variance than that of `thought` and smaller than that of `assimilation`.

The relationship in Figure 2 between the empirical word appearances and the age acquisition distribution demonstrates the following behavior: (a) The variance of the age acquisition distribution goes down as the word appears in more documents, and (b) the mean of the AoA distribution tends to be lower than the mean of the empirical word appearance distribution, and in many cases even smaller than the first grade in which the word appeared. This is to be expected as authors use specific words only after they believe the words were acquired by a large portion of the intended audience.

3.2 Comparison with Oral Studies

Among the related work in the linguistic community, are several studies concerning oral acquisitions of words. These studies estimate the age at which a word is acquired for oral use based an interview processes with participating adults. We focus specifically on the seminal study of acquisition ages performed by Gilhooly and Logie (GL) (1980) and made available through the MRC database (Coltheart, 1981).

There are some substantial differences between these previous studies and our approach. We analyze the age acquisition process through document readability which leads to a written, rather than oral, notion of word acquisition. Furthermore, our estimates are based on documents written with a specific audience in mind, while the previous studies are based on interviewing adults regarding their childhood word acquisition process which is arguably less reliable due to the age difference between the acquisition and the interview. Finally, the GL study was performed in the late 1970s while our study uses contemporary internet data. Conceivably, the word acquisition process changed over the past 3 decades.

Despite these differences, it is interesting to contrast our inferred age acquisitions with the GL study and consider the differences and similarities. Figure 3 displays the relationship between the GL age of acquisition (AoA) and the acquisition ages obtained from readability data based on the $s = 0.8$ quantile. Some correlation is present ($r^2 = 0.34$) but the two measures differ considerably. As expected, the acquisition ages obtained from written readability data tend to be higher than the oral studies. The distributions of differences between the GL acquisition ages and the ones inferred from the readability data appears in Figure 4.

Comparing the acquisition ages obtained from readability data to the GL study results in a mean absolute error of 0.9 to 1.5, depending on the spe-

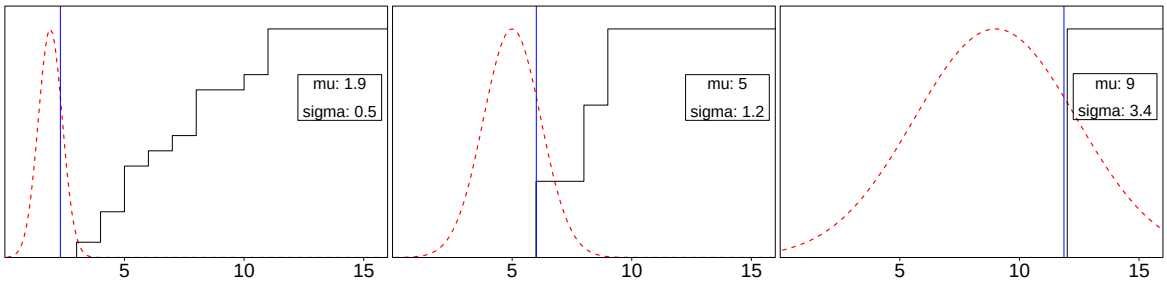

Figure 2: A comparison of empirical word appearances and AoA distributions for three words: `thought` (left), `multitude` (middle), and `assimilation` (right). The empirical cdf of word appearances appears as a piecewise constant line and the estimated pdf is indicated by the dashed curve with its 0.8 quantile indicated by a vertical line.

cific value of the Rasch parameter θ. Interestingly, the tendency for the written acquisition age to exceed the oral one diminishes as the grade level increases. This represents the notion that at higher grades words are acquired in both oral and written senses at the same age.

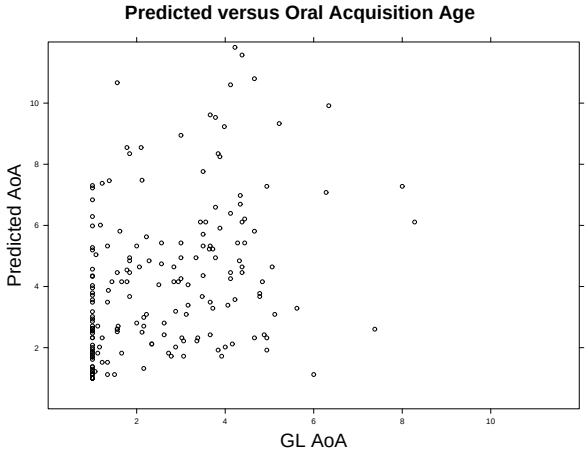

Figure 3: A scatter plot ($s = 80$, $n = 50$) of predicted age of acquisition versus Gilhooly and Logie's values reveals the tendency for the written estimate to exceed the oral estimate ($r^2 = 0.34$).

A comparison to two more recent studies confirms relationships that are similar to those observed with GL AoA. The Bristol Norm study (Stadthagen-Gonzalez and Davis, 2006) was performed in an identical way to the GL study and comparing the lists of acquisition ages results in a mean absolute error of approximately 0.5 which is much lower than the .9 to 1.5 relative to GL. The recent AoA list of Cortese and Khanna (2008) showed an increase in correlation relative to the GL study ($r^2 = 0.43$) potentially reflecting change in the acquisition process due to temporal effects.

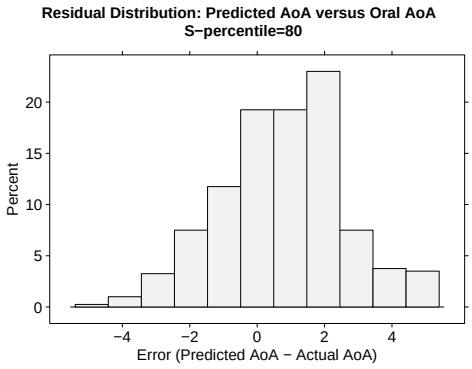

Figure 4: The difference distribution between the GL and the inferred AoA from Web 1-12 is skewed to the right as would be expected since written AoA is higher than oral AoA. Relaxing the definition of readability by decreasing s results in higher inferred acquisition ages. Values of s in $[0.5, 0.9]$ produced reasonable results, with $s = 0.65$ achieving smallest mean absolute error.

Those words that have the same written and verbal acquisition age are partially attributable to those words learned prior to first grade. Many words are learned between the ages of 2 and 5, while reading materials are typically not assigned a grade level of less than 1 or age 6. Approximately 40% of the words assigned the same grade level by both Gilhooly and our prediction had an AoA of 1st grade.

In some cases, the ages of acquisition obtained from readability data is actually lower than the ages reported in the older oral studies. This phenomenon is likely caused by a combination of a shift in educational standards, a change in social standards, or estimation errors due to sample size and modeling assumptions. Approximately

30 years have passed since Gilhooly and Logie's study was conducted. Specifically, society has made efforts to enhance the safety and health of children and to increase the attention to science education in very early grades. For example, the word `drug` appeared in writing 0.94 grades earlier than the age in which it was acquired orally according to the GL study. The newer Bristol Norm study confirms this observation as it predicts a decrease in grade level for `drug` of 0.88 over GL as well. A similar decrease in acquisition age relative to the GL norms was noted for many other words such as `hypothesis`, `conclusion`, `engineer`, `diet`, `exercise`, and `vitamin`.

3.3 Global Readability Prediction

Once acquisition age distributions are available, whether estimated statistically from data or obtained from a survey, they may be used to predict the grade level of novel documents. Specifically, the model predicts readability level t^* for a novel document d if it is the minimal grade for which readability is established:

$$t^* = \min\{t : P(d \text{ is readable at age } t) \geq \beta(t)\} \tag{5}$$

where $\beta(t)$ is a parameter describing the strictness of the readability requirement. Note that we allow $\beta(t)$ to vary as a function of time (grade level). We discuss the justification for this below.

A critical issue for reading difficulty prediction is how to handle words that appear in a new document that have never been seen in the training/development texts. In a statistical approach, the solution to this smoothing problem has two steps. First, we must decide how much total probability mass to allocate to all unknown words. Second, we must decide how to subdivide this total mass for individual words or classes of words using word-specific priors.

Our experience suggests that the first step of estimating total probability mass is particularly important: the likelihood of seeing an unknown word increases as a function of total vocabulary size, which is continuously growing with time. We model this by defining the following dynamic threshold

$$\beta(t) = \frac{\exp(at - 0.5)}{1 + \exp(at - 0.5)}. \tag{6}$$

We learn the growth rate parameter a in (6) from the data at the same time as we learn the readability model's quantile parameters $s = 1 - \epsilon_1$, $r = 1 - \epsilon_2$. The range of the resulting $\beta(t)$ is typically 0.5 in lower grades, increasing to 0.9 in higher grades. We discuss fitting these parameters and their optimal values further in Sec. 3.3.1. We found that using any fixed β value for all grades was generally much less effective than a dynamic $\beta(t)$ threshold, and so we focus on the latter in our evaluation.

For the second (word-specific) smoothing step, we simply assign uniform probability across grades, once the total unseen mass is determined. More sophisticated word-specific priors incorporating word length, morphological features, semantic clusters and so on are certainly possible and an interesting direction for future work.

In the following section we conduct three experiments involving readability prediction. First, we confirm the effectiveness of the AoA-based model compared to other predictive models. Second, we examine how prediction effectiveness is affected when our learned (written) acquisition ages are replaced with existing oral AoA norms. Third, we examine the ability of our model to generalize to new content by training and testing on different (non-overlapping) corpora.

3.3.1 Effectiveness of Readability Prediction

In order to assess the effectiveness of our model in predicting the readability grade levels of novel documents we apply the model to two corpora. First, we use the Web 1-12 corpus to learn optimal parameter values for a , r, and s and then assess prediction error using a test-training paradigm for the proposed model, Naive Bayes, and support vector regression. Second, the trained model is applied with to the Reader A-Z corpus and the results are compared with alternative semantic variables. Because corpora can vary significantly in text homogeneity, amount of noise, document size, and other factors, training and testing across different corpora – rather than relying on cross-validation with a single pooled dataset – gives valuable information about how a prediction method might be expected to perform on data with widely different characteristics. This particular choice of Web 1-12 for training and ReadingA-Z for testing was arbitrary.

To evaluate the best values for the a parameter in (6) and s, r parameters in Definition 1 we gen-

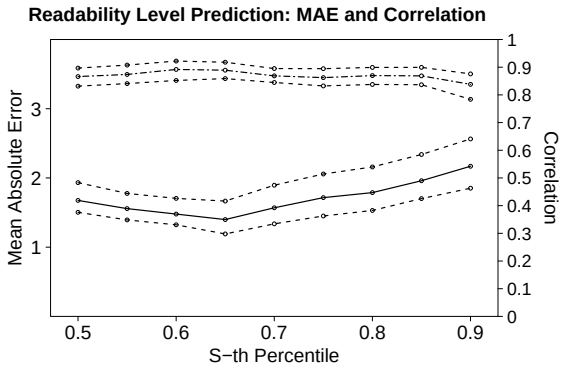

Figure 5: Mean absolute error (MAE) and correlation coefficient as functions of the quantile parameter s at optimal levels of a and r, averaged over 100 training/test samples. The MAE is displayed as the solid line and is aligned with the left axis while the correlation is displayed as a dashed line and is aligned with the right axis. 90% bootstrap confidence intervals are displayed.

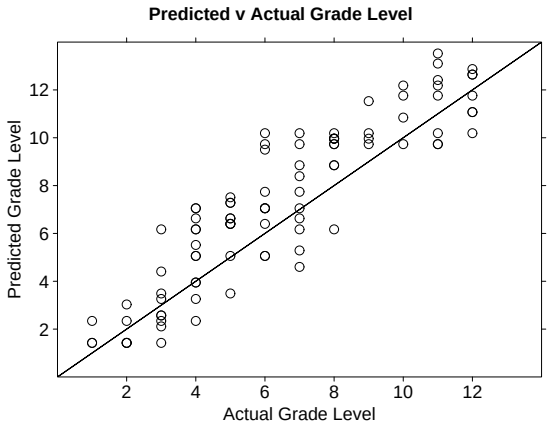

Figure 6: The scatter plot demonstrates the strong relationship between predicted and actual global readability levels.

Prediction Rule	MAE	LB	UB
Age of Acquisition	1.40	1.19	1.67
Naive Bayes	1.98	1.71	2.26
SVR (word frequency)	1.86	1.69	2.06
SVR (AoA percentiles)	1.36	1.22	1.58
Grade 6	2.92	-	-

Figure 7: A comparison of mean absolute error (MAE) across prediction algorithms shows the age of acquisition model compares favorably. The confidence bounds (LB,UB) were computed by repeating each model building procedure 100 times.

erated 100 independent test and training samples and computed the mean absolute prediction error (MAE) and the correlation coefficient between the predicted and actual levels. Figure 5 (left) shows these two quantities: in each group of three lines, the top and bottom lines delineate the upper and lower 90% confidence bounds for the middle line. Each middle line gives mean error or correlation as a function of the quantile parameter s at optimal levels of r and a, averaged over the 100 training/test samples. The optimal value of s for both quantities is around 0.6 (0.65 for the MAE). The optimal value for parameter a was approximately 1.55. The best MAE is 1.4 which compares favorably to the 2.92 MAE obtained by always predicting Grade 6 which is the optimal "dumb" classifier in the sense that of all constant predictors it provides the smallest expected MSE over a uniform grade distribution as is the case with the Web1-12 corpus. Figure 6 is a scatter plot comparing predicted grades vs. actual grades, with a strong correlation of 0.89.

We compared the predictions of model (3) to two standard classifiers: naive Bayes and support vector regression (SVR). SVR was applied twice using different sets of features - once with the document word frequencies and once with the estimated AoA percentiles for the document words. The document word frequency vector is comparable to the semantic component of the machine learning approach used by (Heilman et al., 2008). The 75-25 training-test model building paradigm was used over documents from grades 1 to 12 to obtain predicted values. The MAE for these predictors and their 90% confidence intervals are shown in Figure 7. Predicting readability using word frequencies had inferior performance, with the naive Bayes model performing poorly and the SVR and Rasch model obtaining MAE around 1.4.

In the second experiment, we compared our model to published correlation results (Collins-Thompson and Callan, 2005) for multiple alternative semantic variables using the same Reading A-Z corpus, with the results shown in Fig. 8. Details on these semantic variables, which have been used in previous statistical learning approaches, are available in the same study. Interestingly, the correlation of the model was comparable to ex-

	Correlation		Correlation
GL (Web)	.65	UNK	.78
GL (WR)	.40	Type	.86
Bristol (Web)	.76	MLF	.49
Bristol (WR)	.57	FK	.30
Inferred (Web)	.59	Unigram	.63

Figure 8: Comparison of the correlation of AoA and other semantic variables with grade level for the Reading A-Z corpus, showing the AoA model with the dynamic threshold compares well to existing methods. The competitor methods used are from (Collins-Thompson and Callan, 2005) and comprise the Smoothed Unigram, UNK (relative to revised Dale-Chall), TYPE (number of unique words), MLF (mean log frequency), and FK (Flesch-Kincaid readability).

isting variables, but did vary depending upon the source of AoA. Note that because the Reading A-Z texts were assigned grades by their creators using some of the same semantic variables (e.g. Type), it is not surprising that those variables perform especially well on this dataset.

High quality readability prediction is a worthwhile result in itself; however, we can also use the prediction mechanism to study the validity of Definition 1 and the Rasch model. We do so by applying other predictive algorithms using the inferred acquisition age distribution for each document as the predictor variables and comparing the MAE with the MAE obtained by the estimated Rasch model. In particular, we examine the performance of support vector regression (SVR) using the estimated AoA percentiles for each document as predictor variables. The results displayed in Figure 7 show that SVR and the dynamic threshold prediction rule perform similarly well, suggesting that Definition 1 and the Rasch model are suitable models for readability prediction.

3.3.2 Prediction with Existing Acquisition Age Norms

We now examine how predicting readability of novel documents using acquisition ages obtained in surveys perform in comparison to the ages obtained from the maximum likelihood estimation.

We use the GL and Bristol age of acquisition norms. The intersection of AoA norm data and the Web Corpus are 1217 and 1012 words respectively for the GL and Bristol measure; additionally, the highest grade level associated with these word sets

Prediction Rule	S-th Percentile	Dynamic Threshold
Age of Acquisition	1.69	1.40
GL Norms	1.73	1.42
Bristol Norms	1.97	1.79

Figure 9: The Gilhooly and Logie AoA norms and the Bristol norms are independent sources for ages of acquisition. A comparison of the prediction quality using these norms shows two things: 1) the definition provides comparable prediction quality using expert norms, and 2) the dynamic threshold $\beta(t)$ improves prediction over the static threshold (optimal s-th percentile) for the norms.

AoA Source	Web 1-12	Weekly Reader
Inferred (Weekly Reader)	-	.91
Inferred (Web 1-12)	1.89	-
GL	2.05	1.14
Bristol	1.57	1.34

Figure 10: The readability of WR documents was predicted using 4 sources of AoA data. The parameters of the prediction model were fit using only the Web data, or the WR data, or both sources in the case of the GL and Bristol norms AoA data.

are eight and seven respectively. When applying the prediction rule using AoA norms r is implicitly selected in the norming process as the result is a single value instead of a distribution. Interestingly, the optimal ranges of s-percentile, from 92 to 100, were the same for both the GL and Bristol norms. Table 9 shows that the prediction accuracy obtained using the GL Norms was almost identical to that obtained with the inferred AoA, while the Bristol Norms performed as well as some of the competitor procedures.

3.3.3 Prediction Effectiveness across Different Corpora

To provide additional evidence for our model's ability to generalize to new corpora, we examine how the learned r and s values vary when the model is learned on one corpus and evaluated on another, and how this affects the accuracy of the readability prediction.

Figure 10 demonstrates the corpus used for tuning the readability prediction has a large impact on the quality of the prediction. Comparing the MAE of the readability predictions on WR data

when the age of acquisition is inferred from Web data to the MAE when the AoA is inferred from WR data shows the error rate more than doubles from 0.90 to 1.89. The increase in error rate also appears when the age of acquisition for WR data is predicted using the AoA norm data. In this case the prediction was performed using the parameters identified when the model was trained on Web data and when the model was trained on WR data. In each case a tendency to overfit appears as the MAE increases from 1.14 to 2.05 for the GL norms and 1.34 to 1.57 for the Bristol norms. Interestingly, the Bristol norms perform better on WR data when fit using the Web data, while the GL norms perform better when fit using the WR data.

4 Related Work

Age of acquisition for word reading and understanding has been extensively studied as a learning factor in the psycholinguistics literature, where AoA norms have been obtained using surveys. Examples of relevant literature are (Gilhooly and Logie, 1980; Zevin and Seidenberg, 2002). Our approach differs by connecting AoA to readability through Definition 1 and using readability data to estimate AoA norms from large amounts of authentic language data. A related study is that by Crossley et al. (2007) who used AoA to help discriminate between authentic and simplified texts for second-language readers.

In the past decade, there has been renewed interest in corpus-based statistical models for readability prediction. One example is the popular Lexile measure (Stenner, 1996) which uses word frequency statistics from a large English corpus. Collins-Thompson and Callan (2005) introduced a new approach based on statistical language modeling, treating a document as a mixture of language models for individual grades. Further recent refinements in methods for readability prediction include using machine learning methods such as Support Vector Machines (Schwarm and Ostendorf, 2005), log-linear models (Heilman et al., 2008), k-NN classifiers and combining semantic and grammatical features (Heilman et al., 2007).

The growing number of features investigated by these machine learning approaches reflect the fact that reading difficulty is a complex phenomenon involving many factors, from semantic difficulty (vocabulary) to syntax and discourse complexity, reader background, and others. While a full-featured comparison between previous approaches that includes AoA features would be very interesting, our goal in this study was to provide a clear analysis of the most fundamental factor of readability, semantic difficulty, which accounts for 80-90% of the variance in readability prediction scores (Chall and Dale, 1995). Because AoA is a semantic, vocabulary-based representation, we compare its effectiveness with the corresponding *semantic components* from previous machine-learning approaches in Sec. 3.3.1.

5 Discussion

While there have been several recent studies regarding word acquisition and readability our work is the first to provide a quantitative connection between these two concepts in a statistically meaningful way. The core assumption that we make is Definition 1 which is consistent with standard readability definitions e.g., (Chall and Dale, 1995) and states that document readability level is determined by most people understanding most words.

The connection between word acquisition and readability is both intuitive and useful. It allows two degrees of freedom $s = 1 - \epsilon_1$ and $r = 1 - \epsilon_2$ to handle situations where different readability notions exist. Experiments validate the model and demonstrate interesting trends in word acquisitions as compared to older oral acquisition studies. Experimental results show that the proposed model is also effective in terms of predicting readability level of documents on multiple datasets. It compares favorably to naive Bayes and support vector regression, the latter being one of the strongest regression baselines.

Acknowledgments

Combining Collocations, Lexical and Encyclopedic Knowledge for Metonymy Resolution

Vivi Nastase and **Michael Strube**
EML Research gGmbH
Heidelberg, Germany
http://www.eml-research.de/nlp

Abstract

This paper presents a supervised method for resolving metonymies. We enhance a commonly used feature set with features extracted based on collocation information from corpora, generalized using lexical and encyclopedic knowledge to determine the preferred sense of the potentially metonymic word using methods from unsupervised word sense disambiguation. The methodology developed addresses one issue related to metonymy resolution – the influence of local context. The method developed is applied to the metonymy resolution task from SemEval 2007. The results obtained, higher for the countries subtask, on a par for the companies subtask – compared to participating systems – confirm that lexical, encyclopedic and collocation information can be successfully combined for metonymy resolution.

1 Introduction

Metonymies are a pervasive phenomenon in language. They occur because in communicating, we use words as pointers to a larger body of knowledge, that encompasses various facets of the concept evoked by a given word.

A listener need not understand the cello to be moved by its playing, just as it is unnecessary for a rider to understand technical jargon; all that matters is sensation, and here the **Kawasaki** *excels. The* **cockpit** *is sensibly designed, with a narrow* **front seat** *portion ...*

Kawasaki is a company, it has an organization, facilities, employees, it makes specific products. In the context above, the company name stands in for its products – motorcycles. Motorcycles have parts, the *cockpit* and *front seat* are some of them, and this provides the discourse links between the two sentences. Constraints on the interpretation of a word w in context comes both from the local and global context, and are applied to the information/knowledge evoked by w. The local constraints come from the words with which w is (grammatically) related to. The global constraints come from the domain/topic of the text, discourse relations that span across sentences.

Metonymic words have a rather small number of possible interpretations (also called readings) which occur frequently (Markert and Nissim, 2002). Idiosyncratic interpretations are also possible, but very rare. One can view the possible interpretations of a potentially metonymic word (PMW) as corresponding to the word's possible senses (Nissim and Markert, 2003), bringing the task close to word sense disambiguation.

The approach to metonymy resolution presented here is supervised, with unsupervised feature enrichment. We apply techniques inspired by unsupervised word sense disambiguation, which allow us to go beyond the annotated data provided in training, and quantify the restrictions imposed on the interpretation of a PMW by its grammatically related neighbours through collocation information extracted from corpora. The only annotation required for the corpora are automatically induced part-of-speech tags from which we obtain grammatical relations through regular expression matching over sequences of parts-of-speech. Collocation information is combined with lexical resources – WordNet – and encyclopedic knowledge extracted from Wikipedia to help us generalize the collocations found to determine higher level constraints on a word's grammatical collocates. In the example above, *Kawasaki* is grammatically related to the verb *excel* – it is its subject. To determine the most likely interpretation of *Kawasaki* given that it is in the subject relation with *excel* we look at all the nouns in the corpora

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 910–918,
Singapore, 6-7 August 2009.

that appear as this verb's subjects, and estimate from this the preferences *excel* has for its subjects. Let us say the corpus contains the following collocations in subject position (with frequency information in parentheses): *player (4), musician (50), car (30), computer (12), camera (40), driver (55), bike (20)* .... The knowledge resources – WordNet, *isa* relations extracted from Wikipedia – will help generalize these collocations: *player, musician, driver* to `person` and *car, computer, camera, bike* to `artifact`. This together with frequency of occurrence are used to estimate the probability that the verb *excel* takes a `person` or `artifact`-type subject. These are *excel*'s selectional preferences towards certain collocates, and will help determine which possible interpretation for the PMW *Kawasaki* is appropriate in this context – `organization-for-people` or `organization-for-product`.

The paper continues with related work in Section 2 and the description of the data in Section 3. The representation used is introduced in Section 4. The results and the discussion are presented in Section 5. The paper wraps up with conclusions and future work.

2 Related Work

Analysis of metonymies as a linguistic phenomenon dates back at least to the 1930s (Stern, 1931), and are increasingly recognized as an important phenomenon to tackle in the interest of higher level language processing tasks, such as anaphora resolution (Harabagiu, 1998; Markert and Hahn, 2002), question answering (Stallard, 1993) or machine translation (Kamei and Wakao, 1992).

Until the early 90s, the main view about metonymies was that they violate semantic constraints in their immediate context. To resolve metonymies then amounts to detecting violated constraints, usually from those imposed by the verbs on their arguments (Pustejovsky, 1991; Hobbs et al., 1993; Fass, 1991). Markert and Hahn (2002) showed that this approach misses metonymies which do not violate selectional restrictions. In this case referential cohesion relations may indicate that the literal reading is not appropriate and give clues about the intended metonymic interpretation.

Markert and Nissim (2003) have combined observations from the linguistic analysis of metonymies with results of corpus studies. Linguistic research has postulated that (i) conventional metonymic readings are very systematic; (ii) unconventional metonymies can be created on the fly and their interpretation is context dependent; (iii) metonymies are frequent. The fact that most metonymic interpretations are systematic and correspond to a small set of possible readings allow the metonymy resolution to be modelled as a classifier learning task. Markert and Nissim (2002) and Nissim and Markert (2003) have shown that conventional metonymies can be effectively resolved using a supervised machine learning approach. Moreover, grammatically related words are crucial in determining the interpretation of a PMW. The shortcoming is that manually annotated data is in short supply, and the approach suffers from data sparseness. To address this problem, Nissim and Markert (2003) proposed a word similarity-based method. They use Lin's thesaurus (Lin, 1998) to determine how close two lexical heads are, and use this instead of the more restrictive identity constraint when comparing two instances. This technique is complex, requiring smoothing, multiple iterations over the thesaurus and hybrid methods to allow a back-off to grammatical roles.

The supervised approach to resolving metonymies was encouraged by the metonymy resolution task at the semantic evaluation exercise SemEval 2007 (Markert and Nissim, 2007). The participating systems in this task were varied. Most of them (four out of five) have used supervised machine learning techniques. The systems that beat the baseline used either the grammatical annotations provided by the organizers (Farkas et al., 2007; Nicolae et al., 2007), or a robust and deep (not freely available) parser (Brun et al., 2007). These systems represented instances in a manner similar to (Nissim and Markert, 2005). They used additional manually built resources – WordNet, FrameNet, Levin's verb classes, manually built lists of "trigger" words – to generalize the existing features. Brun et al. (2007) also used the British National Corpus (BNC) for computing the distance between words based on their syntactic distribution.

While lexical resources and corpora are used to estimate word similarity, all these systems rely exclusively on the data provided by the organizers – instance representation captures only information that can be derived from or between the data points provided. The approach presented here goes beyond the given data, and induces from corpora measures that allow the system to determine

what are the preferences of the words surrounding a PMW towards each of PMW's possible readings. The technique employed is adapted from unsupervised word sense disambiguation (WSD). In short, we use the local grammatical context as it is commonly used in WSD approaches, to guide the system in choosing the reading that fits best. The benefits of using grammatical information for automatic WSD were first explored by Yarowsky (1995) and Resnik (1996) in unsupervised approaches to disambiguating single words in context. The method described here uses automatically induced selectional preferences, computed from sense-untagged data, similar to Nastase (2008).

3 Data

We work with the data from the metonymy resolution task at SemEval 2007 (Markert and Nissim, 2007), generated based on a scheme developed by Markert and Nissim (2003).

The metonymy resolution task at SemEval 2007 consisted of two subtasks – one for resolving country names, the other for companies. For each subtask there is a training and a test portion. Figure 1 shows the text fragment for one sample, and Table 1 the data statistics. The *reading* column shows the possible interpretations of a PMW for countries and companies respectively. For example, `org-for-product` would be the interpretation of the PMW *Kawasaki* in the example shown in the introduction.

Occurrences of country and company names were annotated with a small number of possible readings, as shown in Table 1. This reflects previous analyses of the metonymy phenomenon, which showed that there is a rather small number of possible interpretations that appear more frequently (Markert and Nissim, 2002). Special interpretations are very rarely encountered.

Within the framework of the SemEval task, metonymy resolution is evaluated on the given test data, on three levels of granularity: coarse – distinguish between `literal` and `non-literal` readings; medium – distinguish between `literal`, `mixed` and `non-literal` readings; fine – identify the specific reading of the target word/words (potentially metonymic word - PMW).

reading	train	test
locations	925	908
literal	737	721
mixed	15	20

org-for-product	74	67
org-for-facility	15	16
org-for-index	7	3

Table 1: Reading distributions

4 Representation

The method presented in this paper is a supervised learning method, along the same general lines as the systems which participated in the SemEval competition. As such, it represents each PMW in the data through features that describe its context and some semantic characteristics. The minimum set of necessary features is taken to be that presented by Nissim and Markert (2005), and proved to be effective in solving metonymies. These are the *M&N features* (Markert and Nissim features). We expand on these features and estimate preferences from words in a PMW's context towards specific PMW interpretations. These constitute the *selectional preference features*. Finally, Wikipedia is a source of facts which can be used to derive information that can bias the decision towards certain interpretations for a PMW. Each of these features are described in more detail in the following subsections.

4.1 M&N features

The features used by Nissim and Markert (2005) are:

- grammatical role of PMW (subj, obj, ...);
- lemmatized head/modifier of PMW (announce, say, ...);
- determiner of PMW (def, indef, bare, demonst, other, ...);

All these features can be extracted from the grammatically annotated and POS tagged data provided by the organizers.

4.2 Selectional preference features

The grammatical relations and the connected words are important to describe the local context of the target PMW. Because of the limited amount of annotated data (a few thousand instances), lemmas of PMW's grammatically related words will make for very sparse data that a machine learning system would not be able to generalize over. Nissim and Markert (2003) and the teams participating in the metonymy resolution task have then supplemented their systems with Lin's thesaurus, WordNet, Beth Levin's verb groups, FrameNet information, or manually designed lists of words to generalize the grammatically related words and thus find shared characteristics across instances of metonymies in text.

The notion of selectional restrictions used in metonymy resolution – meaning the restrictions imposed on the interpretation of a PMW by its context – is similar to the notion of selectional preferences from word sense disambiguation – meaning the preferences of a word for the senses of the words in its context. We import this notion, and compute selectional preferences for the words in a PMW's (grammatical) neighbourhood, and allow them to influence the chosen reading for the PMW. Applying methods from unsupervised WSD allow us to estimate such preferences from (sense/metonymy) untagged corpora.

A potentially metonymic word (or phrase) has a small number of possible readings. These can be viewed as possible senses, and the task is to choose the one that fits best in the given context. The preference for each possible sense can be determined based on the PMW's grammatically related words. To estimate these sense preferences we use grammatical collocations extracted from the British National Corpus (BNC), detected using regular expression matching over sequences of POS using the Word Sketch Engine (Kilgarriff et al., 2004). The scores are computed following a technique similar to Nastase (2008), which is illustrated using the following example:

The Kawasaki drives well, steers brilliantly both under power and in tight corners ...

The PMW *Kawasaki* is involved in the following grammatical relations in the previous sentence:

(drive,subject,Kawasaki)
(steer,subject,Kawasaki)

SampleID	Lemma	PMW	GrRole	Reading	act	animal	artifact	...	person	...
samp190	say	Sun	subj	org-for-members	0.00056	0.01171	0.01958	...	0.61422	...
samp190	claim	Sun	subj	org-for-members	0.00198	0.00099	0.00893	...	0.50211	...

Table 2: Grammatical annotation file enhanced with selectional preference estimates

The BNC provides the collocations *(drive,subject,X)* and *(steer,subject,Y)*, to determine what kind of subject *drive* and *steer* prefer, in "word-POS:frequency" format:

drive subject chauffeur-n:12, engine-n:30, car-n:62, taxi-n:13, motorist-n:10, disk-n:15, truck-n:11, man-n:75, ...

steer subject power-n:6, car-n:3, sport-n:2, firm-n:2, boy-n:2, government-n:2, man-n:2, people-n:2 ...

The target whose interpretation must be determined is *Kawasaki*. If for a potentially metonymic word representing a company name, there are the following possible interpretations: `company`, `member/person`, `product/artifact`, `facility`, `name`, we compute the preference for each of these interpretations based on the extracted collocations. For the verb *drive* for example, the collocations *engine, car, taxi, truck* are all *artifacts* (according to WordNet), and thus vote for the `product/artifact` reading, while *chauffeur, motorist, man* are all *person*, and vote for the `member/person` reading. Preferences from different grammatical relation for the same PMW are summed.

Formally, we choose the PMWs' "senses" – a set of words which are close to the possible readings of metonymic words in the data. In this work, these senses are the WordNet 3.0 supersenses:

`S = { act, animal, artifact, attribute, body, cognition, communication, event, feeling, food, group, location, motive, object, person, phenomenon, plant, possession, process, quantity, relation, shape, state, substance, time }`.

Because none of these can be seen as a sense for "company", the list is supplemented with `company` and `organization`. Granted, there is no 1:1 mapping from these supersenses to PMW readings, but find such a strict correspondence is not necessary because the context preferences for each of these senses are used as features, and the mapping to PMW readings is found through a supervised learned model.

To compute the preference of a word w in the grammatical context of a PMW t (the target) towards each of t's possible senses, we consider each relation (w, R, t), where R is the grammatical relation. The set C of word collocations are extracted from the BNC

$$C = \{(w, R, w_j : f_j) | (w, R, w_j) \in BNC, \\ f_j \text{is the frequency of occurrence}\}$$

and used to compute a preference score P_{s_i} for each sense $s_i \in \mathsf{S}$:

$$P_{s_i} = \frac{\sum_{(w,R,w_{i,j}:f_{i,j}) \in C_{s_i}} f_{i,j}}{\sum_{(w,R,w_j:f_j) \in C} f_j}$$

where

$$C_{s_i} = \{(w, R, w_j : f_j) | (w, R, w_j : f_j) \in C; \\ \text{supersense}(w_j, s_i) \parallel \text{isa}(w_j, s_i)\}.$$

supersense(w_j, s_i) is true if s_i is a supersense of one of w_j's senses;

isa(w_j, s_i) is true if s_i is a hypernym of one of w_j's senses in WordNet, or is a fact extracted from Wikipedia.

To determine the *supersense* and *isa* relation we use WordNet 3.0, and a set of 7,578,112 *isa* relations extracted by processing the page and category network of Wikipedia[1] (Nastase and Strube, 2008). The collocations extracted from BNC contain numerous named entities, most of which are not part of WordNet. If an *isa* relation between a collocate from the corpus w_j and a possible sense of a PMW s_i cannot be established using supersense information (for the supersenses) or through transitive closure in the hypernym-hyponym hierarchy in WordNet (for `company`

[1] `http://www/eml-research.de/nlp/download/wikirelations.php`

and `organization`) for any sense of w_j, it is tried against the Wikipedia-based links.

This process transforms the grammatical annotation file and enhances it with the collocation estimates, as shown in Table 2 (compare this with a sample of the original file presented in Figure 1).

4.3 Product and event features

Farkas et al. (2007) observed that using the PMWs themselves as features leads to improvement on determining the reading for organization names, and postulate that this is because some company names are more likely to be used in a metonymic way. This is often the case with companies that make products which are commonly used (cars, for example).

Brun et al. (2007) note that certain locations, such as *Vietnam*, are more likely to be used with an *event* reading than others locations. Generally, locations strongly associated with events tend to be used to refer to the event, and more often have a `place-for-event` interpretation rather than a `literal` one.

These two observations have lead us to mine for these pieces of information in the Wikipedia relations, and to add two more features for a target PMW:

has-product will take a value of 1 if any of the PMW's hypernyms (according to the *isa* relations extracted from Wikipedia) contains the string *manufacturer*, will have the value 0 otherwise;

has-event will have the value 1 if any of the PMW's hypernyms refers to an event (movements/operations/riots), and value 0 otherwise.

4.4 Data representation

As mentioned before, the representation built can be seen as consisting of roughly three subsets of features:

- **the M&N features** proposed by Nissim and Markert (2005). To combine the grammatical information from all relations, we transform the grammatical relations into features (as opposed to values). For a relation *subject* for example, we generate a binary `subject` feature that indicates whether for a given target this grammatical relation is filled or not, and a `subject_lemma` feature , whose value is the lemma of the grammatically related word.

- **the selectional preference scores**. Each of these features corresponds to one of the elements of S, presented above. These features combine the selectional preferences of all the grammatical relations for one target PMW.

- **product and event information from Wikipedia** – has-product and has-event.

The grammatical annotation file consists of one entry for each grammatical relation in which a PMW appears. For the final representation, information about all relations of a given PMW is compressed into one instance. Because the basic features were binarized, and instead of having one *grammatical role* feature now each possible grammatical relation has its own feature, combining several entries for one PMW is easy, as it only implies setting the correct value for the grammatical relations that are valid in the PMWs context.

The final representation consists of 63 features + class feature for the subset for company PMWs, 59 features + class feature for the subset containing countries PMWs. The sample ID and the PMW itself were not part of this representation.

5 Results

The models for determining a PMW's correct interpretation are learned on the training data provided, and evaluated on the test portion, using the answer keys and evaluation script provided with the data. For learning the models we use Weka (Witten and Frank, 2005), and select the final learning algorithms based on 10-fold cross-validation on the training data. We have settled on support vector machines (SMO in Weka), and we use the learner's default settings.

Tables 3 and Table 4 show the results obtained, and the baseline and the best results from the SemEval task for comparison (Markert and Nissim, 2007). The baseline in Table 3 corresponds to classifying everything as the most frequent class – literal interpretation. The *M&N feat.* and *M&N feat.bin.* correspond to datasets that contain only the M&N features and the binarized versions of these features, respectively. *SemEval best* gives the best results obtained on each task in the SemEval 2007 task (Markert and Nissim, 2007). SMO_{wiki} are the results obtained with the complete feature set described in Section 4, and SMO_{SP} are the results obtained when only the new features are used – only selectional preference, has-product and has-event features (none of

Table 4: Detailed F-scores

the M&N features). The baseline for detailed reading results in Table 4 reflects the distribution of the classes in the test file. The *max* column shows the best performance for each task in the SemEval 2007 competition (Markert and Nissim, 2007). The SMO column shows the results of learning when Wikipedia information is not used to compute the values of the collocation, has-product and has-event features.

Nissim and Markert (2003) have shown that grammatical roles are very strong features. Experiments on the data represented exclusively through grammatical role features confirm this observation, as the results obtained using only the syntactic features (no lexical head information) give the same results as the *M&N feat.bin.* which does include lexical information.

On the location metonymies, the current approach performs better on all evaluation types (coarse, medium, fine) by 0.9, 1.1 and 0.9% points respectively. The improvement comes from recognizing better the metonymic readings, as it is apparent from the detailed F-score results in Table 4. For the coarse readings, the F-score for the `non-literal` reading is 1.5% points higher than the best performance at SemEval, and 2.5% and 7.7% points respectively for the `metonymic` and `mixed` readings for the medium and fine coarseness. It is interesting that the learning is quite successful even when only selectional preference and Wikipedia-based has-product and has-event features are used – the SMO_{SP} column in Table 3. The grammatical role and the related lemma were used to derive these collocation features, but they do not appear as such in the representation used for this batch of experiments.

For company metonymies the current approach does not perform better than the state-of-the-art. For these metonymies the syntactic information is not as useful. This is evidenced by the lower performance of the classifier that uses only syntactic information (column *M&N feat.bin.* in Table 3), despite the fact that the training dataset for com-

panies is larger than the one for countries. This observation is further supported by the low results when using only selectional preference features. It indicates that for company metonymies the local context does not provide as strong clues as it does for locations. For such PMWs we should explore the larger context. We have made a start with the Wikipedia-based features built following the observation about companies and their products made by Farkas et al. (2007) and Brun et al. (2007). In future work we plan to analyse this matter further, and find a method to derive more such features, and without manually provided clues (such as *manufacturer* or *riots*).

Wikipedia derived information does not contribute very much, but as expected it is helpful to identify other classes than the `literal` one. It is helpful to detect the `mixed` class – 16% F-score when using Wikipedia information compared to 8.7% for the countries data when we estimate preferences using only WordNet. It also increases the performance on the `non-literal`, `metonymic` and `org-for-members` classes in coarse, medium and fine classification respectively for both countries and companies. There is a small improvement for recognizing the `org-for-product` reading for organizations when using Wikipedia-based features. It is an indication that the has-product feature is useful. We cannot draw conclusions about the has-event feature, as there are only 3 training instances for the `place-for-event` reading. The results are encouraging, as we have just scraped the surface of the information that Wikipedia can provide.

The corpus derived selectional preferences perform very well, especially for determining the reading of locations. Analysis of the data and the features gives some indication as to why this happens: in the grammatical annotations provided, when the PMW is a prepositional complement or has a prepositional complement, the grammatically related word is a preposition. We extract only grammatical collocations for open-class words, restricted by the grammatical relation of interest, so we do not extract collocations for prepositions. Location prepositions (*in, at, from*) are less ambiguous than others (e.g. *for*), which are more common for the organization data. We have attempted to bypass this problem by generating parses using the dependency output of the Stanford Parser (de Marneffe et al., 2006), and bypassing the preposition – incorporate it in the grammatical role (*pp_in*, for example), and using as lemma the head of the prepositional complement or the constituent which dominates the prepositional phrase, depending on the position of the PMW. Now we can use the grammatical relation and the associated open-class word to look for collocations. This approach did not lead to good results, because the quality of the automatic parses is far from the manually provided information.

6 Conclusions

We have explored the use of selectional preference scores derived from a sense untagged corpus as local constrains for determining the interpretation of potentially metonymic words. Such methods were previously successfully used for word sense disambiguation, and transfer nicely to the metonymy resolution task. Adding encyclopedic knowledge to the mix improved the results further, by filling in gaps for WordNet, and extracting information particular to PMW. We plan to expand on this, and find methods to extract more such features automatically, without manually provided clues.

For a more comprehensive treatment of metonymies one must take into consideration not only local context but also discourse relations. A possible avenue of research is to build upon coreference resolution systems, and use the mentions they detect and link to each other in a manner similar to using grammatical information and grammatically related words to determine constraints from a larger context. Determining the link between two mentions in a text can take advantage of encyclopedic knowledge, and the system's ability to infer the connection between the mentions.

There is much work on unsupervised word sense disambiguation. Working with untagged data gives a system access to a much larger information base. Since selectional preferences acquired from sense-untagged corpora have worked well for the metonymy resolution task, we plan to push further towards unsupervised metonymy resolution, putting to use the lessons learned from unsupervised WSD.

Abstract

In the early days of email, widely-used conventions for indicating quoted reply content and email signatures made it easy to segment email messages into their functional parts. Today, the explosion of different email formats and styles, coupled with the ad hoc ways in which people vary the structure and layout of their messages, means that simple techniques for identifying quoted replies that used to yield 95% accuracy now find less than 10% of such content. In this paper, we describe Zebra, an SVM-based system for segmenting the body text of email messages into nine zone types based on graphic, orthographic and lexical cues. Zebra performs this task with an accuracy of 87.01%; when the number of zones is abstracted to two or three zone classes, this increases to 93.60% and 91.53% respectively.

1 Introduction

Email message bodies consist of different functional parts such as email signatures, quoted reply content and advertising content. We refer to these as **email zones**. Many language processing tools stand to benefit from better knowledge of this message structure, facilitating focus on relevant content in specific parts of a message. In particular, access to zone information would allow email classification, summarisation and analysis tools to separate or filter out 'noise' and focus on the content in specific zones of a message that are relevant to the application at hand. Email contact mining tools such as that developed by Culotta et al. (2004), for example, might access the email signature zone, while tools that attempt to identify tasks or action items in email (e.g., (Bellotti et al., 2003; Corston-Oliver et al., 2004; Bennett and Carbonell, 2007; Lampert et al., 2007)) might restrict themselves to the sender-authored and forwarded content. Despite previous work on this problem, there are no available tools that can reliably extract or identify the different functional zones of an email message.

While there is no agreed standard set of email zones, there are clearly different functional parts within the body text of email messages. For example, the content of an email disclaimer is functionally different from the sender-authored content and from the quoted reply content automatically included from previous messages in the thread of conversation. Of course, there are different distinctions that can be drawn between zones; in this paper we explore several different categorisations based on our proposed set of nine underlying email zones.

Although we focus on content in the body of email messages, we recognise the presence of useful information in the semi-structured headers, and indeed make use of header information such as sender and recipient names in segmenting the unstructured body text.

Segmenting email messages into zones is a challenging task. Accurate segmentation is hampered by the lack of standard syntax used by different email clients to indicate different message parts, and by the ad hoc ways in which people vary the structure and layout of their messages. When replying to a message, for example, it is often useful to include all or part of the original message that is being replied to. Different email clients indicate quoted material in different ways. By default, some prefix every line of the quoted message with a character such as '>' or '|', while others indent the quoted content or insert the quoted message unmodified, prefixed by a message header. Sometimes the new content is above the quoted content (a style known as 'top-posting'); in other cases, the new content may appear after the quoted

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 919–928,
Singapore, 6-7 August 2009.

content (bottom-posting) or interleaved with the quoted content (inline replying). Confounding the issue further is that users are able to configure their email client to suit their individual tastes, and can change both the syntax of quoting and their quoting style (top, bottom or inline replying) on a per-message basis.

To address these challenges, in this paper we describe Zebra, our email zone classification system. First we describe how Zebra builds and improves on previous work in Section 2. Section 3 then presents our set of email zones, along with details of the email data we use for system training and experiments. In Section 4 we describe two approaches to zone classification, one that is line-based and one that is fragment-based. The performance of Zebra across two, three and nine email zone classification tasks is presented and analysed in Section 5.

2 Related Work

Segmenting email messages into zones requires both text segmentation and text classification. The main focus of most work on text segmentation is topic-based segmentation of news text (e.g., (Hearst, 1997; Beeferman et al., 1997)), but there have been some previous attempts at identifying functional zones in email messages.

Chen et al. (1999) looked at both linguistic and two-dimensional layout cues for extracting structured content from email signature zones in email messages. The focus of their work was on extracting information from already identified signature blocks using a combination of two-dimensional structural analysis and one-dimensional grammatical constraints; the intended application domain was as a component in a system for email text-to-speech rendering. The authors claim that their system can be modified to also identify signature blocks within email messages, but their system performs this task with a recall of only 53%. No attempt is made to identify functional zones other than email signatures.

Carvalho and Cohen's (2004) Jangada system attempted to identify email signatures within plain text email messages and to extract email signatures and reply lines. Unfortunately, the 20 Newsgroups corpus[1] they worked with contains 15-year-old Usenet messages which are much more homogeneous in their syntax than contemporary email, particularly in terms of how quoted text from previous messages is indicated. As a result, using a very simple metric (a line-initial '>' character) to identify reply lines achieves more than 95% accuracy. In contrast, this same simple metric applied to the Enron email data we annotated detects less than 10% of actual reply or forward lines.

Usenet messages are also markedly different from contemporary email when it comes to email signatures. Most Usenet clients produced messages which conformed to RFC3676 (Gellens, 2004), a standard that formalised a "long-standing convention in Usenet news ... of using two hyphens -- as the separator line between the body and the signature of a message." Unfortunately, this convention has long since ceased to be observed in email messages. Carvalho and Cohen's email signature detection approach also benefits greatly from a simplifying assumption that signatures are found in the last 10 lines of an email message. While this holds true for their Usenet message data, it is no longer the case for contemporary email.

In attempting to use Carvalho and Cohen's system to identify signature blocks and reply lines in our own work, we identified similar shortcomings to those noted by Estival et al. (2007). In particular, Jangada did not accurately identify forwarded or reply content in email data from the Enron email corpus. We believe that the use of older Usenet-style messages to train Jangada is a significant factor in the systematic errors the system makes in failing to identify quoted reply, forwarded and signature content in messages formatted in the range of message formats and styles popularised by Microsoft Outlook. These errors are a fundamental problem with Jangada, especially since Outlook is the most common client used to compose messages in our annotated email collection drawn from the Enron corpus. More generally, we note that Outlook is the most popular email client in current use, with an estimated 350–400 million users worldwide,[2] representing anywhere up to 40% of all email users.[3]

More recently, as part of their work on profiling

[3] http://www.campaignmonitor.com/stats/email-clients/

authors of email messages, Estival et al. (2007) classified email bodies into five email zones. Their paper does not provide results for five-zone classification, but they report accuracy of 88.16% using a CRF classifier to distinguish three zones: reply, author and signature. We use their classification scheme as the starting point for our own set of email zones.

3 Email Zones

As noted earlier, we refer to the different functional components of email messages as **email zones**. The zones we propose refine and extend the five categories — *Author Text*, *Signature*, *Advertisement* (automatically appended advertising), *Quoted Text* (extended quotations such as song lyrics or poems), and *Reply Lines* (including forwarded and reply text) — identified by Estival et al. (2007).

We consider that each line of text in the body of an email message belongs to one of nine more fine-grained email zones. We intend our nine email zones to be abstracted and adapted to suit different tasks. To illustrate, we present the zones below abstracted into three classes: sender-authored content, boilerplate content, and content quoted from other conversations. This is the zone partition we use to generate the three-zone results reported in Section 5. This categorisation is useful for problems such as finding action items in email messages: such detection tools would look in text from the sender-authored message zones for new action item information, and could also look in quoted conversation content to link new action item information (such as reported completions) to previous action item content.

Our nine email zones can also be reduced to a binary scheme to distinguish text authored by the sender from text authored by others. This distinction is useful for problems such as author attribution or profiling tasks. In this two-class case, the sender-authored zones would be *Author*, *Greeting*, *Signoff* and *Signature*, while the other-authored zones would be *Reply*, *Forward*, *Disclaimer*, *Advertising* and *Attachment*. This is the partition of zones we use in our two-zone experiments reported in Section 5.

3.1 Sender Zones

Sender zones contain text written by the current email sender. The *Greeting* and *Signoff* zones are sub-zones of the *Author* zone, usually appearing as the first and last items respectively in the *Author* zone. Thus, our proposed sender zones are:

1. **Author:** New content from the current email sender. This specifically excludes any text authored by the sender that is included from previous messages.

2. **Greeting:** Terms of address and recipient names at the beginning of a message (e.g., *Dear/Hi/Hey Noam*).

3. **Signoff:** The message closing (e.g., *Thanks/Cheers/Regards, John*).

3.2 Quoted Conversation Zones

Quoted conversation zones include both content quoted in reply to previous messages in the same conversation thread and forwarded content from other conversations.[4] Our quoted conversation zones are:

4. **Reply:** Content quoted from a previous message in the same conversation thread, including any embedded signatures, attachments, advertising, disclaimers, author content and forwarded content. Content in a reply content zone may include previously sent content authored by the current sender.

5. **Forward:** Content from an email message outside the current conversation thread that has been forwarded by the current email sender, including any embedded signatures, attachments, advertising, disclaimers, author content and reply content.

3.3 Boilerplate Zones

Boilerplate zones contain content that is reused without modification across multiple email messages. Our proposed boilerplate zones are:

6. **Signature:** Content containing contact or other information that is automatically inserted in a message. In contrast to disclaimer or advertising content, signature content is usually templated content written once by the email author, and automatically or semi-automatically included in email messages. A

[4] Although we recognise the need for the *Quoted Text* zone proposed by Estival et al. (2007), no such data occurs in our collection of annotated email messages. We therefore omit this zone from our current set.

user may also use a *Signature* in place of a *Signoff*; in such cases, we still mark the text as a *Signature*.

7. **Advertising:** Advertising material in an email message. Such material often appears at the end of a message (e.g., *Do you Yahoo!?*), but may also appear prefixed or inline with the content of the message, (e.g., in sponsored mailing lists).

8. **Disclaimer:** Legal disclaimers and privacy statements, often automatically appended.

9. **Attachment:** Automated text indicating or referring to attached documents, such as that shown in line 16 of Figure 1. Note that this zone does not apply to manually authored reference to attachments, nor to the actual content of attachments (which we do not classify).

3.4 Email Data and Annotation

The training data for our zone classifier consists of 11881 annotated lines from almost 400 email messages drawn at random from the Enron email corpus (Klimt and Yang, 2004).[5] We use the database dump of the corpus released by Andrew Fiore and Jeff Heer.[6] This version of the corpus has been processed to remove duplicate messages and to normalise sender and recipient names, resulting in just over 250,000 email messages. No attachments are included. Following Estival et al. (2007), we used only a single annotator since the task revealed itself to be relatively uncontroversial. Each line in the body text of selected messages was marked by the annotator (one of the authors) as belonging to one of the nine zones. After removing blank lines, which we do not attempt to classify, we are left with 7922 annotated lines as training data for Zebra. The frequency of each zone within this annotated dataset is shown in Table 3.

Figure 1 shows an example of an email message with each line annotated with the appropriate email zone. Two zone annotations are shown for each line (in separate columns), one using the nine fine-grained zones and the second using the abstracted three-zone scheme described in Section 3. Note, however, that not all of the nine fine-grained zones, nor all of the three abstracted zones, are actually present in this particular message.

[5]This annotated dataset is available from http://zebra.thoughtlets.org/.

[6]http://bailando.sims.berkeley.edu/enron/enron.sql.gz

4 Zone Segmentation and Classification

Our email zone classification system is based around an SVM classifier using features that capture graphic, orthographic and lexical information about the content of an email message.

To classify the zones in an email message, we experimented with two approaches. The first employs a two-stage approach that segments a message into zone fragments and then classifies those fragments. Our second method simply classifies lines independently, returning a classification for each non-blank line in an email message. Our hypothesis was that classifying larger text fragments would lead to better performance due to the text fragments containing more cues about the zone type.

4.1 Zone Fragment Classification

Zone fragment classification is a two-step process. First it predicts the zone boundaries using a simple heuristic, then it classifies the resulting *zone fragments*, the sets of content lines that lie between these hypothesised boundaries.

In order to determine how well we can detect zone boundaries, we first need to establish the correct zone boundaries in our collection of zone-annotated email messages.

4.1.1 Zone Boundaries

A zone boundary is defined as a continuous collection of one or more lines that separate two different email zones. Lines that separate two zones and are blank, contain only whitespace or contain only punctuation characters are called **buffer lines**.

Since classification of blank lines between zones is often ambiguous, empty or whitespace-only buffer lines are not included as content in any zone, and thus are not classified. Instead, they are treated as strictly part of the zone boundary. In Figure 1, these lines are shown without any zone annotation. Zone boundary lines that are included as content in a zone have their zone annotation styled in bold and underlined. The important point here is that zone boundaries are specific to a zone classification scheme. For nine-zone classification of the message in Figure 1, there are six zone boundaries: line 2, lines 10–11, line 12, line 15, lines 17–20, and lines 30–33. For three-zone clas-

Figure 1: An example email message marked with both nine- and three-zone annotations.

sification, the only zone boundary consists of line 12, separating the sender and boilerplate zones.

Based on these definitions, there are three different types of zone boundaries:

1. **Blank boundaries** contain only empty or whitespace-only buffer lines. Lines in these zone boundaries are strictly separate from the zone content. An example is Line 12 in Figure 1, for both the three- and nine-zone classification.
2. **Separator boundaries** contain only buffer lines, but must contain at least one punctuation-character buffer line that is retained as content in one or both zones. In Figure 1, an example is the zone boundary containing lines 17–20 that separates the *Attachment* and *Disclaimer* zones for nine-zone classification, since line 20 is retained as part of the *Disclaimer* zone content.
3. **Adjoining boundaries** consist of the last content line of the earlier zone and the first content line of the following zone. These boundaries occur where no buffer lines exist between the two zones. An example is the zone boundary containing lines 10 and 11 that separates the *Author* and *Signoff* zones in Figure 1 for nine-zone classification.

4.1.2 Hypothesising Zone Boundaries

To identify zone boundaries in unannotated email data, we employ a very simple heuristic approach. Specifically, we consider every line in the body of an email message that matches any of the following criteria to be a zone boundary:

1. A blank line;
2. A line containing only whitespace; or
3. A line beginning with four or more repeated punctuation characters, optionally prefixed by whitespace.

Our efforts to apply more sophisticated machine-learning techniques to identifying zone boundaries could not match the 90.15% recall achieved by this simple heuristic. The boundaries missed by the simple heuristic are all **adjoining boundaries**, where two zones are not separated by any buffer lines. An example of a boundary that is not detected by our heuristic is the zone boundary between the *Author* and *Signoff* zones in Figure 1 formed by lines 10 and 11.

Obviously, our simple boundary heuristic detects **actual boundaries** as well as **spurious boundaries** that do not actually separate different email zones. Unsurprisingly, the number of spurious boundaries is large. The precision of our simple heuristic across our annotated set of email messages is 22.5%, meaning that less than 1 in 4 hypothesised zone boundaries is an actual boundary. The underlying email zones average more than 12 lines in length, including just over 8 lines of non-blank content. Due to the number of spurious boundaries, fragments contain less than half this amount — approximately 3 lines of non-blank content on average. One of the most common types of spurious boundaries detected are the blank lines that frequently separate paragraphs within a single zone.

For three-zone classification, the set of predicted boundaries remains the same, but there are less actual boundaries to find, so recall increases to 96.3%. However, because many boundaries from the nine-zone classification are not boundaries for the three-zone classification, precision decreases to 14.7%.

4.1.3 Classifying Zone Fragments

Having segmented the email message into candidate zone fragments, we classify these fragments using the SMO implementation provided by Weka (Witten and Frank, 2005) with the features described in Section 4.3.

Although our boundary detection heuristic has better than 90% recall, the small number of actual boundaries that are not detected result in some zone fragments containing lines from more than one underlying email zone. In these cases, we consider the mode of all annotation values for lines in the fragment (i.e., the most frequent zone annotation) to be the gold-standard zone type for the fragment. This, of course, may mean that we somewhat unfairly penalise the accuracy of our automated classification when Zebra detects a zone that is indeed present in the fragment, but is not the most frequent zone.

4.2 Line Classification

Our line-based classification approach simply extracts all non-blank lines from an email message and classifies lines one-by-one, using the same features as for fragment-based classification. This approach is the same as the signature and reply line classification approach used by Carvalho and Cohen (2004).

4.3 Classification Features

We use a variety of graphic, orthographic and lexical features for classification in Zebra. The same features are applied in both the line-based and the fragment-based zone classification (to either individual lines or zone fragments). In the description of our features, we refer to both single lines and zone fragments (collections of contiguous lines) as **text fragments**.

4.3.1 Graphic Features

Our graphic features capture information about the presentation and layout of text in an email message, independent of the actual words used. This information is a crucial source of information for identifying zones. Such information includes how the text is organised and ordered, as well as the 'shape' of the text. The specific features we employ are:

- the number of words in the text fragment;
- the number of Unicode code points (i.e., characters) in the text fragment;
- the start position of the text fragment (equal to one for the first line in the message, two for the second line and increasing monotonically

through the message; we also normalise the result for message length);
- the end position of the text fragment (calculated as above and again normalised for message length);
- the average line length (in characters) within the text fragment (equal to the line length for line-based text fragments);
- the length of the text fragment (in characters) relative to the previous fragment;
- the length of the text fragment (in characters) relative to the following fragment;
- the number of blank lines preceding the text fragment; and
- the number of blank lines following the text fragment.

4.3.2 Orthographic Features

Our orthographic features capture information about the use of distinctive characters or character sequences including punctuation, capital letters and numbers. Like our graphic features, orthographic features tend to be independent of the words used in an email message. The specific orthographic features we employ include:

- whether all lines start with the same character (e.g., '>');
- whether a prior text fragment in the message contains a quoted header;
- whether a prior text fragment in the message contains repeated punctuation characters;
- whether the text fragment contains a URL;
- whether the text fragment contains an email address;
- whether the text fragment contains a sequence of four or more digits;
- the number of capitalised words in the text fragment;
- the percentage of capitalised words in the text fragment;
- the number of non-alpha-numeric characters in the text fragment;
- the percentage of non-alpha-numeric characters in the text fragment;
- the number of numeric characters in the text fragment;
- the percentage of numeric characters in the text fragment;
- whether the message subject line contains a reply syntax marker such as *Re:* ; and
- whether the message subject line contains a forward syntax marker such as *Fw:*.

4.3.3 Lexical Features

Finally, our lexical features capture information about the words used in the email text. We use unigrams to capture information about the vocabulary and word bigram features to capture short range word order information. More specifically, the lexical features we apply to each text fragment include:

- each word unigram, calculated with a minimum frequency threshold cutoff of three, represented as a separate binary feature;
- each word bigram, calculated with a minimum frequency threshold cutoff of three, represented as a separate binary feature;
- whether the text fragment contains the sender's name;
- whether a prior text fragment in the message contains the sender's name;
- whether the text fragment contains the sender's initials; and
- whether the text fragment contains a recipient's name.

Features that look for instances of sender or recipient names are less likely to be specific to a particular business or email domain. These features use regular expressions to find name occurrences, based on semi-structured information in the email message headers. First, we extract and normalise the names from the email headers to identify the relevant person's given name and surname. Our features then capture whether one or both of the given name or surname are present in the current text fragment. Features which detect user initials make use of the same name normalisation code to retrieve a canonical form of the user's name, from which their initials are derived.

5 Results and Discussion

Table 1 shows Zebra's accuracy in classifying email zones. The results are calculated using 10-fold cross-validation. Accuracy is shown for three tasks — nine-, three- and two-zone classification — using both line and zone-fragment classification. Performance is compared against a majority class baseline in each case.

Zebra's performance compares favourably with previously published results. While it is difficult to

	2 Zones		3 Zones		9 Zones	
	Zebra	Baseline	Zebra	Baseline	Zebra	Baseline
Lines	93.60%	61.14%	91.53%	58.55%	87.01%	30.94%
Fragments	92.09%	62.18%	91.37%	59.44%	86.45%	30.36%

Table 1: Classification accuracy compared against a majority baseline

	2 Zones		3 Zones		9 Zones	
	Zebra	Baseline	Zebra	Baseline	Zebra	Baseline
Lines	90.62%	61.14%	86.56%	58.55%	81.05%	30.94%
Fragments	91.14%	62.18%	89.44%	59.44%	82.55%	30.36%

Table 2: Classification accuracy, without word n-gram features, compared against a majority baseline

directly compare, since not all systems are freely available and they are not trained or tested over the same data, our three-zone classification (identifying sender, boilerplate and quoted reply content) is very similar to the three-zone task for which (Estival et al., 2007) report 88.16% accuracy for their system and 64.22% accuracy using Carvalho and Cohen's Jangada system. Zebra outperforms both, achieving 91.53% accuracy using a line-based approach. In the two-zone task, where we attempt to identify sender-authored lines, Zebra achieves 93.60% accuracy and an F-measure of 0.918, exceeding the 0.907 F-measure reported for Estival et al.'s system tuned for exactly this task.

Interestingly, the line-based approach provides slightly better performance than the fragment-based approach for each of the two-zone, three-zone and nine-zone classification tasks. As noted earlier, our original hypothesis was that zone fragments would contain more information about the sequence and text shape of the original message, and that this would lead to better performance for fragment-based classification.

When we restrict our feature set to those that look only at the text of the line or zone fragment, the fragment-based approach does perform better than the line-based one. Using only word unigram features, for example, our fragment classifier achieves 78.7% accuracy. Using the same features, the line-based classifier achieves only 57.5% accuracy. When we add further features that capture sequence and shape information from outside the text fragment being classified (e.g., the length of a text segment compared to the text segment before and after, and whether a segment occurs after another segment containing repeated punctuation or the sender's name), the line-based approach achieves a greater increase in accuracy than the fragment-based approach. This presumably is because individual lines intrinsically have less information about the message context, and so benefit more from the information added by the new features.

We also experimented with removing all word unigram and bigram features to explore the classifier's portability across different domains. This removed all vocabulary and word order information from our feature set. In doing so, our feature set was reduced to less than thirty features, consisting of mostly graphic and orthographic information. The few remaining lexical features captured only the presence of sender and recipient names, which are independent of any particular email domain. As expected, performance did drop, but not dramatically. Table 2 shows that average performance without n-grams (across two-, three- and nine-zone tasks) for line-based classification drops by 4.67%. In contrast, fragment-based classification accuracy drops by less than half this amount — an average of 2.26%. This suggests that, as we originally hypothesised, there are additional non-lexical cues in zone fragments that give information about the zone type. This makes the zone fragment approach potentially more portable for use across email data from different enterprise domains.

Of course, classification accuracy gives only a limited picture of Zebra's performance. Table 4 shows precision and recall results for each zone in the nine-zone line-based classification task. Per-

Table 3: Confusion Matrix for 9 Zone Line Classification

formance clearly varies significantly across the different zones. For *Author*, *Greeting*, *Reply* and *Forward* zones, performance is good, with F-measure > 0.8. This is encouraging, given that many email tools, such as action-item detection and email summarisation would benefit from an ability to separate author content from reply content and forwarded content. The *Advertising*, *Signature* and *Disclaimer* zones show the poorest performance, particularly in terms of Recall. The *Advertising* and *Disclaimer* zones are almost certainly hindered by a lack of training data; they are two of the smallest zones in terms of number of lines of training data. The relatively poor *Signature* class performance is more interesting. Given the potential confusion between *Signoff* content and *Signature*s that function as *Signoff*s, one might expect confusion between *Signoff* and *Signature* zones, but Table 3 shows this is not the case. Instead, there is significant confusion between *Signature* and *Author* content, with almost 25% of *Signature* lines misclassified as *Author* lines. When word n-grams are removed from the feature set, the number of these misclassifications increases to almost 50%. These results reinforce our observation that the task of email signature extraction is much more difficult that it was in the days of Usenet messages.

6 Conclusion

Identifying functional zones in email messages is a challenging task, due in large part to the diversity in syntax used by different email software, and the dynamic manner in which people employ different styles in authoring email messages. Zebra, our system for segmenting and classifying email message text into functional zones, achieves performance that exceeds comparable systems, and that is at a level to be practically useful to email researchers and system builders. In addition to releasing our annotated email dataset, the Zebra system will also be available for others to use[7].

Because we employ a non-sequential learning algorithm, we encode sequence information into the feature set. In future work, we plan to determine the effectiveness of using a sequential learning algorithm like Conditional Random Fields (CRF). We note, however, that Carvalho and Cohen (2004) demonstrate that using a non-sequential learning algorithm with sequential features, as we do, has the potential to meet or exceed the performance of sequential learning algorithms.

Abstract

This paper presents a new method of developing a large-scale hyponymy relation database by combining Wikipedia and other Web documents. We attach new words to the hyponymy database extracted from Wikipedia by using distributional similarity calculated from documents on the Web. For a given target word, our algorithm first finds *k* similar words from the Wikipedia database. Then, the hypernyms of these *k* similar words are assigned scores by considering the distributional similarities and hierarchical distances in the Wikipedia database. Finally, new hyponymy relations are output according to the scores. In this paper, we tested two distributional similarities. One is based on raw verb-noun dependencies (which we call "RVD"), and the other is based on a large-scale clustering of verb-noun dependencies (called "CVD"). Our method achieved an attachment accuracy of 91.0% for the top 10,000 relations, and an attachment accuracy of 74.5% for the top 100,000 relations when using CVD. This was a far better outcome compared to the other baseline approaches. Excluding the region that had very high scores, CVD was found to be more effective than RVD. We also confirmed that most relations extracted by our method cannot be extracted merely by applying the well-known lexico-syntactic patterns to Web documents.

1 Introduction

Large-scale taxonomies such as WordNet (Fellbaum 1998) play an important role in information extraction and question answering. However, extremely high costs are borne to manually enlarge and maintain such taxonomies. Thus, applications using these taxonomies tend to face the drawback of data sparseness. This paper presents a new method for discovering a large set of hyponymy relations. Here, a word[1] X is regarded as a hypernym of a word Y if Y is a kind of X or Y is an instance of X. We are able to generate large-scale hyponymy relations by attaching new words to the hyponymy database extracted from Wikipedia (referred to as "Wikipedia relation database") by using distributional similarity calculated from Web documents. Relations extracted from Wikipedia are relatively clean. On the other hand, reliable distributional similarity can be calculated using a large number of documents on the Web. In this paper, we combine the advantages of these two resources.

Using distributional similarity, our algorithm first computes *k* similar words for a target word. Then, each *k* similar word assigns a score to its ancestors in the hierarchical structures of the Wikipedia relation database. The hypernym that has the highest score for the target word is selected as the hypernym of the target word. Figure 1 is an overview of the proposed approach.

In the experiment, we extracted hypernyms for approximately 670,000 target words that are not included in the Wikipedia relation database but are found on the Web. We tested two distributional similarities: one based on raw verb-noun dependencies (RVD) and the other based on a large-scale clustering of verb-noun dependencies (CVD). The experimental results showed that the proposed methods were more effective than the other baseline approaches. In addition, we confirmed that most of the relations extracted by our method could not be extracted using the lexico-syntactic pattern-based method.

In the remainder of this paper, we first intro-

[1] In this paper, we use the term "word" for both "a single-word word" and "a multi-word word."

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 929–937,
Singapore, 6-7 August 2009.

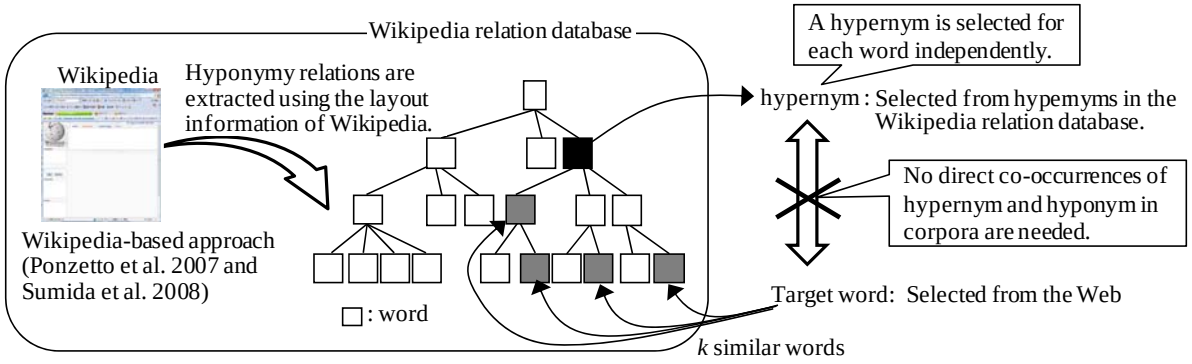

Figure 1: Overview of the proposed approach.

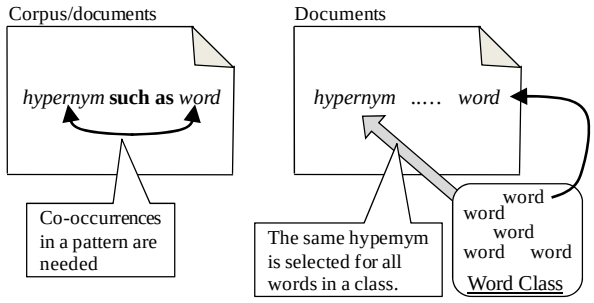
duce some related works in Section 2. Section 3 describes the Wikipedia relation database. Section 4 describes the distributional similarity calculated by the two methods. In Section 5, we describe a method to discover an appropriate hypernym for each target word. The experimental results are presented in Section 6 before concluding the paper in Section 7.

2 Related Works

Most previous researchers have relied on lexico-syntactic patterns for hyponymy acquisition. Lexico-syntactic patterns were first used by Hearst (1992). The patterns used by her included "NP_0 such as NP_1," in which NP_0 is a hypernym of NP_1. Using these patterns as seeds, Hearst discovered new patterns by which to semi-automatically extract hyponymy relations. Pantel et al. (2004a) proposed a method to automatically discover the patterns using a minimal edit distance. Ando et al. (2003) applied predefined lexico-syntactic patterns to Japanese news articles. Snow et al. (2005) generalized these lexico-syntactic pattern-based methods by using dependency path features for machine learning. Then, they extended the framework such that this method was capable of making use of heterogenous evidence (Snow et al. 2006). These pattern-based methods require the co-occurrences of a target word and the hypernym in a document. It should be noted that the requirement of such co-occurrences actually poses a problem when we extract a large set of hyponymy relations since they are not frequently observed (Shinzato et al. 2004, Pantel et al. 2004b).

Clustering-based methods have been proposed as another approach. Caraballo (1999), Pantel et al. (2004b), and Shinzato et al. (2004) proposed a method to find a common hypernym for word classes, which are automatically constructed using some measures of word similarities or hierarchical structures in HTML documents. Etzioni et al. (2005) used both a pattern-based approach and a clustering-based approach. The required amount of co-occurrences is significantly reduced due to class-based generalization processes. Note that these clustering-based methods obtain the same hypernym for all the words in a particular class. This causes a problem for selecting an appropriate hypernym for each word in the case when the granularity or the construction of the classes is incorrect. Figure 2 shows the drawbacks of the existing approaches.



Pattern-based method (Hearst 1992, Pantel et al. 2004a, Ando et al. 2003, Snow et al. 2005, Snow et al. 2006, and Etzioni et al. 2005)

Clustering-based method (Caraballo 1999, Pantel et al. 2004b, Shinzato et al. 2004, and Etzioni et al. 2005)

Figure 2: Drawbacks in existing approaches for hyponymy acquisition.

Ponzetto et al. (2007) and Sumida et al. (2008) proposed a method for acquiring hyponymy relations from Wikipedia. This Wikipedia-based approach can extract a large volume of hyponymy relations with high accuracy. However, it is also true that this approach does not account for many words that usually appear in Web documents; this could be because of the unbalanced topics in Wikipedia or merely because of the incomplete coverage of articles on Wikipedia. Our method can target words that frequently appear on the Web but are not included in the Wikipedia relation database, thus making the results of the Wikipedia-based approach richer and more balanced. Our approach uses distributional similari-

ty, which is computed based on the noun-verb dependency profiles on the Web. The use of distributional similarity resembles the clustering-based approach; however, our method can select a hypernym for each word independently, and it does not suffer from class granularity mismatch or the low quality of classes. In addition, our approach exploits the hierarchical structures of the Wikipedia hypernym relations.

3 Wikipedia Relation Database

Our Wikipedia relation database is based on the extraction method of Sumida et al. (2008). They proposed a method of automatically acquiring hyponymy relations by focusing on the hierarchical layout of articles on Wikipedia. By way of an example, Figure 3 shows part of the source code clipped from the article titled "Penguin." An article has hierarchical structures composed of titles, sections, itemizations, etc. The entire article is divided into sections titled "Anatomy," "Mating habits," "Systematics and evolution," "Penguins in popular culture," and so on. The section "Systematics and evolution" has a subsection "Systematics," which is further divided into "Aptenodytes," "Eudyptes," and so on. Some of these section-subsection relations can be regarded as valid hyponymy relations. In this article, relations such as the one between "Aptenodytes" and "Emperor Penguin" and that between "Book" and "Penguins of the World" are valid hyponymy relations.

First, Sumida et al. (2008) extracted hyponymy relation candidates from hierarchical structures on Wikipedia. Then, they selected proper hyponymy relations using a support vector machine classifier. They used several kinds of features for the hyponymy relation candidate, such as a POS tag for each word, the appearance of morphemes of each word, the distance between two words in the hierarchical structures of Wikipedia, and the last character of each word. As a result of their experiments, approximately 2.4 million hyponymy relations in Japanese were extracted, with a precision rate of 90.1%.

Compared to the traditional taxonomies, these extracted hyponymy relations have the following characteristics (Fellbaum 1998, Bond et al. 2008).

(a) The database includes a more extensive vocabulary.
(b) The database includes a large number of named entities.

Popular Japanese taxonomies *GoiTaikei* (Ikehara et al. 1997) and *Bunrui-Goi-Hyo* (1996)

```
'''Penguins''' are a group of
[[Aquatic animal|aquatic]],
[[flightless bird]]s.

```

Figure 3: A part of source code clipped from the article "Penguin" in Wikipedia.

contain approximately 300,000 words and 96,000 words, respectively. In contrast, the extracted hyponymy relations contain approximately 1.2 million hyponyms and are undoubtedly much larger than the existing taxonomies. Another difference is that since Wikipedia covers a large number of named entities, the extracted hyponymy relations also contain a large number of named entities.

Note that the extracted relations have a hierarchical structure because one hypernym of a certain word may also be the hyponym of another hypernym. However, we observed that the depth of the hierarchy, on an average, is extremely shallow. To make the hierarchy appropriate for our method, we extended these into a deeper hierarchical structure. The extracted relations include many compound nouns as hypernyms, and we decomposed a compound noun into a sequence of nouns using a morphological analyzer. Since Japanese is a head-final language, the suffix of a noun sequence becomes the hypernym of the original compound noun if the suffix forms another valid compound noun. We extracted suffixes of compound nouns and manually checked whether they were valid compound nouns; then, we constructed a hierarchy of compound nouns. The hierarchy can be extended such that it includes the hyponyms of the original hypernym and the resulting hierarchy constitutes a hierarchical taxonomy. We use this hierarchical taxonomy as a target for expansion.[2]

[2] Note that this modification was performed as part of another project of ours aimed at constructing a large-scale and clean hypernym knowledge base by human annotation. We do not think this cost is directly relevant to the method proposed here.

4 Distributional Similarity

The distributional hypothesis states that words that occur in similar contexts tend to be semantically similar (Harris 1985). In this section, we first introduce distributional similarity based on raw verb-noun dependencies (RVD). To avoid the sparseness problem of the co-occurrence of verb-noun dependencies, we also use distributional similarity based on a large-scale clustering of verb-noun dependencies (CVD).

In the experiment mentioned in the following section, we used the TSUBAKI corpus (Shinzato et al. 2008) to calculate distributional similarity. This corpus provides a collection of 100 million Japanese Web pages containing 6×10^9 sentences.

4.1 Distributional Similarity Based on RVD

When calculating the distributional similarity based on RVD, we use the triple <*v*, *rel*, *n*>, where *v* is a verb, *n* is a noun phrase, and *rel* stands for the relation between *v* and *n*. In Japanese, a relation *rel* is represented by postpositions attached to *n* and the phrase composed of *n* and *rel* modifies *v*. Each triple is divided into two parts. The first is <*v*, *rel*> and the second is *n*. Then, we consider the conditional probability of occurrence of the pair <*v*, *rel*>: *P*(<*v*, *rel*>|*n*). *P*(<*v*, *rel*>|*n*) can be regarded as the distribution of the grammatical contexts of the noun phrase *n*. The distributional similarity can be defined as the distance between these distributions. There are several kinds of functions for evaluating the distance between two distributions (Lee 1999). Our method uses the Jensen-Shannon divergence. The Jensen-Shannon divergence between two probability distributions, $P(\cdot \mid n_1)$ and $P(\cdot \mid n_2)$, can be calculated as follows:

$$\begin{aligned} & D_{JS}(P(\cdot \mid n_1) \,\|\, P(\cdot \mid n_2)) \\ & = \frac{1}{2}(D_{KL}(P(\cdot \mid n_1) \,\|\, \frac{P(\cdot \mid n_1) + P(\cdot \mid n_2)}{2}) \\ & + D_{KL}(P(\cdot \mid n_2) \,\|\, \frac{P(\cdot \mid n_1) + P(\cdot \mid n_2)}{2})), \end{aligned}$$

where D_{KL} indicates the Kullback-Leibler divergence and is defined as follows:

$$D_{KL}(P(\cdot \mid n_1) \,\|\, P(\cdot \mid n_2)) = \sum P(\cdot \mid n_1) \log \frac{P(\cdot \mid n_1)}{P(\cdot \mid n_2)}.$$

Finally, the distributional similarity between two words, n_1 and n_2, is defined as follows:

$$sim(n_1, n_2) = 1 - D_{JS}(P(\cdot \mid n_1) \,\|\, P(\cdot \mid n_2)).$$

This similarity assumes a value from 0 to 1. If two words are similar, the value will be close to 1; if two words have entirely different meanings, the value will be 0.

In the experiment, we used 1,000,000 noun phrases and 100,000 pairs of verbs and postpositions to calculate the probability *P*(<*v*, *rel*>|*n*) from the dependency relations extracted from the above-mentioned Web corpus (Shinzato et al. 2008). The probabilities are computed using the following equation by modifying for the frequency using the log function:

$$P(< v, rel > \mid n) = \frac{\log(f(< v, rel, n >)) + 1}{\sum_{< v, rel > \in D} \log(f(< v, rel, n >) + 1} \quad \text{if } f(< v, rel, n >) > 0,$$

where *f*(<*v*, *rel*, *n*>) is the frequency of a triple <*v*, *rel*, *n*> and *D* is the set defined as { <*v*, *rel* > | *f*(<*v*, *rel*, *n*>) > 0 }. In the case of *f*(<*v*, *rel*, *n*>) = 0, P(<*v*, *rel*>|*n*) is set to 0.

Instead of using the observed frequency directly as in the usual maximum likelihood estimation, we modified it as above. Although this might seems strange, this kind of modification is common in information retrieval as a term weighing method (Manning et al. 1999) and it is also applied in some studies to yield better word similarities (Terada et al. 2006, Kazama et al. 2009). We also adopted this idea in this study.

4.2 Distributional Similarity Based on CVD

Rooth et al. (1999) and Torisawa (2001) showed that EM-based clustering using verb-noun dependencies can produce semantically clean noun clusters. We exploit these EM-based clustering results as the smoothed contexts for noun *n*. In Torisawa's model (2001), the probability of occurrence of the triple <*v*, *rel*, *n*> is defined as follows:

$$\begin{aligned} & P(< v, rel, n >) \\ & \quad =_{def} \sum_{a \in A} P(< v, rel > \mid a) P(n \mid a) P(a), \end{aligned}$$

where *a* denotes a hidden class of <*v*,*rel*> and *n*. In this equation, the probabilities *P*(<*v*,*rel*>|*a*), *P*(*n*|*a*), and *P*(*a*) cannot be calculated directly because class *a* is not observed in a given corpus. The EM-based clustering method estimates these probabilities using a given corpus. In the E-step,

the probability $P(a|<v,rel>)$ is calculated. In the M-step, the probabilities $P(<v,rel>|a)$, $P(n|a)$, and $P(a)$ are updated to arrive at the maximum likelihood using the results of the E-step. From the results of estimation of this EM-based clustering method, we can obtain the probabilities $P(<v,rel>|a)$, $P(n|a)$, and $P(a)$ for each $<v, rel>$, n, and a. Then, $P(a|n)$ is calculated by the following equation:

$$P(a \mid n) = \frac{P(n \mid a)P(a)}{\sum_{a \in A} P(n \mid a)P(a)}.$$

$P(a|n)$ can be used to find the class of n. For example, the class that has the maximum $P(a|n)$ can be regarded as the class to which n belongs. Noun phrases that occur with similar pairs $<v,rel>$ tend to be classified in the same class.

Kazama et al. (2008) proposed the parallelization of this EM-based clustering with the aim of enabling large-scale clustering and using the resulting clusters in named entity recognition. Kazama et al. (2009) reported the calculation of distributional similarity using the clustering results. The distributional similarity was calculated by the Jensen-Shannon divergence, which was used in this paper. Similar to the case in Kazama et al., we performed word clustering using 1,000,000 noun phrases and 2,000 classes. Note that the frequencies of dependencies were modified with the log function, as in RVD, described in the previous section.

5 Discovering an Appropriate Hypernym for a Target word

In the Wikipedia relation database, there are about 95,000 hypernyms and about 1.2 million hyponyms. In both RVD and CVD, the words used were selected according to the number (the number of kinds, not the frequency) of $<v, rel>$s that n has dependencies in the data. As a result, 1 million words were selected. The number of common words that are also included in the Wikipedia relation database are as follows:

Hypernyms	28,015 (common hypernyms)
Hyponyms	175,022 (common hyponyms)

These common hypernyms become candidates for hypernyms for a target word. On the other hand, the common hyponyms are used as clues for identifying appropriate hypernyms.

In our task, the potential target words are about 810,000 in number and are not included in the Wikipedia relation database. These include some strange words or word phrases that are extracted due to the failure of morphological analysis. We exclude these words using simple rules. Consequently, the number of target words for our process is reduced to about 670,000.

In the following section, we outline the scoring method that uses k similar words to discover an appropriate hypernym for a target word. We also explain several baseline approaches that use distributional similarity.

5.1 Scoring with *k* similar Words

In this approach, we first calculate the similarities between the common hyponyms and a target word and select the k most similar common hyponyms. Here, we use a similarity threshold value S_{min} to avoid the effect of words having lower similarities. If the similarity is less than the threshold value, the word is excluded from the set of k similar words. Next, each k similar word votes a score to its ancestors in the hierarchical structures of the Wikipedia relation database. The score used to vote for a hypernym n_{hyper} is as follows:

$$score(n_{hyper}) = \sum_{n_{hypo} \in Desc(n_{hyper}) \cap ksimilar(n_{trg})} d^{r(n_{hyper}, n_{hypo})-1} \times sim(n_{trg}, n_{hypo}),$$

where n_{trg} is the target word, $Desc(n_{hyper})$ is the descendant of the hypernym n_{hyper}, $ksimilar(n_{trg})$ is the k similar word of n_{trg}, $d^{r(n_{hyper}, n_{hypo})-1}$ is a penalty that depends on the differences in the depth of hierarchy, d is a parameter for the penalty value and has a value between 0 and 1, and $r(n_{trg}, n_{hypo})$ is the difference in the depth of hierarchy between n_{trg} and n_{hypo}. $sim(n_{trg}, n_{hypo})$ is a distributional similarity between n_{trg} and n_{hypo}.

As a result of scoring, each hypernym has a score for the target word. The hypernym that has the highest score for the target word is selected as its hypernym. The hyponymy relations thus produced are ranked according to the scores.

Figure 4 shows an example of the scoring process. In this example, we use *CitroenAX* as the target word whose hypernym will be identified. First, the k similar words are extracted from the common hyponyms in the Wikipedia relation: *Opel Astra*, *TVR Tuscan*, *Mitsubishi Minica*, and *Renault Lutecia* are extracted. Next, each k similar word votes a score to its ancestors. The words *Opel Astra*, *TVR Tuscan*, and *Renault Lutecia* vote to their parent *car* and the word *Mitsubishi*

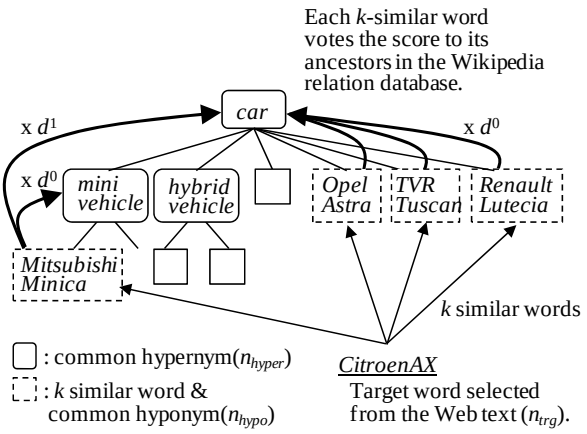

Figure 4: Overview of the scoring process.

Minica votes to its parent *mini-vehicle* and its grandparent *car* with a small penalty. Finally, the hypernym *car*, which has the highest score, is selected as the hypernym of the target word *CitroenAX*.

5.2 Baseline Approaches

Using distributional similarity, we can also develop the following baseline approaches to discover hyponymy relations.

Selecting the hypernym of the most similar hyponym (baseline approach 1)

We use the heuristics that similar words tend to have the same hypernym. In this approach, we first calculate the similarities between the common hyponyms and the target word. The common hyponym most similar to the target word is extracted. Then, the parent of the extracted common hyponym is regarded as the hypernym of the target word. This approach outputs several hypernyms when the most similar hyponym has several hypernyms. This approach can be considered to be the same as the scoring method using k similar words when $k = 1$. We use the distributional similarity between the target word and the most similar hyponym in the Wikipedia relation database as the score for the appropriateness of the resulting hyponymy.

Selecting the most similar hypernym (baseline approach 2)

The distributional similarity between the common hypernym and the target word is calculated. Then, the hypernym that has the highest distributional similarity is regarded as the hypernym of the target word. The similarity is used as the score of the appropriateness of the produced hyponymy.

Scoring based on the average similarity of the hypernym's children (baseline approach 3)

This approach uses the probabilistic distributions of the hypernym's children. We define the probability $P_{child}(\cdot \mid n_{hyper})$ characterized by the children of the hypernym n_{hyper}, as follows:

$$P_{child}(\cdot \mid n_{hyper}) = \frac{\sum_{n_{hypo} \in Ch(n_{hyper})} P(\cdot \mid n_{hypo}) P(n_{hypo})}{\sum_{n_{hypo} \in Ch(n_{hyper})} P(n_{hypo})},$$

where $Ch(n_{hyper})$ is a set of all children of n_{hyper}. Then, distributional similarities between a common hypernym n_{hyper} and the target word n_{hypo} are calculated. The hypernym that has the highest distributional similarity is selected as the hypernym of the word. This distributional similarity is used as the score of the appropriateness of the produced hyponymy.

If a hypernym has only a few children, the reliability of the probabilistic distribution of hypernym defined here will be low because the Wikipedia relation database includes some incorrect relations. For this reason, we use the hypernym only if the number of children it has is more than a threshold value.

6 Experiments

We evaluated our proposed methods by using it in experiments to discover hypernyms from the Wikipedia relation database for the target words extracted from about 670,000 noun phrases.

6.1 Parameter Estimation by Preliminary Experiments

In the proposed methods, there are several parameters. We performed parameter optimization by randomly selecting 694 words as development data in our preliminary experiments. The hypernyms of these words were determined manually. We adjusted the parameters so that each method achieved the best performance for this development data.

The parameters in the scoring method with k similar words were adjusted as follows[3]:

(RVD)

Number of similar words:	$k = 100$.
Similarity threshold:	$S_{min} = 0.05$.
Penalty value for ancestors:	$d = 0.6$.

[3] We tested the parameter values k = {100, 200, 300, 400, 500, 600, 700, 800, 900, 1000}, S_{min}={0, 0.05, 0.1, 0.15, 0.2, 0.25, 0.3, 0.35, 0.4} and d={0.5, 0.55, 0.6, 0.65, 0.7, 0.75, 0.8, 0.85, 0.9, 0.95, 1.0}.

Table 1: Precision of each approach based on the score ranking. CVD represents the method that uses the distributional similarity based on large-scale of clustering of verb-noun dependencies. RVD represents the one based on raw verb-noun dependencies.

	k-similar words (CVD)	*k*-similar words (RVD)	*k*-similar words (CVD, $d = 0$)	Baseline approach 1 (CVD)	Baseline approach 2 (CVD)	Baseline approach 3 (CVD)
1,000	0.940	**1.000**	0.850	0.730	0.290	0.630
10,000	**0.910**	0.875	0.875	0.555	0.300	0.445
100,000	**0.745**	0.710	0.730	0.500	0.280	0.435
670,000	**0.520**	0.500	0.470	0.345	0.115	0.170

(CVD)

Number of similar words: $k = 200$.
Similarity threshold: $S_{min} = 0.3$.
Penalty value for ancestors: $d = 0.6$.

The parameter in baseline approach 3 was adjusted as follows:

Threshold for the number of children: 20.

6.2 Evaluation of the Experimental Results on the Basis of Score Ranking

Using the adjusted parameters, we conducted experiments to extract the hypernym of each target word with the help of the scoring method based on *k* similar words. In these experiments, two kinds of distributional similarity mentioned in Section 4 were exploited individually. The words that were used in the development data were excluded.

We also conducted a comparative experiment in which the parameter value for the penalty of the hierarchal difference, *d*, was set to 0 to clarify the ability of using hierarchal structures in the *k* similar words method. This means each *k* similar word votes only to their parent.

We then judged the quality of each acquired hypernym. The evaluation data sets were sampled from the top 1,000, 10,000, 100,000, and 670,000 results that were ranked according to the score of each method. Then, against 200 samples that were randomly sampled from each set, one of the authors judged whether the hypernym extracted by each method for the target word was correct or not. In this evaluation, if the sentence "*The target word* is a kind of *the hypernym*" or "*The target word* is an instance of *the hypernym*" was consistent, the extracted hyponymy was judged as correct. It should be noted that the outputs of the compared methods are combined and shuffled to enable fair comparison. In addition, baseline approach 1 extracted several hypernyms for the target word. In this case, we judged the hypernym as correct when the case where one of the hypernyms was correct.

The precision of each result is shown in Table 1. The results of the *k* similar words method are far better than those of the other baseline methods. In particular, the *k* similar words method with CVD outperformed the methods of the *k* similar words where the parameter value *d* was set to 0 and the method using RVD except for the top 1,000 results. This means that the use of hierarchal structures and the clustering process for calculating distributional similarity are effective for this task. We confirmed the significant differences of the proposed method (CVD) as compared with all the baseline approaches at the 1% significant level by the Fisher's exact test (Hays 1988).

The precision of baseline approach 2 that selected the most similar hypernym was the worst among all the methods. There were words that were similar to the target word among the hypernyms extracted incorrectly. For example, the word *semento-kojo* (cement factory) was extracted for the hypernym of the word *kuriningu-kojo* (dry cleaning plant). It is difficult to judge whether the word is a hypernym or just a similar word by using only the similarity measure.

As for the results of baseline approach 1 using the most similar hyponym and baseline approach 3 using the similarity of the set of hypernym's children, the noise on the Wikipedia relation database decreased the precision. Moreover, over-specified hypernyms were extracted incorrectly by these methods. In contrast, the method of scoring based on the use of *k* similar words was robust against noise because it uses the voting approach for the similarities. Further, this method can extract hypernyms that are not over-specific because it uses all descendants for scoring.

Table 2 shows some examples of relations extracted by the *k* similar words method using CVD.

Table2: Hypernym discovery results by the *k*-similar words based approach (CVD). The underline indicates the hypernyms which are extracted incorrectly.

Score	Target word	Extracted hypernym
58.6	INDIVI	*burando* (fashion label)
54.3	*kureome* (Cleome)	*hana* (flower)
34.4	UOKR	*gemu* (game)
21.7	*Okido* (Okido)	*machi* (town)
20.5	*Sumatofotsu* (Smart fortwo)	*kuruma* (car)
15.6	*Fukagawameshi* (Fukagawa rice)	*ryori* (dish)
8.9	John Barry	*sakkyokuka* (composer)
8.5	JVM	*sofuto-wea* (software)
6.6	*metangasu* (methane gas)	*genso* (chemical element)
5.4	*me-ru semina* (mail seminar)	*Hon* (book)
3.9	*gurometto* (grommet)	*shohin* (merchandise)
3.1	*supuringubakku* (spring back)	*gensho* (phenomenon)

6.3 Investigation of the Extracted Relation Overlap with a Conventional Method

We randomly sampled 300 hyponymy relations that were extracted correctly using the *k* similar words method exploiting CVD and investigated whether or not these relations can be extracted by the conventional method based on the lexico-syntactic pattern. The possible hyponymy relations were extracted using the pattern-based method (Ando et al. 2003) from the TSUBAKI corpus (Shinzato et al. 2008). From a comparison of these relations, we found only 57 common hyponymy relations. That is, the remaining 243 hyponymy relations were not included in the possible hyponymy relations. This result indicates that our method can acquire the hyponymy relations that cannot be extracted by the conventional pattern-based method.

6.4 Discussions

We investigated the reason for the errors generated by the method of scoring using *k* similar words exploiting CVD. We conducted experiments on hypernym extraction targeting 694 words in the development data mentioned in Section 6.1. Among these, 286 relations were extracted incorrectly. In these relations, there were some frequent hypernyms. For example, the word *sakuhin* (work) appeared 28 times and *hon* (book) appeared 20 times. As shown in Table 2, *hon* (book) was also extracted for the target word *meru-seminah* (mail seminar). It is really difficult even for a human to identify whether the title is that of the book or the event. If we can identify these difficult hypernyms in advance, we can improve precision by excluding them from the target hypernyms. This will be one of the topics for future study.

7 Conclusion

In this paper, we proposed a method for discovering hyponymy relations between nouns by fusing the Wikipedia relation database and words from the Web. We demonstrated that the method using *k* similar words has high accuracy. The experimental results showed the effectiveness of using hierarchal structures and the clustering process for calculating distributional similarity for this task. The experimental results showed that our method could achieve 91.0% attachment accuracy for the top 10,000 hyponymy relations and 74.5% attachment accuracy for the top 100,000 relations when using the clustering-based similarity. We confirmed that most relations extracted by the proposed method could not be handled by the lexico-syntactic pattern-based method. Future work will be to filter out difficult hypernyms for hyponymy extraction process to achieve higher precision.

Abstract

Computing the pairwise semantic similarity between all words on the Web is a computationally challenging task. Parallelization and optimizations are necessary. We propose a highly scalable implementation based on distributional similarity, implemented in the MapReduce framework and deployed over a 200 billion word crawl of the Web. The pairwise similarity between 500 million terms is computed in 50 hours using 200 quad-core nodes. We apply the learned similarity matrix to the task of automatic set expansion and present a large empirical study to quantify the effect on expansion performance of corpus size, corpus quality, seed composition and seed size. We make public an experimental testbed for set expansion analysis that includes a large collection of diverse entity sets extracted from Wikipedia.

1 Introduction

Computing the semantic similarity between terms has many applications in NLP including word classification (Turney and Littman 2003), word sense disambiguation (Yuret and Yatbaz 2009), context-spelling correction (Jones and Martin 1997), fact extraction (Paşca et al. 2006), semantic role labeling (Erk 2007), and applications in IR such as query expansion (Cao et al. 2008) and textual advertising (Chang et al. 2009).

For commercial engines such as Yahoo! and Google, creating lists of named entities found on the Web is critical for query analysis, document categorization, and ad matching. Computing term similarity is typically done by comparing co-occurrence vectors between all pairs of terms (Sarmento et al. 2007). Scaling this task to the Web requires parallelization and optimizations.

In this paper, we propose a large-scale term similarity algorithm, based on distributional similarity, implemented in the MapReduce framework and deployed over a 200 billion word crawl of the Web. The resulting similarity matrix between 500 million terms is applied to the task of expanding lists of named entities (automatic set expansion). We provide a detailed empirical analysis of the discovered named entities and quantify the effect on expansion accuracy of corpus size, corpus quality, seed composition, and seed set size.

2 Related Work

Below we review relevant work in optimizing similarity computations and automatic set expansion.

2.1 Computing Term Similarities

The distributional hypothesis (Harris 1954), which links the meaning of words to their contexts, has inspired many algorithms for computing term similarities (Lund and Burgess 1996; Lin 1998; Lee 1999; Erk and Padó 2008; Agirre et al. 2009). Brute force similarity computation compares all the contexts for each pair of terms, with complexity $O(n^2m)$ where n is the number of terms and m is the number of possible contexts. More efficient strategies are of three kinds:

Proceedings of the 2009 Conference on Empirical Methods in Natural Language Processing, pages 938–947,
Singapore, 6-7 August 2009.

Smoothing: Techniques such as *Latent Semantic Analysis* reduce the context space by applying truncated Singular Value Decomposition (SVD) (Deerwester et al. 1990). Computing the matrix decomposition however does not scale well to web-size term-context matrices. Other currently unscalable smoothing techniques include Probabilistic Latent Semantic Analysis (Hofmann 1999), Iterative Scaling (Ando 2000), and Latent Dirichlet Allocation (Blei et al. 2003).

Randomized Algorithms: Randomized techniques for approximating various similarity measures have been successfully applied to term similarity (Ravichandran et al. 2005; Gorman and Curran 2006). Common techniques include *Random Indexing* based on Sparse Distributed Memory (Kanerva 1993) and *Locality Sensitive Hashing* (Broder 1997).

Optimizations and Distributed Processing: Bayardo et al. (2007) present a sparse matrix optimization strategy capable of efficiently computing the similarity between terms which's similarity exceeds a given threshold. Rychlý and Kilgarriff (2007), Elsayed et al. (2008) and Agirre et al. (2009) use reverse indexing and the MapReduce framework to distribute the similarity computations across several machines. Our proposed approach combines these two strategies and efficiently computes the exact similarity (cosine, Jaccard, Dice, and Overlap) between *all* pairs.

2.2 Entity extraction and classification

Building entity lexicons is a task of great interest for which structured, semi-structured and unstructured data have all been explored (GoogleSets; Sarmento et al. 2007; Wang and Cohen 2007; Bunescu and Mooney 2004; Etzioni et al. 2005; Paşca et al. 2006). Our own work focuses on set expansion from *unstructured* Web text. Apart from the choice of a data source, state-of-the-art entity extraction methods differ in their use of *numerous*, *few* or *no* labeled examples, the *open* or *targeted* nature of the extraction as well as the types of features employed. Supervised approaches (McCallum and Li 2003, Bunescu and Mooney 2004) rely on large sets of labeled examples, perform targeted extraction and employ a variety of sentence- and corpus-level features. While very precise, these methods are typically used for coarse grained entity classes (*People, Organizations, Companies*) for which large training data sets are available. Unsupervised approaches rely on no labeled data and use either bootstrapped class-specific extraction patterns (Etzioni et al. 2005) to find new elements of a given class (for targeted extraction) or corpus-based term similarity (Pantel and Lin 2002) to find term clusters (in an open extraction framework). Finally, semi-supervised methods have shown great promise for identifying and labeling entities (Riloff and Shepherd 1997; Riloff and Jones 1999; Banko et al. 2007; Downey et al. 2007; Paşca et al. 2006; Paşca 2007a; Paşca 2007b; Paşca and Durme 2008). Starting with a set of seed entities, semi-supervised extraction methods use either class-specific patterns to populate an entity class or *distributional similarity* to find terms similar to the seed set (Paşca's work also examines the advantages of combining these approaches). Semi-supervised methods (including ours) are useful for extending finer grain entity classes, for which large unlabeled data sets are available.

2.3 Impact of corpus on system performance

Previous work has examined the effect of using large, sometimes Web-size corpora, on system performance in the case of familiar NLP tasks. Banko and Brill (2001) show that Web-scale data helps with confusion set disambiguation while Lapata and Keller (2005) find that the Web is a good source of n-gram counts for unsupervised models. Atterer and Schutze (2006) examine the influence of corpus size on combining a supervised approach with an unsupervised one for relative clause and PP-attachment. Etzioni et al. (2005) and Pantel et al. (2004) show the advantages of using large quantities of generic Web text over smaller corpora for extracting relations and named entities. Overall, corpus size and quality are both found to be important for extraction. Our paper adds to this body of work by focusing on the task of similarity-based set expansion and providing a large empirical study quantify the relative corpus effects.

2.4 Impact of seeds on extraction performance

Previous extraction systems report on the size and quality of the training data or, if semi-supervised, the size and quality of entity or pattern seed sets. Narrowing the focus to closely related work, Paşca (2007a; 2007b) and Paşca and Durme (2008) show the impact of varying the number of instances representative of a given class and the size of the attribute seed set on the precision of class attribute extraction. An example observation is that good

Table 1. Definitions for f_0, f_1, f_2, and f_3 for commonly used similarity scores.

METRIC	$f_0(x,y,z)$	$f_1(x,y)$	$f_2(\vec{x}) = f_3(\vec{x})$
Overlap	x	1	0
Jaccard*	$\frac{x}{y+z-x}$	$\min(x,y)$	$\sum_i x_i$
Dice*	$\frac{2x}{y+z}$	$x \times y$	$\sum_i x_i^2$
Cosine	$\frac{x}{y \times z}$	$x \times y$	$\sqrt{\sum_i x_i^2}$

*weighted generalization

quality class attributes can still be extracted using 20 or even 10 instances to represent an entity class. Among others, Etzioni et al. (2005) shows that a small pattern set can help bootstrap useful entity seed sets and reports on the impact of seed set noise on final performance. Unlike previous work, empirically quantifying the influence of seed set size and quality on extraction performance of random entity types is a key objective of this paper.

3 Large-Scale Similarity Model

Term semantic models normally invoke the distributional hypothesis (Harris 1985), which links the meaning of terms to their contexts. Models are built by recording the surrounding contexts for each term in a large collection of unstructured text and storing them in a term-context matrix. Methods differ in their definition of a context (e.g., *text window* or *syntactic relations*), or by a means to weigh contexts (e.g., *frequency*, *tf-idf*, *pointwise mutual information*), or ultimately in measuring the similarity between two context vectors (e.g., using *Euclidean distance*, *Cosine*, *Dice*).
